Preface

Principles of Addiction is one of three volumes encompassing the 2500 page series.

Comprehensive addictive behaviors and disorders: In both print and online formats, this series provides the most comprehensive compilation of current knowledge on addictive behaviors and disorders to date. In short, it is the definitive reference work on addictions.

The significance of this series stems from the fact that addictive behaviors and disorders represent major personal, social, and public health problems throughout the world. While research on addictions has grown exponentially over the past 20 years, the primary literature in this field is widely dispersed. For researchers and clinicians, staying abreast of this vast and expanding knowledge is a challenging, if not impossible, task. Researchers specializing in one addiction subspecialty (e.g. clinical research, neuroscience, health services, public policy, treatment, pharmacology, genetics) are unable to keep apprised of the big picture. In addition, research findings on one type of addiction (e.g. alcohol dependence, excessive gambling, methamphetamine dependence) may have relevance to other types (e.g. cocaine or opiate dependence) but such findings are not readily available to all addiction scientists since they are dispersed among so many specialty journals, books and web sites. Until now, there has been no all-encompassing resource that could serve as the "go-to" compendium for information on any and all addictions.

Comprehensive addictive behaviors and disorders fills this void by providing a unique and valuable storehouse of interdisciplinary scientific information for researchers, clinicians, and policy makers that comprehensively summarizes state-of-the-art knowledge. The terms "behavior" as well as "disorder" are used purposefully in the title since the work includes both excessive use (what is often called "at risk" or "harmful" use) as well as true physiological dependence. In addition, there is lack of evidence and some controversy over the issue of whether or not some behavioral excesses (e.g. texting or video gaming) can be classified as true addictions. Finally a number of the more basic, translational chapters cover addictive brain or behavioral processes rather than focusing on "disorders" per se.

Conceptually, the three volumes that make up this series, *Principles of Addiction*, *Biological Research on Addiction*, and *Interventions for Addictions*, cover an extensive range of topics including, but not limited to, the nature of addiction, cravings, comorbidities, types of addictions, behavioral biology, neuroscience, neuroimaging, genetics, neuropharmacology, psychosocial treatments, addiction medications, application of addiction science to practice, public policy, and prevention. With the growing emphasis on translational research, the goal has been to integrate diverse findings into a meaningful conceptualization of all aspects of use and abuse.

The audience for the series includes advanced undergraduates, graduates and postdoctoral students, professors, researchers, clinicians and policy makers. The series can also serve as a valuable aid to instructors and students in the hundreds of university-level addiction degree programs throughout the world. As an encyclopedic series, the mass media as well as the general public will find this work to be a comprehensive source of evidence-based, scientific information on addictions. This is especially important since the field of addiction is continually plagued by anecdotal and misleading information found both in print and online.

SCOPE AND FORMAT

The development and compilation of this series have been a truly collaborative effort. Nine internationally recognized addiction experts have served on the editorial board for this project. The board is composed of Peter Miller, PhD, Medical University of South Carolina; Mary Larimer, PhD, University of Washington; Kyle Kampman, MD, University of Pennsylvania School of Medicine; David Kavanagh, PhD, Queensland University of Technology; Samuel Ball, PhD, Yale University School of Medicine; Phillipe DeWitte, MD, Université Catholique de Louvain (Belgium); Marsha Bates, PhD, Rutgers University; Nancy Petry, PhD, University of Connecticut Health Center; and Arthur Blume, PhD, Washington State University. The board members were chosen to provide a wide range of interdisciplinary expertise.

The board members were responsible for selecting and inviting authors for chapters in their specialty areas and to provide editorial guidance. Chapters are authored by reputable, well-recognized authorities in the addictions field. Authors were selected for their

expertise and experience, with particular emphasis placed on selecting an international group with diverse philosophies and research backgrounds.

Each chapter is approximately 6500 words in length. Chapters consist of approximately 10 printed pages each, ranging from 5 to 15 pages depending on the topic. Many chapters include tables and figures to better illustrate data. Authors were asked to summarize current knowledge in their areas without providing references within the text. Thus, the work reads like an encyclopedia, providing the reader with an overview of the state-of-the-art rather than an in-depth research report. A further reading and web site list are provided at the end of each chapter for those who require research references and more detailed information. In addition, an outline, glossary, list of keywords, and list of cross-references are provided for each chapter.

The hope is that this compendium will provide a universal platform for a more science-based approach to the study, prevention and treatment of addictions. The ultimate goal is to improve the lives of addicted individuals and their families throughout the world through a more comprehensive and detailed understanding of the addictive process.

VOLUME 1: PRINCIPLES OF ADDICTION

This first volume, *Principles of Addiction*, provides scientific information in two broad categories: the nature of addiction and types of addiction. The volume sets off the series by giving an overview of what is known about the addictive process as well as a depiction of each of the known addictive behaviors and disorders.

Chapters related to the nature of addiction are designed to provide basic descriptions of current knowledge of the addictive process in terms of its initial development, mechanisms of action, and basic characteristics. Chapters cover the history of the study and treatment of addiction, its epidemiology as well as its basic definitions, diagnostic criteria, and theoretical models. Essential characteristics of dependence, including loss of control, tolerance, craving, withdrawal, denial, and relapse, are explained and discussed. Chapters cover a wide range of information regarding etiology and developmental course. The influence of gender, stress, family, and peer influence is explained. Associated features such as stress and psychiatric comorbidities (e.g. depression) are included. Coverage of many of these issues includes both excessive use of substances as well as true dependence and why some people "mature out" of these behaviors and others become entrapped in severe addiction.

To demonstrate the all-inclusive nature of this volume, there are chapters on 27 different addictions, both substance-focused and behavioral. Topics of substance-focused use and abuse include alcohol, heroin, cocaine marijuana, hallucinogens, ecstasy/MDMA, inhalants, ketamine, anabolic-androgenic steroids, prescription and over-the-counter medications, tobacco, caffeine and energy drinks, food, areca nut, khat, and water pipe smoking. Behavioral excesses include gambling, shopping, exercise, work, and sex as well as behaviors that have become potential problems in contemporary society such as cybersex, virtual worlds on the internet, video games, cell phone use and texting, and social networking. For both substance-related and behavioral excesses authors were asked to address the issue of whether or not there is enough scientific evidence to classify each as a true "addiction." For example, there is controversy over whether or not excessive sexual activity and food consumption constitute true addictions from a diagnostic sense. Unfortunately, scientific study of many of the behavioral addictions is so recent (with the exception of gambling) that little is known about these syndromes.

A few substances are so new that little is known about them. They were not included in this volume since no major human studies have yet been conducted on their use, mechanisms of action, abuse potential, or health effects. For example, the National Institute on Drug Abuse (NIDA) describes three such emerging drugs: "spice," an herbal mixture with effects similar to marijuana; salvia, an herb that causes hallucinations and psychotic-like symptoms; and "bath salts," a synthetic compound with amphetamine-like effects that result in increased blood pressure and heart rate. In time, more scientific knowledge will be accumulated on these substances but, at this stage, it is apparent that the drug culture is able to stay one step ahead of the addiction specialists in developing new compounds to use and abuse.

In summary, this volume provides a basic understanding of the definitional and diagnostic differences between use, abuse, and disorder. It describes in great detail the characteristics of these syndromes and various etiological models. Finally, it provides detailed descriptions of a variety of addictive behaviors and disorders and their similarities and differences. This volume is especially important in providing a basic introduction to the field as well as an in-depth review of our current understanding of the nature and process of addictive behaviors.

Peter M. Miller

Editors: Biographies

Peter Miller

Peter M. Miller, PhD, is a professor of psychiatry and behavioral sciences in the Center for Drug and Alcohol Programs at the Medical University of South Carolina. He also holds a faculty appointment in the College of Dental Medicine. He is a clinical psychologist and is board certified by the American Board of Professional Psychology. He specializes in research on alcohol and substance abuse screening and intervention in medical and dental settings, with particular reference to alcohol-sensitive diseases such as hypertension and oral cancer. He has published over 100 scientific articles, has authored 11 books and has served as editor on major addictions textbooks and reference works. He is editor in chief of two international research journals, *Addictive Behaviors* and *Eating Behaviors*, and serves on several editorial boards. He is past president of the International Society of Addiction Journal Editors (ISAJE).

Samuel Ball

Samuel A. Ball, PhD, is a professor and assistant chair for education and career development in the Department of Psychiatry at Yale University School of Medicine. He also serves as research director for the NIDA-funded Psychotherapy Development Research Center, NIH-funded BIRCWH Women's Health and Addictive Behaviors program, and The APT Foundation in New Haven, CT. His research focuses on the assessment and treatment implications of personality dimensions, personality disorders, and multidimensional subtypes in substance abuse.

Arthur Blume

Arthur W. Blume is a professor of psychology at Washington State University. Before joining the faculty at Washington State University, Dr Blume was on the faculty at the University of North Carolina at Charlotte and before that at the University of Texas at El Paso. He currently serves as a section editor for this volume, and as an associate editor of the journals *Addictive Behaviors* and *Cultural Diversity and Ethnic Minority Psychology*. From 2007 to 2009, he was an American Indian representative on the National Committee on Ethnic Minority Affairs of the American Psychological Association in the United States. His program of research has focused on addictive behaviors among high-risk populations, especially those from ethnic minority groups in the United States. His extramurally funded research and publications reflect his keen interests in ethnic minority health and well-being.

David Kavanagh

David Kavanagh, PhD, is a research capacity-building professor in the Institute and Health & Biomedical Innovation and School of Psychology & Counselling at Queensland University of Technology, and has adjunct posts at the University of Queensland and Griffith University. He was educated at Sydney and Stanford Universities and led a community mental health service before becoming an academic. He has researched and written widely on addiction, comorbidity and dissemination of evidence-based treatments and is currently researching the elicitation and maintenance of functional motivation. He has been on the editorial boards of several journals, including *Addiction and Addictive Behaviors*, and has served on several state and national expert committees on comorbidity and addiction.

Kyle Kampman

A board-certified psychiatrist specializing in addiction psychiatry, Dr Kyle M. Kampman, MD, received his medical degree from Tulane University School of Medicine. He completed his residency in psychiatry and fellowship in addiction psychiatry at the University of Pennsylvania. Currently, he is a medical director of the Charles O'Brien Center for the Treatment of Addictions, professor of psychiatry, and medical director of the Treatment Research Center at the University of Pennsylvania in Philadelphia. His research interests include pharmacotherapy for cocaine dependence and the cocaine withdrawal syndrome. He is an associate editor of Drug and Alcohol Dependence. He serves on the editorial board of the *Journal of Addiction Medicine* and is an active member of the American Society of Addiction Medicine, College on Problems of Drug Dependence, and the Pennsylvania Society of Addiction Medicine. His contributions to the field have been acknowledged by the Scott Mackler Award for Excellence in Substance Abuse Teaching presented by the University of Pennsylvania School of Medicine and the Caron Foundation's Medical Professional-Physician Award.

Marsha E. Bates

Marsha E. Bates, PhD (Rutgers – the State University of New Jersey), is a research professor of psychology at the Center of Alcohol Studies (CAS) at Rutgers

University and an associate professor of psychiatry at UMDNJ/Robert Wood Johnson Medical School. She directs the Cognitive Neuroscience Laboratory that promotes translation between basic human experimental and clinical science. Her current multiinstitution research project is a component of the NIAAA Mechanism of Behavior Change Interdisciplinary Research Consortium (MIRC) which seeks to build novel approaches to alcohol-related problems via mechanism-based strategies. Dr Bates is vice-chair of the Rutgers Institutional Review Board for the Protection of Human Subjects involved in research. She is a member of the Behavioral and Social Advisory Council of ABMRF/The Foundation for Alcohol Research and vice-chair of the Board of Trustees of Alcohol Research Documentation, Inc. She is an editorial board member of the *Journal of Studies on Alcohol and Drugs* and a past associate editor of Psychology of Addictive Behaviors and Alcoholism: Clinical and Experimental Research. She is a fellow of the American Psychological Association (APA), previously served as president of APA Division 50 (Society of Addiction Psychologists), and received their 2011 Distinguished Scientific Contribution Award. Address: Center of Alcohol Studies, Rutgers – the State University of New Jersey, 607 Allison Road, Piscataway, NJ 08854, USA; E-mail: mebates@rutgers.edu.

Mary Larimer

Mary E. Larimer is a professor of psychiatry and behavioral sciences, an adjunct professor of psychology, associate director of the Addictive Behaviors Research Center, and director of the Center for the Study of Health and Risk Behaviors at the University of Washington. She received her PhD in clinical psychology from the University of Washington and has been a member of the faculty since 1995. Dr Larimer's research and clinical interests include (1) prevention and treatment of alcohol and drug problems among adolescents and young adults (with a particular focus on college drinking prevention), (2) cross-cultural research regarding prediction of initiation of drinking and trajectories of alcohol and substance use during emerging adulthood, (3) comorbidity of substance use with depression, suicide, trauma, PTSD, disordered eating, and gambling problems, (4) evaluation of housing and treatment programs for chronically homeless and incarcerated individuals, and (5) dissemination of evidence-based prevention and treatment approaches into clinical-, school-, and work-site settings. She has published more than 100 articles and book chapters on these topics.

Nancy M. Petry

Nancy Petry is a professor of medicine at the University of Connecticut Health Center, and she earned her PhD in psychology from Harvard University. She developed the prize reinforcement system that has been widely disseminated in the context of treating substance use disorders and is now being applied to address other conditions including overweight/obesity, exercise, medication adherence, and diabetes. She also conducts research related to pathological gambling and its treatment.

Philippe De Witte

Professor De Witte heads the Laboratory of Behavioural Biology at the Université Catholique de Louvain. In 1987, he received a Fulbright grant to complete a specialization in brain research at the NIH. He has also worked as invited professor in Washington State University and the University of Colorado.

He is the editor in chief of *Alcohol and Alcoholism* and on the editorial advisory board of a number of leading journals. He was president of the European Society for Biomedical Research on Alcoholism (ESBRA) for two terms from 1993 to 2001 and was the president of the International Society for Biomedical Research on Alcoholism (ISBRA, 1998–2002). He joined the ERAB Advisory Board in 2003 and became chairman on 1 January 2007.

His research interests include pharmacology and neurobiology of addiction including therapeutics and treatments. He is a member of a number of professional bodies including ESBRA, ISBRA, RSA, The Belgian College of Neuropsychopharmacology and Biological Psychiatry (BCNBP) and the Société française d'Alcoologie (SFA) and has published over 200 articles in scientific journals, twice as many abstracts and book chapters.

Historical Understandings of Addiction

Joseph Westermeyer[*,$]

[*]University of Minnesota, Minneapolis, MN, USA

[$]Minneapolis VA Medical Center, Minneapolis, MN, USA

OUTLINE

BACKGROUND

Rationale for Addiction Terms and Concepts

The term addiction, from the Latin addictionem or a devoting, first appeared in the English language around the sixteenth century. During recent historical times, words that indicate alcoholism or opiate addiction have appeared in many languages. Even in societies without written language, such terms exist. For example, in the Tai-Lao languages of Southeast Asia, these terms involve one word meaning attached to or stuck to be followed by the term for alcohol or opium (e.g. teat-dyafeen, literally stuck, attached, or connected to opium for opium addiction). At times, these terms have a derogatory connotation. For example, in the Tai-Lao languages, a deteriorated person dependent on alcohol may be called khun-kee-lao or literally person-excrement-alcohol. A person who spent most of the day intoxicated on opium might be referred to as khun-kee-dyafeen or person-excrement-opium.

The populace at large uses these terms commonly in societies with widespread alcohol or drug addiction. They are not technical terms employed only by healers, jurists, or literati. Their popular usage indicates that addiction occurs sufficiently often to warrant a special term. When enough people manifest addiction, a term has evolved to ease communication about them, their behavior, or their own personal experience (e.g. "When I became ill after I stopped using, I realized I was addicted").

These special terms foster abstract thought about addiction. Not surprisingly, models have appeared

http://dx.doi.org/10.1016/B978-0-12-398336-7.00001-2

over the centuries to explain or elaborate on the experience or observation of substance use. Related concepts have also evolved, such as ideas regarding causation, related manifestations, or solutions to addiction-related problems. As with all terms in common lay usage, they involve not only denotative or cognitive aspects but also connotative or value-laden aspects. For example, a homeless alcohol-dependent patient wanted me to know that he considered himself a common drunk, but under no circumstances was he an alcoholic.

Models for Episodic Intoxication in Traditional Societies

All cultures have forms of time out in which the daily customs or rules governing roles, responsibilities, and behavior are temporarily in abeyance. These are often time-limited periods of celebration, socialization, relaxation, and/or feasting. For example, Roman festivities involved wine drinking with feasting on special foods. The so-called "drunken comportment" may itself signal respite from one's usual roles and responsibilities.

In some cultures, substance use may involve a highly valued altered state of consciousness. The latter states may provide a means of communing with spirit world, so that individuals may be guided, inspired, or instructed on how to proceed with their lives. For example, in the Americas, aboriginal cultures often employed psychoactive substances to commune with the spirit world. Other methods, including fasting, sleeplessness, and isolation from other people, were used in the quest of supernatural guidance. In addition to ceremonial use at important annual ceremonies (e.g. Passover, New Year), psychoactive substance use has attended numerous rituals in the life of individuals. Examples include important social contracts (e.g. the du-tsen in Germanic cultures, sheltering a stranger in the Middle East, commercial or political relationships in Southeast Asia, life milestones such as graduation, marriage, childbirth, or death).

Medicinal use of psychoactive substances has long been used to relieve illness, or at least the symptoms of illness. For example, opium can relieve acute pain, diarrhea, cough, fear, dysphoria, and other forms of misery. In areas where alcohol was distilled, people added various herbal compounds to alcohol (including opium) for their presumed medicinal properties. Sometimes healers added objects to alcohol (e.g. snakes, insects, minerals) to bring the presumed special attributes of these objects to the suffering individual.

Preparation of beer, wine, and distilled beverages permitted the storage of carbohydrates in the form of alcohol. Used in this way as a foodstuff, beverage alcohol could augment the diet during times of the year that food was not being produced. These drinks introduced tastes that could enhance the taste of food. Beverage alcohol could substitute water in settings where potable water was not readily available (although excessive doses purge body fluids through its diuretic effect). Small doses of some psychoactive substances, such as cannabis, have long been used as condiments in soups and baked goods.

Use of alcohol and drugs served several religious and spiritual functions. During religious ceremonies and rituals, priests and sometimes devotees at large consumed sacramental alcohol and drugs. The latter included consumption of hallucinogenic mushrooms and other plant products (such as peyote) in the Americas. The Native American Church in North America has continued this practice in modern times as a means of communicating with the spiritual world, addressing conflicts and personal distress, and finding one's way into a moral, productive future.

Societal control predominated over individual choice in the traditional use of these psychoactive substances in earlier times. For example, all individuals might have their beverage containers filled at the same time so that no one drank more (or less) than a socially prescribed amount. Occasions of use were socially determined, limiting the frequency of use. This traditional form of control began eroding when masses of people received beverage alcohol as payment for work in industrialized England. People began to drink daily, sometimes even before starting work in the morning. This daylong drinking favored individual choice over drinking, as well as physical dependence on alcohol.

Intoxication Gone Awry: Appearance of Widespread Addiction

Addiction required daily consumption. Such use led to increasing dosage to obtain the desired effects for certain psychoactive substances, including alcohol, opium, cannabis, sedatives, and tobacco. Increased frequency and dosage almost inevitably produced consequences: economic, psycho-physiological adaptation, and biomedical complications. Depending on the substance, these consequences occurred within a few years to a decade or longer. For example, drugs such as heroin and cocaine can produce consequences sooner. Substances such as alcohol and opium require several years to a decade or longer in the average case.

A common manifestation with most psychoactive substances is the need for increasing doses to produce the same, desirable effects. Thus, an alcohol drinker who experienced relaxation and other positive effects from 1 or 2 oz. of alcohol will need twice, then four, and later ten times that amount to produce the same desired effects. The same occurs with opium and heroin, with even higher multiples in some cases. Similar escalations occur with

tobacco, cocaine, and other stimulants, and certain other drugs (e.g. sedatives, cannabis, phencyclidine).

Economic and technical advances have permitted the expenditure of time, resources, and wealth to permit widespread addiction. In past centuries, much effort was required to produce sufficient carbohydrate, opium poppy, or tobacco to permit many people to engage in daily use of large doses. In the Caribbean, slaves on plantations grew sugarcane used to distill rum and gin. Trading ships from England distributed goods along the eastern coast of North America. Before heading back home to England, they picked up ballast in the form of beverage alcohol. Likewise, the English raised poppy in India to use in trade with Southeast Asia, China, and Japan. Thus, the worldwide phenomenon of widespread addiction after 1600 AD depended on such innovations as the following:

- Production of excess carbohydrate in large amounts, as a result of slave labor, or plantation-based mass production, and/or technical innovations (such as the iron plow, use of fertilization, irrigation) to produce alcohol.
- New methods of growing labor-intensive drugs, such as opium, tobacco, or betel-areca nut, again using plantations and new agro-technology.
- Distillation of beverage alcohol and drug preparations to extract active agents (e.g. morphine or heroin from opium), which reduced the cost of transportation over great distances, making lower cost alcohol or drugs available in areas that had no experience, and hence no resistance to their use.
- The short half-life of some purified substances (e.g. heroin) as compared to the parent compound (e.g. opium) hastened the development of addiction as well as the consequences wrought by addiction.

MODELS FOR UNDERSTANDING ADDICTION EXISTING PRIOR TO 1600 AD

People cannot avoid positing causes for observed behaviors, especially when these behaviors are problematic. Inevitably, these causal explanations, also called models or paradigms, tend to lead to interventions.

Moral Model

In many societies after 1600 AD, citizens no longer hued to one tradition governing use of psychoactive substances. Organized religion often fed this diversity, as adherents of one sect forbade use while those in other sects approved moderate use. Eventually, decisions whether to use, when to use, and how much to use fell to individual choice in many times and places. In turn, this led to presumed morality in making such choices. Abstention or moderate use was deemed as morally good, whereas excessive, problematic use was judged as morally bad. Those consistently making bad decisions came to be viewed as morally weak, corrupt, or full-of-sin (sinful).

This model prevails today in many instances. For example, if a society values individual responsibility and accountability, people will view many, if not most of their important decisions as having moral implications. Purchase and consumption of alcohol in significant amounts can deplete families of necessary resources, result in poor health that drains family well-being, and led to irresponsible behavior that harms family members or other members of society.

As addicted persons fail in their attempts to change or curb their own behavior, they often apply this model to themselves. That is, they perceive themselves as morally bad or having weak character. Families and friends may also apply a moral model in judging the consumptive behavior of an addicted person. The moral model may lead to changes in behavior that can be successful in early stages of heavy use or addiction. Later, these models seldom work for any length of time. Most clinicians learn that this model seldom helps in the case of severe addiction.

Organized religions have addressed excessive substance use and addiction as a moral dilemma for their adherents. Many religions have prescribed total abstention as a solution. For example, Hinduism, Buddhism, and Islam have opposed the use of alcohol and recreational drug use for centuries. Although some use may be permitted in some Hindu, Buddhist, and Islamic societies, the clergy and the religious laity have been urged toward total abstinence. In Judaism and Roman Catholicism, the use of alcohol in religious rituals has imparted a message that this sacramental substance should be respected and not abused. Following widespread addiction in the seventeenth and eighteenth centuries, many abstinent-oriented Christian and other sects arose, forbidding use among their members.

Criminal Model

The criminal model bears a strong relationship to the moral model, from which it stems. As societies experienced increasing social problems associated with addiction, some societies defined addictive behavior or excessive alcohol–drug consumption as a crime against society, and not simply a moral failing. Depending on the society and the point in time, any public intoxication might be punished. Or only dangerous behavior associated with intoxication (such as fighting or beating family members) might be punished.

In colonial times in the United States, heavy or addicted drinkers might be placed in wooden stocks, located in a public place. Not only would this punishment restrict the addict's freedom, it would also impose discomforting immobility in the stocks. Since stocks were typically located in a public place, the punishment involved public shaming. Whether it proved effective in ameliorating or reducing addiction is unknown, but it did create a public attitude against addiction.

This model still persists in many venues today. For example, some communities publish the names of those arrested for drunken driving or public intoxication. Pregnant mothers whose use of alcohol or drugs may threaten the development of their baby in utero may have their freedoms circumscribed until childbirth. The war on drugs policy in many modern nations, in which drugs are viewed as foisted on innocent people by criminal producers and traffickers, owes its persistence to this model.

Preternatural Model

In many cultures, alcohol and drugs were imbued with preternatural or even supernatural powers. The preternatural model also owes its origins partially to the moral model, as people believed that no rational person would choose addiction over abstinence of moderate use. That is, the psychoactive substance was viewed as having the ability to take over the person's mind, will, or soul through means that transcended the natural world. This model has sometimes been called the devil in the drug model. In this view, substances such as alcohol, opium, or cannabis are so inherently evil and even demonic that any use is evil. Such use may then be labeled as sinful, so that the person's inherent goodness may be doubted or denied. Although this model is still popular in many settings, increasing knowledge of the neurotransmitter, neuroanatomical, and genetic nature of addictogenic psychoactive substances has challenged these early supernatural explanations, while also providing explanations regarding why alcohol and drugs can weaken the will and moral resolve of addicted persons.

MODELS APPEARING BETWEEN 1600 AND 1900 AD

Epidemic Model

Two epidemics of addictive disorder appeared in the 1600s and spread notably by the early 1700s. They occurred around the same time, although they involved different substances in different parts of the world. Moreover, they both involved a complex of new behaviors not modified by tradition, plus international trade.

The English gin epidemic (which also involved rum) involved the import of cheap distilled beverage alcohol from the Caribbean area. In the early stages of the Industrial Revolution, English ships brought merchandise to Canada, the American colonies, and then the Caribbean. Needing ballast for the return trip to England, they first used stones, then sugarcane and other agricultural products, and finally distilled alcohol. On the docks of Liverpool, a calorie of beverage alcohol could be purchased for less than calorie of bread. Factory owners often paid workers in alcohol. Unfettered by the traditions governing use of mead, workers made their own decisions regarding when and how much to drink. The result was widespread excessive drinking.

Other places in Europe as well as North America similarly became enamored with heavy drinking. Led by England, several responses gradually led to a reduction in alcohol addiction. One of these interventions involved taxing alcohol beverage. Abstinence-oriented Christianity began around this time. In England, popular eight-page booklets described the depredations of alcohol, together with wood-block pictures of the consequences, including fetal alcohol syndrome, child neglect and abuse, fights, accidents, theft, and poor workmanship. In the United States, small residential asylums were developed to treat chronic alcohol abuse.

Within years after contact was established between the Americas and Eurasia, tobacco smoking appeared in the Orient. Tobacco smoking houses appeared, frequently by youth, political dissidents, and other independent-minded people. Several nations of Asia closed these public smoking houses. The result was the wedding of opium, an old substance once consumed only by eating, and smoking, a new method of administration. Opium smoking spread like wildfire in Southeast Asia and the East Orient, including China, Korea, and Japan. As in Europe, many strategies against opium addiction began. One of these was anti-opium societies, whose members endeavored to bring addicted people to residential facilities that provided withdrawal treatment, nourishment, and respite. Several countries also passed laws against the production and/or import of opium. In China, a cabinet-level minister was appointed to limit production, commerce, and use of opium. The United States mimicked many of these measures over time.

Illness Model

As noted above, this model evolved in Asia, Europe, and North America to counter widespread opium and alcohol addiction. During that period, it typically

involved admission to a hospital or residential facility, often in a rural area. So-called moral treatment, developed for psychiatric disorders, included shelter, nourishment, daily activities, supervision, and respectful social interactions.

This model is often inappropriately described as the medical model of addiction. Although the term medical model may apply to the downstream attempts to reverse addiction in medical settings or by physicians, it is the illness model that gave rise to treatment in the first place. This model evolved over two centuries ago when addicted persons were unable to cease addictive use of psychoactive substances on their own.

One of the first instances of this model occurred in the United States around 1800. Small therapeutic households (or asylum) developed in rural areas to provide a period of supervised abstinence for alcohol addicts. Although some physicians were active in developing this resource, nonphysicians established and ran these recovery-oriented households.

During the Opium Epidemic in China and other parts of Asia, small clinics and hospitals were established to support addicted persons through withdrawal and a return to health. Locally established anti-opium societies provided material support and referred addicts to these facilities.

A social concern related to this model has focused on the fear that addicts might present the illness model as a rationale for continued addictive use of a substance. Although this does occur rarely in addicted persons who may want to continue their addictive use, most addicted persons develop a moral imperative to return to responsible living, once they have some months of healthful sobriety. Another fear relates to the worry that unethical clinicians might provide ineffective treatment as a means of accumulating wealth. Again, this can occur; but ethical clinicians do not experience enhanced self-esteem in their healing roles by sponsoring ineffective therapies.

The illness model involves processes that proceed along psychological, psychosocial, and cultural lines. First, the addicted person must view himself or herself as a blighted or diseased person in need of outside help. This step, involving illness behavior, occurs after a period of misery and dysfunction. Second, those around the person must be willing to deed the person a period of relief from ordinary social expectations and responsibilities, in order to permit treatment and recovery. This involved social assignment of a temporary sick role. Third, a culturally approved or licensed health care worker must ordain that disease exists and treatment is warranted. The social assignment of a sick role usually continues as long as the suffering person is willing to undergo the physical, psychological, or social burdens associated with treatment.

MODELS APPEARING SINCE 1900 AD

Personality Disorder Model

During the early 1900s, diagnostic classifications included alcoholism and drug addiction as a personality or character disorder. These disorders were viewed as a form of antisocial personality, since the individual broke social mores, acted primarily in their own apparent self-interest, and often transgressed the rights of others while intoxicated or drug seeking. According to this view, addiction evolved in irresponsible or self-centered people who ignored the effects of their choices and behaviors on others. The second edition of the Diagnostic and Statistical Manual of the American Psychiatric Association typified this perspective.

During this period, personality and character disorders were seen as untreatable. Thus, this model justified the noninvolvement of many clinicians in the care of these patients. Despite this professional viewpoint, many states provided asylum-type care. Private asylum or dry-out farms also operated.

Abandoned by the medical profession, alcoholics in the United States supported one another's recovery in the brotherhood of Alcoholics Anonymous (AA). One of the founding members of AA, himself a physician, used the analogy of allergy to describe the individual, and presumed idiosyncratic response of alcoholics to alcohol. This analogy bears strong resemblance to the Illness Model from the previous century.

Alcoholics Anonymous borrowed heavily from an English self-improvement group that aimed at maturity and balance, using early Christian principles. Although not sponsored by organized religion, it employed spiritual guidance and growth as a means of achieving a rewarding, responsible life way in the modern industrialized world.

Neurotransmitter Model

Alcohol, opium, and other substances of abuse mimic or affect naturally occurring neurotransmitters. Neurotransmission was key to understanding pain and analgesia, anxiety and relaxation, dysphoria and euphoria, dissociation and vigilance. Increased understanding of drug/alcohol-related effects on brain and behavior has led to other theories, as well as to new therapies of addiction. In turn, new information accruing from successful treatment of addiction has enriched our theoretical perspective on addiction.

Various drugs of abuse relate to specific neurotransmitter systems. For example, opioid drugs mimic the effects of endogenous opioid-like substances (i.e. endorphins). Cocaine, amphetamines, and other stimulants affect the adrenergic and dopaminergic systems.

Nicotine affects muscarinic receptors. Cannabis and its active compound tetrahydrocannabinol stimulate an endogenous cannabinoid receptor. Benzodiazepines and other sedatives trip a benzodiazepine receptor, which in turn affects the actions of gamma-aminobutyric acid. Medications anatagonistic to these substances (e.g. disulfiram for alcohol, naltrexone for opioids) have been used in treatment.

Neuroanatomic Model

Certain areas of organelles of the brain are related to alcohol or drug effects. For example, the dopaminergic locus accumbens appears to be a site involved in the reward experienced with psychoactive substance use. Alcohol, sedatives, and opioids reduce the contributions of the frontal lobes that facilitate recall, executive decision-making, interpersonal sensitivity, judgment, and morality.

Awareness of these brain functions and their dysfunction during addiction contributes to an understanding of why addictive behaviors may persist despite their damaging effects on the individual. Damage of particular areas of the brain can aid clinicians in recognizing certain stereotypic conditions associated with addiction. For example, damage to the mammillary body area of the brain can produce a chronic inability to store recent memory, a lesion that produces an inability to live independently. Damage to the frontal lobes can foster disinhibited, intrusive speech and behavior.

Learning Model

This model views addiction as a learned behavior that follows upon certain learned stimuli. For example, a person might experience withdrawal symptoms in a setting where alcohol or drug use had previously occurred. In this example, the effect of the alcohol or drug use is the unconditioned response and the alcohol or drug itself is the unconditioned stimulus. The environmental cues associated with the presence of alcohol or drugs are the conditioned stimuli that can produce drug seeking and drug using.

This model can be used therapeutically by avoiding cues that stimulate urges to use and by extinguishing craving responses to these cues. Recalling and imaging the aversive consequences brought on by use may also be employed. Medications that eliminate the desired drug or alcohol effects can be useful in extinguishing addiction-related learned behavior. On the level of the community, learning can be used to reward behaviors inconsistent with alcohol or drug abuse (e.g. family interactions, employment, abstinent-oriented recreation).

Dyadic Enabling/Rescuing Model

Described first by Eric Berne, this model involves the interaction between at least two people. One of these could be an addicted person, who relates to the second person in a child-like or dependent role. The second individual relates to the addicted person as a parent, helper, or authority figure. This role relationship is apt to accentuate the dependent behavior of the addicted person, while frustrating the second person who expects the proffered help to ameliorate the addiction (which it seldom does, if given without contingencies).

The helper may enable the addictive behavior by providing shelter, food, resources, or even drugs or alcohol to the addicted person. Enabling fosters continued using alcohol or drugs without experiencing the social, economic, or other consequences of use (e.g. poverty, no food or shelter). The ultimate effect is a worsening of the addicted person's condition.

Rescuing involves the parental, helping person saving the child-like, dependent person from social or other consequences of addiction. For example, a policeman may cite a drunk driver for another, lesser offense than the actual offense. Or a judge might not exact a legal punishment because it is a first offense. Rescuing, like enabling, is often undertaken in hopes that the beneficent action will goad the addicted person toward recovery. Unfortunately, rescuing generally exacerbates rather than alleviates addiction.

Route-of-Administration Model

Many substances can be consumed by more than one route of self-administration. Routes that have utilized over time include the following:

Route	Absorption	Rapidity of effect
Eat/drink	absorption	slow (10 to 20 minutes)
Subcutaneous	skin tissue (injection)	slow
Intramuscular	muscle tissue (injection)	slow to medium
Chewing	oral mucosa	medium (several minutes)
Rectal	rectal mucosa	medium
Vaginal	vaginal mucosa	medium
Snuffing	nasal mucosa	rapid (< one minute)
Smoking	pulmonary alveoli	very rapid (< 10 seconds)
Intravenous	blood stream (injection)	very rapid

Biomedical consequences may be linked to the mode of administration, to some extent independent of the substance used. For example, alcohol drinking can cause ulcers or cancers. Tobacco, cannabis, or opium smoking can produce chronic lung infections and airway/pulmonary cancers. Chewing astringent substances, such as tobacco or betel nut, can cause gum inflammation, dental lesions, and oral cancers. Snuffing with cocaine or heroin can produce ulceration and even perforation of the nasal septum. Subcutaneous, intramuscular, or intravenous injection can produce bacterial, fungal, or viral infections. More rapid routes of administration tend to be more addicting, especially if the onset-of-action of the drug is rapid.

Comorbidity Model

This concept suggests that all or much substance use occurs in association with other comorbid conditions. Some of these conditions may occur before the onset of substance use disorder and conduce toward subsequent substance use disorders. This could occur if chronic pain led to excessive opioid drug use, or chronic insomnia or anxiety led to excessive use of sedatives. On the contrary, substance use disorder could lead to comorbid conditions. For example, losses associated with substance use disorder might precipitate depression. Or various routes of administration (see above) might favor the development of biomedical complications.

Virtually any psychiatric disorders can accompany substance use disorders. However, mood, anxiety, and other externalizing disorders are most frequent psychosocial disorders. Psychosis and brain injury occur more often than chance. Numerous medical problems can accompany substance use disorder. These also include various infectious, gastrointestinal, cardiovascular, genitourinary, and traumatic maladies. Alcohol involves several unique metabolic and nutritional problems.

Salutogenic or Self-treatment Model

Drug or alcohol use may be used for various salutogenic purposes. For example, a person may use a substance to feel relaxed in a social situation, to augment sexual experience, or to remain alert when fatigued. Khantzian extended this model to include self-treatment for discomforting or even disabling symptoms. For example, an anxious person might use sedative or opioid drugs or alcohol to relieve chronic anxiety, panic, or phobias. A depressed person may use cocaine or amphetamine to relieve fatigue or lack of concentration.

With time, the drug may have an effect opposite to that intended. For example, opium might enhance sexual function early in its use but ultimately cause loss of libido and impotence. Or alcohol might facilitate social interaction at the beginning but lead to social alienation and isolation with excessive abuse. Moreover, more than one type of drug could be used for a specific disorder. For example, sedatives might be used to relieve insomnia, stimulants to alleviate fatigue, and opioids to relieve a lowered pain threshold.

Genetic Model

The genetic model posits that genes either increase or decrease one's vulnerability to alcohol or drug addiction. Studies of twins and adoptive studies both confirm that genetic inheritance contributes to the development of addiction. Having two parents with addiction further contributes to the severity of addiction. Nonetheless, up to 40% of patients presenting for treatment of addiction do not have a parent with an addictive disorder (but may have a grandparent or other relative with substance abuse). Genetic inheritance may not be a sine qua non for addictive disorders, or genetic vulnerability may not be manifest without certain environmental factors. Recent data suggests that disruptive environment during childhood or adolescence interacts with genetic vulnerability to increase the risk of addiction.

Externalizing Disorder Model

Child–adolescent psychologists and psychiatrists first described externalizing disorders as those involving behavior, including conduct disorders, substance use disorders, pathological gambling, and other behavioral problems. Internalizing disorders consisted of mood, anxiety, and somatic disorders. More recently these concepts have been applied to adults.

This model suggests that a person with any one externalizing disorder is prone to develop another externalizing disorder at some point. For example, an individual recovered from substance use disorder may be at risk for pathological gambling. The application of these concepts in adults remains in its early phases at this time, but early work suggests that this model may be important in ameliorating the longitudinal development of comorbid disorders, among those who already have had a psychiatric disorder of some sort.

Recovery Model

Treatment alone by clinicians cannot alleviate addiction. The active, committed participation of the addicted person is critical to a successful outcome. This patient-focused aspect of the treatment process is often referred to as recovery.

Recovery occurs over time in stages, rather than in a single, sudden step. The first stage of recovery involves breaking from addictive use. The goal of this phase is safety from continued addictive use, with treatment of associated biomedical and psychosocial disorders. Under optimal circumstances, this phase may last several weeks.

The second phase involves stability, including shelter, daily structure, and social support in a setting that reduces continued exposure to alcohol or other drugs of potential abuse. Recurrence of addiction is most apt to occur during this period of increasing comfort, independence, and growing self-esteem. This phase may be as short as several months, but can last longer.

The third stage of recovery involves a return to a comfortable, responsible, and productive life way. The risk to recurrence is present but decreases once the person has achieved 2 years of sobriety. This phase, if successful, requires several years or longer to become firmly established.

This eventual self-actualization associated with this model may lead relatives, clinicians, and various social gatekeepers to insist that the addicted person voluntarily seek recovery. However, the early steps toward recovery are not always so simple. Coercive treatment can help in motivating the initially unmotivated patient. Early on, coercive abstinence or treatment may aid the patient in joining the recovery pathway. In recent years, so-called drug courts have facilitated many addicted persons in turning from a life of property crime and family irresponsibility to a sober, productive life style.

Readiness-to-Change Model

Prochaska and DiClemente have described the addicted person's attitude toward recovery during the process from pre-recovery to full recovery. The first attitudinal stage, the so-called pre-contemplative stage, does not involve any intent to quit substances.

As problems mount, the addicted person may come to realize that continued addiction is causing these problems. The clinician may inform the person that addiction is causing the person's growing problems. These insights may lead to the second contemplation stage, in which the addicted person begins thinking about decreasing dose or frequency of use, or quitting use altogether. Growing ambivalence toward drug or alcohol use predominates at this stage.

The third step involves a decision to stop use, as the ambivalence toward psychoactive substance abuse crystallizes in the direction of reducing the amount and/or frequency of use, or perhaps the type of substance being used. Should this cut back approach fail (as it typically does), the addicted person may decide to seek treatment. The treatment-seeking stage requires collaborating with treatment in achieving safe, then stable, and eventual comfortable recovery.

Finally, continued maintenance of recovery builds a flexible resistance against recurrence. This phase may involve devotion to others, the environment, or some cause or purpose that serves a greater good. It may involve avoiding situations that precipitate craving. Avoiding excessive fatigue, hunger, or stress can also gird the recovering addict against relapse.

The Harm Reduction Model

The harm reduction model has evolved as a public health approach to widespread alcohol and drug addiction. The strategy lies in reducing the consequences of drinking or drugging, while assuming that alcohol and drug addiction will continue. For example, a wet house may permit inhabitants to drink heavily in the privacy of their rooms, so long as they do not aggress others or wander out into public arenas. Similarly, drug sales and injection may be provided in a safe setting, where unsafe injection, robbery, or assault can be prevented. Provision of clean needles to prevent HIV infection is another example.

In some cases, repeated attempts at treatment may end in failure and demoralization. Some addicted persons may give up the difficult struggle required for a successful recovery. For these patients, various harm reduction approaches have been employed. For example, clinicians who provide information to the patient about the harm issuing from their continued use may help the person to reduce the use. Or residence in a quarter-way house in which quiet, private drinking or drug use is permitted. Assessment of an early clinic that tried this approach revealed a high mortality rate over a 2-year period, but with eventual abstinence in a notable number of patients.

At times some social programs appear to follow a harm enabling approach. Providing shelter, income, or other resources that are not tied to a reduction in harm to self and others can increase rather than reduce harm. For example, a pension, trust, or savings can facilitate the continued deterioration of an addicted person. A legally assigned payee can route these funds to pay for shelter, food, clothes, and recovery-oriented expenditures.

CONCLUSION

No one model provides a complete understanding of all aspects of alcohol and drug addiction. A model that may help us in guiding our own use (or nonuse) of substances, such as the moral model, may not help us

in coping with an addicted relative, friend, client, or patient. An illness model may be useful for the addicted person willing to enter treatment, but not help a person who wants to continue addictive use of substances.

Although this list of models for understanding addiction is not exhaustive, nonetheless the list of models above shows the accelerating development of models for helping us to understand addiction. For example, in all the centuries before 1600 AD, only a limited few models were available to help people understand addiction. Major examples included the moral, criminal, and preternatural models.

Then following the first appearance of the widespread alcohol and opium addiction, health-related models appeared. These included the epidemic model and then, around the same time, the illness model of addiction. These new models appeared over a relative brief period of only a few centuries, greatly increasing the rate of new model development for understanding addiction. These new models did not eliminate the earlier moral, criminal, and preternatural models, but they provided useful new models for understanding and acting upon addiction. Diagnostic typologies and novel modes of treatment evolved from these models.

Over the last century, the number of new models has increased at a rate vastly greater than the rate preceding it. These new models have evolved from increased knowledge regarding learning, pharmacology, neurophysiology, and neuroanatomy. Cogent clinical observations have led to our appreciating the mode of administration, the interactions and sometimes disconnections between treatment and recovery, and the coercive role of society in requiring sobriety under certain circumstances. Randomized controlled clinical trials have increased our knowledge of what interventions work, when, and with whom. This knowledge has increased our understanding of the addictions.

Other and newer models will hopefully evolve in the coming decades to aid us in further understanding addiction. The centuries-old quandaries posed by addiction have continued to challenge addicted individuals and their families, along with the best minds in our communities. The history of these developing models has shown that enhanced understanding of the drug–person–society triad ultimately leads to effective prevention, early intervention, treatment, and rehabilitation.

Glossary

AA Alcoholics Anonymous.
Addictogenic substance a psychoactive substance whose use can produce dependence.
Ballast heavy weight stored low in hold of sailing vessels to prevent the vessel from tipping over in a strong wind.
Ceremonial or ritual drinking the use of alcohol takes on shared social or cultural symbolism (e.g. interpersonal, celebratory, or spiritual meanings) beyond the mere consumption of beverage alcohol.
Contingencies rewards or punishments that ensue from an addicted person's behavior.
Du-sten a German ritual in which two people agree to address one another by the informal "du" rather than the formal "Sie" when conversing together.
Endogenous a substance that is produced by the body.
Epidemic high prevalence of disease or disorder, spreading from one person or group to others, so that an entire society may suffer its ill effects.
Fetal alcohol syndrome maternal drinking causes damage to the developing fetus, so that the newborn has mental retardation and characteristic facial configuration.
GABA gamma-aminobutyric acid, a substance that affects neurotransmission.
Half-life of psychoactive substances the time required for half of an ingested substance to be deactivated (by excretion or metabolic breakdown of the substance).
Mead an alcohol-containing beverage derived from honey.
Native American Church a pan-tribal religion practiced by American Indian people in North America; it involves elements of ancient tribal religions and Christianity, with peyote consumed as a sacramental substance as a means of experiencing communication with the spiritual realm.
Neurotransmitter a biologically active chemical that affects transmission from one nerve cell to another; addictive substances mimic or affect neurotransmission.
Passover an annual religious celebration and feast in the Jewish religion.
Peyote a hallucinogenic drug obtained from a mushroom that grows wild in the Americas.
Preternatural events occurring outside of nature, such as by magic or shamanistic powers.
Psychosis a mental disorder marked by hallucinations, delusions, and/or other profound cognitive impairments.
Salutogenic favoring good health.
Smoking the volatilization of a psychoactive substance into a gas, so that it can be inhaled into the lungs and absorbed into the blood within the pulmonary alveoli.
Stocks a punishment in which the individual's extremities, and sometimes their head, are inserted through a wooden or other structure, such that they are restrained from moving about at will.
Tai-Lao languages a related family of languages spoken by hundreds of millions of people in Laos and Thailand (where they comprise the national languages), China, Vietnam, Malaysia, and Burma.
Tradition beliefs or behaviors that persisted across generations within a group.

CHAPTER

2

The Terminology of Addictive Behavior

Meyer D. Glantz[*,$]

[*]National Institute on Drug Abuse, Bethesda, MD, USA [$]National Institutes of Health, Bethesda, MD, USA

OUTLINE

"The beginning of wisdom is the definition of terms" ***Socrates***

"Define your terms, you will permit me again to say, or we shall never understand one another." ***Voltaire***

"Truth does not consist in minute accuracy of detail, but in conveying a right impression." ***Henry Alford, quoted out of context.***

SCIENTIFIC TERMINOLOGY

All effective communication rely on clear language and consistent meaning. However, terms that are used in a scientific context are expected to meet additional standards beyond those for words in everyday communication. The choice of which scientific terms are used and the transparency of their meanings are not trivial or semantic questions nor is the use of scientific terms just proprietary jargon intended to limit public understanding of technical communication.

Specialized technical terminology with formal, systematic definitions ideally provides a precise, standardized, documented nomenclature that goes beyond the goal of general informal understanding and colloquial communication. Effective scientific terminologies serve the purpose of ensuring that statements about scientific information, observations, and theories are explicit in meaning; concrete in applicability; and replicable in the sense that the terms will have the same interpretations and specifiable implications for all users. This consistency in the definition of terms may be achieved by a reproducible operationalization; reference to a formal classification system; comparison to a concrete metric or a standardized assessment; delineation of the necessary, sufficient, and exclusory characteristics; and/or a comprehensive listing of referents included and excluded from the term's meaning.

The highest standards for scientific terms go beyond requiring unambiguous, easily and consistently understood denotations. Scientific terms are usually part of a larger system of related terms and concepts and they often reflect a particular theory, model, or at least a particular perspective. Because of this, technical terms typically have significant connotations that include assumptions and implications. These connotations should ideally be public, identified as to their theoretical framework when possible, and preferably be empirically anchored. A discussion about terminology requires consideration of the underlying concepts of the terms in question.

Every scientific field develops its own set of terms and terminology, which often change over time as do the conceptualizations and frameworks to which they relate. At one time, stating that someone was an "alcoholic" or a "drug addict" was a moral judgment and a condemnation of the person's weak will and "dissolute character." Today, these terms more often imply

Published by ELSEVIER Inc.

psychiatric conditions and as such they reflect a change in the assumptions and larger perspective on substance use problems. The meaning of these terms may well change in the future and, if so, the evolution in the nomenclature will presumably be a productive change that reflects advances in thinking about the subject. For example, a formerly prominent term that is not often used currently is "addictive personality." The term refers to the idea that some individuals have a particular type of personality that makes them especially vulnerable to alcoholism, drug addiction, and/or other compulsive behaviors such as pathological gambling. However, decreased use of the term addictive personality was not because of its connotations or characterological emphasis but because multiple research efforts did not find any empirical support for it.

CONNOTATIONS

A common vocabulary is necessary for communication in any scientific field and the scientific method requires that terms be explicitly and consistently defined to ensure usefulness, standardized identification, and reproducible interpretability of referents and the symbols that represent them. Even when a full, general, consensual common language is not achieved, the goal is that at least for the purposes of a specific communication, all of the important terms used to communicate scientific information will have the same articulated meaning, the same denotation, and/or the same operationalized definition for all of the participants in the communication. If the meanings of the major terms in a field are not clear and consistent then effective communication about science is not possible.

This principle has long been a traditional requirement for scientific and clinical issues related to substance abuse. It is the expectation of most contemporary scientific publications and clinical documents that all major terms be unambiguously, explicitly, and operationally defined. Despite this, significant issues in terminology persist regarding even some of the most fundamental terms related to substance use problems and addiction. For the most part these issues are not simple disagreements about definitions, failures of naming conventions, or referents that have not been operationalized using concrete criteria. In other words, these are not simple semantic difficulties or linguistic confusions.

Instead, many serious problems are related to inadequacies in the clarity and exposition of the connotations and implications that give larger meaning to the terms. The problems are not primarily issues about the terms themselves but about the underlying concepts and conceptual frameworks that ultimately define them and the associations they elicit. Even when it does not seem that there is a problem with terminology, there often is and it is often belied by the appearance of consensually and even operationally defined terms.

It is controversial whether problematic behaviors such as compulsive gambling, binge eating disorders, or Internet addiction should be classified in the same category as problematic substance use. However, even limiting consideration to problematic behaviors involving the use of psychoactive substances leaves many important issues. The term "drug abuse" is a good example. Sometimes it refers to virtually any use of an illegal drug, sometimes it refers to a psychiatric drug use disorder, and sometimes it is an all-inclusive general reference to any problematic substance use including alcohol or tobacco. There is not even a consistent meaning of what is considered to be a drug in the context of the term. "Drug Abuse" is a DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, 4th edition) diagnostic disorder category that is defined by a pattern of drug use leading to particular categories of social consequences or involving use in situations where it is physically hazardous. Alternatively, the ICD-10 (International Classification of Disease, 10th edition) diagnostic taxonomy specifically avoids the term abuse and only includes a category of "Harmful Use," which is defined as persistent use resulting in specifiable physical or psychological adverse consequences. Although the concept of harmful use may seem similar to the DSM-IV concept of abuse, in fact, the ICD-10 diagnosis of harmful use explicitly excludes diagnosis based on the types of substance use-related social consequences that are inherent in DSM-IV abuse. The terms alcohol and drug abuse, dependence and addiction have no consensual or consistent meaning. In reality, outside of formal diagnostic systems such as DSM and ICD, there is no standard vocabulary for problematic substance use and even with these taxonomies there is no consensus on what the cardinal problems of substance use are. Some clinicians and researchers focus on neuroadaptively based substance dependence as the primary dysfunction underlying substance use disorders while others emphasize the severely impaired function and harmful consequences associated with persistent problematic substance use as the essential disordered dimension. Perhaps this is part of the reason that there is no consensually accepted phenotype for substance use problems.

There is consensus that the major defining characteristic of problematic substance use is persistent and/or uncontrolled substance use despite hazard or harm. But there is no consensus on the concepts, connotations, and implicit paradigms associated with many of the basic and critical terms. There is no agreement on whether the primary inimical aspects of problematic substance use are the harmful consequences, the

persistent substance use reflecting a neuropsychiatric dependence, or the antisociality and often criminality of which the substance use is one of many possible manifestations. There is no consensus on whether substance use problems are most accurately viewed from the perspective of psychiatric disorders, self-regulatory deficits, pharmacologically reinforced learned behaviors, neuroadaptive changes, brain disease, and so on.

Terms such as drug abuse, alcoholism, addiction, addictive behavior, and so on, have very different meanings and implications depending on the tacit assumptions and conceptual frameworks behind them. Even seemingly small conceptual variations can lead to significant differences. For example, a long-standing issue in the field is the extent to which the legality of the substance that is used or abused is a critical factor. Some believe that if the substance is illegal, then there is likely to be a strong component of antisocial behavior involved and the illicit "drug abuse" takes on overtones of criminality. In addition, a distinction is generally maintained at a larger social level in which alcohol and tobacco use are widely accepted. For example, it has been observed that legal substances such as alcohol and tobacco have strong commercial interests both supporting and encouraging them that they be distinguished from illegal drugs.

Taking direction from this, many early investigations of drug abuse operationally defined the concept by defining virtually any illicit drug use experience to be drug abuse. These researchers compared abstainers with almost all others without differentiating subjects' levels and types of illegal drug use. Heavy users of alcohol and/or tobacco but not illegal drugs were categorized as nonabusers because the primary criterion was use of an illegal substance. Using "any illicit drug use" as the defining criterion for drug abuse obscured critical information and, not surprisingly, the findings of these studies have proved to have little value in understanding the nature of substance use problems. Assessment of individuals' levels and consequences of substance use is now standard in research.

Nevertheless, relying on the use of an illegal substance as a defining criterion continues to obscure potentially important information and to shape social and policy decisions. While criteria of drug and alcohol use problems vary, they are generally operationally defined in epidemiological studies and are typically reported as being in separate categories. Although some findings are reported in terms of total substance use/abuse, a sum of alcohol and drug use/abuse, more fine-grained analyses are not standard. At the same time, differentiation of marijuana from cocaine or heroin use/abuse is usually limited to more specialized research. While there are numerous and often valid reasons for this, the result is a reinforcement of the view that as a group, drug users/abusers are relatively homogeneous and significantly different from alcohol users/abusers. This realistically reflects some aspects of substance use/abuse, but may be misleading in regard to others. For example, researchers and policy makers often consider changes of prevalences of alcohol and drug use/abuse as independent events and rarely discuss the possibility that a decrease in one and an increase in the other may indicate less overall change in substance use behavior than it might otherwise seem. Taking this a step further are the questions of whether the legal status of tobacco use implies less harm than the use of an illegal drug and whether some people would avoid tobacco use if nicotine dependence were referred to as a drug addiction?

Using legality as a major distinction of alcohol versus drug abuse is not indefensible. It does reflect some important aspects of substance use problems. Being aware of the tacit assumptions behind terms and making them explicit is an important and heuristically powerful step. This is because terms not only reflect the concepts behind them, they also further reify and shape thinking about those concepts.

When units of the National Institute of Mental Health were expanded to independent institute level in the United States National Institutes of Health, separate institutes were created for the study of alcohol and drug problems forming the National Institute of Alcohol Abuse and Alcoholism in 1970 and the National Institute on Drug Abuse in 1974. These both reflected and strongly contributed to the perpetuation of legality as a cardinal distinction between drug and alcohol use problems. Drug and alcohol disorder treatment and prevention programs, research initiatives, and so on, are often still separated. This compartmentalization is being questioned on a broader basis and, interestingly, the Institutes are expected to merge.

Terminologies are more than assigned labels and codified descriptors. Terms are not neutral symbols, they represent concepts and theories and they convey implicit paradigms that structure and direct conceptualizations. Many alcohol and drug abuse terminology issues are a result of fundamental disagreements about the basic nature and critical characteristics of substance abuse. No particular term is necessarily right or wrong to use nor is any particular definition correct or incorrect, true or false. Nevertheless, it matters which terms are used.

EMPHASIS

Problematic substance use is often characterized as maladaptive behavior defined by persistent or uncontrolled proscribed use of pharmacologically

psychoactive substance(s) despite hazard or harm. The particular aspect of this definition that is emphasized influences the orientation and the focus of thinking about problematic substance use and the terms that are used.

The choice of which term is chosen as the primary descriptor of alcohol and/or drug use problems often implies a particular perspective about the fundamental nature and the primary concern related to problematic substance use. While these terms have changed over time in usage and connotation, following are some of the most important of these terms and the contemporary and most prominent ideas that they emphasize:

problematic substance use: a fairly neutral term notable in that it does not emphasize compulsion, physiological processes, or consequences;
substance abuse: a term that emphasizes potential or extant harmful consequences;
harmful use: a term that emphasizes harmful consequences almost exclusively;
substance misuse: a term that contrasts appropriate and inappropriate use and may include instances of unintentional inappropriate use;
substance dependence: a term that emphasizes physiological dependence as primarily indicated by increased tolerance to the substance and withdrawal which is a state of severe deprivation when use is discontinued; there is often a secondary implication of loss of control resulting from neuroadaptation to the substance;
addiction: a term that is closely related to the concept of dependence, used interchangeably by some. Increasingly, addiction has come to emphasize neuroadaptation and chronic compulsion for substance use as a result of alcohol- and/or drug-induced changes in the brain;
addictive behavior: a term that emphasizes compulsive behavior without implications about the mechanisms that underlie the compulsions; the focus of the term is often expanded beyond the use of psychoactive substances to include a broader range of reinforcing behaviors (e.g. gambling addiction);
substance use disorder: a term that emphasizes the psychopathological character of problematic substance use viewing it as comparable to other psychiatric disorders.

The connotations of terms often go beyond the aspects of the phenomena that they emphasize. Problematic substance use terms may also reflect a theoretical framework and an implicit model of the fundamental problem and necessary target for intervention. For example, a focus on problematic substance use oriented around substance dependence not only emphasizes physiological processes but also implies that successfully addressing problematic substance use requires intervention for the physiological state of dependence. Treatments that target physiological habituation, withdrawal, and tolerance such as nicotine replacement or methadone treatment typically use terms such as nicotine dependence or opiate dependence. Alternatively, programs that stress harm reduction are more likely to rely on terms such as substance abuse or harmful use while those coming from a psychiatric perspective or considering issues of comorbid psychopathologies typically refer to substance use disorders.

The implicit paradigms of terms have additional implications. For example, describing someone as having an alcohol or drug use disease implies that their problematic substance use is an involuntary, undeserved affliction while describing someone as an alcoholic or an addict is a more stigmatizing reference suggesting, at least to some, antisocial and defective character and self-inflicted adversity.

To the extent that major terms represent concepts and theories, they also predispose thinking from the implied perspective. This is not intended to suggest an extreme straw man version of this statement and propose that particular terms inflexibly structure or even strongly direct thinking, a theory sometimes described as Linguistic Relativity or the Sapir–Whorf hypothesis. Nevertheless, thinking does tend to go reflexively to the concepts and associations suggested by a term. Further, an individual's cognitive beliefs and perspective are widely accepted as influencing experience and its interpretation and terminology plays a role in the process.

MODELS AND ANALOGIES

Recognizing the influence of the connotations of scientific terms goes beyond saying that words have a positive or negative connotative valence. For example, a discussion of unrestrained alcohol use employing terms such as ego and id will lead thinking in different directions than a similar discussion using terms such as cognitive executive function, sensation seeking, or disinhibition. Taking another example, the terms drug habit, drug dependence, compulsive drug use, and drug addiction have similar and overlapping meanings but for many people they elicit different associations and implications.

Conceptualization of a scientific phenomenon is often supported with an analogy to aid understanding. For example, basic descriptions of direct electrical current often use the model of water flowing through a pipe. Such models use an established concept to convey the nature and function of a new or hard to grasp phenomenon. Though often very useful, such analogies are approximations or metaphors. They are usually limited

and may break down or be misleading beyond a particular point. The hydraulic model of direct current only applies to basic electrical phenomena and will lead to invalid inferences if applied to other electrical phenomena such as alternating current.

Analogies play an important role in how we understand phenomena and the inferences we make. Particular terms are often associated with different basic analogies and elicit different inferences. This is another way in which terminology is influential. It is especially important in the area of substance use problems where analogies and models are as contested as basic theories. The question of which model is the most appropriate analogy for substance use problems is controversial and this not only mirrors our uncertainty and disagreement about the phenomena but has also become a forum for debate about social beliefs and policies.

Public health organizations and advocates for alcohol and drug treatment have attempted to fight social stigma, self-denigration, criminal prosecution, and moral condemnation of those with substance use problems by characterizing substance addiction as a disease. The selection of the term disease rather than a less medically associated word such as dysfunction goes beyond the goal of just reducing stigma or emphasizing the biological aspects of addiction. It is a deliberate attempt to use the influence of the term to shape perception and perspective in a positive way with the contention that alcohol and drug addiction are in essence physiologically based fundamental medical conditions that should be viewed like diabetes, cancer, or other diseases.

Although the disease model acknowledges that behavior and environment play a role in the etiology and course of substance addiction, the emphasis is on physiological and presumably, at least in part, genetic factors. The primary message of characterizing substance addiction as a disease is that, as is the case once any disease has developed, the sufferer should be treated with compassion not condemned or punished. A further implication is that whether the sick person has arthritis, lung cancer resulting from cigarette smoking, heroin addiction, or any other disease, society has some responsibility to provide care for the sick individual. As is often the case with medical models, there is some additional implication that a medical and typically pharmacological treatment is the intervention approach most likely to be effective. More recently, the phrase "addiction is a brain disease" has been used to maintain that substance addiction is neurological in nature and that addictive use of alcohol and drugs characteristically relates to neuroadaptations that involve long-lasting functional disruptions of neural circuits. The implication is that the basic mechanism of addiction impairs the individual's ability to behave in ways that would enable the individual to control the disease.

Framing alcohol and drug addiction as a disease is neither invalid nor deceptive and the focus on treatment rather than blame is commendable. The use of terminology for advocacy (or condemnation) is not unusual. Researchers and clinicians in the field of substance use problems may be forgiving of whatever bias is part of describing addiction as a disease because they are likely to agree with the intent to establish a less pejorative term and perception. Nevertheless, most clinicians or researchers would not expect to find a chapter on addiction in an encyclopedia of brain diseases. Further, some express reasonable concerns that using a disease metaphor de-emphasizes behavioral, psychological, social, and environmental aspects of substance use problems.

DIAGNOSTIC TERMS

The context in which a term is used and the purpose of the terminology can have an important impact on the meaning of a term. "Intoxication," for example, has a potentially different meaning in a legal context than in a medical context. Some specific definitions correspond to operationalized designations developed for specific research projects and publications. However, much of the terminology currently used in the field of substance use problems and addictive behaviors is rooted in a medical–psychiatric framework and is strongly linked to diagnosis and taxonomy. Some terms are taken directly from medical terminology, for example, remission and relapse. Others are applications or extensions of terms in formal diagnostic taxonomies. The major psychiatric classification systems currently in use are the Diagnostic and Statistical Manual of Mental Disorders (DSM) produced by the American Psychiatric Association (currently in its 4th edition with the 5th edition released as of May 2013) and the generally similar International Classification of Diseases (ICD) produced by the World Health Organization (currently in its 10th edition with the 11th edition in development). DSM-IV substance use disorders are differentiated into categories of abuse (defined in regard to consequences) and dependence (as indicated by tolerance, withdrawal, and compulsivity). Other addictive behaviors are either classified separately (such as "pathological gambling," which is categorized as a disorder of impulse) or not specifically included.

DSM-5 combines the diagnoses of abuse and dependence into single substance designated disorders of graded clinical severity, adds a criterion of craving, and eliminates the abuse criterion of recurrent alcohol use-related legal problems. The reformulated diagnostic category now includes both substance use disorders

and non-substance addictions such as Gambling Disorder. From one perspective, the practical implications of the eevision of DSM-IV's classification of Substance-Related Disorders into DSM-5's classification of Substance Use and Addictive Disorders will be relatively minor in that all but one of the diagnostic criteria of DSM-IV has been carried over and only one new though related criterion has been added. Most individuals diagnosed with a substance use disorder under DSM-IV will also be diagnosed with a substance use disorder using DSM-5. Alternatively, the taxonomically modest combination of abuse and dependence may have major influence on the conceptualization of substance use disorders because the differentiating distinction of neuroadaptive dependence and disorder defined by harmful consequences resulting from persistent use is no longer reified by diagnostic categorization but is discouraged by the new nosology and terminology.

The classifications and terminologies of the DSM and ICD taxonomies serve a critical function for alcohol and drug use disorder diagnosis. They provide authoritatively endorsed operationalized criteria for psychiatrically identifying substance abuse and dependence syndromes according to articulated rules. These taxonomies are widely used and relied on, and are the practical standard for clinical and research purposes. Addictive behavior terminologies are so strongly anchored in the taxonomies that for the most part, their default meanings in professional contexts are the diagnostic classification distinctions and criteria.

Several issues should be noted. The DSM and ICD taxonomies are developed by experts in the mental health field and as scientific thought and empirical findings have changed over time, so have the concepts, categories, and criteria of the systems. Some degree of subjectivity, compromise, and supposition is inevitable. For example, it has been reported that the American Psychiatric Association DSM-III-R committee chose the term "dependence" over the term "addiction" by a single vote. The term addiction is becoming more established as a primary term and although it is not included in DSM-IV, the term "addictive disorders" is the category descriptor in DSM-5.

In developing and revising the taxonomies, judgments become formalized into established standards. Some are more structural, such as the number of symptoms required to meet diagnosis for dependence, while others reflect beliefs and conceptualizations, such as the hierarchical distinction of abuse and dependence in DSM-IV. Once terms and criteria have become standardized, they reify the concepts behind them. Clinicians typically adapt to conceptualizing patients with the current approved diagnostic system and researchers usually design projects that are at least compatible with the accepted taxonomy. Following DSM-IV criteria, the seeming actuality of dependence involving multiple symptoms and the hierarchical differentiation of the consequences implicit in abuse from the physiologically based reliance implicit in dependence is reinforced. The nosological framework of DSM substance use disorders, particularly the differentiation of dependence and abuse, is removed in DSM-5 and is likely to lead to changes in conceptualizations, perceptions, and perhaps even research findings about substance use symptoms and disorders.

Overgeneralization is a potential problem in the application of diagnostic terms. DSM and ICD criteria are intended primarily for case identification of psychopathology. The set of criteria for a particular disorder are somewhat like a screening instrument in that the items are intended to identify probable cases of a disorder including differentiation of similar or overlapping disorders. They are not necessarily the equivalent of a full description of the disorder. Relevant criteria may not be included for a variety of reasons including that the symptom may be common to multiple disorders, it may have a high co-occurrence with another criterion of the disorder, it may apply only to a small percentage of individuals with the disorder, it may be difficult to assess, and so on. An assumption that a term anchored in a diagnostic taxonomy is fully representative of the disorder may be inaccurate and misleading. Similarly, variables that are operationalized for the purpose of a research study are not necessarily a comprehensive delimitation of the term that they use to define. For example, a research study may define smoking a pack or more of cigarettes per day as an operationalization of nicotine dependence and the variable be interpreted by the researchers as representing nicotine dependence but it is not the full equivalent of nicotine dependence.

While delineating the fundamental nature and primary characteristics of substance use disorders is critical and controversial, determining the relationship of the symptoms of a disorder (the observable criteria) to the theorized construct of the disorder and articulating the relationship of the symptoms to the associated diagnostic terms and categories also raises significant issues. For example, is the implication of assigning a diagnostic term to a group of individuals: 1) that it designates those with a common set of observable symptoms without specification of the underlying causes or processes, 2) that it usefully corresponds to a group of individuals with related but diverse disorders, or, 3) that it identifies those who are assumed to have a specific underlying characteristic or dysfunction even if their manifest symptoms vary widely?

Assuming that diagnoses are made following the rules and criteria of taxonomy, many fundamental questions

typically remain unaddressed. For example, is it implied that a given diagnostic term has the same meaning when applied to everyone who meets the criteria for that term? Does the DSM-IV diagnostic term "opiate dependent" identify a homogeneous group? What is the relationship of those who meet one particular subset of the diagnostic criteria as opposed to those who meet a different subset, or to those who meet only some of the criteria (a subclinical subset) or even to those who meet none at all? Nevertheless, even when it is not clear exactly what a diagnostic term implies about the relationship of the observable symptoms to a theorized underlying pathology, use of the term in classifying individuals tends to reify belief in the reality of a discrete comprehensively conceptualized disorder.

Consideration of diagnostically standardized terms provides other examples of terminology both reflecting and shaping conceptualization. For the most part, 'craving' has been a central concept in the field. It emphasizes the experience of the alcohol- or drug-addicted individual and focuses on intense desire and impaired impulse control as important explanatory factors of addiction. To some it has a pejorative overtone. The term craving has not been included as a criterion in the DSM-IV or ICD-10 taxonomies for substance use disorders but apparently not because the term or the general concept is rejected. ICD-10 uses the term craving in the context of eating disorders but refers to strong desire or compulsion for substance use disorders. DSM-IV refers to persistent desire as a criterion for substance dependence even though its text notes that "Although not specifically listed as a criterion item, 'craving' (a strong subjective drive to use the substance) is likely to be experienced by most (if not all) individuals with Substance Dependence." The term craving may have been omitted from the criteria because it conveys stronger connotations of subjective experience and impulse control issues or perhaps for some incidental or procedural reason. However, once a lexicon is established it also reifies a particular emphasis. If clinicians and researchers do not ask about craving, they are less likely to be aware of the role of the phenomenon of craving to whatever extent it is different from strong desire, persistent desire, or compulsion. The differences are subtle but not meaningless. DSM-5 specifically incorporates craving as a criterion for substance use and addictive disorders.

Perhaps more importantly, the terms craving and compulsion refer to primary concepts describing presumably critical subjective experiences in addiction. They are the main experiential terms related to explanatory models of addictive behavior. Nevertheless, craving and compulsion are difficult to define, measure, or operationalize and are little more than synonyms for the phrase "strong desire." The new DSM-5 diagnostic criterion is worded as "Craving or a strong desire or urge to use…" Some terminology issues relate to disagreements about theory, pragmatic approaches, and research findings but others may be more a question of there simply not being a clear idea of what the concept is, what the term refers to, or how to measure it.

There are other issues involving the relationship of substance use problem terms and the concepts that they both reflect and shape. Problematic substance use nomenclature tends to include categorical rather than dimensional terminology and addictive disorder models frequently rely on dichotomous characterizations. For example, diagnoses do not currently allow for ratings of degree beyond the number of criteria met, relapse and abstinence are viewed as all or nothing, and quantity and frequency of the use of an illegal drug are often not even assessed. Many current addictive disorder models and the associated terminology promote a relatively homogenous perspective that minimizes the significance of subtypes. There is a strong emphasis on similarities and convergences of drug effects, neurological mechanisms, states of dependence, manifestations of abuse, and so on. Models of comorbidity are not well articulated and neither is the vocabulary designating co-occurrence of problem behaviors. For example, there is relatively little differentiation of single versus polydrug problematic substance use, there is no consensual lexicon to designate the range of possible relationships of co-occurring disorders, and there is no accepted terminology to describe the relationship of an event at one micro–macro level with an event at another level. This last example illustrates the poverty of language and conceptual frameworks available to discuss the relationship of a neurochemical depiction of addictive disorder with a behavioral depiction, to consider relationships of addictive behaviors with broader categories such as antisocial behavior, or to characterize variations in the relationship of predisposing factors to an outcome including whether they are earlier manifestations of that outcome or share a common underlying causal factor. Lastly, current addictive behavior terminology is not oriented toward developmental concepts, models involving transactional influences, or multidimensional factors. Without the words to describe particular types of factors and relationships, it is much harder to conceptualize and explore them.

RISK

Some of the terminology issues in the field of addictive behaviors relate to concerns that apply to most

fields. Issues related to risk are of concern across the range of behavioral and medical fields including the field of addictive behavior. The concept of risk is central to understanding substance use problem etiology, to early identification of vulnerable populations, and to effective prevention. Risk addresses questions regarding the relationship between observable antecedent and/or co-occurring factors and adverse outcomes.

At a basic level, the term "risk" asks, "given the presence of factor (or factors) X, what is the probability that outcome Y will occur?" For example, what is the likelihood that adolescents who have friends who use illegal drugs will themselves use drugs? In this sense, risk is a statement of predictability. In a typical approach, epidemiological data are used to identify factors that are statistically associated with, for example, substance use disorders, and then these factors are used as predictors of substance use disorders. Individuals in that particular data set who have these characteristics, or "risk factors," have a greater statistical probability of also currently or subsequently having the associated alcohol or drug use disorder outcome. Assuming that the epidemiological sample is representative, it is assumed that the predictive risk factors generalize to other populations.

However, whether the original epidemiologically derived risk factors were antecedent or concurrent with the substance use disorder outcome, the association is correlational. As such, while the identified risk factors may be useful markers, signals, or even early identifiers of substance use disorders, they are not demonstrated causes of or even proven contributors to substance use disorders.

Although this is widely recognized in all scientific fields, the use of risk as a probabilistic statement seems to be taken by some to have implications for causality. This is not surprising as there is ambiguity in the use of the term and risk has both a statistical and a causal meaning. In common parlance, risk often refers to circumstances that presumably influence events in a causal way, for example, stating that a person risks having a car accident if they drive while intoxicated or stating that individuals risk progressing to heroin dependence if they use marijuana. Even if the original intent of the risk statement was to report an observation of an association and does not intentionally imply causality, care is required to avoid an inference of causality on the part of the reader of the risk statement.

Analyzing conceptual and practical issues in psychiatric research, Helena Kraemer and colleagues have described how different statements about risk–outcome relationships may use a similar terminology but may be referring to significantly different types of associations. They examined different meanings underlying risk vocabulary and proposed a standard terminology to be used in discussions about risk. Although all of the variations in Kraemer et al.'s risk typology include at least a correlation between factor and outcome and therefore they contribute to the prediction of the outcome given the presence of the factor, they vary in the extent to which there is a presumed or demonstrated causal association. For risk–condition relationships where both correlation and temporal order have been established, they propose use of the following terms:

- *correlate*: a correlated factor; although each correlate may contribute to prediction of the other, neither of the correlated factors is known to be antecedent or causally determinative of the other;
- *risk factor*: referring only to an antecedent correlated factor;
- *marker*: an antecedent correlated factor with no presumed causal involvement in the outcome;
- *causal risk factor*: an antecedent correlated factor that presumably does causally influence the outcome.

Despite the cogency and importance of the points and proposals made by Kraemer and colleagues, the distinctions of risk terminology are often not observed and this leads to problems of miscommunications and invalid inferences. The issues are not scientific disputes about inferring causality from correlations. It is clear that even when it has been established that there is both an antecedent and a correlational relationship between a factor and an outcome, this does not demonstrate a causal relationship even if a plausible mechanism for causal influence can be hypothesized. There are other possibilities including that the antecedent may be a proxy for another influence, there may be an underlying common cause for the factor and outcome (third-factor alternatives), the antecedent may be an earlier form or stage of the outcome, and so on. Unless there is evidence to the contrary, it is safest to assume that markers are no more than correlates, not demonstrated causal influences and therefore not causal risk factors.

A significant challenge for a proposal of any standardized terminology is that unless it is sponsored by a major authoritative organization, it is often not adopted as a standard and if it uses idiosyncratic terms or definitions it is less likely to be used or used correctly. Formulating a set of terms that are explicit as to both denotation and connotation and that avoids relying on words that have multiple common definitions may help with both clarity and utility. Distinctions between causal influences and markers might be more easily and more often applied if the terminology were simpler and more clearly distinguished types of associated factors. Therefore, it would be helpful to reserve any use of the phrase "risk factors" to only include Kraemer's category of causal risk factors and to refer

to any other correlated factor as a "marker" independent of whether there is presumed antecedence. If a temporal distinction is needed, markers determined to exist prior to the predicted outcome could be designated as "antecedent markers." Using the term "risk factor" in this more limited definition may have the added advantage of not inadvertently implying causality for a variable that is only a proxy for the causal factor. Given the scientific complexity of the concept of causality, substituting the concept of having an influence on the occurrence of an outcome and using the term "predisposing" may also be more useful. Following is a revision of Kraemer's proposal. For risk–condition relationships where both correlations have been established, the following terms are suggested:

- *correlate*: one of two (or more) correlated factors; while each of the correlated factors may contribute to prediction of the other, neither of the correlated factors is identified as the outcome or known to necessarily be antecedent or causally determinative of the other, although such a relationship is not excluded as being possible;
- *marker*: a correlated factor with no implication of causal involvement in the outcome; markers are often more readily observable factors in a particular study or circumstance;
- *antecedent marker*: a correlated factor that is shown to be antecedent to the outcome but with no implication of causal involvement in the outcome;
- *predisposing factor*: an antecedent correlated factor that presumably does causally influence the outcome.

The intention of this revision of Kraemer et al.'s risk terminology is to propose a set of terms with the clearest possible definition and the most explicit implications. However, to be as useful as possible, the lexicon must correspond to common scientific thinking about the issue of risk. Contradicting, diverging from, or simply not corresponding to generally held conceptualizations often results in a terminology being misused or not adopted.

Implicit in viewing substance abuse and dependence as pathologies or medical disorders is the assumption that substance use problems are neither healthy nor normal. Therefore, there must be factors that cause the abnormal disease conditions. Construing problematic substance use as a psychopathology implies that it is involuntary, that it is an ailment that happens to individuals, and that there are likely to be physiological, psychological, and environmental contributors to its occurrence and course. Not everyone becomes a substance abuser, not even everyone who has used often abused substances. Therefore, there must be some factors that account for individual differences and increase the likelihood and severity of the disorder for some. Similarly, there are presumably factors that reduce the likelihood and severity for others. Unless and until they change, these concepts are at the core of our basic thinking about problematic substance use and any useful terminology must be correspondent with these fundamental assumptions.

However, it is a narrow linguistic distinction between stating that particular factors are antecedent and have a strong correlational association with an outcome as opposed to stating that particular factors influence that outcome. To reflect strongly entrenched common concepts of risk and to reinforce the distinction of correlated from predisposing factors, a comprehensive terminology of risk must include terms that identify predisposing factors that are thought to be predisposing or not as related to desirable versus undesirable outcomes.

Further expanding the revision of Kraemer's terminology, predisposing factors would be subtyped as follows:

- *beneficial predisposing factor:* a predisposing factor associated with a desirable outcome;
- *detrimental predisposing factor:* a predisposing factor associated with an undesirable outcome;
- *protective predisposing factor:* a predisposing factor associated with the nonoccurrence of an undesirable outcome.

Given that a correlation does not support inference about the operation or mechanism of the association, the determination of whether an antecedent marker is correlated with a desirable or undesirable outcome is a matter of conjecture. Without some assertion of cause, it is not possible, for example, to differentiate whether an antecedent marker has an association with the nonoccurrence of an event or with the occurrence of a different event.

Illustrating this, if parental monitoring is found to be an antecedent marker of lower levels of drug use in adolescents, it may be that monitoring has a direct positive influence on child behavior. Alternatively, it may be the case that monitoring is a signal that a range of parent–child circumstances are relevant and perhaps, for example, parents who monitor their children's activities also are better, more influential parents in many ways including having taught values associated with not using illicit drugs. Given the limitations of correlational information, the only judicious distinction would be to add a statistical description of the correlation and refer to either a positively or negatively correlated antecedent marker of an outcome.

While the concept of risk is often applied to subgroups (e.g. males) or those having some degree of a characteristic (e.g. impulsiveness), risk is often attributed to individuals as a personal characteristic in which case it is usually referred to as vulnerability or resilience. If a risk level label simply reflects that an individual has

a quality found for a group to be a marker or predisposing factor for an outcome, then the terms are not misleading particularly if it is recognized that each member of a group does not necessarily have the same level of risk attributable to the group as a whole. Alternatively, if the risk label is taken to mean that there is a specific quality of vulnerability or resilience and that these qualities are predisposing characteristics, then this is questionable unless there is evidence of such a general independent trait.

Attention to terminology may seem to be an unexciting procedural distraction from important issues. However, terminology is the language of scientific thought and communication and these both represent and shape understanding. Inconsistent or muddled terminology usually reflects concepts and models that are inadequate and counterproductive. Addictive behavior terminology is as controversial as other issues in the field. If that were not the case, this chapter would have been no more than a simple glossary.

DISCLAIMER

The views and opinions expressed in this chapter are those of the author and should not be construed to represent the views of the National Institute on Drug Abuse (NIDA), the National Institutes of Health (NIH), or any of the sponsoring organizations, agencies, or the US government.

Glossary

Diagnostic problematic substance use terms authoritatively endorsed operationalized sets of criteria designating nosological categories for psychiatrically identifying substance abuse and dependence syndromes according to articulated rules developed primarily for case identification of substance use-related psychopathology.

Problematic substance use maladaptive behavior defined by persistent and/or uncontrolled proscribed use of pharmacologically psychoactive substance(s) despite hazard or harm.

Risk in scientific contexts, risk is a probabilistic statement of the relationship between observable antecedent and/or co-occurring factors and adverse outcomes. Although useful in predicting outcomes, risk statements are usually based on correlational observations and when this is the case, risk does not imply causality.

Scientific terms formal, systematic definitions that provide a precise, standardized, documented nomenclature ensuring that statements about scientific information, observations, and theories are explicit in meaning, concrete in applicability, and replicable in the sense that the terms will have the same interpretations and specifiable implications for all users.

OUTLINE

INTRODUCTION

The study of addiction is a multidisciplinary endeavor, encompassing a diverse range of fields such as biology, psychology, internal medicine, psychiatry, genetics, and epidemiology. In this chapter, we will present the epidemiological approach to addiction and provide an overview of our current knowledge of addiction epidemiology in the United States.

DEFINITION OF ADDICTION

Conceptually, addiction can be defined as "a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations" characterized by impaired control or compulsive engagement in a specified behavior despite knowledge of harmful consequences. In the United States, addiction is operationally defined by

Principles of Addiction, Volume 1

TABLE 3.1 DSM-IV-TR Substance Use Disorders

Diagnostic variables	Abuse	Dependence
Diagnostic criteria		
Recurrent substance use resulting in a failure to fulfill major role obligations	X	–
Recurrent use in situations in which it is physically hazardous	X	–
Recurrent substance-related legal problems	X	–
Continued use despite persistent or recurrent substance-related problems	X	–
Tolerance	–	X
Withdrawal*	–	X
Persistent desire or unsuccessful efforts to cut down or control use	–	X
Using in larger amounts or over a longer period than the person intended	–	X
Neglect of important activities because of substance use	–	X
A great deal of time spent in substance-related activities	–	X
Continued use despite substance-related physical/psychological problems	–	X
Diagnostic threshold	1+ criteria	3+ criteria

* *Marijuana and hallucinogen use disorders do not include the withdrawal criterion.*

the *Diagnostic and Statistical Manual* (DSM) as substance abuse or dependence (substance use disorder refers to a diagnosis of abuse and/or dependence). Diagnostic criteria for substance abuse and dependence from the most recent version of the DSM, the DSM-IV-TR, are provided in Table 3.1. While other addictive behaviors exist and are discussed throughout the *Encyclopedia of Addictive Behaviors*, the present chapter will only consider DSM-defined abuse and dependence on substances which produce intoxication, including alcohol, illicit drugs, and prescription drugs. In order to provide a context for the discussion of substance use disorders, we will also briefly consider substance use. However, it is important to note that substance use is not necessarily indicative of addiction and not all substance users develop a substance use disorder.

DEFINITION OF EPIDEMIOLOGY

The field of epidemiology has two primary objectives. First, epidemiological investigation aims to obtain information on the distribution of health outcomes within a population. Distribution includes prevalence, incidence, and persistence. Prevalence is the number of cases of a health outcome that exist within a given population at a specific point in time. Incidence refers to the number of new cases of a health outcome that arise in a given population over a certain time period whereas persistence refers to the proportion of cases who continue to experience a health outcome over a certain time period. Second, epidemiology is concerned with the determinants of a health outcome within a given population, which refers to risk factors for the onset and persistence of health outcome.

Accordingly, this chapter will present information on the distribution and determinants of substance use, abuse and dependence in the United States. In part 1, we discuss the epidemiology of substance use in the United States and provide an overview of the prevalence of alcohol and drug use. In part 2, we present information on the epidemiology of substance use disorders in America. We begin this section with a description of the key substance use disorder epidemiology studies conducted in the United States since 1980. Next, we provide findings from these studies on the distribution of alcohol and drug use disorders including prevalence, incidence, and persistence. Lastly, we will consider epidemiological findings on the determinants of substance use disorders including sex, race, and age.

PART 1. THE EPIDEMIOLOGY OF SUBSTANCE USE IN THE UNITED STATES

Alcohol consumption can be recorded at the population level and individual level, while drug consumption is primarily measured at the individual level.

To determine population-level alcohol consumption, "apparent per capita consumption" is calculated by dividing the total amount of alcohol consumed in the United States given records of alcohol sales by the total US population aged 14 and older.

Alcohol and drug use can be measured at the individual level in United States surveys with questions about the quantity and frequency of consumption. In this chapter we will include data on self-reported alcohol and drug use obtained by the following two important population-level surveys:

1. The National Survey on Drug Use and Health (NSDUH): Funded by the Substance Abuse and Mental Health Services Administration, the NSDUH is a large annual national survey of ages 12 and older designed to track trends in substance use and collects data on current use via self-administered computerized interview. The NSDUH is the most comprehensive and recent source on substance consumption among adolescents and adults in the United States.
2. Monitoring the Future (MTF): Designed to track substance use behaviors, attitudes, and values and funded by the National Institute of Drug Abuse (NIDA), annual MTF surveys are conducted among a large nationally representative cross-sectional sample of US adolescents. The MTF surveys have been conducted annually since 1975 and thus provide an important and unique opportunity to understand trends over time in substance use among adolescents in the United States.

Alcohol

Per Capita Consumption

Figure 3.1 demonstrates changes over time in per capita alcohol consumption in the United States. In 2007, the most recent data available, 2.31 gallons of alcohol were consumed per capita, compared to 2.27 gallons per capita in 2006 and 2.23 gallons per capita in 2005. Indeed, alcohol consumption appears to have steadily increased since 1995 when a low of 2.15 gallons per capita was reported. However, present alcohol consumption is lower than the high level recorded in the early 1980s (2.76 gallons per capita).

NSDUH

Table 3.2 provides information from the NSDUH on individual alcohol use among US teenagers and adults in 2005 and 2006 in three time frames: past month, past year, and lifetime. Findings for 2005 and 2006 are similar. In the total population, approximately 83% report any alcohol consumption in their lifetime, around two thirds (approximately 66%) report past year consumption and about half report past month alcohol use.

The NSDUH sample consists of individual aged 12 and older. However, since alcohol sales under the age of 21 are illegal in the United States, it is important to

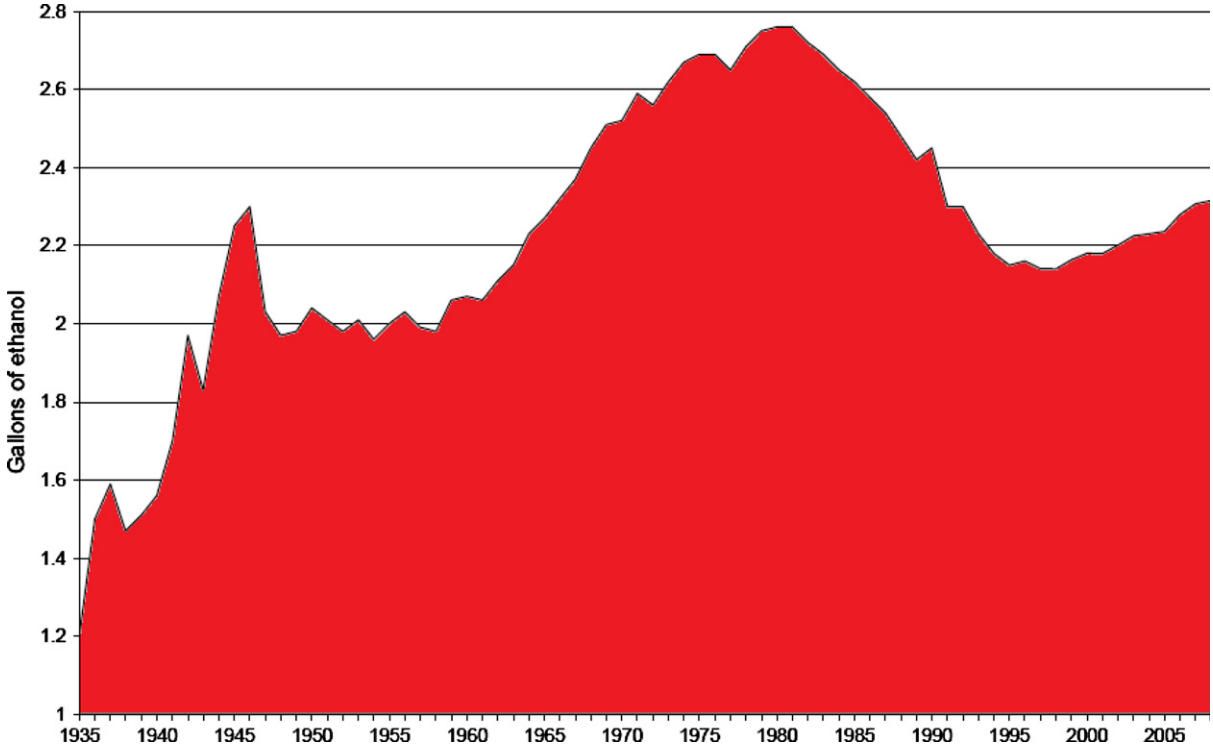

FIGURE 3.1 US per capita alcohol consumption. LaVallee, R., Yi, H. *Surveillance Report #90: Apparent Per Capita Alcohol Consumption: National, State, and Regional Trends, 1977–2008.* Bethesda, MD: NIAAA (National Institute on Alcohol Abuse and Alcoholism), Division of Epidemiology and Prevention Research, Alcohol Epidemiologic Data System, August 2010.

TABLE 3.2 Alcohol Use in the NSDUH

	Prevalence (%)					
	Past month		Past year		Lifetime	
	2005	2006	2005	2006	2005	2006
Total	51.8	50.9	66.5	66.0	82.9	82.7
Ages						
12–17	16.5	16.6	33.3	32.9	40.6	40.4
18–25	60.9	61.9	77.9	78.8	85.7	86.5
26+	55.1	53.7	69.0	68.3	88.2	87.7

consider how this measure varies by age. Less than half (around 40%) of individuals aged 12–17 (for whom purchasing alcohol is illegal in the United States), report any lifetime alcohol use, whereas the prevalence of lifetime alcohol use among the older age groups is more than double that. Although lifetime alcohol use is similar for 18–25-year olds and 26+ year olds, recent consumption of alcohol use is highest among 18–25-year olds (see Table 3.2). For example, in 2006, 62% of 18–25-year olds report past month alcohol use compared to around 17% of 12–17-year olds and 54% of those aged 26 and older. However, while alcohol use is generally homogenous among individuals older than 26, a great deal of heterogeneity of alcohol consumption exists among individuals aged 12–25 years (see Fig. 3.2).

MTF

Monitoring the future surveys reveals that the prevalence of alcohol use among US adolescents declined steadily in the last two decades (see Fig. 3.3). For example, past month prevalence of alcohol use was 25% in 1991 and 15% in 2009 for 8th graders, 43% in 1991 and 30% in 2009 for 10th graders, and 54% in 1991 and 44% in 2009 for 12th graders.

Similar declines in the prevalence of binge drinking (defined as having five or more drinks in a row at least once in the prior 2 weeks) are evident for 8th (11% in 1991 compared to 8% in 2009), 10th (21% in 1991 compared to 18% in 2009), and 12th graders in the United States (30% in 1991 compared to 25% in 2009). However, as shown in Fig. 3.4, adolescent reductions in alcohol use may be reaching a plateau. Data obtained from MTF on past month, past year, and lifetime alcohol use by teenagers in 2007, 2008, and 2009 are presented in Fig. 3.4.

Drugs

NSDUH

Data from NSDUH on past year and lifetime drug use in 2005, 2006, and 2007 are presented in Table 3.3. Marijuana is the most commonly used drug with approximately 40% of the US population reporting lifetime use and approximately 10% reporting past year use. Nonmedical prescription drug use is second to marijuana in terms of prevalence. Of the prescription drug classes, nonmedical use of prescription painkillers

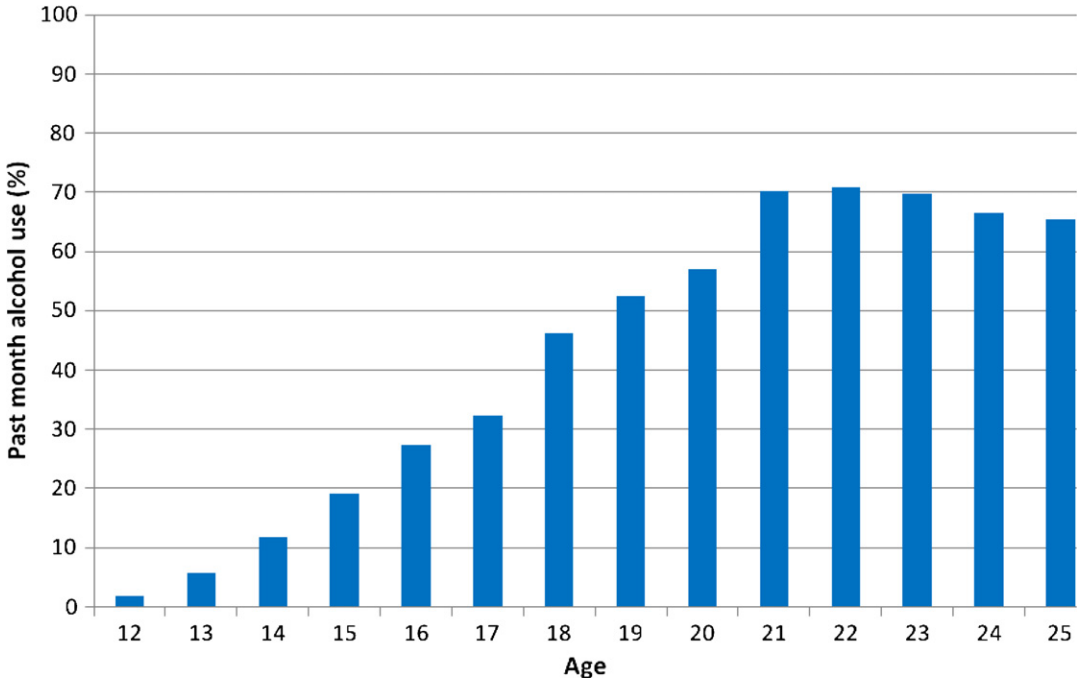

FIGURE 3.2 Past month alcohol use among ages 12–25.

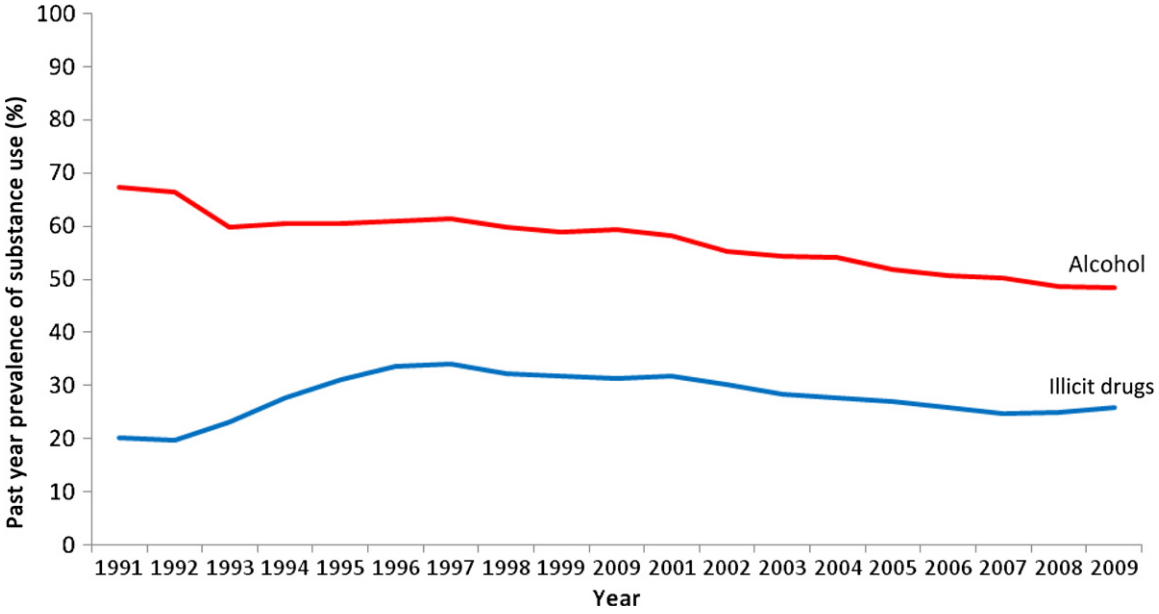

FIGURE 3.3 Past year prevalence of adolescent substance use from 1991 to 2009.

is most frequent, followed by stimulants, tranquillizers, and sedatives. Heroin was the least prevalent drug used, with only 0.1% of the population reporting past year use in 2007.

MTF

Prevalence of any illicit drug use among adolescents increased in the early 1990s and then began to decrease in 1995 for a decade, at which point it appears to start increasing (see Fig. 3.3 for past year illicit drug use). A more detailed summary picture of past month, past year, and lifetime prevalence of illicit drug use among 8th, 10th, and 12th graders in the United States is provided in Fig. 3.5. In general, prevalence of use between 2007 and 2009 was steady for 8th and 12th graders; however among 10th graders; use appeared to decrease between 2007 and 2008, and then increase between 2008 and 2009.

However, trends in drug use among American adolescents since the 1990s appear to differ somewhat by substance. Prevalence of marijuana use among teenagers decreased substantially in the 1990s and early 2000s. However, in recent years use appears to be increasing again. For example, past month prevalence of marijuana use among 8th graders was 11% in 1996, 6% in 2007, and 7% in 2009. Likewise, in 1996, 25% of 10th graders reported past month marijuana use, compared to 18% in 2007 and 19% in 2009, whereas among 12th graders this prevalence was 27% in 1997, 22% in 2007, and 24% in 2009. Ecstasy use peaked in 2001 followed by a sharp decrease until 2005 at which point use began to increase slightly and now appears to be reaching a plateau. Cocaine and heroin use increased in the 1990s, decreased in 2000, and presently appear to be relatively stable over time. Inhalant use has decreased since 1991 whereas nonmedical prescription painkiller, sedative, and tranquilizer use seems to be increasing.

PART 2. THE EPIDEMIOLOGY OF SUBSTANCE USE DISORDERS IN THE UNITED STATES

Substance Use Disorder Epidemiology Studies

Epidemiological investigation into substance use disorders in the United States began in the 1960s with community surveys of psychiatric impairment and subsequent functional impairment. However, these studies measured a general continuum psychopathology and therefore did not provide information on the distribution of specific disorders. Furthermore, these community studies assumed an entirely psychosocial causal mechanism of mental illness which has since been refuted by modern scientific developments in genetics, neuroscience, and psychopharmacology of psychiatric disorders that emerged later. As such, results presented in this chapter will be limited to findings obtained from epidemiologic studies conducted since the 1980s. In addition, to aid in interpretation, we will only include the five US-based epidemiological studies that adhered to the following design and methodological criteria:

1. Substance use disorder diagnoses were based on diagnostic nomenclatures of the American Psychiatric Association (APA) as presented in the

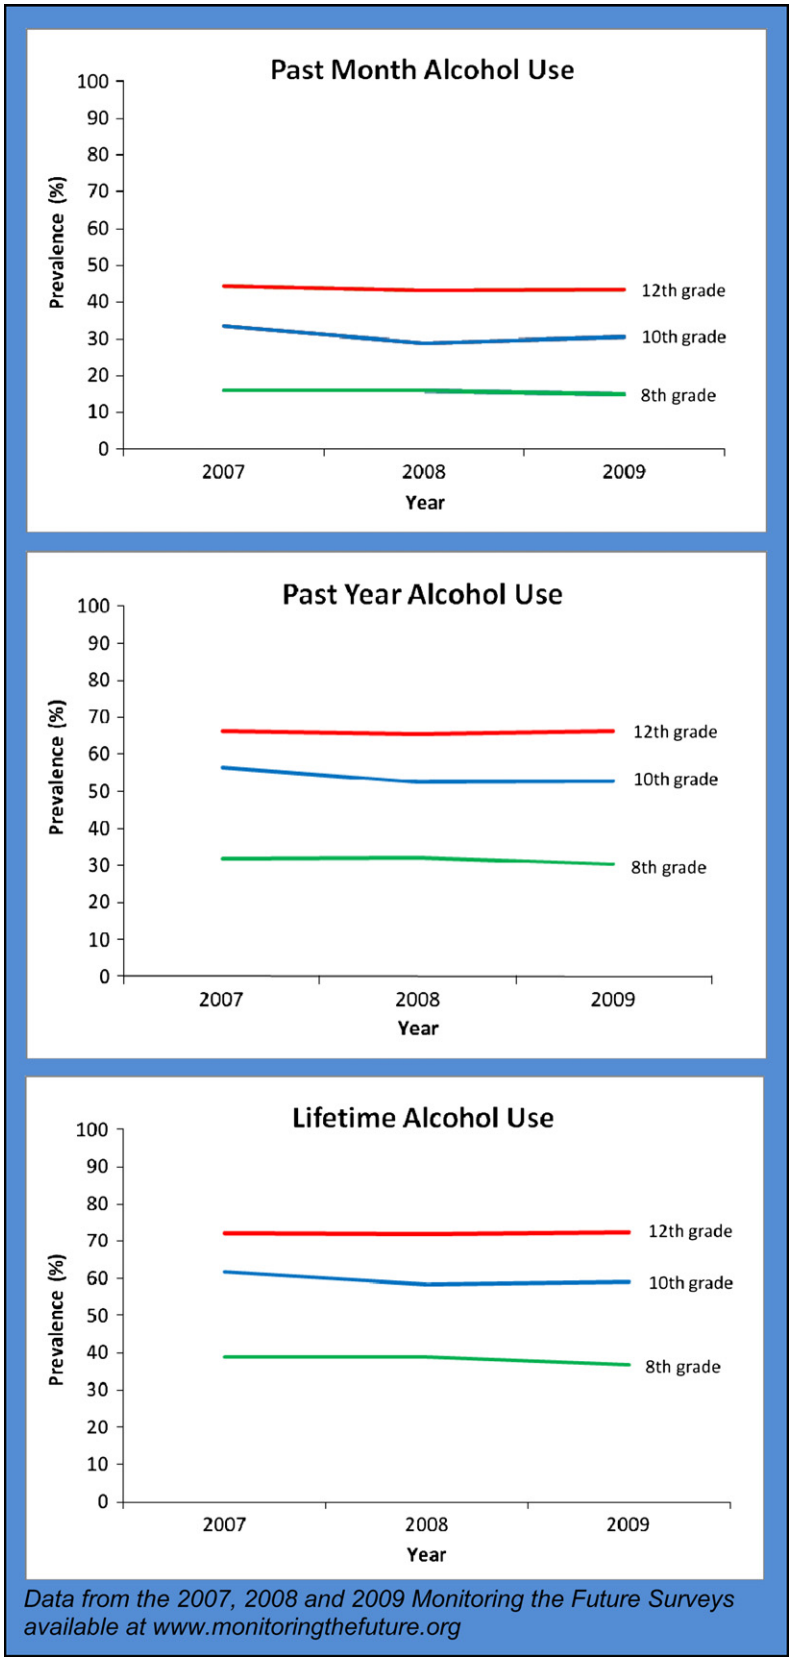

FIGURE 3.4 Past month, past year, and lifetime self-reported alcohol consumption from 2007 to 2009 among US adolescents.

Diagnostic and Statistical Manual of Mental Disorders, third edition (DSM-III), DSM-III-R (revised), or the DSM-IV obtained via standardized diagnostic interviews.
2. The study population was nationally or regionally representative, with a sample size (*N*) of at least 5000 that includes a broad range of adult ages.
3. Results include weighted lifetime and current estimates of distribution accompanied by an indicator of statistical precision such as confidence intervals or standard errors.
4. An explicit response rate was provided.

Epidemiological Catchment Area Study

The Catchment Area Study (ECA) was conducted between 1978 and 1983 in five US communities including New Haven, CT; Los Angeles, CA; Baltimore, MD; St. Louis, MO; and Durham, NC. The ECA obtained DSM-III substance use disorder diagnoses using the Diagnostic Interview Schedule (DIS), which was specifically designed for this purpose. The ECA was revolutionary in its sample size (20 000) and use of modern diagnostic criteria, and thus provided the first reliable and accurate weighted estimates of prevalence of mental health disorders in the United States. However, the ECA did not collect risk factor data in a standardized manner across all five sites, was geared toward treatment needs, and generalizability may have been limited by its use of only five sites.

TABLE 3.3 Prevalence of Drug Use in the NSDUH

	Prevalence (%)					
	Past year			Lifetime		
	2005	2006	2007	2005	2006	2007
Any drug	14.4	14.5	14.4	46.1	45.4	46.1
Cannabis	10.4	10.3	10.1	40.1	39.8	40.6
Cocaine	2.3	2.5	2.3	13.8	14.3	14.5
Heroin	0.2	0.2	0.1	1.5	1.5	1.5
Hallucinogens	1.6	1.6	1.5	13.9	14.3	13.8
Inhalants	0.9	0.9	0.8	9.4	9.3	9.1
Nonmedical prescription drug use	6.2	6.7	6.6	20.0	20.7	20.3
Prescription painkillers	4.9	5.1	5.0	13.4	13.6	13.3
Prescription stimulants	1.1	1.5	1.2	7.8	9.1	8.7
Prescription tranquilizers	2.2	2.1	2.1	8.7	8.7	8.2
Prescription sedatives	0.3	0.4	0.3	3.7	3.6	3.4

National Comorbidity Survey and National Comorbidity Study-Replication

The National Comorbidity Survey (NCS) was a psychiatric epidemiologic survey conducted between 1990 and 1992, with a sample of about 8000. The NCS collected risk factor data on a subset of the respondents. The assessment instrument used in the NCS was the University of Michigan version of the Composite International Diagnostic Interview (UM-CIDI), which obtained substance abuse and dependence diagnoses according to DSM-III-R criteria.

A decade later (2001–02), the National Comorbidity Study-Replication (NCS-R) was fielded, which aimed to obtain information on time trends in psychiatric disorders and provide estimates on the prevalence of psychiatric disorders according to DSM-IV criteria. Unfortunately, a major methodological problem with the NCS-R limits the conclusiveness and representativeness of alcohol and drug dependence results from this study. In brief, the version of the CIDI used in the NCS-R (the World Mental Health-CIDI (WMH-CIDI)) skipped respondents with no abuse symptoms from the dependence module. This is particularly concerning given later work indicating that 33.7% of individuals with current alcohol dependence do not meet criteria for alcohol abuse and 22.0% of individuals with current drug dependence do not meet criteria for drug abuse.

National Longitudinal Alcohol Epidemiologic Survey and National Epidemiologic Survey on Alcohol and Related Conditions

The National Longitudinal Alcohol Epidemiologic (NLAES) and National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) provide a wealth of information on the epidemiology of alcohol and drug use disorders and other psychiatric disorders due to their robust sampling and measurement methods and their unprecedented sample sizes. The NLAES was conducted in 1991–92 and included 42 862 respondents. Wave 1 of the NESARC was conducted in 2001–02 and included 43 093 respondents; 34 653 of whom were followed up 3 years later at Wave 2 (2004–05). The diagnostic interview used in the NLAES and NESARC was the Alcohol-Use Disorder and Associated Disabilities Interview Schedule–DSM-IV Version (AUDADIS-IV). This structured interview, designed for lay interviewers, was developed to advance measurement of substance use and mental disorders in large-scale surveys. Computer diagnostic programs implemented the DSM-IV criteria for the disorders using AUDADIS-IV data.

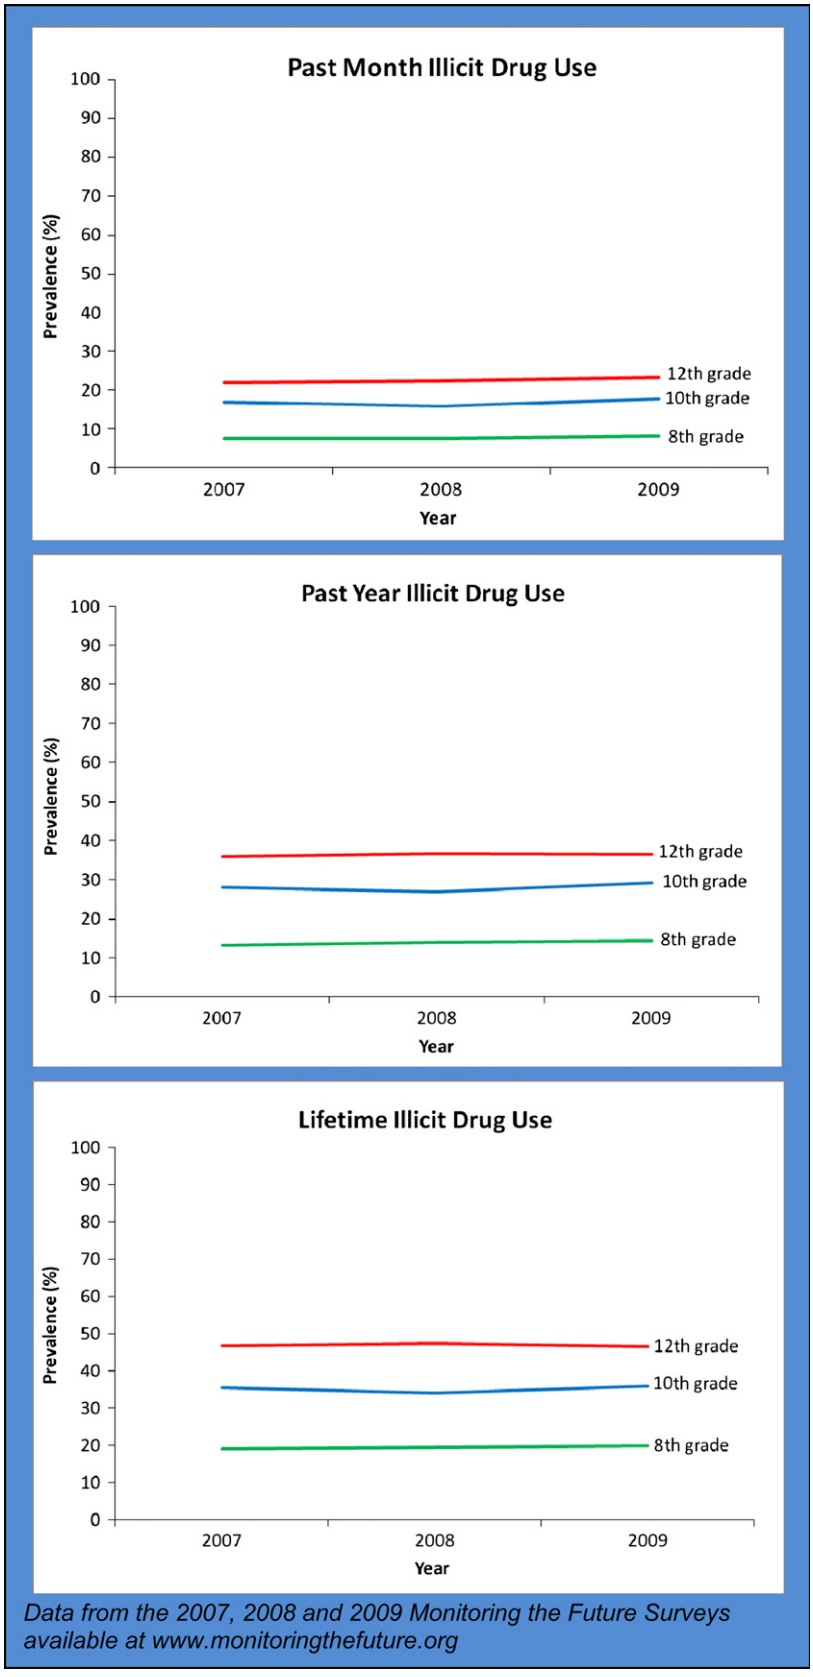

FIGURE 3.5 Past month, past year, and lifetime self-reported illicit drug use from 2007 to 2009 among US adolescents.

Extensive detailed AUDADIS-IV items operationalize DSM-IV abuse and dependence criteria for alcohol among all lifetime drinkers and for 10 drug classes (sedatives, tranquilizers, opiates (other than heroin), stimulants, hallucinogens, cannabis, cocaine (including crack cocaine), inhalants/solvents, heroin, and other drugs) among all lifetime drug users. Consistent with DSM-IV, lifetime diagnoses of alcohol or drug abuse required one or more of the four abuse criteria in the 12-month period preceding the interview or previously. AUDADIS-IV substance dependence diagnoses required three or more of the seven DSM-IV dependence criteria in the last 12 months or during any previous 12-month period. For prior diagnoses of dependence, three or more criteria must have occurred within a 1-year period following the DSM-IV clustering criterion. The withdrawal criterion of dependence diagnoses was measured as a substance-specific syndrome in accordance with DSM-IV.

AUDADIS-IV diagnoses of substance use disorders incorporate important improvements over other survey instruments, particularly the WMH-CIDI (used in the NCS-R), which skipped dependence questions among those with no abuse symptoms. By missing current dependence cases (especially likely among women and minorities), the WMH-CIDI underestimates dependence prevalence and limits the study of comorbidity between alcohol dependence and other psychiatric disorders. In contrast, the NESARC provides complete coverage of DSM-IV alcohol and drug dependence. The robustness of AUDADIS-IV substance use diagnoses is well documented, with good to excellent test–retest reliability, inter-rater reliability and convergent, discriminant and construct validity demonstrated in clinical and general population studies conducted in the United States and abroad.

Further information on the study design, sampling assessment methods of these five studies is provided in Table 3.4. While this chapter will provide findings from all five of the studies described above, given the methodological and measurement advantages of the NLAES and NESARC, we will primarily focus on results from these studies when discussing the epidemiology of alcohol and drug use disorders.

The Distribution of Substance Use Disorders in the United States

Prevalence of Alcohol-Use Disorders

Information on the prevalence of current and lifetime alcohol abuse, dependence, and any alcohol-use disorders using data obtained in the ECA, NCS, NLAES, NCS-R, and NESARC are presented in Table 3.5. The prevalence of current (last 12 months) alcohol abuse is lowest in the ECA (1.9%) and highest in the NESARC (4.7%), while current alcohol dependence was lowest in the NCS-R (1.3%) and highest in the NCS (7.2%). The lifetime prevalence of alcohol abuse ranges from 5.6% in the ECA to 17.8% in the NESARC, while alcohol dependence ranges from 5.4% in the NCS-R to 14.1% in the NCS. This range of alcohol abuse and dependence prevalence estimates is likely an artifact of between-study design and measurement discrepancies summarized in Table 3.5. For example, the very low prevalence of current alcohol dependence in the NCS-R may be explained by the skip pattern in the WMH-CIDI noted above.

Of the five studies listed in Table 3.4, the NLAES and NESARC have the most similar methodology, support for the reliability and validity of the diagnoses, and the largest sample sizes. Their results are less variable than other between-survey comparisons. As such, remaining alcohol-use disorder results presented in this chapter will focus on NLAES and NESARC findings.

Time trends: The high degree of comparability between the NLAES and the NESARC with regard to methodology and measurement of alcohol-use disorders enables analysis of trends in the prevalence of alcohol abuse and dependence in the decade between 1991–92 (when NLAES was conducted) and 2001–02 (when NESARC was conducted).

As shown in Table 3.5, the prevalence of alcohol dependence in the US population decreased significantly from 4.38% in 1991–92 to 3.81% in 2001–02 ($p < 0.01$). This decrease of 0.5% is consistent with other reports from national surveys indicating similar decreases in the percent of heavy drinking during this period. However, conversely the prevalence of alcohol abuse increased by 1.62% from 3.03% in 1991–92 and 4.65% in 2001–02, a statistically significantly change ($p < 0.01$). Grant and colleagues, the authors of this analysis, postulate decreases in the prevalence of heavy drinking and alcohol dependence could be associated with changes in drinking norms including more negative attitudes about maladaptive alcohol use. In turn, this may have led to an increase in alcohol-related social/interpersonal problems, which is a DSM-IV alcohol abuse criterion (see Table 3.1).

Prevalence of Drug Use Disorders

Lifetime and current prevalence of any drug use disorder in the ECA, NCS, NLAES, NCS-R, and NESARC is presented in Table 3.6. Prevalence of current drug abuse is similar in all five studies and ranges from 0.8% (NCS) to 1.4% (NCS-R and NESARC). However, current drug dependence is much higher in the NCS (2.8%) than in the ECA (0.9%), NESARC (0.6%), NLAES (0.5%), and NCS-R (0.4%). Furthermore, lifetime

prevalence of drug dependence is also substantially higher in the NCS.

At the time of the initial publication of NCS results, considerable attention was drawn to the substantially higher prevalence of many disorders in the NCS and drew a number of efforts to explain the findings. This is particularly pertinent for current and lifetime drug dependence, which is markedly different to all other findings. The explanations largely focused on differences between the diagnostic interview used in the NCS and the assessment procedures used in other surveys. For example, the drug dependence gateway questions were asked at the beginning of the CIDI to prevent individuals from learning that gateway questions lead to more extensive questioning. Thus, more respondents may have been screened into the drug disorder module in the NCS than in other studies which may have increased the prevalence of drug dependence in the NCS. In addition, while the ECA, NCS-R, NLAES, and NESARC include ages 18 and older, the NCS sample is limited to 15–54-year olds. Since prevalence of drug dependence decreases with age, exclusion of the oldest age groups in the NCS may have inflated the prevalence in this study compared to other studies. Given that prevalence of drug abuse in the NLAES, which was conducted around the same time as the NCS, is similar to the prevalence obtained in preceding (ECA) and following (NCS-R, NESARC) studies, measurement differences between the NCS and other surveys appear a reasonable explanation for the high rates found by the NCS.

Time trends: As with alcohol, we can discern time trends in the prevalence of drug abuse and dependence in the decade between 1991–92 (when NLAES was conducted) and 2001–02 (when NESARC was conducted), due to the high degree of comparability between these studies.

Compton and colleagues revealed that although the proportion of cannabis users remained steady between 1991–92 and 2001–02, the past year cannabis use disorder prevalence increased significantly from 1.2 to 1.5% in the population ($p = 0.01$), and from 30.2 to 35.6% among past year cannabis users ($p < 0.01$). Blanco and colleagues demonstrated that both the prevalence of

past year nonmedical prescription drug use and past year nonmedical prescription drug abuse/dependence increased significantly between 1991–92 and 2001–02 ($p < 0.001$). However, the increase from 19.9 to 23.6% of nonmedical prescription drug use disorders among past year nonmedical users was not significant ($p = 0.15$).

Incidence and Persistence

Data on incidence and persistence are required to understand the etiology and course of alcohol-use disorders. However, while prevalence estimates can be obtained from cross-sectional data, large, prospectively observed samples are required to generate accurate incidence and persistence estimates. Psychiatric epidemiological studies have rarely been able to provide longitudinal data because the costs and practical difficulties are so great. However, some information on incidence of substance abuse and dependence from the ECA and NESARC has been published and information on the persistence of substance dependence between Waves 1 and 2 of the NESARC is also available.

One-year incidence of alcohol abuse/dependence was 1.79% using combined information from four ECA sites (Baltimore, St. Louis, Durham, and Los Angeles). In the NESARC, 1-year incidence of alcohol abuse was 1.02% and 1-year incidence of alcohol dependence was 1.70%.

Although a popular clinical conceptualization of alcohol dependence is that of a chronic and relapsing disease, an analysis of the persistence of alcohol dependence between Waves 1 and 2 of the NESARC indicated that this disorder persisted in only 30.1% of respondents with alcohol dependence at baseline.

One-year incidence of drug abuse/dependence was 1.09% in the ECA using data from the Baltimore, St. Louis, Durham, and Los Angeles sites. In the NESARC, 1-year incidence of drug abuse was 0.28% and 1-year incidence of drug dependence was 0.32%.

As with alcohol dependence, clinicians often conceptualize drug use disorders as chronic. However, similar to the findings on alcohol dependence, in the NESARC, 3-year persistence of any drug use disorder was 30.1% and 3-year persistence of a cannabis use disorder was 31.5%.

Determinants (Risk Factors) of Substance Use Disorders in the United States

Alcohol

- Sex

  Epidemiological studies consistently indicate that males have an increased risk of developing an alcohol-use disorder compared to females. Indeed, the male to female ratio of lifetime alcohol dependence was 5.0:1 in the ECA, 2.5:1 in the NCS, and 2.2:1 in the NLAES. The prevalence of current alcohol abuse was 4.7% among males and 1.5% among females in the NLAES, and 6.9% among males and 2.6% among females in the NESARC. Similarly, the prevalence of current alcohol dependence was 6.3% among males and 2.6% among females in the NLAES, and 5.4% among males and 2.3% among females in the NESARC. NESARC prevalence estimates are shown in Fig.3. 6. Furthermore, males were significantly more likely than females to develop incident alcohol abuse (odds ratio (OR), 2.3) and dependence (OR, 2.4) between Waves 1 and 2 of the NESARC, controlling for Wave 1 demographic characteristics and psychiatric disorders ($p < 0.01$).

  Of note, clinicians often conceive of alcohol disorders among women as "telescoped" with a later onset of alcohol use but shorter times from use to dependence and treatment. However, in a recent analysis of NLAES and NESARC data, Keyes and colleagues found little evidence for a telescoping effect among women in the population. Furthermore, sex differences in the prevalence of alcohol-use disorders appear to have decreased over time. As a result, younger women may require more targeted prevention and intervention efforts.
- Race/ethnicity

  Alcohol-use disorders are most prevalent among Native Americans and least prevalent among Blacks and Asians. This is true for alcohol abuse and dependence. For example, in the NLAES, among Native Americans 8.1% met criteria for alcohol abuse and 9.0% met criteria for alcohol dependence, while among Asians 1.1% met criteria for alcohol abuse and 2.3% met criteria for alcohol dependence. Figure 3.6 presents information on the prevalence of alcohol abuse and dependence stratified by five racial groups. Compared to Whites, the odds of current and lifetime alcohol abuse and dependence were lower among Blacks and Asians and higher among Native Americans ($p < 0.05$).

  Despite this, incident alcohol disorders in the NESARC varied little by race (note: this analysis did not include Native Americans, possibly due to small sample size). Indeed only one significant race difference was found – Blacks were significantly less likely than Whites and Hispanics to report incident alcohol abuse (OR, 0.6) at Wave 2 of the NESARC, controlling for Wave 1 demographic characteristics and psychiatric disorders ($p < 0.01$).
- Age

  As shown in Fig. 3.6, the prevalence of current and lifetime alcohol abuse and dependence generally decreases with age. Furthermore, a similar pattern is evident for incident alcohol-use disorders in the

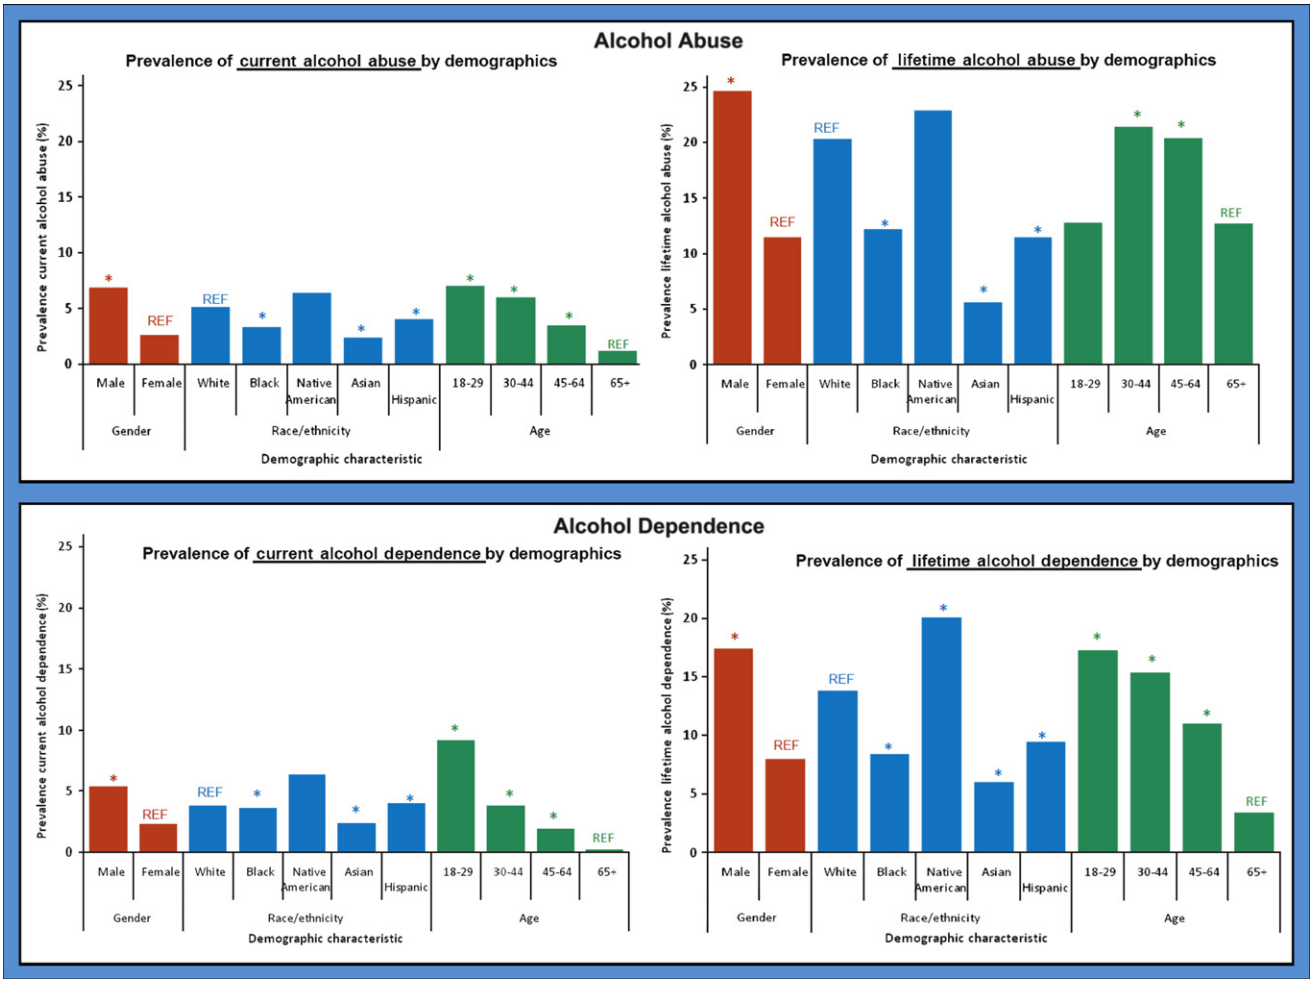

FIGURE 3.6 Sociodemographic correlates of alcohol-use disorders in the NESARC.

NESARC. Specifically, compared to the oldest age group (55 years and older), incident alcohol-use disorders were significantly more prevalent among individuals aged 20–29 (abuse: OR, 11.7; dependence: OR, 8.7) and those aged 30–54 (abuse: OR, 4.3; dependence: OR, 3.5), controlling for Wave 1 demographic characteristics and psychiatric disorders ($p < 0.01$). The finding that younger cohorts were at a higher risk of alcohol dependence and abuse in the NESARC could indicate a true cohort effect or could possibly be the result of under-representation among older cohorts due to differential mortality or poor recall of remote events. Prospective population-based investigation is required to adequately address this issue.

- Environmental factors

Both external and internal environmental factors play a role in alcohol-use disorders. Since alcohol-use disorders can only develop in individuals who have access to alcohol, alcohol availability within an individual's external environment can prevent or facilitate the development of an alcohol disorder. In Western societies, opposing societal forces and social attitudes influences the availability and consumption of alcohol. For example, public health, moral/religious, and governmental organizations try to reduce availability and consumption through public policy and laws, while the alcoholic beverage industry attempts to increase consumption.

Internal environmental factors such as home and family life can also affect the risk of alcohol-use disorders. Childhood environment appears particularly salient, since poor parental monitoring and modeling of heavy alcohol use contribute to the likelihood of adolescent alcohol initiation and binge drinking. Recent epidemiological studies have begun to explore the role of retrospectively reported adverse childhood experiences in the development of adult alcohol disorders.

In the NCS-R, lifetime alcohol abuse was significantly associated with experiencing, as a child,

paternal death, parental divorce or separation, parental psychopathology, repeated sexual molestation, and paternal aggression. There were fewer childhood correlates of lifetime alcohol dependence in this study, with significant associations found only for paternal death and parental psychopathology.

In the NESARC, Thompson and colleagues showed that parental divorce/separation was significantly related to adult lifetime alcohol dependence, after adjusting for parental history of drug, alcohol, depression, and antisocial behavior problems. Pilowsky and colleagues showed that as the risk of adult alcohol dependence increases as a function of the number of childhood traumas experienced (including parental divorce or death, being raised in an institution or by foster parents). Furthermore, Fenton and colleagues showed that childhood sexual abuse, physical abuse, emotional abuse, and physical neglect increased the risk of adult alcohol dependence, independent of experiencing other traumatic childhood events.

Taken together, these findings suggest that it may be important to incorporate an alcohol-use disorder preventative component in harm-reduction interventions conducted among children who experience traumatic events.

- Genetic factors

The important genetic component of alcohol disorders has been well established by findings from population-based epidemiological investigation, familial aggregation studies, adoption studies, and twin studies. At present, the heritability of alcohol dependence is thought to be around 50–60%. Our knowledge of specific genetic causes of alcohol dependence remains limited. However, results from allelic association studies have implicated certain genetic variants including ADH1B*2 (an allele of an alcohol dehydrogenase gene) and Asp40 (an allele of the mu opioid receptor). Understanding the genetic contribution of alcohol-use disorders is critical to the development of effective biological prevention and treatment interventions, and a substantial amount of research in this area is currently underway.

Drugs

- Sex

As with alcohol-use disorders, epidemiological studies show that the prevalence of current or lifetime any drug abuse or dependence is significantly higher among males compared to females (see Fig. 3.7 for NESARC findings). Similarly, studies using NLAES and NESARC data have found that when each drug class is considered specifically, the prevalence of abuse/dependence is higher among males than it is among females. Furthermore, males were significantly more likely than females to develop incident drug dependence (OR, 2.7) (but not abuse) between Waves 1 and 2 of the NESARC, controlling for Wave 1 demographic characteristics and psychiatric disorders ($p < 0.01$).

- Race/ethnicity

Drug use disorders tend to be lowest among Hispanics and Asians and highest among Native Americans; however, racial patterns are less consistent for drug use disorders than for alcohol-use disorders. For example, as shown in Fig. 3.7, in the NESARC compared to Whites Hispanics had significantly lower prevalence of current drug abuse but not of current drug dependence, while Native Americans had significantly higher prevalence of current drug dependence, but not of current abuse. However, lifetime drug abuse and dependence were significantly lower among Hispanics and Asians compared to Whites, whereas lifetime drug dependence (but not abuse) was significantly higher among Native Americans. However, racial differences in nonmedical prescription drug use disorders appear to follow a different trend. The prevalence of nonmedical use disorders was not significantly different for Hispanics, Asians, or Native Americans compared to Whites in the NLAES and NESARC; however, Blacks had significantly lower odds of nonmedical use disorders compared to Whites in both of these studies. Similarly, NSDUH data from 2002 to 2008 reveal that the prevalence of drug abuse/dependence is lowest among Asians and highest among Native Americans/Alaska Natives. For example, in 2008 past year drug abuse/dependence was 4% among Asians, 9% among black, 9% among Whites, and 10% among Hispanics. However, despite these differences in prevalence, there were no significant race differences in the odds of developing incident drug abuse or incident drug dependence between Waves 1 and 2 of the NESARC ($p > 0.05$).

- Age

Epidemiological studies consistently indicate that younger age is associated with an increased prevalence of drug abuse and dependence. For example, Fig. 3.7 reveals that in the NESARC, prevalence of current and lifetime any drug abuse or dependence decreased as age increased and drug specific analyses reveal the same trend for nonmedical prescription drug use disorders and for cannabis use disorders. Likewise, compared to ages 55 years and older, incident drug abuse was higher among ages 20–29 (OR, 50.7) and ages 30–54 (OR, 14.4), and incident drug dependence was higher among ages 20–29 (OR, 8.4), controlling for Wave 1

demographic characteristics and psychiatric disorders ($p < 0.01$).

It is interesting that the two youngest age groups (18–29 and 30–44 years) had almost identical prevalence of lifetime drug dependence (10.1% compared with 10.8%) and very similar prevalence of lifetime drug dependence (4.1% compared with 3.5%) (see Fig. 3.7). Not only are 18–29-year olds generally considered the highest risk group for substance use, but, in addition, epidemiological data indicate that this is the age at which drug use is most likely to begin. For example, in the NCS, the highest risk for initiating marijuana use occurred at around age 18 while the highest risk for cocaine initiation occurred at around age 20. Similarly, in the NCS-R, the median age at onset for any alcohol or drug use disorder was 20 years, within a fairly narrow range of 18–27 years. Thus, the finding that 30–44-year olds do not differ a great deal in terms of drug use from 18–29-year olds may suggest changing social norms and increased acceptance of drug use among older individuals. It is therefore possible that as these cohorts age, population-level increases in drug use among older cohorts may be evident.

- Environmental factors

Unlike alcohol, which can be purchased legally in the United States, it is illegal to obtain drugs for nonmedical purposes. Some neighborhood level factors such as socioeconomic status of residents and prevalence of crime may increase the availability of drugs and therefore increase the risk of drug use among individuals within this environment. Since drug use is a necessary prerequisite for drug abuse and dependence, the risk of these disorders will be increased among individuals living in this environment. Although, to the best of our knowledge, large-scale US-based epidemiological investigation of this phenomenon does not exist, the role of contextual factors in drug use disorders has been increasingly acknowledged since the 1980s.

Many studies have found that low socioeconomic status includes a number of factors that may contribute to a higher likelihood of substance abuse/

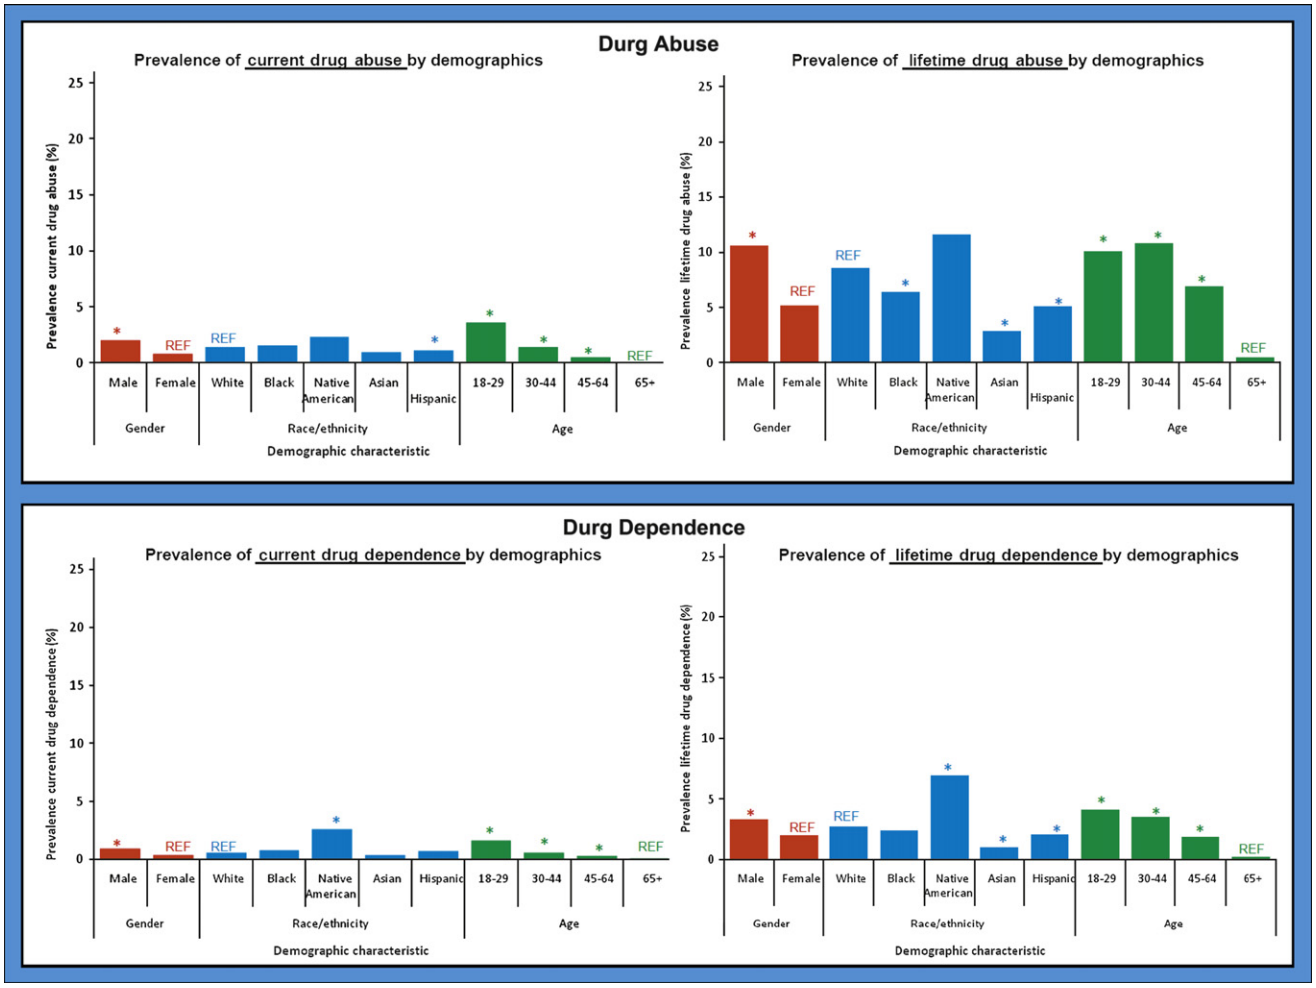

FIGURE 3.7 Sociodemographic correlates of drug use disorders in the NESARC.

dependence. These factors include: (1) residence in impoverished and stressful neighborhoods; these findings support the stress reduction hypothesis, which suggests that drug use disorders are a maladaptive form of coping with hostile environments and negative life events; (2) drug-salient surroundings, which include more drug abusers and drug-abusing social networks; and (3) neighborhood social disorganization, which refers to a lack of cooperation of local residents toward common goals. Neighborhood social disorganization has also been associated with higher rates of local gang activity, which, in turn, is a predictor of drug abuse and dependence. Experiences of discrimination in racial/ethnic minorities have also been associated with increased drug use.

As with alcohol-use disorders, drug abuse and dependence are also thought to be highly influenced by a range of childhood environmental factors. Unfortunately, epidemiological data on the role of childhood adversity in the development of adult drug use disorders are seriously limited. One study using NCS-R data found that lifetime drug abuse was significantly associated with experiencing, as a child, parental divorce or separation, parental psychopathology, isolated and repeated molestation, isolated rape, and maternal aggression, whereas lifetime drug dependence was predicted by parental divorce or separation, parental psychopathology, isolated rape, and maternal aggression. However, as already discussed, the NCS-R did not obtain representative diagnoses of drug dependence.

In light of the gaps in the literature on drug use disorders, it is worth briefly discussing findings on drug use from a large Health Maintenance Organization (HMO) single site study designed to investigate the association between retrospectively reported childhood trauma and adult health outcomes. Using data from this study, Dube and colleagues report that early initiation of illicit drug use (<15 years) was significantly higher among individuals who reported childhood emotional abuse, physical abuse, sexual abuse, emotional neglect, and physical neglect, as a child living with a mentally ill person, witnessing domestic violence, substance abuse, parental separation or divorce, or parental incarceration. Given that NSDUH data indicate that adolescent-onset illicit drug users are at a highly increased risk of developing drug dependence these data are concerning. Future studies to address the relationship between childhood adversity and adult drug use disorders using data including detailed measures of adverse childhood experience and adult drug use disorders a nationally representative sample are required.

- Genetic factors

Genetic epidemiology has established the important influence of genetics in the risk of drug abuse and dependence. Population-based epidemiology studies, clinical studies, and family studies have demonstrated that drug use disorders are familial diseases. Adoption and twin studies indicate that heritability estimates of drug use disorders are somewhat lower than alcohol-use disorders with estimates ranging from around 30 to 60%. However, heritability appears to be higher among males; for example, Kender et al. report that in a sample of 1198 male twins, heritability was 76% for drug abuse, and 69% for dependence.

Association studies involving the dopaminergic and serotinergic systems indicate that drug disorders are positively associated with polymorphisms of dopaminergic receptor genes (DRD1, DRD2, DRD3, and DRD4) and genes associated with serotonin transport (e.g. 5-HTTP). Furthermore, it appears that a combination of several genes may be involved in the development of drug use disorders. However, much remains unknown, and research to identify specific genes and examine interplay between genes and the environment is underway.

CONCLUSION

In contrast to the amount of knowledge on the epidemiology of addiction in the United States available in the 1980s, several large, and nationally representative epidemiological studies have been conducted using standardized diagnostic assessments. These studies provide valuable information on the distribution and determinants of substance use disorders in the United States, and although some variation in prevalence does exist, many of the findings are consistent across studies. It is important to note that interpretation of epidemiological findings should account for possible study limitations such as potential biases stemming from self-report. Nonetheless, epidemiologic studies present the most valid national picture of substance use disorders and findings presented in this chapter and make a significant contribution to our understanding of substance use disorders in the general population.

List of Abbreviations

APA the American Psychiatric Association is a scientific and professional organization that represents psychology in the United States. With 150 000 members, APA is the largest association of psychologists worldwide.

AUDADIS the Alcohol-Use Disorder and Associated Disabilities Interview Schedule, a structured diagnostic interview used to measure substance use and mental disorders in the NLAES and NESARC.

CIDI the Composite International Diagnostic Interview, a fully structured interview designed to assess mental disorders and intended for use in epidemiological and cross-cultural studies and for clinical purposes. Used in the NCS.

ECA Epidemiological Catchment Area Study, a multisite study conducted between 1978 and 1983 that obtained DSM-III substance use disorder diagnoses using the Diagnostic Interview Schedule (DIS), with a sample of about 20 000.

MTF Monitoring the Future, an ongoing study that tracks substance use behaviors, attitudes, and values among US adolescents.

NCS the National Comorbidity Survey, a psychiatric epidemiologic survey conducted between 1990 and 1992, with a sample of about 8000.

NCS-R the National Comorbidity Study-Replication, a follow-up study to the NCS conducted between 2001 and 2003, with a sample of about 10 000.

NESARC the National Epidemiologic Survey on Alcohol and Related Conditions, designed to assess alcohol-use disorders and their associated disabilities in the general population. It is a longitudinal survey with Wave 1 conducted in 2001–02 with a sample of 43 093 and Wave 2 in 2004–05 with a sample of 34 653.

NLAES the National Longitudinal Alcohol Epidemiologic Survey, an epidemiologic survey conducted between 1991 and 1992 that assessed alcohol and drug use disorders and other psychiatric disorders, with a sample of 42 862.

NSDUH the National Survey on Drug Use and Health, a large annual national survey of ages 12 and older designed to track trends in substance use.

OR odds ratio.

Glossary

Epidemiology the study of the distribution and determinants of disease in the population.

Incidence the number of new cases of a health outcome that arise in a given population over a certain time period.

Persistence the proportion of cases of a health outcome that continue to experience that health outcome over a certain time period.

Prevalence the number of cases of a health outcome that exists within a given population at a specific point in time.

Reliability consistency and replicability of measurements. Concerns random errors.

Telescoping effect the finding that women typically initiate alcohol use later than men but progress faster to alcohol dependence, and those who become dependent progress faster to treatment. The course of alcohol disorders in women is thus considered to be compressed, or telescoped, compared to men.

validity accuracy of measurements, whether the measure captures the concept that it is intended to measure. Concerns random and systematic errors.

CHAPTER

4

An Evolutionary Perspective on Addiction

Elizabeth M. Hill

University of Detroit Mercy, Detroit, MI, USA

OUTLINE

INTRODUCTION

Did the propensity for addiction evolve? If so, what is its possible benefit, and how would it function to increase the likelihood that individuals who have this trait will bear more offspring, thus increasing the frequency of addiction over generations? It seems ludicrous to suggest that addiction, with its high cost to society, is beneficial to any individual or group. Nevertheless, taking an evolutionary perspective may help us understand why and how the human brain evolved to be vulnerable to addiction, and why this negative vulnerability has not been eliminated by evolution. While no one would argue that the state of addiction (i.e. physical and psychological dependence on a drug) has an evolutionary benefit and is therefore an adaptation, the precursors of addictive behavior, such as the propensity to take risks, might actually be advantageous in some settings, and they could be the target of natural selection.

There have been several evolutionary approaches to addiction. The first considers vulnerability to addiction to result from the mismatch between our current and ancestral environments. A second proposes that over time humans developed a tolerance to low levels of psychoactive substances, adaptations that are now overwhelmed by the higher concentrations of drugs available. The third approach explains demographic patterns in problematic substance use with evolutionary forces. Human physiology may have evolved to allow us to ingest plant-based drugs for their beneficial effects, and physiology and brain structure that resulted then became vulnerable to exploitation by potent chemicals, resulting in a disease of modern civilization – substance dependence.

Evolutionary approaches to addiction cannot be tested experimentally, in the traditional sense, because the argument is about past events, and the fossil record is not helpful in this instance. Nevertheless, evolutionary scientists may glean insights from studies of preindustrial societies and also from studies with nonhuman animals. While it is difficult to prove one of these hypotheses over another, a thorough examination will help clarify the needs for future research. To evaluate these approaches to addiction, a review of the basic components of evolutionary theory is useful, as is

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00004-8

a careful examination of the terminology for psychoactive substances. Researchers do not use the term, addiction, in exactly the same way. It is also useful to examine newly emerging areas of evolutionary psychology and Darwinian medicine. Evolutionary scientists use criteria for determining whether to consider a trait to be adaptive; these will be described. After the important concepts of evolutionary theory are introduced, evolutionary approaches to human problems will then be described.

For the purposes of this article, *addiction* and *dependence* will be used interchangeably, and the term *substance consumption* will refer to low levels of use, below the levels that induce intoxication or impairment. Dependence is characterized by tolerance, withdrawal, and compulsive use (inability to abstain despite problematic consequences). Abuse and harmful use involve recurrent use resulting in problems but where dependence has not developed. Binge or risky drinking refers to an episode of intoxication, typically defined as consumption of 4–5 drinks at a sitting. This article will mainly concern alcohol and plant-based alkaloids. Alcohol is usually termed ethanol in a medical context. Plant-based alkaloids include nicotine from tobacco, ephedrine from khat, arecoline from betel nut, and cocaine from coca. The term, drugs of abuse, will also be used to describe the set of drugs with high addiction potential. These are cocaine, alcohol, marijuana, amphetamine, and heroin.

WHAT IS AN EVOLUTIONARY PERSPECTIVE?

An evolutionary approach to a psychological or biological phenomenon entails the analysis of "ultimate" questions, as called by Niko Tinbergen, a pioneering Dutch ethologist. Ultimate questions are about why a behavior exists, i.e. what is the function, and what is the evolutionary history. An evolutionary approach to addiction attempts to address function or evolutionary history or both. Does addiction (or consumption of addictive substances) have any function? What is the evolutionary history of addiction (or consumption of addictive substances) among the ancestors of modern humans? Tinbergen's other questions concerned "proximate" levels, understanding mechanism and development. Proximate questions ask about how, rather than why, a behavior exists. A complete analysis of behavior requires answering these questions, also, but they are beyond the scope of this article.

Evolution is usually defined as a change in gene frequency over generations through the process of natural selection. Charles Darwin and Alfred Russel Wallace explained the process of natural selection, which results when characteristics are passed along from parents to offspring, when organisms show variability, and when there is differential reproduction among offspring. Those who reproduce best are considered the most "fit" for a particular environment ("niche").

The origin of variation is through random mutation of genes. Many mutations are deleterious or even lethal, but some confer advantages. Where a mutation is beneficial, the individual bearing it will be more successful in survival and reproduction. The prevailing view has emphasized selection at the level of the gene, leading to the phrase, "the selfish gene." Recent theories have argued that selection at the level of groups can be seen to explain the human tendency toward cooperation and empathy.

Natural selection includes sexual selection, a process that may have a role in the evolution of some aspects of addiction, to the extent that there are gender differences in patterns of use, abuse, and dependence. Sexual selection pertains to an increase in frequency of sex-linked traits that lead to increased reproductive success. These traits generally are not beneficial for survival chances, but are for reproductive competition, such as antlers on a deer or elaborate plumage on the peacock's tail. Some evolutionary biologists consider sexual selection to be simply a special case of natural selection.

Evidence for past evolution comes from fossils and from comparing characteristics of existing species. Evidence for ongoing evolution comes from longitudinal studies of changes in characteristics over time in response to selection pressures. Evolution can be observed as it happens when selection pressures have changed quickly. For example, Rosemary Grant and Peter Grant conducted a long-term study of Darwin's finches on the Galapagos Islands, during a period when rainfall changed dramatically. The researchers examined the beak depths of seed-eating finches. When rainfall was low, only the birds with the strongest beaks survived and reproduced, because the others could not crack enough seeds for sufficient nutrition. The distribution of beak depths in the population changed within a few generations, illustrating natural selection in action.

Another example of natural selection in action is the rapid development of bacterial resistance to antibiotics over the past 50 years. Infectious diseases were treated very effectively using penicillin and other antibiotics when they were first developed. However, sufficient variation existed in the genetic makeup of bacteria that some survived. Genetic variants or new mutations conferred resistance to penicillin. The resistant organisms survived and reproduced. This evolution has occurred again and again in response to new antibiotics. Staphylococcus infection is a critical problem in hospital

settings, and the latest antibiotics are losing effectiveness against it, as did previous generations of medicines.

A new field called Darwinian medicine attempts to uncover why natural selection has not eliminated specific flaws that lead to disease. The application of an evolutionary approach to the study of psychological and medical disorders most often involves an examination of the history and function of the nervous system's vulnerabilities. Most relevant to addiction, the risk for disease may be increased when previously advantageous mechanisms do not operate properly in the current environment. For example, cardiovascular disease and obesity are prevalent in advanced societies. The perspective of evolutionary or Darwinian medicine examines the ancestral or "natural" environment, where the availability of fat and sugar would never exceed healthy levels, and people had more physical activity. The brain and physiological mechanisms controlling taste, eating motivation, and satiety evolved in an environment totally unlike the current one, in terms of the wide availability and concentrations of these foods. These mechanisms result in a vulnerability to obesity and cardiovascular disease.

COULD ADDICTION EVOLVE?

If a characteristic has evolved, it means that it has become more frequent over generations due to natural selection. Natural selection entails differential reproduction by those who possess traits more favored or "adapted" for a particular environmental setting. For substance use to evolve, it must confer an adaptive advantage for those who have the trait. Thus, to consider substance use to be an adaptation, it must have a clear history of being maintained by natural selection, it must be correlated with fitness during its evolution, and it must have solved an adaptive challenge. If these criteria are not met, then substance use is best considered as a co-opted adaptation (exaptation), a functionless by-product, or a co-opted functionless by-product. An exaptation currently increases fitness; such characteristics are sometimes called preadaptions. Tolerance to low levels of substances could perhaps be an adaptation that increased fitness in the past, but excessive consumption of substances today is clearly a functionless by-product of brain structure and other physiological processes. Although it is clear that substance dependence is not adaptive, some facets of the process of developing an addiction might be, such as tolerance of substances at low levels.

Three main evolutionary approaches consider substance dependence to be a by-product of preexisting adaptations. None of these approaches considers dependence as we see it in contemporary society to be adaptive. These different perspectives treat different aspects of our physiology as creating vulnerabilities.

One evolutionary perspective considers addiction to be a disease of modern civilization. Such a disease results from a mismatch between the conditions prevalent during the evolution of our brain's reward pathway and conditions in the contemporary environment relating to psychoactive substances of abuse. The brain's vulnerability to addiction derives from the fact that neural communication is chemical. Drugs, a kind of artificial and external reward, mimic the natural processes, activating and overwhelming the brain pathway, which becomes dysfunctional. Thus, the brain's reward system is adapted, but addiction to external chemicals is an unfortunate functionless by-product. This perspective is referred to as the "mismatch hypothesis" in this article.

The second major evolutionary approach to addiction looks for features of the addiction process that are adaptive and finds evidence for plant–animal coevolution. In this view, the human capacity to tolerate low levels of certain drugs may have evolved at the same time as plants were evolving defenses against predation by animals. Other primates and mammals, and even insects, have demonstrated a similar response to such substances. Coevolution of traits in two species, resulting in a mutually beneficial relationship, is called mutualism. This approach views substance use at naturally occurring levels as functional, rather than a by-product. In theory, animals have coevolved physiological mechanisms to digest toxic substances for their beneficial effects. This approach is referred to as the "mutualism hypothesis" in this article.

The third evolutionary approach to addiction uses life-history theory, an extension of evolutionary theory. It examines patterns of problematic substance use, positing that an evolutionary approach may help understand individual differences in vulnerability to addiction. Substance misuse and other activities that together fall under the rubric of "risk taking" follow a similar demographic pattern. Evolutionary theory understands the marked differences in risk taking by age and between genders within the framework of sexual selection. Risk taking can be seen as a mating tactic that gives young men an advantage in competing with other young men for partners. Risk taking would be less frequent outside the arena of mating competition. This approach is referred to as the "life-history theory" in this article. These three perspectives are described in detail below.

Addiction as a Disease of Modern Civilization: The Mismatch Hypothesis

This theory posits that drug addiction is a nonadaptive epiphenomenon or by-product of our brain

structure. Psychoactive drugs act on brain pathways that evolved to control emotion and behavior. Humans, along with other mammals, have a "reward" pathway in the brain. Referred to as the mesolimbic system, it is a pathway beginning in the midbrain ventral tegmental area and terminating in a forebrain structure called the nucleus accumbens. The pathway then connects to the amygdala and prefrontal cortex. This pathway is activated when we are engaged in seeking reinforcing events, leading Jaak Panksepp to call this pathway the "seeking" system. It is an appetitive system that is critical for responding to reward and punishment. It supports pleasant and aversive states that are essential for survival, such as hunger. The primary neurotransmitter of this pathway is dopamine, with the key target zones in the nucleus accumbens. Other neurotransmitters, such as opioid peptides, also may be involved in mediating the reward response to positive stimuli.

Recent work in neuroscience has delineated several aspects of reward that are important in effective motivation of behavior. The experience of pleasure ("liking") is separable from "wanting," which is the motivation to seek a reward. The aspect of motivation that seems to be mediated by the mesolimbic dopamine system is "wanting" or "seeking" rather than the experience of reward or pleasure.

Different drugs may stimulate unique profiles of brain changes, but virtually all drugs of abuse activate the dopaminergic mesolimbic system, including heroin, cocaine, alcohol, marijuana, amphetamine, and their synthetic forms. According to Eric Nestler, drugs of abuse increase levels of dopamine in the nucleus accumbens, either directly or indirectly. Direct effects occur with stimulants (e.g. cocaine or amphetamines), which increase the release of dopamine from presynaptic neurons. Alcohol indirectly excites nucleus accumbens neurons by activating gamma amino butyric acid (GABA) neurons, among its other actions. Opiates similarly disinhibit dopamine neurons in the ventral tegmental area by inhibiting GABAergic interneurons. In addition, there are opioid receptors on neurons in the nucleus accumbens, and opiates have a direct effect on these. The mechanism of action of other drugs in this pathway is more complicated.

After chronic exposure to various types of drugs, the mesolimbic dopamine system suffers similar problems. Dopamine reservoirs seem to be reduced, so that natural rewards stimulate less response. In contrast, response to artificial drugs is enhanced or sensitized for an extended time. These effects have been demonstrated in animal studies of cocaine, amphetamines, opiates, alcohol, and nicotine. The body's stress response system is also affected by chronic drug exposure. An additional common effect is reduced activity in the frontal cortex, the region of the brain that exerts higher control over behavioral reactions to activity in the mesolimbic system. With hypofrontality due to chronic drug use, impulsivity is more likely.

These systems evolved through natural selection because they were adaptive; they produce positive emotions in response to stimuli that are important for survival and reproduction (sex, food, positive social contact, and infant attachment). The responses to drugs can be larger than those occurring with natural rewards, so that dopamine may become depleted. Addiction has been considered a brain disease due to this process, in which the evolved mechanism for directing us to seek beneficial rewards is "hijacked."

This perspective has been put forth by Randolph Nesse, a psychiatrist who is one of the founders of Darwinian medicine. Artificial drugs or artificial concentrations of natural drugs will impair the operation of normal motivation and emotion because they falsely signal an imminent benefit to fitness or they falsely block negative emotions that are useful. The brain is vulnerable to false incentives from drugs when their levels exceed those our ancestors encountered in ancestral environments. The potency of today's drugs and their administration through quickly absorbing routes can overwhelm the mesolimbic system. Why has the vulnerability to addiction persisted, rather than being winnowed out through natural selection? This question is easy to answer now, because selection against the mesolimbic system would have highly negative consequences. The mesolimbic reward system has benefited humans and other mammals to an extent that those creatures with such systems do better, survive, and reproduce more, than those who lack such a system. The mesolimbic system enables more effective motivated behavior.

Nesse also asks whether it is wise to block negative emotions such as anxiety by using mood-elevating drugs. The utility of anxiety in the natural environment is well known. However, some negative emotions may no longer be useful, such as panic attacks. Scientific knowledge about the evolutionary function of negative emotions is lacking, and consequently we have no knowledge of the possible wisdom of medicating or self-medicating such feelings.

According to Eric Nestler, particular drugs can be discriminated, primarily through their effects beyond the dopaminergic mesolimbic system. Effects on other parts of the nervous system and on the cardiovascular system differ among various drugs. In addition, there are differences in the effects of chronic use on specific receptor systems that are directly stimulated or antagonized by various drugs, such as the effects of opiates on opioid receptors and nicotine on nicotinic cholinergic receptors. The fact that drug profiles are not identical

has led to criticism of a unitary reward model for drugs of abuse.

Plant–Herbivore Coevolution: The Mutualism Hypothesis

The mismatch theory described above contends that drugs available in current environments are novel and overwhelm evolved mechanisms. In contrast, another evolutionary approach argues that there may be a long history of human substance use, that our exposure to psychoactive chemicals is not a recent development.

The use of psychoactive substances by current hunter-gatherer groups has been documented. Written records and archeological evidence trace the cultural use of drugs back about 10 000 years. The most common drugs in the world today are caffeine, ethanol, nicotine, and betel nut. Alcohol is the most commonly recorded substance used in earlier civilizations, from ancient Egyptians and Greeks to ancient China and India. The use of betel nut can be dated to over 10 000 years ago, and use of coca plants to over 5000 years ago; both of these plants have stimulant effects. Fermentation was invented about 9000 years ago in prehistoric China, according to some sources, but the fermentation of alcohol from grain, honey, or fruit can also be traced to ancient Egypt, Greece, and India.

Early human ancestors, other primates, indeed other mammals, would have access to plants as food. Fruit-eating, frugivory, is thought to expose animals to low levels of ethanol, and plant-eating, herbivory, is thought to expose them to low levels of various chemicals. Fruit-eating relates to the history of alcohol use, and eating chemicals produced in leaves and seeds relates to the use of a number of other drugs.

Fruit and Ethanol

Robert Dudley, a biologist, proposed that an attraction to ethanol might have a function. In the ancestral lineage leading to humans, fruit-eating (frugivorous) monkeys and apes (anthropoids) predominate. Our closest ancestors are primarily frugivorous, the hominoids (gorilla, chimpanzees, orangutans, and gibbons). Subsisting on fruit entails some ingestion of fermenting fruit, and the anthropoid lineage may have been exposed to low levels of ethanol through eating fermented fruit. Yeasts ferment plant sugars to yield ethanol. Microbes compete for access to plant sugars, and they are common within plant reproductive organs (of which fruit is part). It has been suggested that the adaptive function of fermentation by yeast was the killing of bacterial competitors for fruit sugars. Bacterial growth is inhibited by ethanol at levels that can be tolerated by yeast. Ethanol within ripe and fermenting fruit is a natural and common occurrence (various reports measured 0.5–1.6% ethanol in pulp of ripe and 0.6–2.6% in overripe fallen fruit). Decomposition of fruit by fermentation is not desirable to the plant's reproduction, however, if ingestion and dispersal of seeds is deterred by decomposition.

Dudley theorized that the ubiquitous presence of ethanol in ripe fruit could enable its use as a cue for frugivores. Ethanol could serve various roles as a cue. For example, ethanol odors could help animals locate ripe fruit, and ethanol could then take on a role as an appetitive stimulus to rapid consumption of a transient nutritious resource. At present there is no direct evidence for this hypothesis, and the potential uses of ethanol as a cue would pertain for any fruit-eating animal.

A physiological response to ethanol could have been retained in humans as we evolved a more diverse omnivorous diet over the past 2 million years. Humans probably consumed a lot of fruit until the advent of agriculture about 10 000 years ago. These previously advantageous behaviors could represent a vulnerability to negative effects when humans are exposed to the much more concentrated and more widely available levels of ethanol in the present day contemporary environment. This argument is similar to Nesse's mismatch theory described above. Exposure to higher concentrations of ethanol than are naturally available (0.5–1.6% ethanol in pulp of ripe and 0.6–2.6% in overripe fallen fruit) may cause harm, whereas metabolic capacity to handle the natural levels would be favored by evolution.

A recent report supports the potential role of the primate diet in vulnerability to addiction. Species of small mammals in Malaysia were documented to specialize on eating fermented floral nectar, which contains ethanol. The bertam palm has flower buds that are home to fermenting yeast. The alcohol concentration in nectar samples averaged about 0.5% and was as high as 3.8%. The small mammals pollinate the palm through their nectar ingestion, carrying pollen grains on their hair from flower to flower. This situation is an example of mutualism, where coevolution has undoubtedly occurred.

The mammals seen to drink fermented nectar included pentailed treeshrews, a primitive mammal that is similar to extinct species found over 55 million years ago. It is in the lineage ancestral to primates. Other species considered likely to consume substantial amounts of alcohol through nectar included the common treeshrew, plantain squirrel, and slow loris (a larger prosimian primate). Hair analysis of ethyl glucuronide, an ethanol metabolite, showed evidence of chronic ethanol consumption in the plantain squirrel, common treeshrew, and pentailed treeshrew. Loris hair was not sampled in this study. The actual blood alcohol

concentration reached when drinking palm nectar is unknown, however. Bertam palm nectar seemed to be the preferred food source of the pentailed treeshrews and slow lorises.

Despite consuming levels of ethanol that would typically be dangerous, these mammals showed no obvious signs of intoxication to observers. They seem to have evolved sufficient physiological tolerance to allow their exploitation of palm flower nectar as a food source. They can be considered adapted to a unique ecological niche. Thus, such adaptations are within the realm of possibility for other animals. The physiological basis for consumption of nectar might serve as a preadaptation or exadaptation as defined above. Given the ancient presence of these mammals, the relevant physiological accommodations to ethanol could be widespread in the mammalian lineage. However, this level of specialization on an alcoholic food source is rare.

Plant Allelochemicals

Robert Sullivan and Edward Hagen, two anthropologists, provide historical and archaeological evidence that substance use was common among hunter-gatherer, indigenous groups before contact with Westerners. The plants commonly utilized included tobacco (nicotine), khat (ephedrine), betel nut (arecoline), pituri (nicotine), and coca (cocaine). These plants were eaten as food. Plants have evolved defenses against consumption, in the form of alleochemicals that mimic neurotransmitters and bind to receptors in the nervous system of mammals that consume plants (herbivores). Plant neurotoxins disturb the nervous system, structurally or functionally. Herbivores, in turn, have evolved defenses against these toxins that enable continued consumption. For example, humans and other primates eat clay and charcoal to bind the dietary toxins. It is a paradox that these types of drugs from plants are not pleasant on ingestion; rather they are aversive, yet people and other animals consume them, nevertheless. Sullivan and Hagan proposed that mammals evolved adaptations to enable consumption of allelochemicals for their beneficial effects.

Plants and herbivores have undergone a long evolutionary conflict. An example is nicotine, from a domesticated North American tobacco plant. At least 20 different herbivore species of insects and mammals eat this plant. The presence of nicotine in leaves has been shown experimentally to deter ingestion. Countermeasures evolved by herbivores include metabolic processes and enzymes that counteract or detoxify the toxins (or sequester them) and mutualistic relationships with microbes that can allow the extraction of nutrients.

The presence of metabolic physiology implies that humans had regular exposure to plant toxins. The cytochrome P450 (CYP) proteins apparently serve as detoxification enzymes. These are very common throughout the animal kingdom. Their central function is in fatty acid metabolism and synthesis of cholesterol and steroids. Other forms of CYP metabolize drugs (CYP 2 and 3). Some variants of CYP genes may be more common in geographic areas where exposure to certain plants is more common. There may have been population-specific directional selection for the polymorphism CYP2D6 in North East Africa, Turkey, and Saudi Arabia, where khat and the opium poppy are ingested. Such variation in gene frequency is suggestive of fairly recent exposure to different ecologies, while the fact that much of CYP function is conserved suggests older and continued function in more universal metabolic pathways.

Sullivan and Hagen admit that the phenomenon of addiction to modern euphoric drugs might be due to an evolutionary mismatch but they contend that the use of these drugs is far less frequent than another category they call mundane drugs (tobacco, cannabis, and betel nut). Their interest is to create a general theory of drug use based on mundane drugs, rather than the rarer euphoric drug use. Tobacco and cannabis are used by far more people than are heroin, cocaine, and amphetamines.

Plant toxins may have some beneficial effects when ingested by mammals. The toxins present in plants may be useful in herbivores as protection against parasites. Studies of the tobacco hornworm revealed that parasitism by a wasp was less likely for larvae that had ingested nicotine. The hornworm had developed a counter measure to use the plant toxin. Toxic plants may be useful against intestinal parasites. Farmers use tobacco and arecoline from betel nut as an antiworm (helminth) treatment for cattle and sheep. A human example is our use of spices; it has been proposed that spices deter bacterial infection.

Our contemporary society has manufactured better medications for helminth infections than tobacco, but it is plausible that more natural populations might benefit from physiological tolerance to the tobacco plant to exploit its medicinal properties against parasites. Another potential beneficial effect of drugs derived from plant toxins is analgesia. Marijuana was used for medicinal purposes in ancient China, and opium from poppy flowers was used in eastern cultures (Islamic cultures, India, China, the Middle East) for its analgesic effects.

Various hallucinogens and stimulants were used in religious rituals by hunter-gatherer peoples. The Incas chewed coca leaves containing cocaine during religious ceremonies. Hallucinogens have been used for centuries in religious ceremonies, such as psilocybin from mushrooms, which was used by the Aztecs in Mexico and Central America. Psychoactive mushrooms may have been used in ancient India. These substances are thought

to have been used to augment a trance state and induce mystical experiences during religious rituals. Further research is needed to evaluate whether any of these beneficial effects might have a role in the evolution of metabolic processes to utilize these plants, to support the hypothesis of coevolution. Unfortunately, the practices of earlier societies are exceedingly difficult to study.

Demographic and Geographic Patterns in Addiction: Life-History Theory

Extensive research has focused on assessing individual differences in risk factors for drug and alcohol addiction. Much clinical research has this focus: vulnerability factors in the biological and psychosocial realms. These literatures are beyond the scope of this article, which concerns the characteristics of all humans as a species, rather than differences among individuals. There are, however, two areas of research where an evolutionary perspective is relevant.

First is the area of geographic variation in alcohol metabolism. There are geographic patterns in metabolic enzymes that covary with a history of exposure to alcohol. Response to alcohol is affected by variations in the liver enzymes alcohol dehydrogenase (ADH) and acetaldehyde dehydrogenase (ALDH). Ethanol is converted to acetaldehyde by ADH, then ALDH catalyzes acetaldehyde to acetate. The characteristics of metabolism can differ depending on which of the several variants of these enzymes are present. With slower-acting ADH enzymes, less of the aversive acetaldehyde accumulates, and where ALDH is of a slow form, toxic acetaldehyde accumulates. A faster form of ALDH can clear it more quickly. An accumulation of acetaldehyde is associated with an aversive reaction including nausea and flushing. With slower-acting ADH enzymes, the experience of drinking is more pleasant (euphoric, anxiolytic). Genetic studies have shown that risk for alcohol dependence is associated with variants of ADH and ALDH. In one such study of Japanese and Taiwanese alcoholic patients, the frequencies of faster acting forms were lower for ADH and higher for ALDH, compared with nonalcoholic comparison groups.

The geographic distribution of alcohol-metabolizing enzymes can be understood using an evolutionary approach such as the one used to explain the spread of lactase persistence. Natural selection pressures can maintain genetic variation where there are environmental differences. Mammalian milk contains the sugar lactose. Infants digest lactose until weaning, but then stop synthesizing the necessary enzyme. After that stage, gastric distress will result when fresh milk is consumed. Exceptions to this norm are found in northern European, North African, and Arabian populations, who have lactase persistence as adults. These populations are also ones who practice dairying but not farming. The advantages of an ability to digest fresh milk are obvious in these ecological settings. Interestingly, lactase persistence evolved in Europe and Africa by independent mutations in different genes for the metabolic enzyme.

A similar analysis could explain patterns in the geographic distribution of genetic variants in alcohol-metabolizing enzymes. A team of Chinese scientists has examined 38 populations across East Asia, comparing the prevalence of one specific ADH polymorphism to geographic variation in diet. In particular, they looked at the spread of rice cultivation, which emerged about 10 000 years ago. There is a gradual shift from east to west, as shown by cultural relics. Southern and south-eastern China grew rice earliest (10 000 years ago), followed by central China (3000–6000 years ago), with Korea and Japan domesticating rice within the past 3000 years. Fermentation of rice is thought to have followed rapidly afterward, beginning about 9000 years ago in southern China. The initial dietary use is thought to be for food preservation. Variation in enzymes related to alcohol metabolism would enable some individuals to utilize fermented foods more readily.

The 38 populations show different frequencies of the particular ADH variant, ranging from 98.5% to a low of 1.7%. This ADH variant metabolizes ethanol faster than the ancestral variant. The statistical correlation of the prevalence of the derived, evolutionarily newer, allele with the geographic order of rice-culture origins was a strong one ($r = .769$, $p < .01$). This pattern cannot be explained by random genetic drift. Rather, the results are consistent with natural selection for tolerance to ethanol that resulted in differences among ethnic groups.

The second area of research on individual differences where an evolutionary perspective is relevant is focused on patterns of drug use that may result from selection pressures. Gender and age patterns in substance misuse follow a similar pattern as many risky behaviors, such as reckless driving and physical fighting. Excessive drinking or illegal drug use may be an outgrowth of risk taking in general. Risky drinking is usually defined as consuming more than five drinks at a sitting for men and four drinks for women. This level of consumption is typically intoxicating to most drinkers. A number of research studies have reported gender and age differences in rates of risky drinking, alcohol abuse, and alcohol dependence.

The highest rates of alcohol problems are shown by young men, measured using lifetime alcohol abuse or dependence over the lifetime, past year, or past 2 weeks.

Rates for men are 3–4 times as high as those for women, throughout the lifespan. Surveys of college students report higher rates of risky drinking by men than women. Similarly, men report higher rates of driving while intoxicated.

With regard to age, the onset of alcohol abuse is low during childhood and early adolescence, peaks during the ages 15–29, and declines thereafter. The rate of onset becomes negligible after age 35. Diagnoses of alcohol abuse and dependence reach the highest rates between ages 18 and 29 for both men and women, decreasing at older ages. Epidemiological studies of these diagnoses have found that prevalence decreases steadily to less than 1% for those over age 80. Risky drinking (five or more drinks/occasion) and weekly intoxication rates were highest for men aged 18–29, steadily decreasing at older ages. Women showed lower rates of these consumption patterns overall, with higher frequencies during ages 18–49, decreasing with age.

Another demographic pattern relates to marriage and parenthood. Risky drinking and dependence become less frequent after people marry and start families. Rates of alcohol abuse/alcohol dependence are consistently lowest for married people and highest for those who are unmarried (never married or separated/divorced), as reported by national surveys. College students follow the same trend, with married students being half as likely to consume alcohol at risky levels. Alcohol-impaired driving shows the same difference. Longitudinal studies that follow individuals have determined that declines in alcohol use occur after marriage and parenthood, rather than preceding these events.

Elizabeth Hill and Krista Chow used life-history theory to understand these demographic patterns. Life-history theory examines biological characteristics of the life cycle (e.g. age at maturation, average number of offspring). According to this theory, these hallmarks are subject to natural selection and reflect adaptation to ecological circumstances such as predation rate. Biological effort is finite, and evolutionary pressures determine the best allocation mix to the tasks of survival, current reproduction, and future reproduction. Gender and age-related differences in risk taking can be understood from this perspective.

The gender that is more specialized in parenting will necessarily devote less effort to mate attraction and retention. If one gender specializes, the other gender is freer to engage in mating with multiple partners. If the females of a species devote more effort to parenting, then males can compete among themselves for multiple mates. This situation leads to higher variability in reproductive success for males than for females. Some males are not able to mate at all, while others monopolize more than one mate. In this situation, female outcomes would be less variable and would not depend on competing with other females for more sex partners. Human males in many societies are faced with this situation, where some are excluded from reproduction, and taking great risks is required for success. When status and resources are at stake, men are more likely than women to engage in physical conflict. This phenomenon has been called the "young male syndrome" by the evolutionary psychologists Margo Wilson and Martin Daly. During the life stage of competing for mates, the potential gain from risk taking is great, but after one reaches a stage of successful mating and is actively engaged in parenting, risk tolerance is expected to decline. Human decisions about status, reproduction, and risk taking are not necessarily conscious; the ultimate consequences are of interest from an evolutionary perspective.

The idea that impulsive risk taking could be functional, i.e. adaptive, is more clearly seen when examining other animals. Extensive studies of rhesus macaques over many generations have shown that alcohol consumption is correlated with a propensity toward impulsivity. The underlying trait of impulsivity may be beneficial in certain contexts, according to the primatologists Melissa Gerald and Dee Higley. The fact that impulsivity is associated with increased alcohol consumption is thus an unfortunate consequence of a trait that has been beneficial in evolutionary terms. The benefit occurs because the genes that contribute to increased mortality through impulsive risk taking may also increase the probability of reproducing. To reproduce, male rhesus monkeys migrate to other groups. Risk-averse, less aggressive males may not be able to defend themselves during migration, or they may fail to leave the natal group. Genes with pleiotropic effects, beneficial at a young age but deleterious later, are difficult for natural selection to eliminate. With increasing age, the power of natural selection declines, relative to its action before reproduction. If the same genes increase the probability of early reproduction but decrease the likelihood of survival later, natural selection could favor these genes under some conditions. Impulsivity could thus create vulnerability for excessive consumption of alcohol and other substances, which has deleterious effects in the current environment of humans.

CONCLUSION

Addiction is not adaptive, but vulnerability to become addicted resulted from natural selection for other traits. An evolutionary perspective can help understand this vulnerability. Three main evolutionary

approaches were reviewed, the mismatch hypothesis, the mutualism hypothesis, and life-history theory. Vulnerability to addiction may result from the mismatch between our current and ancestral environments. Alternately, over time humans may have developed a tolerance to low levels of psychoactive substances present in plants. Lastly, life-history theory aids our understanding of demographic patterns in problematic substance use. Each approach has weaknesses, but each also suggests a number of areas for future research.

The weakness of the mismatch hypothesis is the incomplete state of knowledge about common actions of drugs on brain reward systems. Which is more important, the unique drug profiles or the common actions of drugs? Regardless of the eventual resolution of this question, it is apparent that treatments or medications for addiction should not interfere with the mesolimbic reward pathway, to avoid damaging our responses to natural rewards.

The weakness of the mutualism hypothesis is that coevolution requires that mammals benefit from ingesting toxins or rotting fruit. The nutrition derived from plants eaten is a clear benefit but are there benefits from the ethanol or toxins themselves? Perhaps plant toxins help control parasites, but much more research is needed in this area.

The weakness of the life-history theory approach is its lack of practical or clinical applicability. While this perspective can synthesize a number of patterns in use and abuse of alcohol and other drugs, it does not easily generate ideas for improving treatment.

In conclusion, humans and other animals consume plants for nutrition, and our mammalian ancestors underwent a coevolutionary arms race with plants to enable digestion and metabolism of the antiherbivore chemicals they produce and the other microbes and organisms that compete with us for fruit pulp. Humans and other animals became adapted to tolerate some alcohol and some neurotoxins that must be ingested to survive on plants. These adaptations left us vulnerable to addiction when high dosages became widely available. Chemicals that affect the brain's natural reward system are the most addictive. The mesolimbic system is ancient, but the potent drugs available now are novel compared with natural rewards or naturally available concentrations. Our ability to distill and concentrate doses is a modern phenomenon. It is also new, in terms of mammalian evolution, to administer drugs through routes with faster absorption than oral ingestion. The motivational and emotional systems involved are essential and adaptive in most environments, so selection cannot act to eliminate these pathways. Unfortunately, humans will probably remain vulnerable to addiction.

Glossary

Alkaloids nitrogen-containing organic compounds produced by plants, such as nicotine, morphine, caffeine, and atropine.
Analgesia decrease or relief of pain sensation without loss of consciousness.
Cytochrome P450 a superfamily of liver enzymes that are involved during breakdown of drugs and toxins.
Dehydrogenase an enzyme that catalyzes the removal of hydrogen atoms in physiological reactions.
Helminth a parasitic worm, including flukes, tapeworms, and roundworms.
Herbivore animal whose diet consists entirely of plants and plant products.
Satiety a state of feeling satisfied.

CHAPTER

5

International Perspectives on Addiction

Jo Thakker

University of Waikato, Hamilton, New Zealand

OUTLINE

DRUG USE ACROSS TIME AND PLACE

Some researchers have speculated that drug taking may have been a normal part of life at the time that our species was emerging, about 120 000 years ago. However, in terms of concrete evidence, we are limited to more recent history. For example, excavations in modern-day Iraq indicate that both wine and beer were routinely given to Mesopotamian soldiers 5500 years ago and recipes for beer have been found in 5000-year-old Mesopotamian clay tablets. It is well known that wine has long played a prominent role in Mediterranean cultures and its use in these cultures dates back at least 2000 years. Also, Egyptian papyri dating to 1700 BCE contain many references to alcoholic drinks, including regulations regarding their consumption. Further, regulations around the consumption of alcohol were at times seen in both ancient Rome and ancient Greece.

Research suggests that other psychoactive substances were also used in ancient societies. For instance, evidence from Neolithic sites in modern-day Switzerland indicates that opium poppies were grown in this area more than 6000 years ago. There is also evidence that ancient Egyptians used opium poppies as analgesics and sedatives to manage temperamental infants. Similarly, it appears that in both ancient Greece and ancient Rome opium was widely used for medicinal purposes. For example, opium is referred to in Homer's "Odyssey," wherein it is described as a substance that can "quiet all pains and quarrels" (Scarborough, 1995). Also, opium is frequently referred to in the prominent "Materia Medica" (written by Dioscorides in about 70 CE) which suggests that it could be used for a range of ailments, including pain, digestive problems, and insomnia.

The use of cannabis also appears to date back many years. There is evidence that it was used in China at least 6000 years ago and in India about 4000 years ago. Although, it is unclear whether its early use in China was as a drug or as a source of fiber. But, in both locations, it was clearly used for medicinal purposes at some points in history. Further, it appears that it was also used in religious ceremonies in India. Many years later the Greek historian Herodotus described a purification ritual (in the fifth century BCE) conducted by Scythians who were nomadic tribes that inhabited an area that incorporates modern Ukraine, Russia, and Asia. Apparently, the Scythians threw hemp seeds onto hot stones inside a tent so that they could inhale the intoxicating smoke.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00005-X

It can be concluded then that drug use has been present throughout much of human history; however, it is unclear whether addiction was present or common in early human societies. Given the addictive properties of some of the substances that were used historically, such as opium and alcohol, it is possible that drug dependence would have occurred if the substance was available in sufficient quantities. It is probably impossible to draw any definitive conclusions about the supply of such substances, although, clues may be seen in the way that communities lived in ancient times. For instance, a regular supply of opium was probably not available prior to the advent of agriculture about 10,000 years ago. Also, in many ancient human societies, life was tough and individuals who typically lived within small social groups were expected to contribute to the group. It is hard to imagine that drunks would have been tolerated in these sorts of social contexts as their level of contribution to the group would likely have been severely limited. Thus, it may be the case that individuals would not have allowed themselves to succumb to addiction because of the high personal and social costs that would have been associated with the development of substance dependence.

Today drug use and addiction are seen in most societies, although the substances differ across different cultural settings. Kava (a beverage made from the roots of the kava plant) is commonly used in the Pacific region, whereas betel nut (the seed of the areca palm) is commonly used in India and Southeast Asia. While substances such as these are used in specific regions, other substances, such as tobacco and alcohol are used around the world by almost all cultural groups. One particularly important point to note is that in many countries the drug of choice has changed over time. This is particularly true in countries that have been colonized as often the colonizing country brings with it particular drug use practices that greatly influence the drug use habits of the indigenous people. Australia provides an excellent example of this process.

Prior to European colonization, aboriginal Australians used a number of substances, including, alcohol, native tobacco, and pituri (a native shrub). Interestingly, although alcohol was made from a variety of native plants, its use was apparently uncommon due to difficulties with supply and transportation. It seems that the most commonly used substance prior to the arrival of Europeans was pituri which is a hallucinogen. It was used in a variety of ways, including as an anesthetic, an amnesic, and as a means of inducing altered states of consciousness during various ceremonies. It has been widely argued that one of the reasons that substance use, such as the Aboriginal use of pituri, did not become substance abuse, was that its use was rigidly controlled by social norms and traditions. In other words, people accepted the predominant social view pertaining to the appropriate use of the drug.

Today, indigenous Australians are overrepresented in drug abuse statistics. For example, there are widespread problems among these populations with the use of alcohol and inhalants, both of which are highly addictive. Furthermore, unfortunately, in regard to inhalants, children and adolescents are especially vulnerable. Evidence indicates that these substance abuse problems are closely associated with socioeconomic issues, such as poverty and poor housing, and also with social isolation. Furthermore, those with abuse and dependence problems are also more likely to end up in the criminal justice system.

It has been suggested that one of the reasons that novel substances become a problem in indigenous populations is because they lack a social structure that might control the use of the substance. For instance, in many Western societies, alcohol is used in specific settings, such as special occasions or after regular weekly events (such as a Friday after work). Another example of this is the fact that most people would not consider drinking before the evening, except perhaps on special occasions such as Christmas. In this way, alcohol use has a certain place within an individual's regular schedule and this assists in limiting and controlling its use. In contrast, populations that have been introduced to the substance more recently have no social structure for controlling its use and thus they are vulnerable to developing substance use problems.

A similar picture is seen in New Zealand and Canada; both of which have a colonial history. In both regions, indigenous populations are overrepresented in drug use and addiction statistics. Furthermore, in both nations, indigenous populations are more likely to live in impoverished environments, to be unemployed, and to have poor health outcomes. Thus, substance use problems are closely associated with a range of other life challenges. Subsequently, it is has been widely theorized that addictive behaviors arise, at least in part, because of general life difficulties. Using a substance provides a means of psychological escape from the challenges of daily life. Also, in some instances, substance use and even addiction is normalized, such that it is difficult for a young person to choose a different path.

EVOLUTIONARY AND BIOLOGICAL EXPLANATIONS

Evolutionary explanations are important in psychology because they purport to have relevance for all human groups; in other words, they attempt to explain general human behavior. Evolutionary

psychologists propose that the mind of modern humans is comprised of various psychological mechanisms that evolved in ancient times due to the fact that they promoted survival and therefore enhanced reproductive fitness. Evolutionary psychologists argue that behavior in modern humans may be understood by analyzing these mechanisms because the mechanisms have changed little since modern humans evolved. Thus, even though the environment has changed markedly, the human brain and its mechanisms are largely unchanged. It is important to note that evolutionary psychologists offer distal explanations that refer to adaptation and phylogeny. As such, they are generally complimentary to (and not in competition with) other more proximal explanations.

In light of the ubiquity of drug taking, it is reasonable to ask whether such behavior is due to the presence of a particular adaptive psychological mechanism. In considering this question, it is important to acknowledge the distinction between adaptations and by-products of adaptations. While the former are generally a direct result of the process of evolution, the latter are simply by-products of that process. For example, the kidneys' key function is to filter waste from the blood and they are adapted to this specific purpose. However, they also have other properties such as their color, which serve no real purpose but which have nonetheless arisen through the same natural selection process.

There are a number of ways in which drug use may have boosted reproductive fitness in ancestral environments. Stimulants such as tobacco and coffee have the effects of decreasing the need for sleep and suppressing one's appetite. Analgesics such as opium can be used to relieve pain and discomfort. Thus, it is possible that early humans' chances of survival would have been increased if they used substances for these purposes. However, if this was the case, it is unclear exactly what would have been selected for. For instance, it may simply have been the case that this sort of use would have been more likely to have been utilized by smart individuals, and thus, all that would be passed on in this case was smartness.

With regard to ethyl alcohol, a clear case has been made for the role of a more specific psychological mechanism. It has been suggested by some researchers that we have evolved a preference for ripe fruit because eating such fruit provided an important source of energy that was able to be metabolized quickly. Such fruit typically contains significant quantities of ethanol. This is reflected in the fact that in many cultures throughout human history, alcohol has been viewed as an important source of food. Thus, some researchers have suggested that human beings have evolved a tendency to view ethanol as nutritionally rewarding. Interestingly, in backing up this claim some researchers have pointed to the myriad of examples of this sort of association in the animal kingdom. For example, monkeys, elephants, and butterflies have all been observed to consume overripe fruit to the point of intoxication.

One important issue when considering evolutionary explanations is the mismatch between ancestral and modern environments. What may have been adaptive in a primitive preagricultural setting may not be adaptive today. For instance, a 100 000 years ago, a preference for food high in ethanol was probably not problematic because ethanol was not available in large quantities. In contrast, someone who consistently desires large amounts of ethanol today can probably acquire an endless supply (although this may depend on how much money they have). This difference between modern and ancient environments is important in determining how and why mechanisms evolved and in considering how these mechanisms may come to play in modern times.

One particularly important brain mechanism which is often mentioned in biological explanations of drug addiction is the mesolimbic reward pathway. To fully understand the role of this pathway, it is necessary to first ask the question of why people use drugs. Essentially, they use drugs because drugs make them feel good. Further, the reason they feel good is because the drugs they use short-circuit neurological mechanisms that have evolved to play a key role in the manifestation of positive experiences. From an evolutionary point of view, the role of emotions is to motivate individuals to pursue adaptive experiences and avoid harmful experiences. Thus, adaptive activities such as eating and engaging in positive social interaction feel good; and this means that people are more likely to keep doing them. It has been theorized that the reason these sorts of activities feel good is because they activate the mesolimbic reward pathway in the brain. This pathway connects areas in the frontal cortex with the nucleus accumbens and the ventral tegmental area, in the limbic system. In terms of drug use, as suggested above, it is thought that when people use drugs they activate this pathway thereby creating positive sensations and experiences. The primary neurotransmitter that is widely believed to be instrumental in this pathway is dopamine and the effects of many drugs seem to be associated with changes in dopamine function. For example, cocaine and amphetamines block the reuptake of dopamine thereby increasing the levels of dopamine in the synapse.

Another important aspect of the biology of substance abuse and dependence is the research on genetic factors. Most of the research in this area has focused on the genetic component of alcohol addiction and there is now a growing body of research that shows that

alcoholism has a genetic component. Interestingly, what is most important in terms of the discussion herein is that genetic factors have been used to explain the varying levels of alcoholism across ethnic groups. The program of research that has explored this issue has focused on the genes that code for the liver enzyme aldehyde dehydrogenase (ALDH) which plays an important role in the metabolization of alcohol. Research indicates that the presence of ALDH2*2 is associated with a deficiency in ALDH2 which seems to protect individuals from the development of alcohol problems. Those who have this deficiency experience a range of aversive physiological consequences when they drink, due to a buildup of acetaldehyde. The presence of the ALDH2*2 allele has been found to vary across ethnic groups; it is close to zero in Europeans, Africans, and Native Americans, but it is present in between 30 and 50% of Northeast Asian populations.

A number of researchers have reported finding an association between the presence of the ALDH2*2 allele and a reduced likelihood of alcohol abuse and dependence. Furthermore, the association has been found to be particularly strong in individuals who carry two copies of the ALDH2*2 allele. These individuals have been found to have almost no risk of developing alcohol dependence. However, it is important not to overemphasize the role of genetic factors in addiction as research has also found that the role of genes is not absolute but is influenced by cultural factors. For example, a study which examined the protectiveness of the ALDH2*2 allele over time in Japanese populations found that the protective effects decreased as Japanese people became more accepting of alcohol and increased their consumption. Thus, it has been hypothesized that over time Japanese peoples' use of alcohol yielded to the social and cultural pressures that rewarded its use and paid less attention to the physiological effects.

So, why are evolutionary and biological factors important in understanding addiction across cultures? They are important because they are a part of the causal picture. The process of evolution and its resultant biology inevitably plays out in the manifestation of every drug use problem. While sociocultural factors are also important, neural processes provide the foundation for the thoughts, feelings, and behaviors of the individual drug user. Also, as illustrated above, there may be subtle differences across ethnic groups in the physiological effects of substances on the human body. Furthermore, in terms of substance abuse, and in particular, addiction, there are significant physiological changes that take place within the individual which contribute significantly to their ongoing drug dependence.

NORMS, VALUES, AND EXPECTATIONS

Social norms are widely believed to account for differences in substance use and abuse across cultures. The social norms surrounding the use of alcohol in various cultures provide a good example of this. There are many cultural groups which prohibit the consumption of alcohol in all contexts. These groups include Mormons, Muslims, Alcoholics Anonymous organizations, and some Protestant factions. However, it is important to keep in mind that teetotalism is not strictly adhered to by all members of these groups. For example, in some Muslim groups, consumption of alcohol is not unheard of.

Many cultures, while allowing the use of alcohol, nonetheless have norms which discourage excessive alcohol consumption and drunkenness. This is seen in particular in Jewish culture, but also in Chinese, Italian, and French cultures. However, these norms are not static; they change over time and they differ across various sectors of society. Also, the strength of the influence of cultural norms and values depends on the extent to which an individual is immersed in his or her cultural environment. Interestingly, one study found that Russian Jews who had immigrated to Israel had higher rates of alcohol use than Israeli Jews – perhaps because of the culturally accepted pattern of heavy drinking in Russia. Thus, in some cases, individuals who move to a new cultural environment will continue with the pattern of substance use that they learned in their country of origin. Another study found that American-born Chinese generally consume more alcohol than Asian-born Chinese and this exemplifies the significance of social–cultural factors in patterns of use.

One of the most widespread cross-cultural norms pertaining to the use of alcohol relates to women. In almost all countries, alcohol use is seen as being less acceptable in women than it is in men. Furthermore, in some countries it is forbidden for women to drink. In Nigeria and Lesotho, women who abuse or become dependent on alcohol are judged harshly by their society and are often marginalized and ostracized. In other societies, such as Japan, Mexico, and Peru, the stigmatization is not as extreme but still drinking in women is widely discouraged.

In many Western societies, heavy drinking by both men and women is viewed as normal. Although heavier patterns of drinking are more often seen in young men. In New Zealand, individuals who refuse to drink in social settings may be subjected to criticism and ridicule by others. Thus, there is often social pressure to binge drink to the point of significant physical illness. Also, in many Western societies, even the signs of physical illness (e.g., vomiting and loss of consciousness) that

accompany binge drinking are normalized. However, in contrast, alcohol addiction would probably not be seen as normative in most Western societies and would normally be frowned upon by mainstream society. While regular excessive alcohol consumption is seen as reasonably normal and acceptable, the sort of use seen with dependence would not be accepted. On the other hand, dependence on other drugs, such as methamphetamine, would probably be normalized in some social groups in the West. Therefore, whether addiction is seen as acceptable in Western societies would depend on the drug and the social context.

Another important dimension of the interaction between cultural factors and the effects of a substance on an individual is the beliefs and expectations of the individual. In Mexico, drinking sessions associated with drunkenness and violence are common. Similar links between alcohol and violence are also seen in some Papua New Guinean tribes. And of course, in many Western countries, such as the United States and New Zealand, there is a strong association between drinking and violence. However, in contrast, there are many cultural environments in which high levels of alcohol consumption are not associated with violence, such as among the Camba of Eastern Bolivia and the Yaruna Indians who reside in the Amazon. Thus, many researchers have concluded that the behaviors that arise following the consumption of alcohol depend on the beliefs and expectations of the individual and these have their roots in cultural norms.

Several studies have explored the connection between alcohol use and expectations (often referred to as expectancies). They have found that expectancies have a profound effect on the individual's response to drinking. For example, studies have found that if people believe they have been consuming alcohol, when in fact they have been imbibing a nonalcoholic beverage, then they will behave as if they are intoxicated. Further, with regard to other substances, it has been reported that the cultural context influences the content of the drug user's experience. For instance, if an individual has a vision while taking a drug in the context of a ceremony, the vision will typically reflect the purpose or context of the ceremony.

Beliefs and expectations can also influence the process of addiction. For example, some researchers have argued that if people believe that they have no control over their drug use, then they will be more likely to develop an addiction. Accordingly, if people believe that cocaine is highly addictive then they will be more likely to become addicted and to have an ongoing addiction problem. The drug-related attitudes and beliefs that an individual adopts probably come from his or her immediate sociocultural environment. Particular important sources within that environment might include media reports, cultural norms, personal experiences, and family knowledge that is passed down over the generations.

It is useful to consider the way that tobacco-smoking habits have changed in many Western countries over the last few decades. While rates of smoking have been falling steadily in many countries over the last 50 years, there has been a more significant drop-off in the last two decades. This is mostly explained in relation to the increased understanding of the harmful effects of tobacco on human health. However, this message has been delivered to varying extents around the globe. While some countries require that health warnings are placed prominently on cigarette packets, some countries do not. Also, rates of cigarette use vary around the world and it remains popular in many Asian countries. What is perhaps most important in regard to this discussion, is that the social norms surrounding the use of tobacco in the West have changed markedly such that it is no longer considered to be socially acceptable. Subsequently, many people in Western countries now hide their addiction to tobacco. In this way, the attitudes, beliefs, and behaviors surrounding tobacco addiction have changed over time and these changes have been associated with a significant reduction in tobacco use.

RECONCEPTUALIZING DRUG ABUSE AND ADDICTION: A CULTURE-INCLUSIVE APPROACH

Over the years, there have been many different approaches to classifying mental disorders and various mental disorders have come and gone from taxonomic systems. For example, diagnostic manuals previously included disorders such as drapetomania (which referred to slaves who ran away from their masters) and childhood masturbation disorder. What is most telling about the appearance and subsequent disappearance of these sorts of disorders is that the perception of what constitutes a disorder has changed. Furthermore, in the case of drapetomania, the social context has changed, rendering the so-called disorder redundant and irrelevant. Of course, looking back, it would seem that this disorder was borne out of a desire for social control of a particular group of people. So, to some extent mental disorders are social constructions which are influenced in important ways by the social and cultural and social context in which they are utilized.

Understandings of addiction have also risen and fallen on the tide of social change. At times, the disease model of alcoholism has been especially popular and at other times, social and psychological models have

prospered. Anyone familiar with the disease model debate will know that it continues to this day, although perhaps it is reasonable to suggest that there is now a growing body of researchers who take the view that alcoholism is caused by a combination of biological and social factors. With regard to drug problems, the conceptualization of the phenomenon is important because it is typically closely tied to the treatment approach. For example, generally those who adhere to the disease model of alcoholism recommend that alcoholics should abstain from using alcohol because the disease renders them helpless to control their use even if they attempt to consume very small quantities. This is of course the approach of Alcoholics Anonymous.

Arguably, one of the most influential contemporary models of mental disorder is unable to take into account the cross-cultural diversity of addiction. The model espoused by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) is based on a biomedical view. Accordingly, discrete diagnostic entities are listed, each of which is associated with a particular treatment approach. There are four key aspects to the DSM definition of mental disorder: distress, disability, expectability, and dysfunction. The notion of distress captures the subjective and experiential aspects of mental disorder while disability refers to the more observable sequelae. The concept of expectability is understood with reference to statistical norms; so a condition is seen as abnormal if it is unexpected in a particular context. It is in this aspect that the DSM takes context into account. Finally, the term dysfunction, which may be "behavioral, psychological, or biological," encapsulates the idea that there is a breakdown in the normal function of the person.

In terms of taking account of cross-cultural differences in addiction, the DSM definition is problematic. One key problem with the definition is that in some groups there may be no distress associated with the drug dependence. For example, people who are on methadone maintenance typically have an addiction to an opiate; however, they may not be distressed by it. Similarly, tobacco is used all over the world and is highly addictive; however, many people are not distressed by their addiction to the substance. Similarly, at certain times and places in history, addiction to substances such as coca, opium, and coffee has not necessarily been distressing for people. Coffee is a good example because it is a commonly used addictive substance that is socially condoned and its use is not usually associated with feelings of distress.

Another problem with the DSM definition of mental disorder lies in the use of the term expectability. As outlined above, this concept is used to stipulate that in order for a condition to meet the criteria for a mental disorder it must not be expectable (or statistically likely) within the particular cultural group in which it occurs. With regard to drug addiction, this is problematic because drug use and even dependence is socially accepted and reasonably common in some populations. For example, inhalant use and addiction among young aboriginal Australians is so common in some settings that it is not unexpected or unlikely. Similarly, opium dependence among some Afghanistan communities has reached very high levels in recent years; in some areas, it is estimated that approximately half of the community is addicted to opium and in some cases whole families, including children, are dependent on the substance.

In response to the lack of cross-cultural applicability of the DSM model of mental disorder, the writer developed an alternative model that attempted to take account of the diverse nature of mental disorders. Based on a constructivist approach, the model aimed to provide a more flexible and culturally sensitive understanding of mental health problems. Constructivism is a philosophical approach that lies on a continuum between social constructionism and realism. It does not deny the possibility of objective knowledge; however, it sees subjective experience and interpretation of the empirical world as important and capable of influencing the process of knowledge acquisition. According to the constructivist model of mental disorder, there are four key components, all of which interact with each other. As shown in the model below, these components are cultural–historical variables, biological variables, psychosocial variables, and the self (Fig. 5.1).

Cultural–historical variables are included in the model in order to acknowledge that drug-taking practices and addiction often arise out of historical and cultural traditions. The forces of history play out in the way that individuals understand a drug and in the way that they interact with it. For example, the way in which kava is used in various Pacific Island settings today owes much to the way it was used in decades past in Pacific societies. As people grow up in various societies, they imbibe the attitudes and beliefs of previous generations. Furthermore, current legislation may also impact on drug use and dependence and this too has evolved over time.

As the name suggests, psychosocial variables incorporate both psychological processes and social factors. This variable rests on the assumption that these two factors have an important interaction. The individual's psychology is embedded in a social context and cannot be understood outside of this context. An example of the significance of this variable can be seen in New Zealand where there is a significant methamphetamine dependence problem. Generally speaking, individuals are introduced to this drug by their social group and, furthermore, it is often normalized within this group.

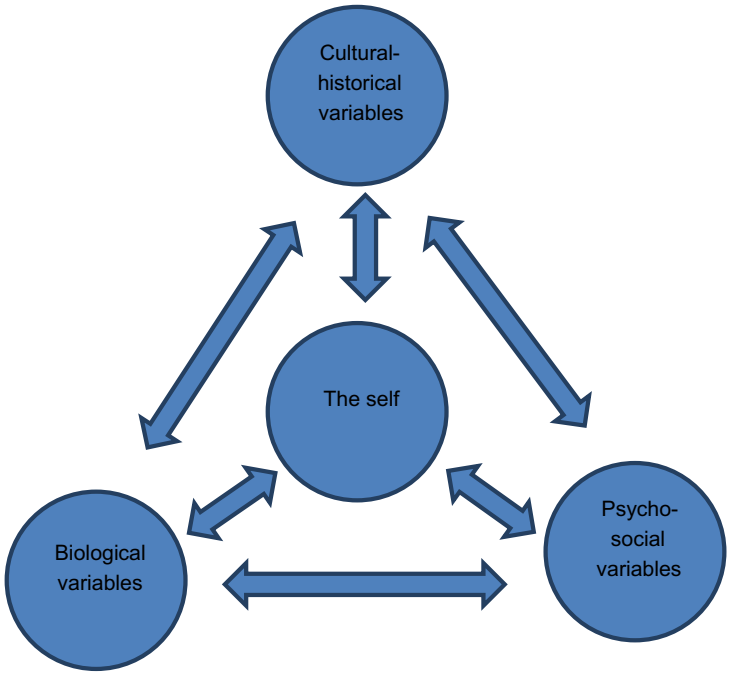

FIGURE 5.1 A constructivist definition of mental disorder. *Adapted from Thakker, J., Ward, T. & Strongman, K.T. (1999). Mental disorder and cross-cultural psychology: A constructivist perspective. Clinical Psychology Review, 19, 843–874.*

Thus, people begin using methamphetamine because their peers are using it and making it available to them. Inhalant use in aboriginal Australians is also an example of the importance of sociocultural factors as inhalant use is normalized in some aboriginal populations.

As explained earlier, biology is also important in explaining drug use and dependence. Drug addiction occurs because of the presence of particular physiological mechanisms. Furthermore, drug dependence involves a range of physical phenomena, in particular, withdrawal symptoms on attempting to stop the drug use and tolerance with chronic use. Also, different drugs have different main effects and side effects which may also influence the experience of drug dependence.

The final part of the model, the self, is the central part of the model, through which each of the other three factors interact; although they may also interact directly with each other. The self is conceptualized as being central to the model because regardless of the level of influence of the other factors, the individual is always unique and his or her drug problem is therefore also unique. The individual will inevitably interpret and respond to social, cultural, and historical influences and he or she will not take on such influences without processing them. Also, with regard to biological factors, while these will be similar across individuals, people will nonetheless respond to these factors in unique ways. Two people exposed to the same drug in the same setting may respond to the presence of the drug in different ways. One may experiment with the drug while another may not. One may become addicted to the substance while another may use it several times and thereafter desist in using it.

One important aspect of this model is that it is flexible. In explaining mental disorders, different factors may be more important for different disorders. For instance, biological factors are particularly important in explaining dementia whereas bulimia nervosa is probably best explained in terms of social and cultural factors. Similarly, in terms of conceptualizing drug dependence, different factors may be more or less salient depending on what is being explained. For example, if we want to understand why regular use of alcohol leads to tolerance, it is probably best to refer to biological theories. However, individuals may experience tolerance to alcohol in different ways depending on their beliefs and expectations and on the cultural context in which they are drinking. Thus, psychological and social explanations will also be important in understanding the process of tolerance.

The strength of this model lies in the fact that different parts of the model can be more or less salient, depending on what the investigator is attempting to explain. Also, it takes account of both historical and cultural variables and thereby acknowledges the broader context of the addictive process. As highlighted in this discussion, drug use and drug addiction differ around the world; therefore, any model of the addictive process needs to be sufficiently flexible to be able to take such differences into account.

DIVERSE TREATMENT APPROACHES

There is a growing understanding among clinicians and researchers that in order to tackle substance abuse and dependence, cultural factors need to be acknowledged and incorporated into the treatment process. As suggested above, an individual's drug-taking experience will be influenced by his or her attitudes and expectations, and by the norms and practices of his or her sociocultural environment; thus, it is important to consider such aspects in treatment.

First, it is important to acknowledge that there are differences across cultures in the availability and accessibility of treatment. There may be pragmatic barriers, such as cost, which may be more problematic for ethnic minorities, especially if they are more likely to be in lower socioeconomic groups. Also, there may be differences in the way that the treatment is perceived by various cultural groups. For example, in Japanese society, psychological problems are heavily stigmatized and are often believed to bring shame on an entire family. Therefore, individuals in Japan may avoid treatment as engaging in treatment would signify that the individual had a problem. Also, it has been reported that some African-Americans and Hispanics in the United States are reluctant to engage in methadone maintenance because they believe it is a form of control and oppression.

Around the world a number of culture-sensitive treatment programs have been developed. In New Zealand, specific treatment approaches for drug use problems have been designed for Maori. These approaches typically utilize indigenous models of health and wellness which tend to take a more holistic view in responding to health problems. One such model is "Te Whare Tapa Wha" which translates as the four-sided house. The "Te Whare Tapa Wha" model uses the image of a house to depict the four key elements of well-being, namely "te taha tinana" (the physical body), "te taha hinengaro" (the psychological aspect), "te taha wairua" (the spiritual realm), and "te taha whanau" (the family and community). The image of the house is used to demonstrate the interaction and interdependence of all of these elements; for example, if one aspect is weak then the house itself is weakened. This is a particularly significant metaphor for Maori as traditionally, the house or "whare" is seen as the spiritual center of the community. Furthermore, the model highlights the importance of taking a holistic and integrated approach to health and well-being.

In treating substance abuse and dependence, there are a number of ways in which the model can be utilized. The model may be used to conceptualize the individual's drug use problem through an examination of how well he or she is functioning in each of the key areas. For example, an examination of whanau links may reveal that the individual is socially isolated and not well connected with family. On the other hand, an analysis of "tinana" may indicate that the person has an unhealthy lifestyle characterized by poor eating habits and little or no physical activity. The model may also be used as an overarching framework for the delivery of conventional treatment approaches. For instance, cognitive behavior therapy may be delivered via the "Te Whare Tapa Wha" conceptualizations of health and well-being. Applications of the model in treatment aim to encourage clients to develop a strong identification with their culture and with the predominant beliefs and ideas, which form the basis of their culture with the goal of strengthening their self-belief and their sense of empowerment.

Similar approaches to substance use problems have been taken in Canada in the provision of treatment to indigenous populations. Clinicians there are now beginning to understand the importance of incorporating indigenous understandings of human health in their treatment programs. Again, there is a focus on family and community, and on traditional concepts of spirituality. Like the approach in New Zealand, the emphasis is on seeing the person as a holistic being who is connected with his or her physical and social environment. Also, many of the Canadian programs foster a strong sense of cultural identity through reference to indigenous norms, values, and traditions.

One of the key aspects of these sorts of drug treatment approaches in indigenous populations is the acknowledgment that social and cultural factors play an important role in the development of the problem. In some cases, individuals are socially isolated and there is a breakdown in their family connections. Also, they may experience a range of significant life problems such as lack of education, limited income, and lack of employment opportunities. Therefore, treatment needs to take a broad approach and attempt to address the underlying factors that may contribute to a person's drug-related problems. Also, common among indigenous treatment approaches is the inclusion of a spiritual component. This aims to encourage drug users to contemplate issues of meaning and purpose in their lives. It is not necessarily related to organized religion, but rather to the idea that developing a strong sense of meaning in life will assist in establishing clear future goals and finding fulfillment. In this way, the drug then becomes less appealing and hopefully inconsistent with the new outlook.

CONCLUSION

Drug use can be traced back many thousands of years. For millennia, human beings in many different parts of the world have been using drugs for various purposes. Perhaps they were primarily used for medicinal purposes originally, but over time they began to be used for their mind-altering properties. It is difficult to ascertain when the problem of addiction first arose although it was probably not seen in preagricultural times. Then, as human beings began to settle in particular areas and grow crops, supplies of drugs would have become more stable and reliable. However, the loss of productivity that would have been associated with developing an addiction would have meant that those who developed such problems would most likely have been unpopular or perhaps even ostracized. So historically such problems were probably uncommon. Likewise, today addiction is generally not seen as being socially acceptable in any sociocultural groups.

Nonetheless, addiction is present in many populations around the world. Most likely, this ubiquity is due to the presence of specific pathways in the brain and a common pattern of physiological processes, although there are some biological differences across ethnic groups in the way that some substances are metabolized. However, in explaining substance abuse and addiction, it is important to examine the individual's unique perspective and his or her sociocultural context. Thus, any model of substance use problems needs to be multifaceted and able to incorporate different levels of explanation. Further, in responding to substance abuse and addiction, it is essential to acknowledge and incorporate cultural-specific factors so that the individual is comfortable with the treatment approach. In a growing number of Western countries, including New Zealand and Canada, specific treatment approaches have been developed for indigenous people which utilize indigenous models of health and well-being and these have shown promising results to date.

Glossary

Analgesic drug that is used to relieve pain.
Allele member of a pair or series of genes that occurs at a specific location on a specific chromosome.
DSM Diagnostic and Statistical Manual
Dioscorides Greek physician and botanist who lived from 40 to 90 AD.
Enzyme protein that catalyzes chemical reactions.
Ethanol pure alcohol.
Herodotus Greek historian who lived from 484 to 425 BCE.
Limbic system set of structures in the human brain which is located between the brain stem and the inner cortex. It influences the endocrine system and the autonomic nervous system and is involved in a variety of functions, including emotion and behavior.
Materia medica a multivolume work by Dioscorides which documented the use of plants, animals, and minerals for medicinal purposes. Written between 50 and 70 AD, it remained in use for approximately 1500 years.
Mesopotamia an area surrounding the Tigris-Euphrates river system which covers modern-day Iraq, Turkey, Syria, and Iran.
Neolithic also referred to as the New Stone era, this is the latter part of the Stone Age, when it is believed that *Homo sapiens* began using agriculture and domesticating animals.
Nucleus accumbens the main part of the ventral striatum in the human brain. It is understood to play a vital role in the experience of pleasure and reward.
Phylogeny the evolutionary development of a group of organisms.
Synapse a small gap, usually between nerve cells in the human brain, in which neurotransmitters convey nerve impulses from one neuron to another.
Ventral tegmental area a group of neurons located at the base of the midbrain. This region is understood to play a vital role in the experience of pleasure and reward.

The Biopsychosocial Model of Addiction

*Monica C. Skewes**, *Vivian M. Gonzalez*[$]

[*]University of Alaska Fairbanks, Fairbanks, AK, USA, [$]University of Alaska Anchorage, Anchorage, AK, USA

OUTLINE

BIOPSYCHOSOCIAL VS. BIOMEDICAL MODELS OF ADDICTION

The biopsychosocial model of addiction posits that biological/genetic, psychological, and sociocultural factors contribute to substance use and all must be taken into consideration in prevention and treatment efforts. This model emerged in response to criticisms of the biomedical model, which has historically dominated the field of addiction studies. The traditional biomedical model was developed and is espoused by medical scientists for the study of disease, and its proponents also view addiction as a chronically relapsing brain disease with a genetic/biochemical cause. The biomedical or disease model of addiction views addiction as the manifestation of disturbances in measurable biochemical or neurophysiological processes in the afflicted individual. Contemporary medical disease models acknowledge the influence of social, psychological, and behavioral dimensions of addiction; however, these dimensions are viewed as relatively less important in the etiology and treatment of addiction. The medical disease model favors reductionism, whereby underlying biomedical causes for addiction are primarily implicated in the etiology/cause of the disorder, and mind–body dualism, where the mind and the body are viewed as separate and as not significantly affecting one another. Despite widespread favor among many scientists and healthcare practitioners, evidence from research studies of addictive behaviors does not support the medical disease model of addiction; instead, a biopsychosocial model that gives equal importance to biological/genetic, psychological, and sociocultural factors better fits the available data.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00006-1

In 1977, psychiatrist George Engel authored a seminal paper calling for the abandonment of the biomedical model of illness in favor of a biopsychosocial model. Engel identified numerous problems with the biomedical model that would be alleviated by the adoption of a biopsychosocial model that recognizes biological, psychological, social, and cultural influences on illness. For example, the biomedical model views biochemical abnormalities as the cause of any illness, and posits that correcting the biochemical abnormality will cure the illness. However, in many disorders, a person may remain ill after the biochemical abnormality has been corrected and, conversely, a person may never become ill even in the presence of an abnormality. For example, when infected with the virus that causes the common cold, some research participants become ill and some do not. The biomedical model does not account for the finding that, among people with similar genetic predispositions or physiological problems, some people develop an illness while others remain well. Engel surmised that psychological and sociocultural factors must explain the differences in the disease state among people with the same biochemical abnormalities.

It has been well established that illness is not merely the result of biochemical dysfunction or abnormality, as some people become ill in the absence of an abnormality or dysfunction. The effects of stress on illness have been well supported in the literature, as has the role of expectation on illness and health. The placebo effect, where an inert ingredient can result in biochemical reactions for the person who believes he or she is ingesting a drug, is evidence for the role of expectation in illness, and supports Engel's view of a connected mind–body experience. There also is evidence for the importance of the patient–provider relationship in healing; if psychosocial variables were not important, it would not make sense for rapport building and communication between the physician and the patient to have such strong influences on health outcomes. Moreover, if illness is caused only by the existence of a physical abnormality, then it should be cured by correcting the deviance, but this is not always the case. Most illnesses, disorders, and syndromes, including disorders of addiction, are caused by the interaction of numerous factors – biological, psychological, social, cultural, cognitive, and environmental. Therefore, these factors must be addressed in order to result in a recovered state.

CONCEPTUAL MODELS OF ADDICTIVE BEHAVIOR

A discussion of helping and coping by Brickman and colleagues identified four models of addiction based on beliefs about attributions of responsibility for acquiring the addictive problem and the responsibility for solving the addictive problem. The moral model holds that people who suffer from problems of addiction are responsible for both acquiring and solving the problem. People who become addicted are seen as morally weak with poor willpower, and they must will their way through addiction in order to recover. There is little support for this model in the literature. The enlightenment model holds that the person is responsible for developing the addiction, but is not responsible for solving the problem. The enlightenment model is espoused by Alcoholics Anonymous and other 12-step philosophies, and requires people to seek recovery by turning the problem over to a higher power. Only a higher power can cure addiction, and it is the person's task to form and strengthen a relationship with a spiritual entity so that this entity can solve the addiction problem. The medical/disease model emerged in response to the moral and enlightenment models that placed blame on the addict for his or her problem. In the medical model, the addict is responsible neither for the development of the problem nor for its resolution. This model posits a biological/genetic predisposition for addiction, an underlying disease process, and assumes that the disease is progressive. The medical/disease model fails to account for the finding that many people with problems of addiction do recover without professional treatment. Finally, the compensatory model holds that people are not responsible for developing the addictive problem, but are responsible for their own recovery. In the compensatory model, the role of multiple factors in the development of addictive behavior is noted (including biological predisposition, early experiences, and social and cultural variables), and the continued use of substances is viewed as a way to cope with stress. Of these four models, the compensatory model is the most similar to the biopsychosocial model.

BIOPSYCHOSOCIAL MODEL OF ADDICTION

Science has not discovered a single factor that can explain why some people are able to use substances without progressing to addiction, while others abuse or become dependent on substances. Instead, the available evidence suggests that biological, genetic, personality, psychological, cognitive, social, cultural, and environmental factors interact to produce the substance use disorder, and multiple factors must be addressed in prevention and treatment programs. The interaction of these factors to produce substance use problems is the core tenet of the biopsychosocial model of addiction. This model is a way to understand and explain the problem of addiction, but has not generated testable

hypotheses as have theories of behavior change like the Health Belief Model or the Theory of Reasoned Action/Theory of Planned Behavior (TRA/TPB). The essence of the model is that the mind and the body are connected and both the mind and the body affect the development and the progression of addiction within a social and cultural context. Only by considering all of these factors can addiction be accurately conceptualized.

BIOLOGICAL FACTORS AND THE DEVELOPMENT OF ADDICTIVE BEHAVIORS

Given the right environment, biological and genetic predispositions may increase the risk of substance use problems. Adoption and twin studies have found that substance abuse is to some extent heritable. Male children of an alcohol-dependent parent have four times the risk of becoming problem drinkers compared with the children of nondependent parents, while female children of alcohol-dependent mothers evidence a threefold greater risk. It has been reported that 30.8% of people with alcohol dependence had at least one alcohol-dependent parent. Among adults with alcohol dependence, 27% have alcohol-dependent fathers and 4.9% have alcohol-dependent mothers, compared with alcohol dependence among 5.2% of fathers and 1.2% of mothers of people without alcohol dependence. Among twin pairs in which one twin was diagnosed with alcohol dependence, there is a significant difference in the proband concordance rate among monozygotic (54.2%) and dizyogtic twins (31.5%). Calculated heritability ranges from 40–90% across studies, with more chronic and severe forms of alcohol dependence showing greater estimates of heritability. However, it is important to note that someone with a strong genetic predisposition to addiction still needs to engage in substance use before the addictive behavior becomes manifest.

Once alcohol is consumed, however, children of an alcohol-dependent parent experience the effects of alcohol differently than the children of nondependent parents. For example, research on subjective experiences of alcohol intoxication and body sway while intoxicated found that sons of an alcohol-dependent parent respond less intensely to moderate doses of alcohol. When given the same amount of alcohol as controls, sons of an alcohol-dependent parent had less body sway and were less likely to report feeling intoxicated. Follow-up studies have found that decreased subjective intoxication predicted later development of alcohol use disorders. Other studies have found that the children of an alcohol-dependent parent are less sensitive to the negative consequences of alcohol, resulting in increased alcohol consumption. Further, sons of an alcohol-dependent parent have decreased EEG alpha rhythms, also found in people with current alcohol dependence. Other studies have found that the sons of an alcohol-dependent parent have lower language functioning, lower learning achievement, lower verbal intelligence, and other neuropsychological differences when compared to controls. There is evidence that children of an alcohol-dependent parent who become alcohol dependent themselves have a worse prognosis than alcohol-dependent people who are not the children of alcohol-dependent parents. For example, the children of an alcohol-dependent parent show symptoms of alcohol problems earlier, have greater physical dependency on alcohol, and report less control over their drinking.

A genetic predisposition toward addiction does not influence the substance of choice to which a person may become addicted; instead, it is associated with an increased propensity toward addictive behavior in general. It also is important to note that genetic factors may be protective against alcohol use disorders. People of Asian descent are more likely to lack one isozyme of a liver enzyme known as alcohol dehydrogenase that aids in the metabolism of alcohol in the liver. People with this genetic variation have a flushing reaction to alcohol, characterized by flushed, reddish skin, and are much less likely to ever develop alcohol problems.

Research from the fields of genetics and biochemistry has identified other biological risk factors for addiction. People with impulse control disorders, including people with substance abuse problems and gamblers, are statistically more likely to have the dopamine D2A1 gene than controls. This genetic polymorphism is associated with reduced D2 receptor density and deficits in the dopaminergic reward pathway. Research has found that those with low D2 receptor density are more likely to seek out pleasurable activities including alcohol use, drug use, and gambling. This may translate into increased likelihood of experiencing problems associated with addictive behaviors.

Further evidence of the heritability of the risk for alcohol dependence can be found in animal studies. Researchers have been able to use selective breeding to develop strains of rats that differ in their liking of alcohol. One strain of rat (C57BL/6) has been bred to prefer alcohol over water. These animals seek out alcohol, ingest it willingly, engage in efforts to get alcohol, and become physically dependent on it, showing signs of tolerance and withdrawal. Other strains of rats have been bred to self-administer other drugs of abuse at high rates. The fact that an alcohol-preferring strain of rat has been developed is strong evidence of the influence of heritability on alcohol use behavior. Furthermore, studies have found deficits in serotonin in particular brain regions of rats that have

been bred to like alcohol. Despite the strong evidence of the role of genetic influence on alcohol use behavior, biology is still insufficient to account for the entirety of the problem. There still remain cases where people with no known genetic risk become addicted and cases where people with great genetic risk do not. The biopsychosocial model of addiction acknowledges that psychosocial variables also are needed to explain these occurrences and that these variables may interact with genetic and biological risks to cause addiction.

PSYCHOSOCIAL FACTORS AND THE DEVELOPMENT OF ADDICTIVE BEHAVIORS

Researchers have discovered consistent predictors of drug use initiation and subsequent use across multiple substances of abuse, including personality variables, learning factors, and higher-order cognitive processes. Substance abuse is highly comorbid with affective disorders and other psychiatric diagnoses, although some psychiatric problems (e.g. depression and anxiety) may be effects of the substance use as well as causal factors. Many (but not all) substance abusers have a history of antisocial behavior, nonconformity, deviance, acting out, impulsivity, and low self-esteem; however, these also can be the effects of substance misuse. Research establishing the role of psychosocial factors in the development of addictive behaviors provides evidence that addiction is a multifactorial problem, not a disease solely caused by a measureable underlying physiological abnormality or deficit, and provides support for the biopsychosocial model of addiction.

Risk Factors in Children

Much research has been conducted on childhood variables that increase the risk for alcohol dependence and substance use disorders. Consistently found in the literature is evidence for an increased likelihood of addiction among children who are victims of abuse and who exhibit externalizing behaviors such as those seen in conduct disorder, attention deficit/hyperactivity disorder, and oppositional defiance. In particular, antisocial and deviant behaviors such as aggression, hostility, vandalism, sadistic behavior, rebelliousness, and association with deviant peer groups place one at risk for substance use disorders later in life. One study found that problem drinkers exhibited more externalizing behaviors in childhood than did moderate drinkers, and moderate drinkers exhibited more of these behaviors than did light drinkers. Other research has found that tolerance of deviance in adolescence is a strong predictor of alcohol and other substance abuse in adulthood. Antisocial personality disorder is highly comorbid with substance abuse and dependence, and antisocial behaviors in childhood are strong predictors of substance problems in adulthood, independent of a family history of substance abuse.

Personality and Temperament

Addictive behaviors result from the interaction between genetic predisposition and psychosocial variables, including personality and temperament. Personality variables that impact later substance use include high novelty/sensation seeking, low harm avoidance, negative affectivity, and reward dependence. Other temperament variables that predict later substance problems are low attention capacity, high emotionality, low sociability, and impulsivity. A difficult temperament in childhood – defined as a high activity level, low flexibility, low task orientation, mood instability, and social withdrawal – has been shown to predict substance abuse in adolescence. One research study found that a difficult temperament in childhood was a stronger predictor of later alcohol dependence than a family history of alcohol dependence. Regarding the Big Five factors of personality (neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness), a family history of alcohol dependence is positively associated with openness to experience and negatively associated with agreeableness and conscientiousness. Unconventionality and deviant behavior are strong predictors of substance abuse across multiple research studies. In addition to increasing risk for substance use, temperament may influence adolescents' decisions when forming peer groups, which may then directly impact substance use. Adolescents who are more deviant and less conventional tend to select peers who also are more deviant and less conventional, further enhancing their risk for substance abuse.

Classical and Operant Conditioning

Classical and operant conditioning are learning processes that affect animal behavior, including addictive behaviors among humans. Classical conditioning works to establish a link between reflexive, involuntary behaviors and antecedent conditions, whereas operant conditioning concerns the modification of voluntary behavior in response to its consequences. In classical conditioning, an unconditioned stimulus (US) is paired with a conditioned stimulus (CS), resulting in a conditioned behavioral response (CR) to the conditioned stimulus. For example, Pavlov's dogs learned to associate the sound of a bell (the CS) with food (the US) to produce salivation (the CR). After several pairings of the bell with food, the bell itself became sufficiently linked

with food to produce salivation even in the absence of food. Among people engaging in addictive behaviors, an unconditioned stimulus (e.g., drug paraphernalia) can become paired with a conditioned stimulus (the drug) to produce a conditioned response (psychomotor stimulation). People (such as an addict's drug-using social network), places (such as locations where drugs are purchased or used), and things (such as drug paraphernalia, alcohol bottles, or substance-related words) are linked to the unconditioned stimulus (the substance) and take on the role of conditioned stimulus, evoking a conditioned response (e.g., craving). Encountering the conditioned stimuli associated with substance use (i.e., triggers) is a strong precipitant of relapse among people in recovery from substance use disorders.

In operant conditioning, behavior is reinforced via punishment, positive reinforcement (reward), or negative reinforcement (the removal of an adverse consequence). Reinforcement is any consequence that increases or decreases the likelihood that a behavior will be repeated. Among people engaging in addictive behaviors, operant conditioning affects the probability that the behavior will recur. For example, smoking behavior may be positively reinforced by pleasurable sensations caused by nicotine and simultaneously negatively reinforced by the elimination of nicotine cravings. All drugs of abuse act on the central nervous system and initially produce pleasant feelings and a hedonic state, but people differ in how reinforcing they find these feelings to be. People who enjoy the sensations produced by substance intoxication (i.e., find intoxication to be positively reinforcing) are more likely to use substances to the point of intoxication again in the future than are people who do not enjoy the feeling of intoxication. One study found that the degree of perceived reinforcement following initiation of drug use was predictive of the magnitude of the resultant drug problem.

Classical and operant conditioning work together to produce a behavior chain, or a sequence of behavior that can be understood in terms of both its antecedents (classical conditioning) and consequences (operant conditioning). Antecedents are also known as cues. Once a behavior chain has been activated, each cue serves as the reinforcer of the behavior that occurred previously as well as the antecedent of the behavior that follows. Cued habitual behaviors are both classically conditioned and reinforced or punished via operant conditioning. For example, encountering a liquor store may serve as a classically conditioned cue for a problem drinker, which results in craving. Craving may then serve as a cue to consume alcohol, and this behavior may then be negatively reinforced by alleviating stress or negative mood. By determining and understanding the behavior chain involved in addictive behaviors, intervention can be aimed at breaking the classically conditioned link between a cue and the behavior, by altering the reinforcement for the behavior, or both.

Substance use functions as positive reinforcement when the pleasant effects of intoxication are interpreted as rewarding to an individual. At the same time, people use substances to cope with unpleasant emotions, to manage stress, and to alleviate negative symptoms of withdrawal. In these ways, substance use also functions as a negative reinforcement. The more frequently one uses substances as a reward or as a way of coping with negative emotions or life events, the stronger the association becomes and the more difficult it is to extinguish the substance use behavior. This partially accounts for the finding that treatment is more difficult and relapse is more likely among individuals who have longer histories of substance use. It also has been suggested that use of substances to cope leads to an erosion of alternative coping behaviors, thereby making continued substance use and dependence more likely.

Outcome Expectancies

One area of research that has uncovered some of the strongest and most reliable effects of psychology on addictive behavior is that of alcohol outcome expectancies. Addiction is not merely a physiological response to something that feels good and is rewarding; it is influenced strongly by the labeling, interpretation, and meaning that a person ascribes to a substance of abuse. Outcome expectancies are conditioned cognitions; this refers to a person's beliefs about the effects that using alcohol (or another substance) will bring about. People who develop substance use problems report that using a substance results in positive, desired effects such as the ability to avoid or escape negative mood states. Common alcohol expectancies, as identified and described by Alan Marlatt, include relaxation and tension reduction, positive global changes in experience, sexual enhancement, social and physical pleasure, increased assertiveness, and increased arousal and interpersonal power. People may learn what they can expect from alcohol from prior experience or vicariously; indeed, evidence suggests that one need not have experience with alcohol in order to form strong expectancies about its effects. Watching others model the behaviors associated with intoxication (e.g., becoming louder, becoming more socially confident and engaged, and developing looseness of speech) can teach an observer what the effects of alcohol consumption are, thereby creating outcome expectancies. Experience with drinking may then reinforce previously held beliefs about the positive effects of alcohol. Expectancies also influence motives to drink – people who state that they expect alcohol to help relieve tension are more likely to turn to alcohol when stressed. Heavier drinkers report more positive alcohol

outcome expectancies and fewer negative outcome expectancies than lighter drinkers.

Self-efficacy

Another psychological variable that influences the development of substance use disorders is Bandura's concept of self-efficacy. Self-efficacy is defined as an individual's belief in his or her ability to perform a certain behavior in order to achieve a desired outcome. Self-efficacy for substance use is developed when one observes a model obtain and use substances. For example, an adolescent may develop self-efficacy for smoking by observing peers purchasing cigarettes at a location that does not check identification, lighting a cigarette, and inhaling the smoke. The adolescent's confidence in his or her ability to smoke is thereby increased. However, self-efficacy also refers to one's belief that he or she is capable of handling a stressful or challenging situation without using substances. Research has found that people are more likely to use substances in situations where they feel unable to cope with the demands of the situation or negative affect. As one uses substances more and more often to cope with stress or other life problems, the use of other more adaptive coping strategies decreases, which then results in reduced self-efficacy for the use of these alternative coping skills. This also translates into decreased self-efficacy in one's ability to refuse substances in the face of challenging life circumstances.

Social Influences on Substance Use

Families

In addition to genetic factors, addictive behaviors are transmitted between generations in families due to social influences. Social Learning Theory posits that modeling influences behavior, and that adolescents who observe substance use in their parents are more likely to use substances themselves. This assertion is supported in the research literature. However, there is evidence that modeling is not the only way in which parental influence on adolescent behavior takes place – parents also influence adolescents' behavior via norms and perceived attitudes. Numerous studies have found support for the association between parental approval of substance use and adolescent use of alcohol, tobacco, and marijuana – adolescents whose parents have positive attitudes toward substance use are more likely to use substances. Among college students, perceptions of parental approval of alcohol consumption were positively associated with experiencing a drinking problem. Perceived parental approval of illicit drugs was found to predict earlier first use of drugs and increased current frequency of drug use. Families also play a protective role against the development of substance abuse. Parental monitoring (supervision) and consistent discipline are associated with lower risk for substance abuse among children. Among women, becoming a parent also is associated with decreased risk for drinking problems.

Peers

Peers influence adolescents' values, attitudes, and behavior in multiple domains, including substance abuse. Having a peer group that uses substances is a strong predictor of adolescent substance use, as is the perception that one's peer group endorses substance use. When adolescents associate with peers who hold socially deviant attitudes and beliefs, the risk of substance use increases. Friends' smoking is among the strongest predictors of adolescent smoking behavior. Peer group involvement is thought to impact substance use through interaction with other risk factors, including family problems, stress, mental health, and self-esteem. Among adolescents who drink, the most important reasons for alcohol use were to socialize with friends, cope with tension and anxiety (especially regarding interactions with the members of the opposite sex), improve mood, and alleviate boredom. Male adolescents, who have higher rates of alcohol use than females, also have higher rates of involvement with peer groups that maintain deviant attitudes.

Peer influences on substance use behavior are not only important during adolescence. Studies have shown that alcohol use among adults is likewise influenced by peer drinking. College students' alcohol use was found to be positively correlated with their friends' alcohol use and with the students' perceptions of their friends' drinking. Often, college students who drink heavily report that their peers drink at the same levels as they do. Interventions for college students in which they are given feedback about how much they are drinking in relation to normative drinking for peers of the same gender and age demonstrate that high-risk drinkers are in fact consuming more alcohol than is normative for their peer group. Normative feedback interventions also demonstrate that heavy drinkers overestimate what is normative drinking, such that they erroneously believe most students drink as they do. These interventions consistently have been shown to result in decreased alcohol consumption and related problems for college students. Other research has found a positive correlation between alcohol use in adults and their perceptions of their peers' alcohol use. Heavy-drinking adults report having larger drinking social networks than do light or moderate drinkers. Social networks are important influences on adult substance use as well as adolescent substance use. Several studies have found support for the assertion that greater alcohol

involvement among one's peer network is associated with heavier drinking among both men and women. This relationship is independent of sociodemographic and individual difference variables and alcohol expectancies.

Spouses and Intimate Partners

Among adults, spouses and intimate partners are the most important and influential social connections people have. Research has supported spousal concordance in substance use behavior – wives and husbands tend to use the same substances, and heavy drinking or drug use in one partner predicts heavy use in the other partner. Problem drinkers are disproportionately more likely to be married to other problem drinkers. Marriage, however, also is a protective factor as it is often associated with a decrease in drinking.

Other Individual Difference Variables that Influence Substance Use

Ethnicity and Culture

National surveys have documented racial/ethnic differences in rates of substance use, with certain ethnic minority groups (e.g. African Americans, American Indians/Alaska Natives) reporting disproportionately high rates of substance use and dependence. There are numerous reasons for disparate rates of use and dependence among ethnic minorities, including increased risk factors such as poverty, discrimination, microaggressions, and stress among minority groups. Ethnicity also has been shown to moderate the associations between the risk factors and substance use. One study found that substance availability and perceived parental approval differed among Whites, African Americans, and Asians, resulting in ethnic differences in substance use initiation and stated intentions to use substances. With regard to cigarette use, White adolescents were most strongly influenced by adult and peer smoking; for African Americans, however, risk taking was a stronger predictor of smoking behavior than social norms. Among Hispanics, the perception of adult and peer approval of smoking was the strongest predictor of adolescent tobacco use; among Asians, peer and family influence was not as important for the prediction of adolescent smoking as poor academic performance and low self-esteem.

Other research has found that ethnic labels and ethnic identity influence substance use. In a study of middle school students, having a strong sense of ethnic pride was protective for African American, Mexican American, and mixed-ethnicity students, as these students reported less exposure to drugs and less drug use than those with lower levels of ethnic pride. The opposite was true for ethnically proud White students, who reported greater drug exposure and use. Also, ethnic minority students who reported having behavior, speech, and looks that are common in their ethnic group reported greater drug exposure and use, whereas White students who viewed their behavior, speech, and looks as typical of their ethnic group reported lower exposure and use of drugs. Among Mexican Americans and American Indians, a stronger sense of ethnic identity was associated with decreased substance use.

Gender

Across cultures, males smoke more, use more drugs, consume more alcohol, and have more alcohol and other substance use disorders than females. Gender differences in alcohol consumption may be due to differences in availability of alcohol and other substances; they also may be partially attributable to adherence to traditional gender roles. Females who espouse more traditional gender role attitudes drink less than their less conventional counterparts, while the opposite holds true for males. Among women, but not men, becoming a parent also is associated with decreased risk for drinking problems. Peer influence on smoking is stronger for females than for males. Research has found that females respond more than males to the reinforcing properties of substances and may develop drug abuse and dependence more rapidly than males. Other risk factors for addiction, such as childhood physical and sexual abuse, depression, intimate partner violence, and posttraumatic stress disorder may play a more important role in the initiation and maintenance of drug use among women than among men. One study found that women's tobacco use was more influenced by social factors than physiological dependence when compared with men's tobacco use. Women also report a greater propensity to use substances to alleviate negative affect than men.

Environmental Influences on Substance Use

Availability of substances has been shown to be a major factor in the initiation of substance use and the development of substance use disorders. In order for a genetic predisposition to result in addictive behavior, one must interact with the agent of addiction (e.g., alcohol or drugs). Increased availability of alcohol or drugs makes increased contact with substances possible. Rates of smoking are increased in areas with no smoking area restrictions and are decreased when laws prohibiting indoor smoking are enforced. The prevalence of alcohol use and alcohol use disorders is greater in neighborhoods with more bars and liquor stores, and research suggests that there are more bars and liquor stores in ethnic minority neighborhoods, which may account for some ethnic group differences in rates of alcohol-related problems. Socioeconomic

status also affects substance use behavior. Poverty is an established risk factor for alcohol and drug problems, and low income is associated with alcohol dependence and comorbid psychiatric disorders. Research on neighborhood disorganization, operationalized as high population density, physical deterioration, high crime rates, and the presence of illegal drug trafficking, has found that residing in disorganized neighborhoods strongly increases the likelihood of adolescent substance use.

Social engineering and public policy approaches to substance-related problems have had some success, adding further support to the biopsychosocial model of addiction. For example, when alcohol was made illegal during prohibition, national rates of drinking and associated health consequences such as cirrhosis of the liver were reduced. There also are areas within the United States (e.g., villages in rural Alaska) where alcohol is illegal. For example, the Alaska State Local Option Law, implemented in 1981, allowed Alaska Native communities to decide whether to permit drinking and what kind of alcohol control policies to implement. Research shows that the rates of homicide and accidental death are lower in communities that opted to ban the sale and importation of alcohol. Laws regulating the sale of alcohol and tobacco to persons under the minimum age limit have served to decrease use of these substances. Between 1970 and 1975, 29 states lowered the minimum drinking age with negative effects on public health; rates of adolescent alcohol consumption, alcohol-related injuries, and automobile fatalities increased during this period. When the minimum drinking age was later increased, there were reductions in adolescent alcohol consumption, alcohol-related injuries, and automobile fatalities. Raising the minimum drinking age also resulted in decreased prevalence of alcohol abuse and dependence in the following years. Research on taxation of alcohol and tobacco supports the use of taxes as a means to decrease alcohol and tobacco use. Among 18–20 year olds, increasing the price of alcohol resulted in decreased automobile fatalities. Such approaches to ameliorating addiction problems would not make sense and would not be effective if the biomedical model of addiction was accurate.

THE BIOPSYCHOSOCIAL MODEL AND ADDICTION TREATMENT

The most successful addiction treatment programs incorporate strategies to enhance coping, reduce craving, manage triggers, and prevent relapse. Some programs involve medication, but pharmacotherapy often is not considered an essential part of recovery from problems of addiction. Instead, finding ways of managing difficult emotions, coping with negative life circumstances, enhancing social support for sobriety, and establishing a lifestyle free of substance abuse is essential to long-term recovery. Recovery from addiction requires a biopsychosocial approach with attention paid to biological, psychological, and social aspects of addiction.

Natural Recovery

According to the biomedical model, addiction is a chronically relapsing brain disease that will progress unless treated. The biopsychosocial model, on the other hand, recognizes the occurrence of natural recovery. Natural recovery, or recovery in the absence of professional treatment, is one of the most common methods of recovering from substance abuse problems. Studies of the reasons for natural recovery have identified many precipitants to change, including a meaningful religious or spiritual experience, suffering a loss, support from family and friends, a personal injury or illness, or the substance-related injury or the illness of another person. These reasons are external motivators, aspects of one's social and cultural environment. In recovering from addiction, strategies that support successful self-change include the establishment of social support for sobriety, adoption of new coping skills and stress management techniques, and overall lifestyle changes such as changing one's social network, restructuring leisure time, and avoiding triggers that cause craving. One research study found that people with higher levels of motivation to change, greater commitment to change, more frequent and persistent use of coping strategies, and more frequent use of self-reinforcement strategies were more likely to be successful in self-change of addictive behaviors.

Medication

Medication is the treatment of choice for disease under the biomedical model. There are several medications that are helpful during substance abuse treatment, but no medication has been shown to cure or prevent addiction, as would be expected under the biomedical model. For smoking, nicotine replacement therapies such as the nicotine patch, gum, and nasal spray have been shown to double one's chances of successfully quitting. These tools work by gradually reducing the smoker's dependence on nicotine while extinguishing the smoking behavior, with the goal of slowly tapering off the nicotine until one is free of the substance. For opiate dependence, methadone and buprenorphine have been shown to be effective at reducing cravings and avoiding withdrawal symptoms, but these medications have side effects and other consequences. People in treatment for alcohol dependence may be prescribed

Antabuse to classically condition them to develop an aversion to alcohol, but this is only modestly effective under ideal circumstances. Naltrexone, an optiate receptor agonist, when combined with medical management, showed evidence of being equally effective in treating alcohol dependence as an intervention that combined elements of several effective behavioral treatments. Treatment for substance dependence in general may benefit from anxiolytic or antidepressant pharmacotherapy to help manage the negative mood that previously was managed by alcohol or other substance use. Overall, medication can be a helpful adjunct to psychosocial treatment, but no medication has been shown to solve the problem of addiction, and recovery in the absence of pharmacological treatment is common.

PSYCHOSOCIAL FACTORS IN THE TREATMENT OF ADDICTION

Readiness to Change

Of particular relevance to the treatment of addiction is the psychological factor of motivation or readiness to change. Research has found that motivation increases the likelihood that someone will seek out treatment and complete a treatment program or will be successful in changing his or her substance use in the absence of formal treatment. Greater motivation at treatment initiation also is predictive of better long-term outcomes. According to the Transtheoretical Model, a leading model of behavior change that was developed to explain how people change addictive behaviors, readiness to change is a function of decisional balance, or the cognitive appraisal of the pros and the cons of changing. People who rate the cons of changing their substance use as more salient than the pros of changing report being less motivated to reduce their substance use. People for whom the pros of changing outweigh the cons of changing their substance use are more motivated to change and have greater success in attempts to limit their consumption of substances. Readiness to change can be impacted by processes of change such as consciousness raising, dramatic relief, and self-liberation. Motivational interviewing is one therapeutic style that has been shown to be especially effective with substance users who are low in motivation to change and to bring about greater readiness to change. The extensive body of literature demonstrating the impact of readiness to change on subsequent substance use provides additional support for the biopsychosocial model over the biomedical/disease model of addictive behavior.

Self-efficacy

Self-efficacy is a cognitive factor that is crucial to recovery from addiction. In order to refrain from using substances, one needs to believe that he or she is capable of managing difficult situations in other ways. Self-efficacy can be built through experience and exposure to different behavioral options. For example, when a smoker foregoes a cigarette in favor of a brisk walk to manage stress, he or she builds self-efficacy by proving to himself or herself that a response other than smoking is possible for the individual, and that stress can be relieved in the absence of cigarette smoking. The greater experience one has with using coping strategies other than substance use, the greater his or her self-efficacy becomes.

SUMMARY

In summary, there is a great deal of evidence supporting the biopsychosocial model of addiction, which gives weight to biological, psychological, and social factors in understanding the development and progression of substance use problems. Research supports the role of biological factors such as genetic predisposition in the development of addictive behaviors. At the same time, psychological and cognitive factors such as outcome expectancies, self-efficacy, and readiness to change and social factors such as family, peer, and intimate partner influences on substance use are equally important. In order to prevent and treat addictive behaviors, attention must be paid to the biological, psychological, and social factors that interact to produce and maintain disorders of addiction. The evidence clearly indicates the importance of factors in all three realms, and successful treatment programs will benefit from taking a biopsychosocial view of the problem of addiction.

Glossary

Biopsychosocial the influence of biological, psychological (including cognitions, emotions, and behaviors), and social (including culture and environment) factors on the development, maintenance, and treatment of disease.

Health Belief Model the Health Belief Model is an empirically supported theory of health behavior change developed to understand and predict the use of health services. The model posits that health behaviors are influenced by perceived susceptibility to and perceived severity of disease, as well as perceived benefits and barriers to changing behavior. In recent years, two additional constructs (cues to action and self-efficacy) have been incorporated in the Health Belief Model to allow for the prediction of more general health behaviors.

Theory of Reasoned Action/Theory of Planned Behavior the Theory of Reasoned Action/Theory of Planned Behavior (TRA/TPB) is a combination of two psychological theories of health behavior change developed by Fishbein and Azjen to explain and predict human behavior. The models posit that the most important aspect of behavior change is one's intention to change. The intention comprises a person's attitude toward the behavior and subjective norms. Attitudes, in turn, represent a combination of behavioral beliefs, evaluations of behavioral outcome, normative beliefs, and the motivation to comply with recommendations. The model has empirical support and allows for the prediction of human behavior.

Disease Model

Arthur W. Blume, Desiree M. Rudisill, Shai Hendricks, Natalia Santoya

Washington State University, Vancouver, WA, USA

OUTLINE

HISTORY AND OVERVIEW

The disease model views addiction as a physiological disease with specified symptoms and course. The disease model is a biomedical model that understands addiction as a physiological pathology that requires medical or pharmacological interventions. Because the disease model defines addiction as a sickness, proponents of the model use medical terminology to describe important addiction processes and treatment. The term treatment (rather than therapy, as an example) is used for the provision of health care services meant to intervene on addiction. Treatment modalities are defined medically (such as inpatient, outpatient, and day treatment). People who seek treatment are usually referred to as patients (rather than clients). Diagnostic definitions also reflect a disease model understanding of the nature of the problem (e.g. full and partial remission from the *Diagnostic and Statistical Manual* published by the American Psychiatric Association).

In the model, addiction is defined as a chronic disease for which there is currently no medical cure. The model also views addiction as a disease with symptom progression; not only is the condition chronic and incurable, but also the symptoms progressively worsen over time. Severity of the disease is often determined by the progression of various physiological symptoms, such as tolerance and withdrawal. Symptom progression is viewed by some proponents of the disease model as continuing in a latent fashion even when a patient is abstaining, so if the patient were to return to active addiction, it is likely that a progression of symptoms (when compared to when they had abstained) would be observed almost instantaneously upon return to the addictive behaviors even if the person had abstained for a significant amount of time.

In addition to these worsening symptoms over time, two physiological processes perpetuate the course of the disease: cravings and loss of control. Cravings as defined by the disease model are physiological responses often triggered by withdrawal processes that create a strong desire in the patient to seek out and use the substance. Loss of control is a disease process that contributes to an inability of patients to predict or control how much or how long they will engage in the addictive behavior (e.g. how much or how long they will use during a drinking or drug using event). Loss of control has also been referred to colloquially as powerlessness over a substance (first by members of Alcoholic Anonymous (AA)), and that powerlessness tends to cause unmanageability in everyday life (from the First Step of AA).

The disease model represents the first serious attempt to define addiction processes within the spirit of scientific inquiry. In the United States, Dr Benjamin Rush was the first to recognize the public health risks

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00007-3

associated with excessive alcohol consumption and to discuss alcohol abuse as a medical condition. He referred to the possibility of progression of alcohol symptoms in his model (1785), but his model suggested moral solutions rather than medical treatment when considering how temperance would be attained. In 1849, Magnus Huss, a Swedish physician, is credited with first referring to alcoholism as a disease that could result from heavy drinking of alcohol.

The disease model as it is generally understood and practice today was largely due to the work of American E. Morton Jellinek in the mid-twentieth century. Jellinek investigated the symptoms of alcoholism among a limited sample of chronic inebriates in an effort to determine common symptoms and course of the disease that could be used to plot progression and determine prognosis. From this investigation, Jellinek created a chart now referred to as the Jellinek curve that mapped out the progressive course of the disease of alcoholism symptom by symptom as determined from the interviews discussed above. The Jellinek curve (so named because of the U or V shaped curve of progression of symptoms on the chart) was also classified into progressive stages of severity in the disease based upon the progressively worsening symptoms, with the first stage referred to as prealcoholic, the second as prodromal, the third as crucial, and the fourth and last stage referred to as chronic alcoholism. The bottom of the curve (often colloquially referred to as rock bottom) leaves alcoholics with few options: imprisonment, insanity, death, or recovery (which then leads to the ascending side of the U or V shape as patients incur more recovery time and show symptom improvement).

Interestingly, Jellinek later revised his understanding of the disease of alcoholism in the 1960s, indicating that his research had suggested multiple presentations of alcoholism, rather than only one trajectory as first suggested in his curve. He subsequently described different typologies of alcoholism: alpha (psychological but not physical dependence), beta (chronic abuse that leads to health problems but may not include physical dependence), gamma (similar to the symptoms and course described in the curve), delta (similar to gamma but without loss of control), and epsilon (binge patterns). Jellinek considered gamma and delta alcoholism to operate under disease principles, but was less certain about whether the other typological categories did.

American Medical Association Defines Alcoholism as Disease

In 1954, the American Medical Association (AMA) publicly declared that alcoholism was a disease. This was a watershed event in the treatment of addictions and at the time was a radical, compassionate act that paved the way for third party reimbursement for the treatment of addictive disorders. Before this declaration, addiction was mostly viewed as a moral problem by the general public and government policies treated those with addiction accordingly. The declaration of the AMA not only increased the likelihood of effective treatment services, but also reduced some of the stigma in seeking help for alcohol-related problems. The declaration also put into motion subsequent legislation that allowed for federal funds to be used to support treatment and eventually provided funding streams for researchers investigating addiction. Although some critics have suggested that the AMA declaration was made more out of professional self-interests than compassion, the declaration created the necessary conditions for addressing addiction as a health problem rather than a moral problem in the United States.

The declaration also contributed to the rise of the treatment industry in the United States. With the onset of third party reimbursement for treatment, many hospitals and agencies saw the possibility of treatment as a profitable business as well as providing a community health service. Health care entities with exclusive specialization in addiction treatment delivery were constituted. Today, the treatment industry remains a large force in health care delivery in the United States with literally thousands of treatment centers generating revenues in the billions of dollars.

Most treatment facilities today practice what has been referred to as the Minnesota Model of treatment. The name is derived from the pioneering work of treatment centers in the state of Minnesota, such as Hazelden and Johnson, which as industry leaders developed a unique integration of services incorporating ideas and principles from both the disease model and the Alcoholics Anonymous/Narcotics Anonymous spiritual-based recovery model to determine the nature of therapeutic process of treatment (discussion of disease allied with work on the 12 steps and participation in recovery groups). It is worth noting that this was an unusual merger of conceptual models in what amounted to treating a biomedical disease with a spiritual recovery program. Since the disease model views addiction as incurable, proponents were forced to look outside of medical care for help in treating the problem. The logical source for finding help would be the existing 12-step recovery programs, which at the time of the rise of treatment centers would have been the only high-profile programs with a track record of success for some people. Today the Minnesota Model of treatment continues to be the most widely practiced in the United States, and large high-profile institutions such as Hazelden and Betty Ford tend to mostly operate under disease model principles today.

It is important to keep the timing of the AMA declaration in historical context. National prohibition had been the law of the land only 20 years earlier. Although some

of the impetus for prohibition legislation was centered on health concerns related to drinking alcohol, most of the effort was because of concerns about national morality and the belief that alcoholism was contributing to the moral degradation of the United States. The United States has a rather unique history when it comes to public policies related to addiction, including its somewhat lengthy history of experimenting with national prohibition. This unique history also contributed to the preeminence of the disease model as the theoretical framework for the treatment industry in the United States. The disease model arguably arose as a reaction to the generally uncompassionate and widely professed moral model beliefs that viewed addictive behaviors as a sign of a significant moral flaw (often thought of as sin) in a person and viewed behavior change as a matter of personal choice and willpower. The disease model challenged those beliefs by describing addiction as a disease that contributed to loss of control. Loss of control meant a person had no choice in the matter of addictive processes and was in fact sick rather than fundamentally flawed.

Other nations outside the United States did not necessarily experience the same history, and therefore did not have the need to challenge a moral model belief system. Some have referred to the disease model as uniquely American and its use beyond the United States is not widespread. The disease model continues to be predominantly practiced in most treatment centers in the United States, although other recovery models have made inroads as science has demonstrated the efficacy of their treatment techniques (cognitive behavior therapy in particular).

A Disease of the Brain

In more recent years, the belief that addiction is a disease has evolved somewhat to reflect the growing body of research in genetics and neuroscience. There are many that believe that addiction may be genetically predetermined (running in families) and that genetic research has demonstrated that addiction is a disease with hereditary risk (like heart disease for example). Neuroscientists and neurobiologists have determined physiological mechanisms of addiction and how addiction specifically impacts brain function. The new empirical findings have led many to conclude that addiction is a disease of the brain. The advancement in understanding the biological processes related to addiction over the last decade or two has been nothing short of miraculous, and it is increasingly clear that complex physiological processes are involved in the development and maintenance of addictive behaviors. It also seems clear that people who may be at the highest risk for developing addictions often have family histories for addiction, suggesting genetic and biological predispositions for risk of onset.

However, as many scientists have noted, there seems to be a large gulf between where the science of the field is today and what is being delivered clinically to patients in treatment centers. With regard to the disease model, most treatment centers continue to operate under disease model assumptions that in some cases have evolved little since first formulated 70 years ago. In addition, much of the new information being discovered by neuroscientists and neurobiologists is not being incorporated into treatment protocols. The result is that the evolving brain disease model being discussed among researchers is generally significantly different and more sophisticated than the traditional disease model philosophy being transmitted by treatment centers to their patients.

STRENGTHS OF THE DISEASE MODEL

The many strengths of the disease model have contributed to the evolution of addiction research and treatment. First, the rise of the disease model allowed compassionate health care to be provided to patients with addictive behaviors and improved accessibility to treatment services. Second, the disease model acknowledges the importance of biological processes at work in addiction. Third, related to the second point, the disease model has contributed to an explosion of biomedical research related to understanding and treating addictive behaviors. And fourth, use of the modified disease model by patients in recovery has improved the quality of the lives of many people struggling with addictions. Perhaps, the greatest legacy of the model is that it has provided hope for many people, especially during a period of history when none existed. The disease model was a compassionate alternative when first proposed as compared to the moral model. Many success stories in treatment and recovery have been documented among people who sought treatment services in facilities that operate under the assumption that addiction is a physical disease.

CRITIQUE OF MODEL

One important critique concerning the original conceptualization of the disease model involves the methods by which the model was developed. Critics of the model have pointed out that the small studies Jellinek used to determine the symptoms and course of the disease of alcoholism were populated by people who were essentially outliers with severe addiction symptoms. Studies involving outliers would not necessarily be applicable to all people engaging in addictive behaviors. Another criticism is that the symptoms and trajectory of the disease were qualitative interpolations of

what research participants reported retrospectively rather than deduced by empirical means with use of prospective data and rigorous experimental methods. Another critique of the methods has been that since the symptoms and course were assessed in study participants retrospectively, there may have been errors in what research participants recalled. Especially given the severity of addiction in the study participants, where memory problems would be of concern, participants would likely be poor historians with regard to what symptoms were experienced when. As mentioned, Jellinek moved away from the original model later in his career with his research about different typologies, suggesting that he too had lacked faith in it. However, the Jellinek curve continues to be used by many disease model proponents in clinical settings even though it was developed for use 70 years ago.

Another critique comes from those who point out that not everyone has benefitted from Minnesota Model treatment based on the principles that addiction is a disease that contributes to powerlessness and unmanageability. As an example, there have been estimates that of the millions of patients who have received treatment for addictive behaviors, only a small proportion have membership in the 12-step recovery groups after treatment as recommended by Minnesota Model centers. Some research has demonstrated that certain groups, such as ethnic minorities and women, do not associate with 12-step recovery programs in the numbers that would be expected, and 12-step fellowship groups tend to be more heavily populated by men and European Americans in general. There is also evidence that people who do not view spirituality or religion as important are less likely to seek out the 12-step recovery programs. In addition to these groups that have difficulties with the 12-step recovery culture or philosophy, there are also people who do not view their own addictive processes as chronic or progressive, and may not accept that they are powerless. People with these views often are uncomfortable with the traditional Minnesota Model treatment and unlikely to seek out 12-step recovery. Some of those who have not benefitted from traditional Minnesota Model treatment have found help in therapy that uses other models of recovery (cognitive-behavioral, for example).

Research concerning the success of treatment for those who do seek traditional Minnesota Model services has yielded interesting results. To be certain, treatment works, but not often in the way that would be predicted by those who are proponents of a chronic progressive disease. Researchers have found that abstinence rates for patients after treatment tend to be modest, and for a number of years those findings contributed to some concern that treatment may not be as effective as professionals would like. However, when treatment outcomes were examined by including data about reduction in addictive behaviors and improvement in quality of lives along with data concerning abstinence, the impact of treatment became clearer. It was discovered that many clients who graduate from traditional treatment programs that insist on abstinent goals were opting for reductions rather than abstinence and simultaneously reporting improvements in the quality of lives without abstinence. Treatment is indeed successful for many, if not most, of clients, but not in the manner predicted by the disease model. Critics of the disease model have concluded from these findings and other parallel research that patient's perspectives about their own addictive behaviors may be more important to consider rather than assuming the disease must be treated in a certain way in order for recovery to occur.

Relevant to these findings is new research on behaviors that have been typically labeled as denial. Research that contributed to development of Motivational Interviewing, an empirically supported intervention for addictive behaviors, revealed that what is often called denial/resistance in treatment was actually a function of interpersonal interactions between client and therapist. Researchers found that resistance and denial changed in a therapy session as a result of the type of strategies used by the therapist; increased confrontation led to increased coding of denial and resistance by behavioral observers, and denial/resistance would decrease when the therapist switched to a less confrontative style. Neuroscientists have investigated similarities between what was referred to as denial with neurocognitive impairment subsequent to addiction (memory problems, anosagnosia). Today, many researchers believe that what has been typically been referred to as denial, a term that has become arguably judgmental, would be better described as lack of trust in the interpersonal dynamic, lack of awareness of problems or the need to change, or perhaps indicative of a cognitive/perceptual problem.

Research on cravings has demonstrated how they can be triggered psychologically as well as physiologically. Scientists and clinicians alike had been baffled for years about why cravings would occur long after physiological withdrawal would be expected to have ended. It became increasingly clear that cravings also can be learned behaviors, classically conditioned and linked to specific cues in the environment that trigger the craving response. In addition, cravings also can be triggered by cognitions (thoughts, beliefs) such as positive outcome expectancies. The disease model has long conceived of cravings as the consequence of physiological processes, but substantial evidence now exists that cravings can occur independently of physiological processes and cravings can be effectively intervened upon by psychological means.

In addition, there is a substantial body of research that has demonstrated that loss of control may not

always occur among people with addictions. For example, scientists have determined that subgroups of people with addictive behaviors are able to mature out of the behaviors (young adults) as they age or are able to experience natural recovery without treatment (older adults). Some people who have met the criteria for substance dependence have been able to return to light or moderate engagement in the addictive behavior without demonstrating loss of control subsequently. Psychological studies, such as the one conducted by G. Alan Marlatt referred to as the balanced placebo drinking study, have demonstrated that people with alcohol dependence do not necessarily lose control of substance use when drinking alcohol, and that for some people loss of control may be more a function of beliefs about drinking circumstances than physiological responses. Different typologies of addiction may help to explain why some do not lose control or can regain control, but the empirical support for maturing out and natural recovery tends to dispute traditional assumptions inherent in the disease model.

Other research has demonstrated the potency of psychological and social/environmental factors on addictive processes in a way that would not necessarily be predicted for a biomedical condition. Psychological principles concerning reinforcement and cognitions have been found to be particularly effective in predicting not only subsequent addictive behaviors but also success in treatment. It is also known that interpersonal and environmental factors are associated with the risk for and predictive of the course of addictive behaviors. Like many other disorders, many researchers believe that addictive behaviors are thought to be best understood within the context of a biopsychosocial model that accounts not only for physiological processes such as genetics and the reward pathways of the brain, but also for psychological and social/environmental processes known to be associated with addiction. Belief in addiction as a brain disease must adequately account for the psychological functions inherent in the human brain as well as physiological processes.

The disease model tends to heavily focus on a biomedical approach to understanding and treating addictive behaviors in spite of the significant evidence that addictions are more appropriately understood as biopsychosocial processes. In defense of the biopsychosocial model, many professionals have noted how patients in disease model treatment have often been derailed in their recovery by psychosocial stressors, and in fact many Minnesota Model treatment centers have incorporated psychosocial interventions (often cognitive-behavioral such as relapse prevention) to accompany biomedical and 12-step interventions. Critics have suggested that the evolution of Minnesota Model treatment over time to include psychosocial interventions indicates that biomedical and 12-step model provided insufficient means alone for addressing many of the psychosocial factors that impact addiction, and this is an evidence of the importance to view addiction from a biopsychosocial perspective.

One final note is that the disease model represents a Western view of medicine that does not necessarily match well to other world perspectives on medicine and illness. The disease model has not been widely accepted or practiced in areas of the world where other models of medicine and illness exist. The disease model also has not been widely accepted among immigrants to the United States from areas of the world who have different perspectives of medicine and illness than those posited in the disease model. The difference in beliefs regarding medicine and illness has in some instances created a mismatch between client worldviews in treatment and the model of the treatment provider providing care. In other instances, people with different views of medicine and illness will simply avoid the use of traditional treatment services, usually seeking out cultural relevant methods instead.

POSITIVE CONTRIBUTIONS OF THE MODEL

In spite of criticism, the original disease model represented a qualitative improvement over existing models when first described by Jellinek and others. Addiction was often viewed as a moral problem and therefore compassionate care was lacking. People with addiction were often sent to asylums or spent time in prison. Only after the advent of the disease model was there interest and means to treat people for their addictions in a health care setting. Addiction became a diagnosis rather than a moral problem, and research was stimulated to find treatments and cures. The disease model was radical when proposed: It represented a compassionate reconceptualization of addictive processes. Years of subsequent research have revealed that addictive processes are much more complex than initially realized, but without the first conceptualization of addiction as disease, that empirical inquiry likely would not have occurred.

The introduction of the disease model and subsequent declaration by the AMA in 1954 paved the way for third party reimbursement for treatment. The disease model not only made treatment possible, but also increased its accessibility to those in need. Without third party reimbursement for addictive disorders, the number of treatment centers in the United States would likely be greatly reduced in numbers and potentially even more expensive than found today.

SUMMARY AND FUTURE DIRECTIONS

The disease model was the first modern conceptualization of addictive behaviors. Because it was the first empirically derived model, its legacy is immense. Without the development and acceptance of the disease model, both clinical practice and research would look much different today, especially in the United States. As discussed, the model as traditionally conceived has its flaws and limitations. However, the disease model has stimulated many promising areas of inquiry into addictive behaviors, including in medicine, neurobiology, neuroscience, pharmacology, and the social sciences. The future of the disease model is difficult to determine. On the one hand, significant biomedical research gains have been made that support the strength of association between the brain and addictive processes. On the other hand, many supporters of the disease model have focused so intently on the biological processes of addiction that they have lost sight of the importance of psychological and social/environmental processes in understanding and treating addiction. It is difficult to conceive of a model effectively defining and treating addictive behaviors in the future that ignores its psychological, social, and environmental factors. It seems likely that treatment centers will continue to use pragmatic methods to improve care by cobbling together treatment techniques that are derived from many different models for understanding addiction, perhaps suggesting the disease model will evolve with the introduction of these new treatment ideas.

The gulf between how researchers define addiction as disease and how practitioners define addiction as disease is immense and presents the greatest challenge. At all but a very few select treatment centers, the disease that is discussed is derived from information largely out of date. In addition, a substantial amount of what is practiced in many traditional Minnesota Model treatment centers today has not been empirically validated as effective or demonstrated to be best practice. The greatest challenge for disease model proponents in the future will be to bridge the gap between science and practice in a way that greatly accelerates the benefits that patients receive as the result of new scientific discoveries.

Glossary

Alcoholism colloquial term often used with disease model to describe alcohol dependence.
Controlled drinking the ability of some people to return to some use of alcohol use without loss of control after being diagnosed with alcohol dependence.
Biomedical model belief that disorders like addictions have their root causes in biological mechanisms and that the best treatment for such disorders is medical.
Compulsion an irresistible physiological impulse to engage in the addictive behavior and contributes to loss of control
Denial originally a defense mechanism in Freud's model, it has been widely used to describe when patients refuse to acknowledge powerlessness over addiction over take action to change their behavior.
Disease model model that posits that substance abuse operates under biomedical principles and is a chronic and progressive disease with prescribed symptoms and predictable course.
Genetic predisposition belief that a person will be at increased risk for addiction because of genetic loading.
Natural recovery many people are able to spontaneously recover from addictions without treatment or therapy.
Powerlessness (loss of control) concept originally derived from the first of 12 steps of Alcoholics Anonymous; the belief that addictions contribute to complete loss of control of the behavior that leads to unmanageable lives.

OUTLINE

INTRODUCTION

Substance use and dependence is characterized by a difficulty to control consumption and a tendency to persistence despite its increasing adverse consequences (DSM-IV, CIE-10). Current neuropsychological models conceive addiction as a neuroadaptive process leading to significant alterations in the frontal-striatal circuits, including several sections of the prefrontal cortex (orbitofrontal, dorsolateral, and medial), limbic and paralimbic regions (amygdala, hippocampus, insula), and basal ganglia. Alterations in these circuits affect the activity of the motivational, emotional, and executive control systems. Dysfunction of motivational systems is made evident by the overestimation of the reinforcing, adaptive value of drug-related stimuli and the underestimation of the value of other natural reinforcers, fundamental to our survival. This motivational bias promotes the development of impulsive behaviors, which are fostered by the expectation of immediate reinforcement (drug use–related), whereas little consideration is given to its potential, long-term consequences. Continuous exposure to drug use turns these impulsive behaviors into habits, that is, impulsivity gives way to compulsion, thus consolidating motor programs that go off automatically in the presence or anticipation of drug-related signals. Repeated consumption also provokes important changes in the interoceptive and emotional systems. Recent studies highlight the role that detection of body signals related to drug-taking experiences plays in the generation of emotional states leading to drug-seeking behavior, such as craving. In addition, a persistent sensitization of the stress systems takes place and the drug-seeking behavior rockets in an attempt to rebalance the body's hedonic tone. Alongside this adaptation of the motivational and affective systems, addiction is associated with a deterioration of the executive control mechanisms, which depend on the functioning of the prefrontal cortex. The dysfunction of executive mechanisms leads to alterations of processes which are considered of a more cognitive nature, such as the ability to update and monitor multiple sources of information (cognitive, affective, and motivational) aiming to design plans and reach

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00008-5

goals. In addition, it hinders the ability to inhibit and effectively switch response patterns according to the changing demands in the environment, as well as the capability for making adaptive decisions that guarantee both our survival and our survival quality.

The notion of lack of awareness of addiction and its consequences is inherent in a number of the neuropsychological dysfunctions reviewed above. Neuroadaptations in interoceptive, motivational, and affective systems may contribute to a persisting attentional bias on drug-related needs that prevents considering other homeostatic signals. The results of recent neuroimaging studies show that dysfunction of the insula (a key region for processing and integrating interoceptive signals) may underlie the difficulties of addicted individuals to gain access to the emotional signals that are necessary to realize the implications of the disorder and develop alternative behaviors. In addition, the consolidation of an impulsive response pattern implies a lack of consideration of the input associated to delayed information, which would include most of the negative consequences of addiction. In this sense, we know that the ability to imagine future emotional events is related to the functioning of the medial orbitofrontal cortex, one of the most affected regions by addiction. On the other hand, once the addictive process is established, many processes oriented to drug seeking and taking (e.g. programming of motor habits) may operate in a sophisticated manner without full conscious supervision or control. Finally, dysfunction of executive mechanisms affects mainly the individual's ability to maintain the correspondence between intention and action and to compile all necessary information to become aware of his/her deficits and their repercussions on the family milieu and social environment. To sum up, to be aware of the symptoms and repercussions of any disorder, we need to have access to all relevant information (internal and external) and be able to properly compile and monitor this information to understand its implications and use it to establish goals and implement change-oriented behaviors. In addiction, however, we find that many processes underlying these capacities are significantly deteriorated. In these cases we may talk about lack of awareness – but not denial as a meta-cognitive deficit resulting from deterioration of information processing and integration at different levels. This deterioration is linked to the dysfunction of frontal-striatal circuits involved in addiction.

The concept of denial implies an implicit knowledge that can be accessed depending on the state of the organism in a particular situation, as well as an elaboration process aimed to minimize or suppress this input. Parallel neuroadaptive processes typical of addiction can also help understand this phenomenon. In their extreme form, denial processes could be compared with the symptoms of confabulation observed in neurological patients. Symptoms of confabulation are common in patients with damage in the medial orbitofrontal cortex, one of the key brain regions both in self-referential processes and in addiction. There is evidence that confabulations in these patients are related to (not necessarily conscious) efforts to maintain a positive self-concept or a self-referential sense of coherence, thus building a valid argumentation to maintain a status quo that will not put their own identity at risk. These confabulation mechanisms oriented to maintain a status quo could help explain the phenomenon of denial in addicted individuals. On the other hand, partial access to input regarding disorder implications may exacerbate the reactivity of the stress systems, leading to intense discomfort and undermining the individual's self-efficacy expectations on his/her capacity to cope with the problem. This unbearable rise in stress levels makes the individual react by expelling this information from his/her conflict resolution system. These psychological processes would depend on the dialog between the brain regions responsible for the motivation and conflict (anterior cingulate cortex) and the neuroendocrine systems regulating the response to stress (hypothalamic–pituitary–adrenal axis), which are persistently altered in the addictive processes. Other authors have also highlighted the role of the cross-talk between the cognitive styles of both brain hemispheres (right hemisphere, specializing in processing novelty vs. left hemisphere, specializing in contextualizing information according to preestablished patterns) as a substrate of these dissociations. Finally, a milder form of denial may result from the predominance of motivational resources driving drug seeking and taking on those resources in charge of motivation to change. In these cases patients would be partially aware of their disorder and the need for change, but they would tend to minimize or defer it. Classical models on stages of change claim that denial would be a process inherent to the precontemplation stage. In this stage the individual considers the possibility of changing his/her drug use behavior but may deny the problem in different manners, including resignation due to lack of self-efficacy necessary to produce change, or deferral of the change. In agreement with this notion, recent studies indicate that drug users present decision styles characterized by procrastination.

In sum, we understand lack of awareness and denial are two separable neuropsychological processes. However, we believe that they both have underlying neuropsychological (motivational, emotional, and meta-cognitive) alterations related to addiction-related neuroadaptations in frontal-striatal circuits. In the following sections we shall: (1) define a neuroscientific conceptual framework to understand the phenomena

of lack of awareness, denial, and lie in addiction; (2) describe the relationship between neuropsychological processes and symptoms of anosognosia and denial; and (3) review the empirical studies having dealt with this phenomenon from different approaches over the last decade.

AWARENESS, LIE, AND DENIAL IN ADDICTION: A NEUROSCIENTIFIC APPROACH

Self-Awareness

Being conscious and the conscious experience may be explained by models based on the more proximal brain function, related to general neuronal action patterns. However, we all agree that awareness is more than that. When we say that someone is not aware of something, we are referring not only to tacit knowledge, but also to other relevant aspects, such as the implications of that knowledge. In the case of addiction, when we talk about lack of awareness, we refer not only to aspects such as insight of the cognitive deficits associated with drug use, but also to awareness itself about suffering this disorder. The latter would be more closely linked to the concepts of self-awareness and self-concept, which use defense or self-protection mechanisms to avoid the emotional consequences of accepting that one suffers a disorder. Self-awareness has been defined as a human tribute that allows not only awareness of the self but also awareness of one's position in his/her social environment. In a hierarchical organization of mental functions, the ability of self-awareness would be in the vertex of the pyramid, since its function is to control one's own mental activity, representing current experiences in relation to previous ones, using acquired knowledge to solve new situations, or guiding decision making for the future. According to Prigatano, self-awareness is the ability to perceive oneself in relatively objective terms, maintaining a sense of subjectivity. This aspect of self-awareness implies a cognitive process, as well as an emotional state, and the integration of both.

The critical neural system for self-awareness is located in the prefrontal cortices, whose neuroanatomic position favors this purpose because (1) they receive signals stemming from all sensory regions where conscious experiences are formed (including images making part of our thoughts); (2) they receive signals from somatosensory cortices representing past and current body states; (3) they receive signals from bioregulatory sectors of the brain, among which neurotransmitters of the brainstem and basal prosencephalon, as well as the amygdala, the anterior cingulate, and the hypothalamus; and (4) they categorize the situations that affect the body, that is, they classify any contingencies in our life experience. Therefore, the prefrontal cortex is often a convergence zone that works as a deposit of dispositional representations for properly categorized, unique contingencies of our life experience. In this sense, it seems evident that, to exist, self-awareness needs information from signals coming from both outside of the self and our thoughts (which are also images). Also, it needs to have access to previously categorized information (the categorization criteria are probably based on the emotional value of the experiences). At this point, we create representations that become unique dispositions, as they are based on our life experience, which is also unique.

From this point of view, and according to Stuss and colleagues, the alterations of awareness related to lesions in the prefrontal cortex have some peculiarities that should be taken into account: (1) these alterations are connected to the self and become evident generally in behavioral rather than cognitive functioning; (2) these alterations may occur irrespective of any cognitive or sensory deficits, even with an intact IQ; (3) executive functions (i.e. higher order abilities involved in the generation and control of goal-directed behavior) are important, since they are more specifically related to prefrontal systems and their damage may be linked with the alteration in awareness of deficits in behavioral functioning; (4) there may be a fractioning of awareness in relation to specific connections between the prefrontal cortex and other specific regions; (5) self-awareness is more than mere knowledge, it is the ability to reflect on the implications of this knowledge; and (6) self-awareness does not only refer to the past and the present, but it also projects to the future. In this sense, we would depict awareness not only as knowledge, since knowledge does not have implications if devoid of emotional valence. In the case of addiction, structural and functional alterations in the prefrontal cortex have been described by several neuroimaging studies in abusers of a number of drugs. Furthermore, the main corollaries of prefrontal cortex–related awareness alterations largely overlap with the neuropsychological alterations described in addicted individuals. Specifically, addicted individuals: (1) show a wide range of behavioral alterations associated with the functioning of the circuits connecting the prefrontal cortex with subcortical regions and basal ganglia (including symptoms of apathy, disinhibition, and behavioral disorganization); (2) show important alterations in executive functions, even in the presence of normal, general cognitive functions and IQ; (3) have problems to think about the consequences that these and other drug use-related alterations bring about in their daily functioning and their family milieu and social environment; and (4) show difficulties

in associating cognitive scenarios with appropriate emotional states, especially when it comes to anticipate emotional consequences associated with future events.

This more neuropsychological approach claims that there are different forms of deteriorated awareness, depending on the brain systems suffering the damage or dysfunction. In Fig. 8.1 we present a schematic representation of the different brain systems linked to awareness-related deficits. In this line, neuroscientific models have proposed in a generic manner that bilateral lesions of the frontal cortex are specifically associated with the lack of awareness on social behavior and executive functions, and with self-awareness as a whole. Clinical experience shows that there is a particular type of awareness for each knowledge module, which is fed by updated information from that particular module, whose goal is to guarantee the best adjustment of the individual. In this sense it seems that this awareness for each specific area is affected when the brain damage affects the function and its awareness locus. We must take into account that addiction-related brain alterations may interfere with the neural substrate of self-awareness. Therefore, if a prejudicial drug use pattern produces a deficit in the cognitive, emotional, and behavioral sphere that the subject is not aware of, this lesion affects both the locus of the relative processes and the locus of their awareness. In other words, it would affect the cognitive function, the emotional sphere or its behavioral patterns, as well as the metacognition of the cognitive, emotional, or behavioral function. We could state, in a graphic manner, that the individual does not know that he/she does not know and this first aspect would make reference to concepts such as change of personality, suffering provoked to others, empathy, etc. In addition, awareness for a specific knowledge module may be affected by the degradation

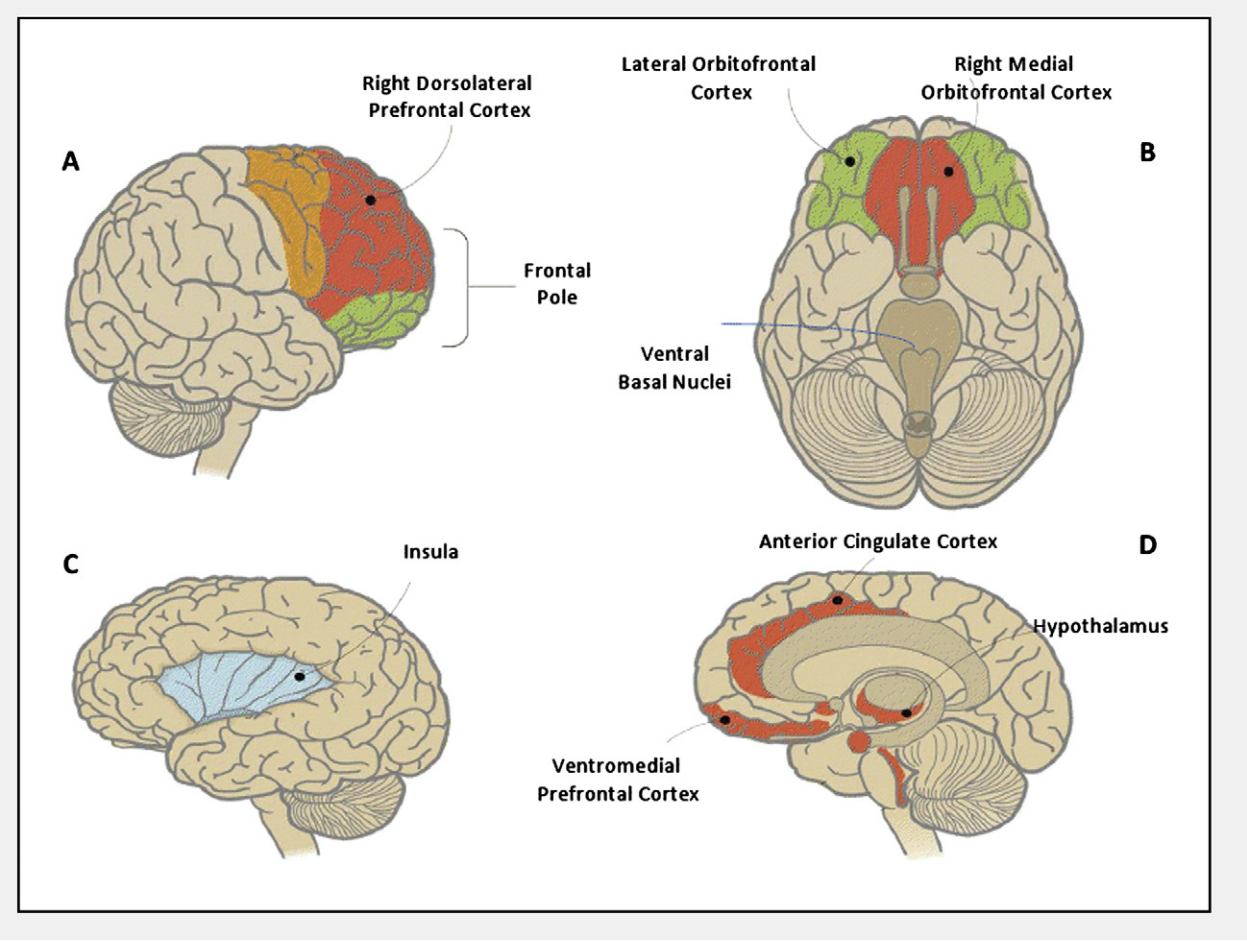

FIGURE 8.1 Schematic representation of the main brain regions supporting awareness and denial-related deficits in substance-dependent individuals. 1. Right dorsolateral prefrontal cortex (Panel A) and right medial orbitofrontal cortex (Panel B), along with insula (Panel C), are involved in deficits of lack of awareness. 2. Interhemispheric right-left cross-talk or connections between anterior cingulate cortex and stress systems stemming from hypothalamus mediate processes of denial (Panel D). 3. Medial/lateral orbitofrontal cortices and frontal pole are key structures for the emergence of confabulations (Panels A and B). 4. Dorsolateral prefrontal cortex and dorsal anterior cingulate control are necessary systems for lie (Panels A and D).

of feedback of its response or output or because the internal representation of the cognitive processes is also affected as a result of the brain impairment. For example, drug use may affect attentional mechanisms, which would lead to a degradation of the information sent to the brain. Thus, the subject cannot be aware due to the affectation of input mechanisms (Wernicke's aphasia may be the clearest example in neurological patients). In other words, we find that drug use leads to the affectation of cognitive, emotional, and behavioral functions, as well as the affectation of cognitive, emotional, and behavioral mechanisms implied in self-knowledge and self-awareness.

Denial

Some studies have proposed the existence of different kinds of alteration of awareness of one deficit according to the three basic levels of information processing: information collection, neuropsychological, and emotional. Thus, the lack of awareness itself would be the result of the patient not receiving information or this information being degraded. Also, it is possible that the patient does not understand the meaning of the information (e.g. it has been proved that alcoholic people have difficulties in processing faces expressing some basic emotions, such as sadness, relevant to understand damage inflicted to others). Regarding the level of implication of this information, the subject cannot take the self as an object or understand the implication of the deficit. Additionally, the arousal level for awareness may also be poor (a phenomenon frequently observed in benzodiazepine or opiate addicts). In this case, the deficit occurs at the information processing and access level. However, there are other phenomena related to the lack of awareness of different nature and characteristics. The phenomenon of minimization is characterized by the fact that the patient cannot understand or extract his/her own consequences and/or implications from the information. On an emotional level, the patient knows but cannot stand the effect of the information, thus reducing it to tolerance levels. Finally, in the case of denial, the patient has an implicit knowledge about the problem, but he/she cannot believe the information, which is too stressful, and expels it from his/her aware experience (*see* Table 8.1). On the other hand, studies have shown that denial observed in some chronic alcohol abusers does not necessarily need to be explained as a consequence of a maladaptive defense of the self, but as a manifestation of the neurotoxic effects of alcohol.

Prigatano has investigated the alterations in awareness of deficits in patients suffering brain damage, based on Weinstein's pioneer studies in the 1950s. Weinstein reckoned that the way that patients adapt and symbolically represent (a term with dynamic connotations) their deficits is determined by a series of factors, such as: (1) the type, severity, and location of brain damage; (2) the nature of the incapability; (3) the meaning that this deficit may have in terms of premorbid values and

TABLE 8.1 Nature of the Consciousness Problem Considering Three Possible Levels of Information Processing

Nature of the consciousness problem	Level 1 – Information	Level 2 – Implications (Neuropsychological)	Level 3 – Integration (Emotional)
Lack of awareness	- The individual cannot access the information. - The individual has not enough cognitive resources to understand the meaning of the information. - Main symptom is anosognosia.	- The individual cannot take the "self" as an object. - The individual cannot understand the information. - The individual cannot retain or remember the information. - Insufficient arousal for full conscious experience.	- No strong emotional implications.
Minimization	- No alterations at this level.	- The individual cannot extract from the information its consequences and implications.	- The individual knows but cannot tolerate the effect of the information, thus reducing it to tolerance levels.
Denial	- No alterations at this level.	- No major neuropsychological alterations although sensitization of stress systems and cross-talk between conflict control and stress systems or right vs. left hemispheres cognitive styles may contribute.	- The individual cannot believe the information, it's too stressing and therefore it is expelled from conscious experience.

experiences; and (4) the context in which the behavior is elicited and observed. According to Weinstein, denial must be understood as a loss of insight and is related to confabulation, lie, or symbolic disorientation. Also, Weinstein exposed the importance of premorbid personality factors to understand the mechanisms of denial, as well as the presence of implicit knowledge. In this sense, the mechanisms of denial are adaptive as long as they represent and explain the patient's incapability, giving it a sense of reality. In this line, Prigatano claims that denial of a deficit is due to several factors affecting superior levels of brain integration. In this sense, the cognitive capability of patients with brain dysfunction may be affected in evaluating the feedback about their functional limitations received from the environment. In addition, and despite receiving information about their own problems and limitations from the environmental feedback, they persist in maintaining a somewhat indifferent attitude toward this information. In fact, recent studies seem to prove that the insula plays an important role in the awareness of affective states, perhaps because the information on these affective states is produced by the brain mapping of associated body states. These connections may contribute to explain why in addiction profoundly altered body states and behavioral problems do not lead to full recognition of the disorder (*see* Fig. 8.1).

About Lie

Lie is a constant in approaching the phenomenon of drug addictions, contaminating very often the therapeutic relationship with patients. Lie does not refer to the consumption of toxics alone; deception goes beyond that and has to do with the perception of the problem. In fact, it is surprising that a patient denies having problems with his/her partner, children, or at work due to alcohol use (alteration of central awareness), and even more that he/she can create an unreal autobiographic story, where there seems to be no problem whatsoever (alteration of extended awareness). In therapeutic intervention, it is frequent to find patients that deceive or lie. In fact, distrust in patients' claims is the ultimate cause of taking urine samples for analysis.

The first question is: why do patients lie? The response is simple: what do they win by telling the truth? Cognitive psychology suggests that a basic stone for the treatment of drug addicts is anticipation of the consequences of their behavior, so that they will behave accordingly. This leads to a second question: to what point do they need to anticipate? The variable time is essential in brain functioning: if the anticipated consequences are negative in the short term, behavior inhibits the truth. It is a brain functioning mechanism: my brain has an image of what I am and how I am; a self-protecting image that compares data coming from experience to expel them if they contradict the image of myself, thus maintaining my *status quo.* There are patients that obviously know that they are lying, but they do it to protect themselves from the consequences of truth. When a subject generates mental images of the consequences of being honest, these images generate a negative emotion that inhibits the behavior, thus lie having an adaptive preservation value. Actually, it can be claimed that awareness is a human tribute that allows realizing the own reality and position in the social environment. Lie can, therefore, maintain the concept of reality and social status. In this sense, it can be claimed that the lack of awareness of a problem has the invented truth as a basic pillar to convert subjectivity into objectivity, so that this subjective, unique, private interpretation of my reality will be perceived by others in the way I perceive it. This will allow my maintaining the situation and more importantly the image I have of myself.

Trivers has suggested an ingenious explanation of the evolution of self-deception: in everyday life there are many situations where we need to lie. In this regard, researchers like Ekman have proved that liars always give themselves away with a somewhat feigned smile, an expression of tension, or a false tone of voice that can be detected by others. This is because the limbic system (involuntary and prone to tell the truth) controls the spontaneous expressions, whereas the facial expressions we make when we lie are controlled by the cortex (not only responsible for the voluntary control, but also the place where lies are invented). For Trivers, this problem has a solution: to effectively lie to another person, it is necessary to lie to oneself first. If we believe that the thing we are saying is true, our expressions will be real, with no trace of deception. However, this statement incurs into an internal contradiction, since it contradicts the proposal of self-deception, which implies that one can have access to the truth at any time; otherwise, self-deception would no longer be adaptive.

Ramachandran proposes a way to avoid this problem and states that a belief is not necessarily unitary: it is possible that self-deception is located in the left hemisphere, whereas the right hemisphere continues to know the truth. For this author, the key for self-deception lies in the working division between both brain hemispheres and our need to create a feeling of coherence and continuity in our lives. It is well known that the brain consists of two symmetrical halves, each of which specializes in different mental capabilities; the most noticeable brain asymmetry is related to language. Alongside these known function divisions, Ramachandran suggests the existence of an even more essential difference between the cognitive styles of both hemispheres, which can help explain the modalities of denial and lack of awareness. In this regard, Gazzaniga's

research on split brain is most revealing. This author has studied a series of patients with a disconnection between both hemispheres, which allows us to know the information stored by each of them separately. In Case P.S., one of the paradigmatic cases reported, the individual's left hemisphere is asked what he wants to do after finishing school, the answer being: I want to be a draftsman. However, when the right hemisphere is asked the same question, the answer was: automobile racer. This case, like others in the literature, proves that both brain hemispheres live different realities and suggests that everyone can have a mute brain inside the head with a reality and a perception of oneself very different to what we daily believe we are.

In any moment of life, the brain can feel overwhelmed by a continuous information cascade that must be integrated into a coherent perspective of the own image and the image that others expect from oneself. To generate coherent actions or to maintain a given *status quo*, the brain must have a type of mechanism that allows filtering and ordering this information in a stable, internally coherent scheme. This is what the left hemisphere is in charge of: integrating the information into the previous image of self. What happens when a piece of information on the own behavior does not fit into the script? The left hemisphere disregards this information completely or distorts it so that it fits into the preexisting frame to maintain the stability. These everyday defense mechanisms, far from being adaptive defects, prevents the brain from being doomed to incoherence and lack of direction due to the multiple combinatory possibilities of the scripts that can be written with the material collected by our experience. The problem is that one lies to oneself and to the others, but this is an efficient and affordable price compared with the coherence and stability that the whole system acquires.

The adaption strategies used by both hemispheres are basically different (*see* Fig. 8.1). The task of the left hemisphere is to create a model, a belief system, and to fit every new experience into this system. When it finds information that goes against this belief system, it turns to denial: it represses and invents a story that allows maintaining the *status quo*. However, the right hemisphere's strategy involves acting by calling this *status quo* into question, and searching for global inconsistencies. When the anomalous information reaches a certain threshold, the right hemisphere undertakes a global review of the model. In other words, the right hemisphere imposes a change of paradigm. This threshold is specific for each individual and depends on different aspects such as the features of personality or the type of experience. This would partly explain why after a stay in hospital for organic problems some individuals are able to accept their *status* as alcoholics, whereas others deny it at all costs, or why some individuals accept a relapse after the first time, while others need several relapses before they finally admit it.

Table 8.2 depicts a conceptual model of the psychological, psychopathological, neuropsychological, and relational implications of the three concepts presented

TABLE 8.2 Distinctive Features of the Different Forms of Reality Distortion Typically Found in Addicted Individuals

Features	Lie	Confabulation	Denial	Lack of awareness
Psychopathology	No	Yes	Yes/No	Yes
Intentionality	Yes	Yes/No	Yes	No
Consciousness	Yes	Yes/No	No	No
Type of knowledge	Explicit	Implicit	Implicit	Does not exist
Occurs within healthy individuals	Yes	No	Yes	No
Function	Deception	To make sense of a personal narrative	Self-deception	Don't have
Premeditation	Yes	No	No	No
Access to the truth	Yes	No	Yes	No
Plausibility	Yes	Yes/No	Yes	Yes
Receptor	The other	Oneself/the other	Oneself/the other	Oneself/the other
Neuropsychological impairment	No	Yes	No	Yes

SELF-AWARENESS, DENIAL, AND COGNITIVE DEFICITS

We have seen that neuroscientific evidence links the symptoms of lack of awareness and denial with cognitive and emotional alterations derived from a dysfunction of the frontal-striatal circuits. In this section we shall review the neuropsychological studies that have addressed this issue in a direct manner. These studies can be classified according to three methodological approaches: (1) studies on the connection between measurement of denial level in addicted individuals and their performance in neuropsychological performance tasks; (2) studies on the concordance degree between the results of objective performance measurement and the individual's insight of the own performance; and (3) studies on the concordance degree between the subjective information provided by addicted individuals and that provided by relevant informants regarding the problems derived from their addiction.

Regarding the first approach, Rinn et al. studied the connection between clinical estimations of denial levels in a group of alcoholic individuals under treatment and their neuropsychological performance on memory and executive function tests. At the beginning of the treatment they identified specific objectives related to denial symptoms that alcoholic subjects had to achieve during the test. To obtain a quantitative measure of the individual's denial level, they calculated the proportion of treatment objectives specifically for symptoms of denial that had not been completed. This measure was correlated with the performance indices from neuropsychological tests. The results showed that the degree of denial in addicted individuals significantly correlated to the impairment of the processing speed, memory, and executive function processes.

In the light of these results, the challenge lies in finding the nature of the relationship between these cognitive functions and the mechanisms of denial. Regarding processing speed and denial, these data could show that the speed to understand information from outside is affected in addicted individuals. On a psychological level, this impairment produces a degradation of the input arriving at the brain. On an anatomical level, it reduces the connectivity between different regions (processing speed deficits have been associated to alterations in the white matter). Both levels are essential to create a coherent, unified global image of oneself and the surrounding world. As for the relationship between memory and denial, we must understand that self-awareness is the capability of being conscious of a wide range of entities and facts, which generates a sense of individual perspective and space–time continuity. Therefore, it can be stated that we generate pulses of conscious experience for a goal, while generating an accompanying set of reactive autobiographical memories at the same time. Without these memories, we would not have a feeling of past or future, nor would a historic continuity exist (self-awareness). In other words, without conscious experience and memory, there is no self-awareness. At this level, we can locate confabulation phenomena oriented to reconstruct a sense of autobiographical coherence in addicted individuals. In fact, significant confabulation error rates have been observed in verbal memory tasks in psychostimulant users. Regarding the relationship between executive functions and denial, we consider that cold executive function processes can be more closely linked with the cognitive aspects implied in the insight, such as the updating of information about our own behavior or the cognitive flexibility that allows us change our rules and response patterns according to the feedback received. Therefore, they would be more closely related to the concept of knowledge of what is happening. However, there is a cognitive-emotional component necessary for the arising of insight, so that the subject can knock down his/her defense mechanisms (by saying defense, we do not adopt the dynamic vision, as we consider that each behavior has a brain correlate). In this sense, studies taking the Iowa Gambling Task as a paradigm highlight that addicted individuals have their decision-making processes affected, thus being guided by the immediate reinforcement and ignoring the long-term consequences of drug use. Furthermore, we know that this process is the result of the juxtaposition of cognitive processes and emotions, which takes place in the ventromedial prefrontal cortex, one of the regions that drug addiction most negatively effects. In this line, it is interesting that empathy of subjects with ventromedial affectation seems to be affected, which includes awareness of the potential damage inflicted to others. In addition, recent studies have proved the relationship between the activation of the ventromedial sector and self-knowledge. Both research lines offer a link between hot executive functions and self-awareness and insight.

The second approach consisted on studying the correspondence between measures of objective performance and the individual's insight on his/her own performance. Goldstein et al. have used a monetary effort attentional task (i.e. participants have to rapidly respond to get different amounts of money) in two groups: individuals with cocaine use disorders and healthy controls. The authors correlated participants' performance in the task with subjective measures of motivation toward the

monetary stake (a measure of state motivation). The results of these studies showed that, unlike healthy individuals, there was no correspondence between the subjective information provided by cocaine users about their level of motivation toward the monetary stakes and their actual performance in the task. Following a similar approach, several studies have shown that there is a certain level of dissociation between intention and action in addicted individuals. Two consecutive studies by Moeller et al. used a probabilistic learning task where participants (cocaine abusers and healthy individuals) had to choose between images with a pleasant, unpleasant, neutral or cocaine-related content. Additionally, subjective reports on the participants' preferences in these choices were collected. The results of both studies showed that, contrary to what happened in healthy individuals, cocaine abusers showed significant inconsistency levels between the images chosen and their subjective preference reports. One of this study also showed that this inconsistency was especially obvious in current cocaine users, as opposed to abstinent users. Noticeably, within the abstinent consumer group, the highest inconsistency levels were observed in individuals with higher cocaine consumption in the month before the onset of treatment. Similarly, Verdejo-García et al. used a self-regulation task where participants (cocaine-dependent and healthy individuals) had to discover on the go an implicit strategy that would allow them to improve their performance. Seventy percent of the consumers managed to correctly identify this strategy when they were debriefed about it. However, after analyzing their performance scores, these were significantly inferior to those of healthy individuals (i.e. despite having identified the optimal strategy, they had failed to implement it to optimize their performance).

Finally, a last approach is based on the analysis of the concordance degree between the subjective information provided by addicted individuals and the one provided by relevant informants to them (e.g. close relatives or friends) regarding addiction-derived problems. Following this approach, the study by Verdejo-García et al. examined the degree of awareness of substance-dependent individuals about their potential behavioral problems linked to alterations of frontal-striatal circuits. These behavioral problems were assessed in the Frontal Systems Behavior Scale, which questions both the patient and an objective informant (typically, a relative) on symptoms of apathy, disinhibition, and behavioral disorganization. The analyses contrasted the patients' scores with those of the relatives in two time moments: during drug use and during abstinence. The results showed that substance dependents reported significantly lower levels of apathetic and disorganized symptomatology compared with the reports of their relatives. Also, the severity degree of cocaine and alcohol use correlated negatively with the level of discrepancy between addicts and relatives, which suggested an association between the severity of drug use problems and greater levels of lack of awareness on the implications of the addiction.

CONCLUSIONS AND CLINICAL IMPLICATIONS

Deficits in the processes of awareness and denial of addiction and their consequences can have important implications in the treatment and rehabilitation of drug users. During active drug use, the deficits in these processes may be associated with reduced perception of need for treatment, for example, due to lack of insight about the problems or to a tendency to overestimate the own ability to control drug taking without help of others. Furthermore, during rehabilitation, lack of awareness on the own neuropsychological deficits may be associated with reductions in the motivation for treatment, lack of motivation and involvement in conducting the necessary tasks for the achievement of the intervention goals, or a higher feeling of control on the execution of risk behaviors like those entailing the contact with a drug-related context. For this reason, the inclusion of tools aiming to increase the individual's self-awareness during the treatment of addiction could entail significant improvement in the recovering process. These measures could be used to reeducate the interoceptive system leading to an increase of the insight and the perception of body signals anticipating the craving for consuming drugs and potential relapses.

Finally, based on the existing evidence and despite the great efforts made to distinguish the processes' lack of awareness and denial, we still observe a certain overlap between both processes in the neuropsychological studies undertaken in addicted individuals. A more detailed research using specific measure tests of these processes in drug users could help obtain more enlightening information on the involvement of both phenomena in the course of addiction.

Glossary

Confabulation implicit attempts to create an unreal autobiographical story to preserve a personal sense of coherence and continuity in our lives.

Denial implicit suppression of cognitive or emotional information relevant to have adequate knowledge of oneself's current status and of the implications of that status.

Executive functions of higher order abilities involved in the generation, monitoring, and control of complex goal-directed behavior. They are critical to enact and integrate cognitive and emotional input necessary for adequate self-awareness.

Intention–action dissociation lack of correspondence between explicit intention and the translation/implementation of that intention into actual behavior.

Lack of awareness alterations in the access, processing, compiling, or monitoring of cognitive and emotional information critical to have adequate knowledge of oneself's current status and of the implications of that status.

Lie explicit omission of cognitive or emotional information relevant to understand oneself's current status and make it understandable to others. This is done in an attempt to protect oneself from the consequences of truth.

Neuropsychology science investigating the link between brain function and dysfunction and behavior (including cognitions, emotions, and acts).

Self-awareness ability to perceive oneself in relatively objective terms, maintaining a sense of subjectivity. The construct encompasses the cognitive processes necessary for adequate self-knowledge, the emotional processes necessary to understand the implications of the current status for oneself and others, and the integration of cognition and emotion to adjust behavior to one's and others' needs.

CHAPTER

9

Gateway Hypothesis

Hamdy Fouad Moselhy
UAE University, United Arab Emirates

OUTLINE

INTRODUCTION

Gateway hypothesis describes a pattern (sequences) of drug use, beginning with alcohol and tobacco, followed by cannabis, then more dangerous hard drugs, such as heroin and cocaine. Since the publishing of the original article of gateway hypothesis in *Science* in 1975, a growing body of studies has been pointing to the important role of alcohol, tobacco, and marijuana as gateway drugs. In addition, gateway hypothesis underlies much of the current United States and international drug policy. However, the idea that one behavior leads to another is an old one going back hundreds of years. Development of the gateway hypothesis started with the earlier stepping stone hypothesis. Stepping stone hypothesis was first tested at around 1940 in response to questions about whether marijuana use was the first step toward the use of other drugs. According to the stepping stone hypothesis, the use of one substance or drug increases the probability of consuming another, possibly more harmful, drug later and that the probability increases with frequency of use. It predicts that people who use one substance such as nicotine will probably go on to drink alcohol, to smoke marijuana, and progress on to use hard drugs such as cocaine. Each step is seen as leading to the next step in substance use. Although it might be widely accepted by the public, it has lost credibility and support among research scientists because of the lack of evidence supporting any causality. In contrast, a number of studies tested the gateway hypothesis with findings that supported the gateway sequence. Both longitudinal and cross-sectional studies conducted with general populations in the United States and internationally supported a sequence of drug use progression, beginning with soft licit drugs (both alcohol and cigarettes), followed by illicit drugs (such as marijuana), and ultimately other hard drugs such as heroin and cocaine. One of the most robust findings in adolescent drug use over the past few decades has been that almost all adolescents who have tried cocaine and heroin, first used alcohol, tobacco, and cannabis. The more regularly adolescents use cannabis, and the earlier the age at which they begin, the more likely they are to use other illicit drugs. For example, in one longitudinal study, men who had used both alcohol and cigarettes by age 15 had a 52% greater chance of using marijuana, compared with men who had never used alcohol or cigarettes by age 25. For women, the increased chance of marijuana use among alcohol and cigarette users

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00009-7

was 46%. Similarly, for the next stage, men who had used marijuana by age 15 had 68% greater chance of initiating the use of other illicit substances, compared with those who had never used marijuana. For women, the increased probability was 53%.

Although pharmacological differences exist among the different classes of abused drugs, the one factor that all drugs with a strong dependence potential share is a rewarding or reinforcing property. It is not known why drugs with such different pharmacological properties should share the property of primary reinforcement, and the underlying neuronal mechanisms are not understood. However, several lines of evidence suggest that dopaminergic pathways are implicated in at least some reward circuits and different drugs may activate or "switch on" the circuits at different points.

However, not all research supports the gateway hypothesis. A study of an inner city among New York heavy drug users found that only 33% of drug users followed the gateway hypothesis sequence (i.e. alcohol use to marijuana to hard drug). Another earlier research found that a majority of drug users from the general population were experimental users, and thus relatively few individuals proceeded to regular use of hard drugs (e.g. heroin or cocaine). Most significantly, studies consistently show that individual variations (e.g. genetic makeup, personality traits) and environmental factors (e.g. drug availability, peer influences, life events) may help explain why young people initiate drug use and move on to additional forms of drug use later in life.

There is no question that the sociological, economic, and psychological factors leading to inappropriate use of mood-altering drugs are exceptionally important. However, recent evidence unequivocally establishes the existence of neurobiological determinants of both initial and especially continuing drug uses. All drugs, which have been misused, have one thing in common: they enhance the activity of specific neurobiological circuits. These circuits are commonly described as "brain reward system." The most prominent neurotransmitters and neuropeptides in this process are dopamine, serotonin, glutamate, gamma-aminobutyric acid, and the endorphines (endogenous opioids). Dopamine appears to be playing the primary role in producing most of euphoria seen with drug of abuse and is known to contribute to the positive reinforcing effects of heroin and other opiates.

The Gateway Pattern of Drug Use

The gateway pattern describes the typical sequence of progression to hard drug use. The sequence most often reported is that alcohol and tobacco use come first, followed by marijuana, and then other illicit substances. Obviously, several factors affect such a sequence, including drug availability and background prevalence. Some illicit drug use is significantly more common among more recent birth cohorts and the pattern of availability has changed. Possibly, it is not astonishing that a "reverse gateway" has been described for cannabis in Australia (where cannabis use has been linked to increased risk of subsequent initiation to tobacco use). Some variations in the typical sequence have been found for individuals of different sexes, racial and ethnic groups, and cultures. There have been investigations of the extent and significance of violations of typical gateway patterns. Studies in the United States of problematic drug users and homeless youths have found that significant proportions had not progressed through the typical pattern of progression, with many beginning cannabis use before they had first used alcohol, and some starting other illicit drug use before using alcohol or cannabis. In those studies, individuals with "atypical" patterns of progression were found to come from more disadvantaged backgrounds, and also, were found to be heavier polydrug users than users who followed the normative progression. However, those studies presented limited unrepresentative samples of heavy drug users and did not adjust for premorbid mental health or demographic factors that might have been related to progression. Another study was done that considered all of these confounding possibilities using data from a representative sample of the US adult population, from the National Comorbidity Survey Replication. The study showed that deviations from the gateway order of onset were found to occur only for a minority of persons (5.2%). The most common pattern was other illicit drug use before cannabis (3.4%), and the least common was other illicit drugs use before both alcohol and tobacco use (0.8%). There were some strong cohort differences in the likelihood of these patterns: they were less common among the oldest age group than the younger ones. These findings are consistent with historical trends in drug use; cannabis use is much more common in more recent birth cohorts, so it is not surprising that cannabis is also more likely to occur earlier in the sequence of drug use for some younger people. One significant predictor of deviations from normal pattern was the early development of internalizing mental disorders such as depression, posttraumatic stress disorder, social phobia, or generalized anxiety disorder. The authors suggested that premorbid mental illnesses are related to precocious initiation of illicit drug use. Adolescents who already developed mental illness are at risk for deviations from the normative sequence of drug initiation and for the development of dependence. However, this study was cross-sectional retrospective survey with some limitations including, some of the observed cohort differences might be traced

to higher mortality among individuals in the older cohorts who began drug use at an early age. Additionally, retrospective reporting of the age of first drug use may be subject to error, given that respondents are being asked about events that may have occurred decades ago. Finally, patterns of progression from one drug to another are not, however, consistent or predictable for all individuals. They can vary widely, depending on numerous individual and contextual factors and on characteristics of the use itself, such as age of onset, type of drug, frequency, and quantity of substance used.

THE MECHANISMS OF PROGRESSION IN DRUG USE

Soft drug abuse can be an important contributor to later hard drug abuse, by affecting an individual physiologically, psychologically, and socioculturally.

Physiological Mechanisms

Some authors have speculated that the pathway from use of alcohol and tobacco to illicit drugs may be facilitated by effects of early-stage drug use on central reward circuitry. Such suggestions are based on observations in animal models that exposure to some drugs alters future behavioral responses to the same or other drugs. Neuroanatomical, neurochemical, and molecular studies in animals show that nicotine exposure during adolescence produces a sensitization to drugs of abuse in young adulthood. So far, the mechanisms reported due to nicotine administration include alteration in the dendritic morphology of medium spiny neurons within the nucleus accumbens; reduced choline acetyl tranferase activity and increased hemicholinium-3 binding within the midbrain; increased dopamine transporter densities and decreased serotonin transporter densities; reduced DNA content within the midbrain, cerebral cortex and hippocampus; and an increased expression of specific nicotinic acetylcholine receptor subunits within the ventral tegmental area. The persistent neurobiological effects of periadolescent nicotine priming within structures associated with the reward pathway may translate into a sensitization to various drugs of abuse by the production of an increased response within the reward pathway itself. The potential for an increased response within the reward pathway may be mediated through localized alterations in neurotransmitter systems, namely dopamine, within the ventral tegmental areas, nucleus accumbens, or prefrontal cortex.

Addictive substances affect processes in the brain operating through reward systems and can produce drug tolerance and dependence. Tolerance manifests itself when, to produce a given response (e.g. a high), an individual must ingest more of a substance. It is the state in which repletion of the same dose of a drug has progressively less effect or in which the dose needs to be increased to obtain the same degree of pharmacological effect as was caused by the original dose. Although tolerance itself does not directly increase the likelihood of continued or compulsive use of drugs, such as narcotics or CNS depressants, it can affect the pattern of abuse by increasing the dose to experience the reinforcing effects. Use of increased amounts in turn enhances the risk of toxic effects and problems (including expenses) connected with securing the drugs.

The mechanisms involving the development of tolerance are only partially understood. In animals, tolerance often occurs as a result of induction of hepatic microsomal enzyme synthesis concerned with drug biotransformation (drug-disposition or pharmacokinetic tolerance) or of neuronal adaptation to drug action "pharmacodynamic, tissue, or cellular" tolerance. Further mechanisms of tolerance have been investigated at the level of "receptors," or at the molecular levels concerning synthesis and metabolism of protein or various neurotransmitters.

Physical dependence is viewed as one of several factors that contribute to the development of, and to the tendency to relapse after, withdrawal. It has been suggested that withdrawal symptoms associated with several classes of drugs of abuse are characterized by rebound effects in the same physiological systems that were initially modified by the drug (rebound hyperexcitability). Many theories have been proposed to explain the phenomena of physical dependence. However, at present it is difficult to explain by any single model all the complex phenomena associated with different types of drugs causing tolerance and dependence. Involvement of multiple mechanisms is very likely in these phenomena.

The development of physiological tolerance and dependence can contribute to the progression from one drug to another drug. Repeated use of different drugs may lead to the development of two phenomena: cross-tolerance and cross-dependence. Cross-tolerance is defined as "the state in which tolerance to one drug has the effect of causing tolerance to another drug of the same or a different chemical type." On the other hand, cross-dependence is the ability of one drug to suppress the withdrawal manifestations of another and to maintain the state of physical dependence produced by the latter. This phenomenon can be complete or partial. Cross-dependence is generally seen between the potent opioids. Animal studies also show a high degree of cross-dependence among general CNS depressants. In humans, partial cross-dependence is seen between alcohol and barbiturates.

Another important phenomenon in the physiological mechanism of polydrug use is "drug as a reinforcer." Certain drugs when administered create a psychological condition, which the user would like to experience again by repeating the drug use. Such a condition may be a feeling of pleasure, relief of pain and discomfort, or even an altered perception. Such a reinforcing effect that is experienced after self-administration of a drug by its abuser has also been demonstrated in experimental animals such as rats, monkeys, and baboons in the laboratory environment.

Finally, interactions of different classes of drugs have been proposed to support the physiological mechanism of gateway hypothesis. Historically, cannabinoids were used in combination with opioids for the treatment of different types of pain in humans due to their synergistic interactions in the modulation of noxious stimuli. Cannabinoids produce a variety of pharmacological effects very similar to those elicited by opioids. Direct and indirect interactions with opioid system have been proposed to explain some cannabinoid effects such as analgesia and attenuation of opioid-withdrawal syndrome. Evidence has been found in support of the notion that rewarding properties of cannabinoids and opioids might be functionally linked. In particular, a growing body of studies points to an important role of endogenous cannabinoid system in the modulation of opioid rewarding and addictive effects. It is generally acceptable that the use of cannabinoids is related to their positive modulatory effects on brain-rewarding processes along with their ability to positively influence emotional states and remove stress responses to environmental stimuli. Cannabinoids have been tested on a variety of behavioral models of addiction, most of which revealed functional interactions between the endocannabinoids and opioid systems in the modulation of reciprocal rewarding and addictive effects.

Cannabinoids and opioids share many pharmacological properties, including antinoception, hypothermia, sedation, and inhibition of intestinal motility. Chronic administrations of both agents produce tolerance to their analgesic and hypothermic effects and lead to the development of physical dependence, although with different intensities. Besides analgesia, endogenous cannabinoids interact with the opioid system in a variety of biological functions, including emesis, intestinal motility, and immune activity as well as modulation of anxiety, stress, emotion, and exploratory behavior. When the caudate-putamen (CP) of rats are treated with repeated administration of central cannabinoids (CB1) receptor ligand, delta 9-tetrahydrocannabnoid, there is an increase in proenkephalin gene expression and u-opioid receptor activation of G-proteins, a time-related decrease in central cannabinoids (CB1) receptor gene expression, and a reduction in CB1 receptor activation of G-proteins. These findings suggest a possible interaction between the cannabinoids and opioid systems in a brain area (i.e. caudate-putamen).

These mechanisms are consistent with "priming effect" which was suggested by researchers. Priming effect is the effect in which exposure to a stimulus repetition, perceptual or conceptual, influences response to a later stimulus. Animal experiments in addiction showed that after a period of drug self-administration followed by a period of abstinence, resumption of self-administration occurs much more readily than in animals never exposed to the drug. This priming effect of the first small dose after prolonged abstinence is thought to play an important part in provoking full-blown relapse. Many research projects suggest by the speculation that the conditioned cue causes "priming" by release of an endogenous activator of the reward pathway. Drug-related cues evoke conditioned drug-like effects which can "prime" a return to drug taking. The priming effect can readily explain why drug-related cues tend to evoke craving in drugs, without appealing to conditioned withdrawal symptoms. However, very few animal experiment have been conducted in relation to gateway hypothesis, and most have focused on priming one class of drug on the subsequent use of the same drug.

Psychological Mechanisms

The use of soft drugs may contribute to further abuse of harder drugs through psychological processes as well. For example, an initial successful experience of use may reduce an individual's fear about the first drug, thus opening the way to continued use and progressing to use other drugs. Additionally, continued use of substances can also impair the learning processes including the ability to remember lessons learned in earlier stages. Furthermore, developmental processes may be slowed, which may obstruct decision making about the use of drugs. The personality profile of the abuser may play important roles in initiation and maintenance of drug abuse. Individuals with certain personality deficits (inadequate, immature, rather unstable person with a low tolerance for frustration) may be more vulnerable to drug abuse. However, most people with such personality traits do not become chronic drug users unless other predisposing factors are present. But such individuals are vulnerable to these predisposing factors. They become motivated to have drug-induced experiences, particularly those providing pleasure, relief of pain, and altered perceptions.

One factor that can influence whether youths will use tobacco, alcohol, or illicit drugs is the extent to which youths believe these substances might cause them harm. National Survey of Drug Use and Health (NSDUH) in

the United States, 2008 respondents were asked how much they thought people risk harming themselves physically and in other ways when they use various substances in certain amounts or frequencies. Response choices for these items were "great risk," "moderate risk," "slight risk," or "no risk." The percentages of youths reporting binge alcohol use and use of cigarettes and marijuana in the past month were lower among those who perceived great risk in using these substances compared with those who did not believe as great risk. The results show that 5.0% of youths aged 12–17 who perceived great risk from "having five or more drinks of an alcoholic beverage once or twice a week" reported binge drinking in the past month (consumption of five or more drinks of an alcoholic beverage on a single occasion on at least 1 day in the past 30 days); in contrast, past month binge drinking was reported by 11.5% of youths who saw moderate, slight, or no risk from having five or more drinks of an alcoholic beverage once or twice a week. Past month marijuana use was reported by 1.5% of youths who saw great risk in smoking marijuana once a month compared with 9.4% of youths who saw moderate, slight, or no risk.

Sociocultural Mechanisms

Several hypotheses have focused on either personality characteristics or environmental circumstances in the use of drugs and the progression of drug abuse. Sensation-seeking traits have been hypothesized to predict the initial incursion into testing with drugs. Because of the relative ease of obtaining nicotine and alcohol, these drugs would be most likely to be used first. Initial use of other illicit drugs may follow as a result of continuing search for new sensations and exposure to environmental conditions that are more willing to obtaining these drugs. Although genetic variability accounts for some amount of drug use behaviors and likelihood of addiction, there are other individual factors related to drug use such as deviance proneness and personality variables (e.g. impulsivity, negative emotionality, rebelliousness, low self-esteem, poor scholastic achievement, truancy, decreased academic aspirations, and lack of motivation).

Furthermore, an individual who initiates use may begin to participate in a subgroup that encourages use, such as adolescent peer groups. Peer group is a very strong shaper of behavior, including drug-taking behavior. Numerous research findings reveal the influence of peer groups as the most dominant factor for an adolescent's initiation and recent use of drugs. Other group level factors relevant for drug use among adolescents include parental attitudes and behaviors, and lifestyle patterns (e.g. frequently going out at night).

Community level factors relevant for drug use behaviors include drug availability in neighborhoods and the popularity of specific drugs. Such social and cultural environment encourages, reinforces, maintains, and increases substance use. Alcohol and nicotine are legal drugs in many countries. Even though these drugs are "socially acceptable" for adults, they are, to one degree or another, controlled substances for youth throughout the world. However, smoking teaches drug acquisition skills to the youngsters. In addition, children who smoke get firsthand experience in using a substance to adjust their emotional states.

The social environment of an abuser, where drug abuse is accepted and prevalent among friends and associates may be one of the most important factors in inducing and maintaining the drug use. The environment with its settings and rituals may serve as a secondary reinforcement. Sometimes such social reinforcement maintains drug use behavior in the initial experimental stage until the newcomer begins to appreciate the primary drug effect or becomes tolerant to some initial aversive effects of a particular drug. For example, some young people may not like the initial effects of smoking tobacco, or may not experience anything pleasurable in smoking marijuana, or may experience nausea and vomiting with an initial dose of heroin; the social reinforcers may maintain the drug use behavior until these initial difficulties are conquered.

Experimental studies with animals and humans have corroborated the secondary reinforcing effects of environment. Acute drug effects, withdrawal manifestations, and their relief by drugs have been shown to be conditioned to environmental stimuli. These phenomena also play important roles in the relapse of drug addiction. Thus a former narcotic dependent may feel craving for the drug when he or she returns to a familiar environment; an alcoholic may have a similar experience when exposed to the sight and smell of alcohol.

Several theories may explain the deviance behavior. First, differential association theory postulates that deviance arises when the values of membership in one group conflict with the values of more powerful groups who are able to embody their definitions into law. People engage in acts defined as deviant because of the values of their reference groups, not because of any abnormal processes. Using the social learning model, researchers demonstrate that the differential association variables explain the most variance in both alcohol and drug use among adolescents. In agreement with prior research, the strongest predictor of substance use is having friends who use drugs and alcohol. Second, control theory posits that deviance arises when young people lack sufficient ties to conventional social groups such as

families, schools, and churches. From this point of view, youths deviate not through frustrated desires or actions in accordance with their own reference groups but because their ties to conventional groups are broken or underdeveloped. Finally, strain theory emphasizes entirely different processes than either differential association or control theory. Its central thesis is that people become prone to deviation when society is unable to satisfy their fundamental needs. A broad version of strain theory views various forms of deviance as mechanisms that allow people to cope with the stresses of everyday life.

Meanwhile, the problem behavior theory has shown that drug abuse is one of a cluster of problem behaviors that also include truancy, delinquency, unhealthy eating habits, excessive TV watching, reckless driving, and premature or reckless sexual behavior. These behaviors do not cause one another; rather, they are common manifestations of traumatized and aimless lives. Moreover, some young people are more vulnerable to destructive habits than others. They are more vulnerable because of psychological maladjustment, family disruption, and economic and social deprivation. So problem behavior theory suggests that what may explain progression from one drug to the next is not only the nature of the first drug used, but also factors in the various systems of which a person is part. That is, individuals, group, community factors interact to increase the risks of rebellious behavior including drug abuse. At the same time, the integrated system theory suggests that numerous factors at various levels of analysis – from cell to society – affect the likelihood of deviant behavior, including drug abuse.

AN ASSESSMENT OF THE VALIDITY OF GATEWAY HYPOTHESIS

Irrespective of the mechanism of association, several studies support the gateway pattern in drug addiction. In the Australian adolescents study, a random sample of 1943 adolescents was recruited from secondary school age 14–15. The participants were interviewed on eight occasions until the age of 24–25 years. The strongest predictor of use at age 24 was the use of other drugs, particularly cannabis at age 20. Furthermore, in the twin study of Virginia Commonwealth University, they found that cannabis was strongly predictive of use of other drugs in the future.

Based on national data that look at both children and adults and all gateway drugs, using 1991 National Household Survey, the Centre on Addiction and Substance Abuse at Columbia suggests that the early the use of gateway drugs, tobacco, alcohol, or cannabis, the more likely they are to move on to other drugs. Youth who drank alcohol were 50 times more likely to use cocaine, and those who smoked tobacco cigarettes were 19 times more likely to use cocaine. Nearly 90% of cocaine users had smoked tobacco, drank alcohol, or used marijuana first. Adults who drank as children are six times more likely to be regular cocaine users. This study, based on 30 000 households, established a clear progression that began with use of gateway drugs of alcohol, tobacco, or cannabis and led to use of other drugs. Using data from a cross-sectional survey in California, 11 239 subjects (46.3% male) from 31 high schools entered the study. After controlling for seven variables, the risk ratio of the last 30-day alcohol use among prior smoking initiators versus noninitiators was 5.82 for non-Hispanic whites, 4.25 for blacks, 8.37 for Asian Indians, 3.99 for Chinese, 3.45 for Filipinos, 3.48 for Japanese, 5.41 for Koreans, 7.57 for Vietnamese, 4.02 for Mexicans, 2.44 for South/Central Americans, and 5.95 for adolescents with multiethnic background. Comparison of the 11 ethnic groups indicated that adolescents from different ethnic groups but with similar cultural background had similar risk level; such a pattern existed after controlling for acculturation, parents' monitoring, and school performance. The risk ratio did not differ by gender and grade. There is an association between prior cigarette smoking initiation and current alcohol use among adolescents from different ethnic backgrounds, including those of multiethnicity, which supports the generalizability of gateway drug effect of cigarette smoking on alcohol use. NSDUH, 2005, found that compared with lifetime nondrinkers, adults who have consumed alcohol were statistically much more likely to currently use illicit drugs or abuse prescription drugs in the past year. Effects were strongest for cocaine (26 times more likely) and cannabis (14 times more likely). Furthermore, lifetime drinkers were six times more likely to abuse or be dependent on illicit drugs than lifetime nondrinkers. Use of illicit drugs and alcohol was more common among current cigarette smokers than among nonsmokers in 2005, as in 2002 through 2004. Among persons aged 12 or older, 20.2%, of past month cigarette smokers, reported current use of an illicit drug compared with 4.1% of persons who were not current cigarette smokers. Past month alcohol use was reported by 67.6% of current cigarette smokers compared with 46.6% of those who did not use cigarettes in the past month. The association also was found with binge drinking (43.8% of current cigarette users vs. 15.7% of current nonusers) and heavy drinking (16.1 vs. 3.5%, respectively). More recent research has supported the gateway sequence. For example, one study of thousands of adolescents found that marijuana users were twice as likely as nonusers to use illicit drugs as young adults. Although shared environmental factors mediated

much of the relationship between adolescent marijuana use and drug use as a young adult, the association remained even when controlling for familial and other factors. Another study, using data from the National Youth Survey, could not discount the possible casual influence of marijuana on other illicit drug use even after controlling for factors predicted by strain, social bonding, and differential association theories. Furthermore, another study published in 2008, examined the applicability of the gateway hypothesis to drug use patterns of secondary school students from a nonmetropolitan area in Tennessee. The data were collected from students in the 8th, 10th, and 12th grades at three secondary schools, using self-administered questionnaires under the supervision of teachers. Although there is some support for the gateway hypothesis in the data, there is also evidence that what differentiates those who move from initial marijuana use to use of harder drugs have risk factors unique to individuals and their environments, consistent with the predictions of problem behavior theory and integrated system theory. Finally, in a 2008 survey, the rate of current illicit drug use was more than nine times higher among youths aged 12–17 who smoked cigarettes in the past month (49.0%) than it was among youths who did not smoke cigarettes in the past month (5.3%). Past month illicit drug use also was associated with the level of past month alcohol use. Among youths aged 12–17 in 2008 who were heavy drinkers (i.e. consumed five or more drinks on the same occasion on each of the 5 or more days in the past 30 days), 68.5% also were current illicit drug users, which was higher than the rate among nondrinkers (4.3%). The rate of current illicit drug use among youths reporting heavy drinking in the past month increased from 60.1% in 2007 to 68.5% in 2008, and a similar increase in illicit drug use (from 37.9 to 42.6%) was seen among youths who engaged in binge drinking (i.e. consumption of five or more drinks on the same occasion on at least 1 day in the past month).

Preclinical studies added more evidence for the gateway hypothesis, in that the Karolinska Institute in Sweden used rats to investigate the effect of cannabis use and the subsequent use of other drugs in the future. The findings supported the gateway hypothesis showing that adolescence cannabis exposure has a lasting effect on hedonic processing resulting in enhanced opioid intake, possibly through the alteration of limbic opioid neurons. On examining the brain cells of the rats, they found that tetrahydrocannabinoids (THC) alters the opioid system that is associated with positive emotions, which decreases the effects of opioids on rat's brain and caused them to use more heroin.

Animal studies results establish a relationship between nicotine use by adolescents and a subsequent involvement with drugs of abuse in adulthood. The rodent model of periadolescence correlates strongly with the behavioral parameters that characterize human periadolescence: periadolescent rodents display increased impulsivity, amplified novelty seeking, diminished novelty-induced anxiety, and increased risk-taking. Exposure to nicotine during the periadolescent period affects integrated learning in the postadolescent rat by enhancing performance on the passive avoidance test in the posttreatment period. Importantly, periadolescent nicotine priming produced chemical alterations in anatomical structures comprising the reward pathway. Furthermore, periadolescent exposure to nicotine increase dopaminergic turnover in the young adult rat within the midbrain. Moreover, periadolescent nicotine priming was shown to increase young adult animal's sensitivity to the reinforcement of cocaine in the conditioned place preference paradigm of reward and reinforcement. Finally, nicotine conditioning produced a dose-dependent place preference in the periadolescent rat but did not produce a place preference in the postadolescent rat. Another study shows that rats treated with only nicotine during periadolescence showed a sensitization to the subthreshold dose of diazepam utilized during conditioning. These studies support the role of nicotine in the production of a gateway drug effect as periadolescent nicotine priming has shown to produce sensitization to nicotine itself, cocaine, and diazepam. Finally, the periadolescent period appears to be a critical time in the development of the neural system and encompasses a time of neurobehavioral vulnerability to gateway drugs and the production of persistent, behavioral adaptation in the young adult.

CHALLENGING ACCOUNTS OF THE GATEWAY HYPOTHESIS

While some research discussed earlier support the gateway hypothesis, other research challenges these findings. In the Harvard alcohol survey, 7 in 10 students had drunk in the last month. But according to a 1994 government survey, only 12% of 18–25 years old and 6% of 12–17 years old had taken marijuana during past month, only 1% of 18–25 years old had taken cocaine, and far fewer had taken crack or heroin. The study of "Marijuana and Medicine: Assessing the Science Base," in 1999, by the Division of Neuroscience and Behavioral Health at the Institute of Medicine found no evidence of a link between cannabis use and subsequent abuse of other illicit drugs on the basis of its particular physiological effect. In 2002, a study by RAND Drug Policy Research Centre casts doubt on claims that marijuana acts as a "gateway" to the use of cocaine and heroin. RAND researchers tested the marijuana gateway theory

by creating a mathematical model simulating adolescent drug use. Rates of marijuana and hard drug use in the model matched those observed in survey data collected from representative samples of youths from across the United States. Without assuming any gateway effect, the model produced patterns of drug use and abuse remarkably similar to what is experienced across the nation, showing that the marijuana gateway effect is not needed to explain the observed behavior. The association can result from known differences in the ages at which youths have opportunities to use marijuana and hard drugs, and known in individuals' willingness to try any drugs. In 2004, a study comparing cannabis users in San Francisco to those in Amsterdam was done to test the effects of the differing drug policies in the two cities on drug use patterns. The Netherlands has a drug policy of decriminalization in which cannabis can be bought by adults over 18 in quasi-legal coffee shops and used publicly, while in the United States cannabis is criminalized and must be bought in black market and used secretly. The results found that the San Francisco cannabis users were significantly more likely to use cocaine, crack, amphetamine, ecstasy, and opiates despite similar cannabis use patterns and a more permissive drug policy in the Netherlands. One explanation is that the black market itself acts as a gateway to harder drugs, as opposed to the effects of cannabis per se. In 2006, a 12-year gateway drug hypothesis study on 214 boys aged 10–12 by the American Psychiatric Association concluded that adolescents who used cannabis before using other drugs, including alcohol and tobacco, were more likely to develop a substance abuse disorder than subjects in the study who did not use cannabis prior to using other drugs. This means that changing the order of gateway drugs did not change the outcomes. Finally, new research from the University of New Hampshire, published in September, 2010, shows that the gateway effect of marijuana is overstated. The researchers used survey data from 1286 young adults who attended Miami-Dade public schools in 1990s. Within the final sample, 26% of the respondents are African American, 44% are Hispanic, and 30% are non-Hispanic white. The researchers found that young adults who did not graduate from high school or attend college were more likely to have used marijuana as teenagers and other illicit substances in young adulthood. In addition, those who used marijuana as teenagers and were unemployed after high school were more likely to use other illicit drugs. However, the association between teenage marijuana use and other illicit drug abuse by young adults fades once stresses, such as unemployment, diminish. In addition, once young adults reach age 21, the gateway effect subsides entirely.

Research from animal studies showed that cannabis derivatives have proved to exert highly specific drug discrimination effects, which are not substituted by other classes of drugs (i.e. opioids) nor are they reversed by antagonists of various neurotransmission systems, supporting the idea that the drug discrimination effects only involve the cannabinoid system. Accordingly, morphine does not substitute for THC. In addition, the hypothesis that prior cannabis exposure increases the likelihood of becoming addicted to other drugs was evaluated by giving rats a THC, then allowing them to self-administer other drugs. THC exposure did not alter the acquisition of cocaine self-administration or the amount of cocaine taken under a fixed-ratio schedule.

SUMMARY

The sequence of drug use is far from clear and any discussion of this topic generates much controversy. According to the gateway hypothesis, there is a progressive and hierarchical sequence of stages of drug use that begins with tobacco or alcohol and proceeds to marijuana, and from marijuana to other illicit drugs, such as cocaine and heroin. The basic idea of the hypothesis is that taking part in different classes of drugs is not opportunistic but follows definite pathways; an individual who participates in one drug is at risk of progressing to another. Evidence from research has shown that there does appear to be an agreed-on model of sequential stages of involvement with substances, which typically begins with alcohol. In addition, there is a clear association between frequency of use of a lower-stage drugs and likelihood of initiating high-stage drugs. However, this conclusion can be challenged on the grounds of having several confounding factors in most of these studies, which can include genetic, environmental, and individual variables. A recent study found that the strongest predictor of whether someone will use other illicit drugs is their race/ethnicity, not whether they ever used marijuana. Also, teenagers who are stressed and unemployed after graduation from high school were more likely to use other illicit drugs. Although most hard drug users were soft drug users, there is no conclusive evidence that the gateway drugs are causally linked to subsequent abuse of other illicit drugs as association does not mean causality. In addition, the link between marijuana and other illegal drugs stems from the fact that they are illegal and only available in the black market. Young people who go into the drug market are more at risk to be exposed to drug users and drug dealers and so urged to try more drugs. In conclusion, the pattern of drug addiction and its pathways are likely to be both multifaceted and complex. There is likely to be an intricate

relationship between pre-existing neuropsychological vulnerabilities, the age of initiation of substance use, patterns of substance use (type, dosage, and duration), availability of the drugs, and associated adverse events.

Glossary

Cannabis cannabis products made entirely of plants in the genus *Cannabis sativa*. It is a weedy annual that grows abundantly in the tropical and temperate zones of the world. It is the sole species containing the psychoactive substances (cannabinoids) and is of two varieties: *C. sativa indica* and *C. sativa americana*.

Gateway drug a drug (as alcohol or marijuana) whose use is thought to lead to the use of and dependence on a harder drug (as cocaine or heroin).

Gateway hypothesis gateway hypothesis describes a pattern (sequences) of drug use, beginning with alcohol and tobacco, followed by cannabis, then more dangerous hard drugs, for example, heroin and cocaine.

Hard drugs a psychoactive drug that is considered relatively strong, likely to cause addiction and perceived as specially damaging such as heroin and crack cocaine. The terms "hard" and "soft" when applied to drugs have no legal or pharmacological validity.

Priming effect effect in which exposure to a stimulus repetition, perceptual or conceptual, influences response to a later stimulus. Animal experiments in addiction showed that after a period of drug self-administration followed by a period of abstinence, resumption of self-administration occurs much more readily than in animals never exposed to the drug. This "priming effect" of the first small dose after prolonged abstinence is thought to play an important part in provoking full-blown relapse. Many research projects are suggested by the speculation that the conditioned cue causes "priming" by release of an endogenous activator of the reward pathway. drug-related cues evoke conditioned drug-like effects that can "prime" a return to drug taking. The priming effect can readily explain why drug-related cues tend to evoke craving in drugs, without appealing to conditioned withdrawal symptoms.

Soft drug a drug of abuse that is considered relatively mild and not likely to cause addiction such as cannabis and LSD. The term "soft drug" is considered controversial by its critics because it implies that the drug causes no or insignificant harm.

Stepping stone hypothesis the use of one substance or drug increases the probability of consuming another drug later and that the probability increases with frequency of use.

Tobacco tobacco products are products made entirely or partly of leaves of plants of the genus *Nicotiana tobacco*. They are used as raw material, which are intended to be smoked, sucked, chewed, or snuffed. All contain the highly addictive psychoactive ingredient, nicotine.

CHAPTER

10

Adolescent Substance Use: Symptoms and Course

Tammy Chung

University of Pittsburgh Medical Center, Pittsburgh, PA, USA

OUTLINE

ADDICTION: A DEVELOPMENTAL DISORDER

Addiction is a developmental disorder that often begins in adolescence. The adolescent developmental period, which generally covers ages 12–18, involves rapid changes in physical, cognitive, and affective domains that contribute to a drive for greater independence, as well as to a normative increase in risk-taking behavior, such as substance use. These adolescent-specific changes converge to make adolescence a period of peak risk for substance use onset and provide the rationale for using a developmental approach to understanding addiction. A developmental approach proposes that multiple systems (e.g. individual, family, school, neighborhood, country),

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00010-3

operating at multiple levels (e.g. individuals nested within families that are contained within neighborhoods), interact to influence an adolescent's trajectory of substance use. In this approach, risk factors (e.g. peer drug use) interact with protective factors (e.g. high parental supervision) dynamically over time to influence trajectories of substance use. Most risk and protective factors for substance use are common across substances; substance-specific risks generally involve processes related to drug-specific metabolism. Differences between adolescent and adult substance users with regard to, for example, legality of alcohol and tobacco use, contexts and reasons for use, duration and severity of use, and type of substance-related problems most often experienced, also point to the importance of using a developmental approach to understanding adolescent substance involvement.

Substance use ranges along a continuum from no lifetime use, experimentation, regular use, and heavy use through addiction. Addiction refers to a pattern of compulsive substance use, often despite significant harm or impairment in functioning caused by substance use. Progression of substance involvement is probabilistic, not inevitable. Only a minority of individuals who initiate use of a substance progress to addiction, and among substance users, periods of escalation in use may alternate with periods of reduction in use and desistance. Trajectories of substance use in adolescence typically represent developing (rather than fully formed) entities or phenotypes, only some of which eventuate in addiction. The following sections review adolescent-specific maturational processes that contribute to risk for substance use, externalizing and internalizing behavior pathways of risk, the sequence of substance use initiation, the prevalence of adolescent substance use, contexts and motives for use, prototypical trajectories of adolescent substance use, the prevalence of substance use disorders (SUDs) in youth, and the course of adolescent substance-related problems. A final section reviews implications for intervening with youth.

ADOLESCENT DEVELOPMENTAL MATURATION AND RISK FOR SUBSTANCE INVOLVEMENT

Developmental changes specific to adolescence that have been associated with risk for substance use include early pubertal maturation, continuing brain development, and increased sensitivity to drug effects. Early pubertal maturation increases risk for adolescent substance use because precocious physical development can facilitate association with older peers, who might provide access to drugs and socialize youth to substance use. In addition, among early maturers, cognitive and social skills often lag behind physical development, potentially resulting in situations in which an early maturer might lack the interpersonal skills and cognitive control needed to refrain from engaging in risky behavior, such as substance use. Continuing brain development during adolescence, which occurs independent of pubertal maturation, involves earlier maturation of neural systems associated with emotion and reward processing, relative to cognitive control systems. The later maturation of cognitive control, relative to emotion processing, is thought to underlie the normative adolescent increase in risk-taking behavior and contributes to the developmentally specific increase in risk for onset of substance use during adolescence.

Another biologically based developmental risk factor involves adolescents' greater sensitivity to the positive or rewarding effects of alcohol and other drugs, compared with adults. For example, an animal model research suggests that adolescents, compared with adults, are more sensitive to alcohol's stimulant and social facilitation effects. In addition, adolescent animals are less sensitive to alcohol's sedative effects, which serve as cues to limit intake. Adolescents' greater sensitivity to "positive" alcohol effects, coupled with decreased sensitivity to "negative" effects, contributes to adolescents' propensity to engage in episodes of high-volume consumption, a particularly risky pattern of drinking. Likewise, adolescent rats self-administer nicotine more often and in higher doses than rats initially exposed as adults. Individual differences in initial sensitivity to a drug may further augment adolescent-specific sensitivity, resulting in a "double-dose" of vulnerability for certain youth. Another possible effect of substance use during adolescence involves "sensitization." The initiation and use of certain substances, particularly during adolescence, can result in sensitization to the substance, that is, potentially long-lasting changes (e.g. substance-induced changes in gene expression) that increase risk for heavy use.

These biologically based developmental changes, which are specific to the adolescent developmental period, occur in the context of a social environment that provides increasing opportunities to engage in substance use (e.g. decreased parental monitoring, greater access to substances). Importantly, individuals actively seek out and participate in the creation and maintenance of the social environments that they inhabit. Thus, interventions that aim to reduce risk for adolescent substance use need to address the adolescent's active role in selecting and participating in environments that increase risk for poor outcomes. Although adolescence is a period of increased risk for substance use initiation, and experimental use of alcohol and tobacco can be considered normative, protective

factors (e.g. parental supervision, minimum legal drinking age) operate to keep overall levels of substance use low during adolescence. The variety of biological, social, and psychological changes that occur during adolescence highlight the importance of strategically timed, developmentally matched interventions that strengthen cognitive control over behavior in environments that minimize exposure to addictive substances.

TWO DEVELOPMENTAL PATHWAYS OF RISK FOR EARLY SUBSTANCE INVOLVEMENT

Two main pathways of risk for early substance involvement have been identified: *externalizing* (e.g. behavioral undercontrol, impulsivity, conduct problems) and *internalizing* (e.g. negative emotionality, depression and anxiety, sequelae of sexual and physical abuse) pathways. In one pathway, externalizing behaviors, which include behavioral disinhibition, impulsivity, and novelty seeking, robustly predict early onset and problematic use of substances in longitudinal research with youth. Because externalizing behaviors are typically present in childhood, before the onset of substance use, youth with high levels of externalizing behavior can be targeted for early intervention. The second, internalizing risk pathway has not been consistently linked to risk for substance use. The mixed findings across longitudinal studies for the internalizing risk pathway may be due to differences, for example, in the ages studied, and how internalizing symptoms were measured. Youth with high levels of both externalizing and internalizing symptoms are at greater risk for substance use than youth with symptoms in a single pathway, because the two pathways seem to have an additive effect on risk for substance involvement. The presence of high levels of externalizing and/or internalizing symptoms can escalate the progression of substance involvement and increase its severity and duration. In brief, externalizing and internalizing pathways of risk, signs of which are typically evident before the onset of substance use, suggest the important role of the dysregulation of behavior (e.g. high sensitivity to reward, low response inhibition) and affect (e.g. high mood lability, chronic depressed mood) as key risk factors for adolescent substance involvement.

PEAK PERIODS OF RISK FOR SUBSTANCE USE ONSET

There are two peak periods of risk for substance use initiation: during early adolescence, coincident with pubertal maturation, and during the transition to young adulthood, when many youth start to live independently, begin college, and enter the workforce. Around age 12, the prevalence of substance use begins to increase and continues to rise into young adulthood (mid-twenties) before leveling off. The early period of risk suggests the potential roles of early pubertal maturation, the normative adolescent increase in risk-taking behavior, and changes in the social environment (e.g. transition from grade school to high school) in the onset of substance use. The later period of risk suggests the possible roles of greater autonomy (e.g. driving a car, earning money), increasing influence of peers relative to family, and changes in the social environment (e.g. transition to independent living) on risk for substance use.

SEQUENCING OF SUBSTANCE USE INITIATION

The substances most commonly used by adolescents include alcohol, tobacco, and marijuana. The sequence of substance use initiation typically begins with the use of alcohol and tobacco before marijuana use; use of marijuana often precedes the use of other illicit drugs. Rates of other illicit drug use, such as cocaine and opiates, are generally low among youth. However, misuse of prescription medications, such as opiate-based painkillers and stimulants, is increasing, particularly among younger adolescents, who may have access to these medications at home. The fairly predictable sequencing of substance use initiation has led to the "gateway hypothesis," which proposes that use of a substance early in the sequence causes use of the next substance in the sequence. Support for the gateway hypothesis, however, is mixed, since environmental factors such as availability and access to certain substances influence the sequencing of substance use initiation.

PREVALENCE OF ADOLESCENT SUBSTANCE USE

Alcohol Use

Alcohol is the substance most often used by adolescents. More than 40% of youth have initiated alcohol use by age 16, and roughly 80% report some alcohol use by age 18. These numbers are cause for concern because alcohol use before ages 14–15 is associated with increased risk for developing an alcohol use disorder, and for using other substances. Youth who report alcohol use tend to engage in a particularly risky pattern of use known as heavy episodic ("binge") drinking (HED), in which five (for males)/four (for

females) or more standard drinks (standard drink = one can of beer, one shot of liquor, or one glass of wine) are consumed in a row. A national survey in 2008 found that 15% of 16-year-olds reported HED in the past 30 days, with the largest increase occurring between ages 17 (20%) and 18 (28%).

Tobacco and Illicit Drug Use

Similar to alcohol, the prevalence of tobacco use increases with age during adolescence. A national school-based survey found that 7% of 8th graders, 12% of 10th graders, and 20% of 12th graders reported cigarette use in the past month. For illicit drugs, the type of illicit drug most commonly used in the past month differs by age. Among 12- to 13-year-olds, a national survey found that 1.4% of youth reported misuse of prescription medication (e.g. pain relievers, tranquilizers, stimulants) and 0.9% reported marijuana use. In contrast, among 14- to 17-year-olds, marijuana was the illicit drug used most often in the past month (6% among 14- to 15-year-olds and 13% among 16- to 17-year-olds), followed by misuse of prescription medication (3% among 14–15 year olds and 5% among 16–17 year olds). The majority (67%) of individuals who try marijuana do so between the ages of 12 and 17. The difference between younger and older adolescents in the type of illicit drug most often used points to the importance of access to and availability of substances in the immediate environment as an important risk factor in adolescents' substance involvement.

Narrowing Gender Gap and Ethnic Differences in Substance Use Prevalence

Historically, adolescent males generally have had higher rates of substance use compared with females. However, the gender gap in rates of adolescent substance use has narrowed, with females approaching or surpassing rates of use reported by males at certain ages, and for certain substances. For example, 2008 national household survey data indicated little difference among 12- to 17-year-olds in rates of recent alcohol use (14.2% of males, 15.0% of females) and cigarette smoking (9.0% of males, 9.2% of females). However, males had slightly higher prevalence of marijuana use compared with females (7.3% vs. 6.0%), and females had higher prevalence of prescription drug misuse compared with males (3.3% vs. 2.5%).

With regard to ethnic differences in substance use, national school-based survey data indicate that among the three largest ethnic groups in the United States (i.e. whites, blacks, Hispanics), black students, compared with white students, had lower rates of use for most substances, including lower rates of any illicit drug and cigarette use. Hispanic students had rates of use that were generally lower than that of white students, but higher than that of black students. By 12th grade, however, Hispanic students had the highest rates of use of certain drugs (e.g. crack, crystal methamphetamine). The narrowing gender gap and ethnic differences in substance use suggest the potential utility of gender-specific, culturally sensitive interventions to reduce risk in targeted subgroups of youth.

CONTEXTS AND MOTIVES FOR ADOLESCENT SUBSTANCE USE

Societal constraints on substance use, such as a minimum legal drinking age of 21 and legal tobacco purchase age of 18, contribute to differences between adolescents and adults in primary contexts and reasons for use. Adolescent substance use typically occurs in groups of similar age peers (including siblings), and often in locations where adult supervision is minimal or absent (e.g. city parks, unsupervised home settings). Research on adolescents' "activity spaces" indicates that the use of specific substances (e.g. alcohol, tobacco, marijuana, prescription drug misuse) varies with location (e.g. someone's home, at school) and with the companions present. The illicit nature of youth substance use suggests that use is often opportunistic and that prevention efforts need to modify environments that promote substance use (e.g. through greater adult supervision and strict enforcement of underage alcohol and tobacco legislation).

Understanding a youth's motives for substance use can reveal processes underlying escalation and desistance from substance use. Research on adolescents' motives for substance use has focused largely on alcohol and tobacco. For alcohol, starting in early adolescence, three frequently reported reasons for drinking include enhancing positive feelings, facilitating social interaction, and coping with negative emotions. Importantly, adolescent HED is associated with enhancement and coping reasons for drinking, which may reflect externalizing and internalizing risk pathways, respectively. Among adolescents experimenting with cigarette use, curiosity and peer influence are the reasons for use most often reported. In contrast, among adolescent regular smokers, pleasure, relaxation, and difficulty quitting are the reasons most often reported for cigarette use. In sum, adolescents' reasons for substance use, particularly during early stages, include enhancing positive affect and experiencing positive drug effects, as well as peer influence. As adolescent substance involvement increases, motives for use increasingly tend to include coping reasons (e.g. alcohol) and difficulties in controlling use and craving (e.g. cigarette use).

TRAJECTORIES OF ADOLESCENT SUBSTANCE USE

Prevalence data provide a snapshot of substance use among adolescents at a specific time point. Longitudinal data, however, are needed to describe change over time in an individual's pattern of substance use. Trajectories capture heterogeneity in the course of substance use across individuals and provide information on individual differences in onset of substance use, rate of change in substance use, and developmentally specific turning points in substance use (e.g. escalation associated with the transition to high school). Across longitudinal community-based studies of youth, the most common trajectory types include stable low, chronic high, developmentally limited, and later onset increasing trajectories of substance use. In community samples, the most common or modal trajectory during adolescence for alcohol, cigarette, and marijuana use involves experimental to moderate use of alcohol and tobacco, and no use to experimental use of marijuana. The least common youth trajectory type involves stable, heavy use of a substance (e.g. <10% of youth report stable, heavy alcohol use).

Adolescent substance users, compared with their adult counterparts, are more likely to engage in a pattern of polysubstance use, typically involving alcohol, tobacco, and marijuana. Among youth who report use of more than one substance, trajectories for alcohol, cigarettes, and marijuana use tend to change together over time. However, onset of marijuana use generally follows onset of alcohol and tobacco. Despite generally parallel trajectories across the substances used by an individual, frequency of use may vary across substances, and drug substitution effects (i.e. use of one drug increases as use of another decreases) may occur. The general tendency for substance use trajectories to show parallel trajectories suggests common risk factors (e.g. trait disinhibition) and mechanisms (e.g. peer substance use) that underlie the similarity in overall trajectory of use across substances (e.g. alcohol and tobacco).

PREDICTORS AND OUTCOMES OF ADOLESCENT SUBSTANCE USE

Risk and Protective Factors

The primary systems of influence on risk for substance use include the individual (e.g. genetic liability, prenatal substance exposure, attitudes toward substance use, sensitivity to drug effects, reasons for use) family (e.g. parental substance use, family conflict), and extended social environment (e.g. peer substance use, transition to high school and college, school-level prevalence of substance use, neighborhood enforcement of minimum legal drinking age, media portrayals of substance use). Risk factors have been shown to predict initiation and escalation of use. Protective factors operate to modify risk for substance use (e.g. high parental monitoring, positive bond to school). Membership in stable, heavy substance use trajectories has been linked to risks such as family history of substance use problems, the adolescent's temperament (e.g. impulsivity) and co-occurring psychopathology (e.g. conduct problems, depression, response to trauma), and peer substance use. Youth in low substance use trajectories tend to have a low overall number of risk factors, as well as the presence of protective factors. The adolescent shift in the importance of peers in relation to family suggests the critical role of peer selection and influence on adolescent substance use trajectories.

Outcomes Associated with Substance Use Trajectories

As may be expected, youth with trajectories representing no to low substance use into young adulthood tend to have the best outcomes in multiple areas of functioning, such as academic, interpersonal (family and peer), and physical and mental health domains. By contrast, youth with more chronic and severe trajectories of substance use, including increasing substance use during the transition to adulthood, tend to have poor social, academic, employment, legal, and health outcomes in adolescence (e.g. greater risk for sexually transmitted disease, substance-related injury and auto accidents). These adverse outcomes may persist into young adulthood, and compromise young adult functioning. In addition, there is emerging evidence that suggests the negative effect of alcohol consumption on the developing human brain. For example, HED among adolescents is associated with damage to white matter tracts that connect regions in the hippocampus and prefrontal cortex. In addition, youth who report HED, compared with nondrinking peers, showed subtle cognitive impairments on a verbal learning task. Although these findings are suggestive of alcohol's effects on the developing brain, further research is needed to determine the persistence of these effects, and the extent to which such differences existed before or were exacerbated by substance use.

DIAGNOSTIC AND STATISTICAL MANUAL DEFINITION OF SUD

Core features of addiction are proposed to involve physical, behavioral, and psychological components.

These core features are distinguished from ancillary problems (e.g. interpersonal or legal problems) that can occur as a consequence of substance use. The *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV), recognizes two SUDs: abuse and dependence. The two SUDs attempt to preserve the distinction between substance-related negative consequences of use (i.e. abuse diagnosis), and a pathological pattern of compulsive drug seeking and use that indicates addiction (i.e. dependence diagnosis). DSM-IV substance abuse is defined by certain negative consequences resulting from substance use (e.g. substance-related interpersonal problems; impaired functioning at school, home, or work due to substance use; substance-related legal problems) or hazardous substance use (e.g. repeated episodes of driving while intoxicated). The presence of one of four criteria is needed for an abuse diagnosis. The DSM-IV substance-dependence diagnosis is intended to identify a compulsive pattern of substance use (i.e. addiction), in which three of seven criteria are present within the same 12-month period. Dependence criteria represent physical symptoms (i.e. tolerance or withdrawal), salience of drug-taking behavior (e.g. much time spent using, reduced activities to use), and impaired control over substance use (e.g. using more or longer than intended, difficulties quitting or cutting down on use, continued use despite physical or psychological problems caused by substance use). The diagnosis of a DSM-IV SUD requires evidence of clinically significant impairment or subjective distress resulting from substance use. The substance abuse diagnosis is generally considered a milder illness relative to dependence, due to its one symptom threshold, and because a diagnosis of dependence precludes a diagnosis of abuse, indicating the hierarchical relation between the two disorders.

LIMITATIONS OF DSM-IV SUDS

Valid diagnosis provides a standard operational definition of an illness that provides information on cause, prognosis, and treatment. DSM-IV–defined SUDs represent evolving working definitions, which were developed based primarily on clinical observation and empirical findings involving adult patients. Research generally supports the reliability and validity of DSM-IV abuse and dependence diagnoses. However, important limitations of these diagnoses have been identified. First, diagnoses impose relatively arbitrary distinctions (i.e. illness present or absent) on a continuum of substance use severity. The thresholds are artificial constructions, and result in symptomatic cases that nevertheless fall short of the threshold for illness. Second, because no symptom is necessary for a diagnosis, a high degree of heterogeneity exists among those with the same SUD diagnosis, which complicates efforts to identify the cause and improve treatment. Third, DSM-IV criteria do not correspond well to emerging research findings on the neurobiology of addiction, which suggests important roles for reward processing and motivation, deficits in cognitive functioning (e.g. response inhibition, memory), and dysregulation of behavior and affect. Although there is some consensus regarding a basic definition of addiction, fundamental questions remain regarding how to optimally define and assess its core features and boundary conditions.

Limitations of DSM-IV SUDs that are more specific to youth include thresholds that were developed for use with adults, and the need to consider symptoms and symptom manifestations that are relevant to youth substance involvement. The application of DSM-IV SUD thresholds to identify youth with an SUD may result in under-identification of problem use in youth, because lower levels of problem severity, compared with adults, may indicate treatment need among adolescents. In addition, the type of symptoms used to identify DSM-IV SUDs do not cover the types of problems most likely to manifest in young substance users, particularly during early stages of problem use. For example, youth who are beginning to experience substance-related problems are less likely to endorse a strong desire or attempts to limit use. Further, some symptoms, such as substance-related legal problems, may have different meaning in adolescents, for whom alcohol use under age 21 is a status offense. Other symptoms, such as driving when intoxicated as an indicator of hazardous use, also are less applicable to youth who do not drive. These limitations of DSM-IV SUDs can result in under-identification of youth who may benefit from intervention.

DEVELOPMENTALLY TAILORED ASSESSMENT OF SUBSTANCE INVOLVEMENT IN YOUTH

Adolescent substance users, compared with adults, tend to have shorter histories of use and generally experience milder substance-related problems. These developmental differences emphasize the need to adapt addiction constructs and SUD criteria to make them relevant to, and properly scaled for, an adolescent's developmental stage. Specifically, certain symptoms can manifest and be interpreted differently in adolescents and adults. For example, youth may report the dependence symptom "spending much time trying to obtain alcohol, drinking, or getting over its effects" due to difficulties in obtaining alcohol due to minor status, rather than as an indicator of a compulsive pattern of use. Other symptoms need to be appropriately scaled to

indicate a problematic level of use in youth. For example, a high level of "tolerance" indicating dependence is challenging to assess in adolescents, because on-going physical development, rather than addiction-related processes, may explain increases in consumption to obtain the same effect. Alternatively, some youth may report dependence symptoms (e.g. withdrawal) at low and infrequent levels of use, particularly in relation to tobacco. In these situations, it is unclear whether inexperience with the substance and the adolescent's interpretation of the symptom results in a "false-positive" endorsement of the symptom, or whether the youth's self-report indicates an early stage of addiction, albeit at a very low level of use that is not traditionally considered to indicate addiction. Valid assessment of substance-related problems in youth involves tailoring symptom assessment to the adolescent's developmental and social context, and appropriately scaling symptoms to minimize false-positive and false-negative symptom and diagnostic assignments.

DEVELOPMENT OF SUDS IN ADOLESCENTS

Among adolescents who initiate use and progress to SUD, time to SUD onset occurs, on average, within roughly 3 years of initiation. Despite individual differences in rate of symptom development, and type of symptoms experienced, there is some regularity in the sequential emergence of SUD symptoms in adolescents. For alcohol, alcohol-related interpersonal problems tend to emerge within the first 2 years of the onset of regular drinking, followed by other alcohol-related negative consequences and symptoms of dependence, with withdrawal typically emerging last. For tobacco, the first symptoms tend to emerge within 1 year of the onset of monthly use and typically involve symptoms of impaired control over cigarette use (e.g. strong craving). For marijuana, similar to tobacco, within a year of the onset of regular use, a symptom of impaired control over substance use (i.e. use more than intended) tends to emerge first, followed by the onset of marijuana-related physical or psychological problems 1 year later. Cross-drug differences in order of symptom onset suggest possible differences in a substance's addictive liability, such that early report of impaired control over use for tobacco and marijuana could be interpreted to indicate their higher addictive liability, relative to alcohol, among youth. However, the extent to which early self-reports of impaired control over substance use truly indicate a compulsive pattern of use, particularly during relatively early stages of use, or difficulties in controlling use that may be related to trait impulsivity (rather than compulsion), remains to be determined. Findings regarding symptom development need to be interpreted with caution given the need to consider methodological issues in symptom assessment among youth.

PREVALENCE OF ADOLESCENT SUDS

Similar to the prevalence of substance use, SUD prevalence increases with age during adolescence, and peaks in young adulthood. The most prevalent SUDs among youth involve alcohol, tobacco, and marijuana. In 2008, national survey data indicated that 7.6% of 12- to 17-year-olds met DSM-IV SUD criteria in the past year (most often for the milder abuse diagnosis), compared with 20.8% of 18- to 25-year-olds. Up to an additional 17% of youth are estimated to be "diagnostic orphans," who report substance-related problems but do not meet criteria for an SUD. Orphans may have up to two DSM-IV dependence criteria, and although they generally report a level of substance use similar to youth who meet criteria for abuse, orphans do not qualify for an SUD diagnosis. Orphans are of particular interest because the DSM-IV dependence diagnosis represents a "mature" or fully developed phenotype, typically observed in adult substance users, after many years of heavy use. Youth who are sub-threshold for SUD (e.g. orphans) are at risk for progression to SUD and warrant intervention and follow-up to halt progression to full-blown SUD. Certain settings (e.g. juvenile justice, psychiatric) report high rates of adolescent SUD, relative to the general population. Compared with adults, adolescent substance users are more likely to be in early stages of problem use and to report milder substance-related problems that highlight the need for early identification and intervention to reduce risk for progression and adverse outcomes.

ADOLESCENT SUD COURSE IN COMMUNITY SAMPLES

Longitudinal epidemiologic studies indicate that risk for more chronic alcohol, tobacco, and marijuana use disorders is concentrated within the subgroup of individuals with early onset of substance use (e.g. before age 14–15 for alcohol, age 16 for marijuana). These early onset youth are more likely to establish a regular pattern of substance use during adolescence, which has been associated with greater risk for progression to chronic and heavy substance use. Furthermore, studies of adolescent substance use trajectories indicate that among early-onset substance users, although some show developmentally limited patterns of substance use, others show a stable high level of use and associated risk for SUD into adulthood. The persistence and

stability of heavy substance use during adolescence is robustly predicted by temperament (i.e. behavioral disinhibition) and, relatedly, co-occurring psychopathology (e.g. conduct problems).

ADOLESCENT SUD TREATMENT

Among youth with an SUD, there is high unmet treatment need. Most (~90%) youth with an SUD in a 2008 national survey reported receiving no treatment. In part, low rates of adolescent treatment utilization reflect the fact that most youth do not refer themselves to treatment, and are typically mandated to treatment (e.g. by court, school), or attempt to reduce substance use on their own. Although many youth with lower levels of substance use severity are able to reduce use on their own, those who engage in heavy substance use warrant formal intervention.

Treatment services for substance using youth include a continuum of care ranging from brief interventions (e.g. 20-min feedback to motivate efforts to stop substance use), outpatient, intensive outpatient, partial hospitalization, inpatient, and residential placement. Most youth who receive treatment for substance use are treated at the outpatient level of care. Substance use treatment for youth typically involves the adolescent's family and often includes consultation with psychiatric and medical specialists to address the adolescent's problems in multiple areas of functioning (e.g. depression, sexually transmitted disease). More than half of the youth in substance use treatment are estimated to have a co-occurring psychiatric condition (e.g. conduct problems, depression, trauma-related), which may predate, result from, or be exacerbated by heavy substance use. Among empirically supported treatments, no single type of treatment content for youth (e.g. 12-step based cognitive-behavioral) has been shown to be clearly superior to any other. However, receipt of treatment results in better outcomes compared with wait-list control groups, and both longer duration of treatment and treatment completion predict better outcomes. Due to a history of heavy substance use, some youth may require more than one episode of treatment, as well as participation in a program of continuing care, to stably maintain long-term reductions in substance use.

POST-TREATMENT TRAJECTORIES OF ADOLESCENT SUBSTANCE INVOLVEMENT

Post-treatment Substance Use Trajectories

Although treated adolescents generally show reductions in substance use, there is variability in the course of adolescents' post-treatment substance use. Research on post-treatment trajectories of adolescent substance involvement has identified stable low and stable high levels of use, and decreasing, as well as increasing (for a minority of youth) patterns of use for alcohol and marijuana. In the year after substance use treatment, many youth (roughly half) are in abstinent or infrequent use trajectories, with smaller proportions classified in persistent high or slowly decreasing substance involvement trajectories. Analyses of concurrent trajectories of change after treatment for alcohol, marijuana, and other drugs indicate a moderate level of cross-drug concordance in a pattern of change over a 3-year follow-up. The similarity in pattern of change across substances (excluding tobacco, which tends to show little change after substance use treatment) provides support for similar underlying mechanisms of change after treatment, for most substances.

Outcomes Associated with Post-treatment Trajectories

As may be expected, youth in stable post-treatment abstinence and low use trajectories had better interpersonal, health, and academic/work outcomes compared with youth in chronic heavy use trajectories. More chronic trajectories frequently reflect the adverse effect of co-occurring psychopathology in the course of adolescent substance use. Changes occurred at different rates for various areas of functioning, with improvement in school performance occurring within a year after treatment, but improvement in family functioning was only evident 2 years after treatment. Despite reductions in substance use, treated youth continued to show greater problem severity in a number of domains, compared with a community comparison sample, suggesting the adverse effect of adolescent substance use.

Predictors of Post-treatment SUD Course

During treatment, factors such as family involvement and higher motivation to abstain predict better adolescent substance use outcomes. Because most youth are mandated to treatment, youth may be reluctant to reduce substance use and to "give up" friends and a "lifestyle" that supported substance use. Thus, an important role for treatment involves boosting and supporting an adolescent's motivation to reduce substance use and helping youth to identify alternative healthy social activities and environments. Post-treatment factors, such as affiliation with substance using peers and ability to cope with stressors, account for more of

the variance in long-term treatment outcome than before and during treatment factors.

Studies of reasons for relapse indicate differences between adolescents and adults in the reasons most often reported as a precipitant of relapse. Among youth, social situations (e.g. attending a party where alcohol and marijuana were present) and peer use are frequently reported relapse reasons for alcohol and marijuana. In contrast, among adults, craving and relief of negative emotions are often cited as reasons for relapse. Differences in relapse reasons suggest the relative importance of the social environment in influencing relapse for youth, in accord with youths' generally milder substance use severity, whereas coping and compulsion-based reasons predominate for adults. Among youth attempting to stop cigarette use, however, compulsion-based reasons for relapse are often reported. These findings suggest the generally milder severity of substance involvement in youth, compared with adults, and among youth, suggest cross-drug differences as reasons for relapse that seem to be linked to the degree of addiction severity.

IMPLICATIONS FOR IMPROVING ADOLESCENT SUBSTANCE USE PREVENTION AND INTERVENTION

The approach to addiction as a developmental disorder highlights the importance of prevention and early intervention among youth to reduce substance-related harm. Developmental changes that are specific to adolescence result in a convergence of risk for initiation of substance use. The two main pathways of risk represented by externalizing and internalizing symptoms, suggest targeting youth with high levels of these symptoms for early intervention to delay substance use onset and halt progression of use. In addition to targeted intervention, universal prevention efforts that are coordinated across national and community levels are needed to strengthen protective factors (e.g. enforcement of drug control policy, effective parenting) that aim to minimize environmental risks for adolescent substance use. Although environmental factors (e.g. drug availability) play an important role in risk for substance use onset, as substance use progresses, individual factors (e.g. externalizing behavior, reasons for use), in combination with the adolescent's social environment, become increasingly important targets for intervention. Adolescent substance use trajectory data can usefully inform the timing of interventions. Emerging findings on adolescent brain development, reward sensitivity and decision-making processes, and social cognition can be used to develop interventions specifically tailored to maturational stage and salient social contexts. Research is needed to better specify the neurobiological pathways and environmental contexts involved in the onset, maintenance, and desistance from addiction, specifically in relation to developmental stage of maturation and the shift to compulsive drug taking.

Glossary

Addiction a compulsive pattern of substance use, often maintained despite significant personal harm (e.g. physical or psychological problems due to use) or impairment in functioning caused by substance use.

Diagnostic and Statistical Manual (DSM) of Mental Disorders the DSM is published by the American Psychiatric Association and provides operational definitions for common mental disorders. DSM is currently in its fourth edition (DSM-IV; 2000); a fifth edition will be published in 2013. DSM-IV recognizes two substance use disorders: abuse and dependence (see below).

Diagnostic orphans individuals who are symptomatic (e.g. may have up to two DSM-IV dependence criteria for a given substance), but who do not qualify for a substance use disorder diagnosis. Diagnostic orphans illustrate a limitation of the DSM-IV classification for substance use disorders.

Externalizing behaviors behaviors that reflect impulsivity or behavioral under-control, high novelty or sensation seeking, conduct problems and aggression, and delinquency.

Heavy episodic ("binge") drinking (HED) episodes of high-volume alcohol consumption in which at least five (for males) or four (for females) standard drinks (see below) are consumed in a row.

Internalizing behaviors behaviors that reflect negative mood states such as depression and anxiety, and/or an interpersonal style that could be described as withdrawn and inhibited.

Sensitization increased sensitivity to drug effects with repeated dosing, which may be long lasting (e.g. substance-induced changes in gene expression).

Standard drink standard unit of measure for alcohol consumption that is equivalent to one 12-ounce can of beer, one shot (1.5 ounces) of 80-proof liquor, or one 5-ounce glass of wine (12–14% alcohol).

Substance abuse one of the two DSM-IV substance use disorders, which involves meeting one of the four criteria related to certain negative consequences of substance use (i.e. impairment in role functioning due to substance use, hazardous substance use, substance-related legal problems, substance-related interpersonal problems).

Substance dependence one of the two DSM-IV substance use disorders, which requires that three or more of seven criteria (i.e. tolerance, withdrawal, using more or longer than intended, strong desire or failed attempts to limit use, much time spent using, reduce activities to use, substance-related psychological or physical problems) co-occur within a 1-year period.

SUDs substance use disorders.

OUTLINE

INTRODUCTION

Alcohol is the most widely used drug in the world. Beverage ethanol is legally sold in the United States, and despite age restrictions on sales to those less than 21 years old many begin drinking at an early age, often before age 15. Alcohol is used in a variety of ways and the patterns and amounts of drinking vary among drinkers (e.g. infrequent, regular, binge, and heavy drinking). The ingestion of alcohol produces a variety of actions on the brain and behavior. The effects can be acute, caused immediately after the ingestion of alcohol, or chronic, resulting from repetitive heavy drinking. The acute effects of alcohol are dose dependent, with higher doses of alcohol producing larger effects on biological process and a more marked effect on behavior than lower doses of alcohol. While the acute effects of alcohol can be temporary, the continuation of regular intoxication can lead to chronic heavy drinking and alcohol dependence. Alcohol dependence is associated with adverse physical and psychological health, as well as family and other social consequences. This chapter will review the symptoms and conditions associated with heavy drinking and alcohol dependence and their effects on the course of alcohol use disorder.

HEAVY DRINKING AND ALCOHOL USE DISORDERS

The pattern of consumption most notably associated with chronic alcohol-related problems is heavy drinking. Heavy alcohol use, as defined by the National Institute on Alcohol Abuse and Alcoholism, includes consuming five or more standard drinks per day (or 15 or more per week) for men and four or more drinks

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00011-5

per day (or eight or more per week) for women. One standard drink is equivalent to 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of 80-proof spirits. Frequent heavy drinkers tend to develop alcohol dependence.

According to the DSM-IV-TR that was published by American Psychiatric Association (APA), alcohol dependence is characterized by a maladaptive pattern of alcohol use, leading to clinically significant impairment or distress. The DSM-IV criteria for alcohol dependence require at least three of seven symptoms to be clustered in a 1-year period. These symptoms include two indicators of physical dependence (i.e. tolerance and withdrawal), three indicators of loss of control (e.g. drinking alcohol more than intended), a persistent desire or unsuccessful efforts to cut down or control use, and continued use despite physical or psychological problems caused by drinking. There are two additional indicators for spending excessive time on drinking-related tasks: A great deal of time spent on activities necessary to obtain, use, and recover from the effects of alcohol and giving up important activities due to drinking. The DSM-IV criteria specify early and sustained full remission from alcohol dependence, when criteria for dependence are no longer met. Early remission is defined as no positive symptoms for 1–12 months, while sustained remission lasts for a period of 12 months or longer. Partial remission is specified when one or more symptoms are present, but do not meet dependence or abuse criteria. The severity of alcohol dependence and alcohol-related conditions vary from person to person, depending on gender, age, family history of alcohol dependence, comorbid psychiatric conditions, and the amount and duration of heavy drinking.

The proposed DSM-V criteria, to be published by APA in 2013, will make several changes to the DSM-IV/DSM-IV-TR. First, both alcohol dependence and alcohol abuse will be subsumed under the single label of alcohol use disorder. Currently under the DSM-IV, alcohol abuse is a separate diagnosis from alcohol dependence specified by one of four symptoms for abuse (i.e. recurrent alcohol use resulting in a failure to fulfill major role obligations, recurrent use in situations in which it is physically hazardous, recurrent substance-related legal problems, continued substance use despite having persistent social or interpersonal problems caused or exacerbated by the effects of alcohol). The DSM-V will use 11 criterion symptoms to define an alcohol use disorder; the current legal problems symptom for alcohol abuse will be excluded from the DSM-V alcohol use disorder criteria and a new craving symptom will be added. An alcohol use disorder is characterized by "maladaptive patterns of alcohol use leading to clinically significant impairment or distress as manifested by 2 of 11 symptoms within a 12-month period." The DSM-V will also use new specifications for severity; a moderate diagnosis is 2–3 criteria positive and a severe diagnosis is 4 or more criteria positive. The new criteria will specify an alcohol use disorder with and without physiological dependence by the presence or absence of tolerance or withdrawal. The APA is currently conducting a field trial and soliciting feedback from the community on these changes.

EARLY ONSET OF DRINKING AND THE DEVELOPMENT OF ALCOHOL DEPENDENCE

There is an abundant empirical literature supporting an early age of onset of drinking as a major risk factor for the development of alcohol dependence, from both retrospective and longitudinal studies. Young and colleagues surveyed 3072 adolescents drawn from three community-based family samples in Colorado. According to the survey, by 18 years of age, 1 in 10 adolescents abuse alcohol and 3.5% of adolescents, age 12–18 years old meet criteria for alcohol dependence. The National Survey of Drug Use and Health (NSDUH) in 2004 found that among 14 million alcohol dependent adults aged 21 or older, more than 13 million started using alcohol before age 21. Further, the NSDUH showed that early onset alcohol users (first use before age 15) were five times more likely than later onset alcohol users (after age 21) to develop alcohol dependence. A 16-year prospective follow-up study of adolescents also reported that both moderate and drunkenness-oriented drinking at 16 years of age are associated with excessive alcohol use in adulthood.

An early age of onset of drinking also affects the developmental course of alcohol dependence. The epidemiological literature shows that many adolescents who experiment with alcohol at an early age also develop alcohol dependence and related problems at an early age. Data from the 2001–2002 National Epidemiological Survey of Alcohol Related Conditions (NESARC) show that an early drinking onset is associated with an onset of alcohol dependence within 10 years of the first drinking experience. Consequently, those who develop alcohol dependence at an early age experience severe alcohol dependence symptoms and related health and psychiatric conditions. Hingson and colleagues reported that individuals who develop alcohol dependence before age 18 experience chronic relapsing, multiple, and longer dependence episodes with a wider variety of symptoms in the NESARC data.

The association between an early age of onset of alcohol problems and the severity of symptoms has also been documented in clinical samples. Bucholz and

her colleagues conducted a latent class analysis of 36 alcohol dependence symptoms in a sample of biological relatives of alcohol-dependent probands in the Collaborative Studies on Genetics of Alcoholism (COGA). This study found that the cluster characterized by an early age of onset of regular drinking and/or intoxication was associated with an early onset of alcohol problems and more severe alcohol-related symptoms.

Further, the men who began having alcohol problems before age 25 as compared to those who experienced problems at a later age, tended to use other drugs and experienced a greater number of drug-related problems. Similarly, Schuckit and colleagues found that alcohol-dependent persons whose alcohol diagnosis was preceded by antisocial personality disorder tended to begin to have alcohol problems before age 25. Despite their younger age, they had heavier alcohol involvement, drug abuse, and social and legal problems and had contact with treatment at a younger age.

In summary, there is consistent evidence linking an early age of onset of alcohol use and the development of alcohol dependence at an early age. In addition, an early age of onset of alcohol use is also associated with the severity and a relapsing course of alcohol dependence.

GENDER AND THE PROGRESSION OF ALCOHOL DEPENDENCE

Men compared to women are generally more likely to be alcohol dependent and to have a more severe course of alcohol dependence. For example, in the COGA sample, men report an earlier onset of weekly drinking and more alcohol use disorder episodes. However, drinking-related problems appear to develop more rapidly for women than men in another study. Studies support a "telescoping" effect in the progress of alcohol dependence among women, characterized by a shorter time from the onset of drinking to treatment entry and by the earlier onset of alcohol-related complications. The study of alcohol-dependent women with opioid and cannabis dependence also found that women had a faster progression to treatment entry than men despite no gender difference in the age at onset of regular use of any substance. Further, women reported greater psychiatric and employment problems and comparable alcohol and drug severity and medical problems compared to men at treatment entry, despite showing fewer pretreatment years of use. Similar findings were reported in COGA subjects. Despite reporting a later age of regular drinking and onset of alcohol dependence, women sought help from a health professional and reported the physiological symptoms of shakes and full withdrawal at a similar age to men. The average delay between the onset of dependence and initiation of help was 4 years for women and 6 years for men. However, despite these differences alcoholic men and women had many similarities in the course of their disorders. The progression of symptoms, or order in which problems occurred did not differ dramatically by gender.

The literature thus far indicates that while there is evidence of a telescoping effect in the development of alcohol dependence and time to first treatment among women, there is little evidence of gender differences in terms of the natural history of alcohol dependence.

ALCOHOL DEPENDENCE AND PHYSICAL HEALTH

There is well-established evidence regarding the direct causal associations between chronic heavy drinking and excess morbidity and mortality. Many studies document the effect of chronic heavy alcohol use on a wide range of adverse physical conditions, including acute hepatitis, alcoholic cirrhosis, diabetes, degeneration and atrophy of nerve cells, stroke, certain malignancies, traumatic injuries, cardiomyopathy, hypertension, gastritis, pancreatitis, muscle weakness and pain, infertility, and gestational problems. Diseases related to the direct toxic effects of ethanol use include the liver conditions of acute hepatitis and alcoholic cirrhosis, cardiomyopathy, degenerative disease of the heart muscle, injury to skeletal muscles, and diseases of the gastrointestinal tract including gastritis and pancreatitis. Other chronic effects can be attributed to specific vitamin deficiencies (e.g. thiamine). Thiamine deficiency, common in chronic alcoholics, has been linked to such nervous system conditions as degeneration of nerve cells, disturbed cognition, and severe memory loss (including Korsakoff's).

While moderate alcohol consumption has been consistently associated with reduced risk for cardiovascular diseases by raising high-density lipoprotein cholesterol and reducing plaque accumulations in the arteries, chronic heavy drinking can lead to high blood pressure, alcoholic cardiomyopathy, congestive heart failure, and hemorrhagic stroke. Heavy drinking also raises triglyceride levels. Significant increased risks were found at higher rates of alcohol intake for coronary heart disease and ischemic stroke at 100 g day^{-1} and for hemorrhagic stroke at 50 g day^{-1}. Excessive alcohol consumption is 1.5–2 times more likely to affect high blood pressure. This association increases dramatically when alcohol intake exceeds 5–6 drinks per day.

Chronic heavy drinking is also associated with an elevated risk for various types of cancer. It is estimated that 2–5% of all cancer cases are directly or indirectly related to alcohol use. An age-specific distribution of

adult drinkers obtained from the World Health Organization's (WHO) Global Burden of Disease project was used to estimate the number of cancer cases deaths linked to alcohol use. Buffeta and colleagues attributed 3.6% of all cancers (5.2% in men and 1.7% in women) and 3.5% of all cancer deaths to heavy drinking. Among women, breast cancer accounted for 60% of alcohol-attributed cancers, while for men 60% of cases were cancers of the oral cavity, pharynx, and esophagus. A meta-analysis of 156 studies involving 116 702 subjects also found strong direct risks for cancers of the oral cavity, esophagus, and larynx, as well as hypertension, liver cirrhosis, chronic pancreatitis, and injuries due to heavy alcohol consumption. Direct relationships with heavy drinking were also found for cancers of the colon, rectum, liver, and breast, although these risk trends were not as strong. Significant increased risk for all conditions were found beginning at 25 g day^{-1} of alcohol intake, corresponding to approximately two drinks per day.

Empirical studies thus far indicate several consistent findings. First, moderate alcohol consumption is associated with a reduction in cardiovascular disease and mortality in the general population. A second consistent finding is the wide variety of adverse health effects that result from chronic heavy drinking. These findings are consistent across different countries.

ALCOHOL DEPENDENCE AND PSYCHIATRIC COMORBIDITY

Chronic heavy alcohol consumption and alcohol dependence are not only associated with poor physical health, but also with a variety of psychiatric conditions. Findings from the general population 2001–2002 NESARC indicated that among respondents with a current alcohol use disorder, 13.7% had major depression, 17.1% had any anxiety disorder, and 28.6% had at least one personality disorder, with antisocial personality disorder (ASPD) being the most common. Anxiety and mood disorders were more prevalent in respondents diagnosed with current alcohol dependence (any anxiety, 23.25%; any mood, 27.55%) as compared to those diagnosed with alcohol abuse (any anxiety, 11.81%; any mood, 11.73%).

Psychiatric comorbidity has also been found among clinical samples. Major depressive disorder was the most prevalent comorbid disorder reported, with lifetime diagnosis rates ranging from 52 to 70% among women and 34 to 55% among men who received inpatient treatment for alcohol dependence. The majority of depressive symptoms were alcohol related. The rate of ASPD was also high, ranging from 25 to 39% for men and 11 to 31% for women in the clinical sample.

There are gender differences in comorbid psychiatric disorders. Women with alcohol use disorders in both treatment and community samples compared to men have higher rates of axis I co-occurring mental disorders. Watkins studied patients in outpatient treatment and found that women are more likely than men to have co-occurring mental health and substance use disorders. Depressive and anxiety disorders were more common in women with alcohol use disorders, while ASPD was more prevalent in men. In the 2001–2002 NESARC study, 10% of men as compared to 7% of women with lifetime alcohol use disorders met DSM-IV criteria for ASPD. However, despite men showing a higher prevalence of ASPD than women, men and women with co-occurring ASPD and alcohol use disorders reported similar ages at first drink and at the onset of an alcohol use disorder, and similarities in the duration of longest alcohol use disorder episode and the volume and patterns of alcohol consumption during the period of heaviest drinking.

Comorbid mental health and alcohol use disorders are associated with more severe course of alcohol dependence and greater alcohol-related problems. Depression and ASPD, in particular, have been recognized to negatively impact alcohol use and related conditions among alcohol-dependent persons. In the 2001–2002 NESARC study, alcohol use was most severe for individuals with co-occurring lifetime alcohol use disorders and ASPD. Individuals with ASPD reported a greater prevalence of family history of alcohol dependence (82.1%) than individuals with no antisocial behavior syndrome (63.0%), as well as younger ages of first drink (mean: 15.3 versus 17.9 years), onset of alcohol use disorders (mean: 19.4 versus 23.3 years), and first treatment episode (mean: 25.9 versus 33.7 years). Compared to the no ASPD group, individuals with ASPD were more likely to have two or more episodes of alcohol use disorder (45.9 versus 28.8%), and to drink both more (mean ounces of ethanol/drinking day: 6.79 versus 3.14 oz) and more often (>312 days $year^{-1}$: 35.8 versus 19.3%) during the period of heaviest drinking.

While depressive disorders are associated with the severity of alcohol dependence, the COGA study found little evidence that depressive symptoms lead to the initiation of alcohol use among adolescents. However, once heavy regular alcohol use has begun, depressive symptoms and major depressive disorder predict an early age of onset of alcohol dependence and the severity of drinking problems. Many studies show strong associations between depression and relapse to alcohol use after treatment. Depression and the severity of depressive symptoms were associated with an increased risk for relapse among Veterans Administration patients. Greenfield and colleagues found that subjects diagnosed with comorbid depression relapsed

more quickly after treatment. A study conducted in Iceland similarly showed that the co-occurring diagnoses of alcohol dependence and anxiety disorder were associated with relapse after the treatment; patients with no comorbid psychiatric disorders had fewer lifetime detoxification center admissions. Agoraphobia and panic disorder predicted readmission to a detoxification center among treatment recipients with fewer than two prior admissions, while polysubstance abuse was associated with three or more readmissions.

An association between relapse to depression and drinking has been supported by long-term follow-up studies. Hasin and colleagues analyzed 5-year follow-up data among patients participating in the Collaborative Study of Depression who were diagnosed with comorbid alcohol dependence. They identified a persistent depressive disorder as a significant predictor of relapse to alcohol use, while improvement in alcohol use was associated with reduced depressive symptoms.

Depressive symptoms that are alcohol induced should be distinguished from symptoms independent (not associated) of alcohol use among alcohol-dependent persons, as they may be differentially associated with the course of alcohol dependence. In a COGA sample, alcohol-induced depression was associated with persistent alcohol dependence and alcohol-induced depression 5 years later, while nonalcohol-induced depression was associated with persistent nonalcohol-induced depression.

The review of the literature clearly shows a high prevalence of psychiatric comorbidity and alcohol dependence. It is also clear that psychiatric comorbidity has significant adverse effects on the course of alcohol dependence with increased risk for relapse.

ALCOHOL DEPENDENCE AND CO-OCCURRING SUBSTANCE USE

Drug use disorders frequently co-occur with alcohol dependence. Based on both community and national samples, individuals with alcohol use disorders compared to those without alcohol use disorders are more likely to abuse or be dependent on illicit drugs. The Epidemiological Catchment Area (ECA) Study found that individuals diagnosed with alcohol abuse or dependence were 35 times more likely than those not diagnosed to use cocaine, 13 times more likely to use opioids, and 6 times more likely to use marijuana and related drugs. From NESARC data published 20 years later, a concurrent drug use disorder was identified in 13.05% of respondents with a current alcohol use disorder. Among those with co-occurring alcohol and drug use disorders, 73.9% were male. The most prevalent comorbid drug use disorders were cannabis (9.89%), cocaine (2.51%), and opioids (2.41%).

The NESARC study found that substance use and the related consequences of use are more severe when alcohol and other drugs are abused in combination than when abused alone. For example, the abuse of other drugs among alcohol-dependent persons is associated with poor treatment outcomes. Brown and his colleagues found at 6 months post substance abuse treatment completion that higher incidences of relapse and overall alcohol and drug use were reported by dual alcohol–cocaine users compared to alcohol-only users. Both groups showed improvement in functioning along legal, social, psychological, alcohol and drug dimensions at follow-up. Hoffmann and Miller found intravenous drug use and a history of antisocial behavior to be important predictors of relapse. Among 351 patients in Iceland, who sought alcohol detoxification, readmission during a 28-month follow-up period was associated with polysubstance abuse.

Patkar investigated the relationship between alcohol use and medical symptoms among cocaine-dependent patients, and found that patients who used alcohol had more respiratory, cardiovascular, digestive, head/neck, eye, and general health symptoms than cocaine-dependent patients who were nonalcohol users. Individuals who abuse both alcohol and drugs are also more likely to engage in behaviors that place them at risk to contract HIV, the human immunodeficiency virus. Stein and colleagues identified alcohol consumption as an independent risk factor for needle sharing among needle exchange program participants. Twenty-eight percent (28%) of needle exchangers met DSM-IV criteria for alcohol abuse during the previous 6 months. The odds of needle sharing for persons with at risk drinking was 2.3 times and with alcohol abuse was 2.5 times that of persons who drank no alcohol or low-risk levels of alcohol. Stein et al. also found that needle sharing and drinking were likely to occur together. Drinking was determined to occur on 40% of days when needles, cotton, or cookers were shared. In addition, needle exchange participants were found to be 1.5 times more likely to share needles, cottons, or cookers on alcohol use days.

Many individuals with alcohol use disorders smoke, putting them at high risk for such tobacco-related health problems such as cancer, lung disease, and heart disease. McAlister and Edmundson reported that heavy alcohol use was correlated with cigarette smoking and other forms of personal neglect. According to the 2001–2002 NESARC, 24.9% of the general population are current cigarette smokers. The rate of nicotine dependence was greater for individuals dependent on alcohol (45.4%) than for those with alcohol abuse (25.5%), and three times greater than those in the general population

(12.8%). Like comorbid alcohol and drug dependence, co-occurring alcohol and tobacco use is associated with health consequences in treatment populations. Hurt followed patients over 10 years after inpatient treatment for alcohol and other drugs to determine the impact of tobacco on alcohol-related deaths. Among deceased subjects, 50.9% died of tobacco-related illness and 34.1% died from an alcohol-related cause.

In summary, comorbid substance use disorder is not only prevalent among alcohol-dependent persons, but is also associated with many other physical, psychiatric, and social problems.

ALCOHOL DEPENDENCE, TREATMENT, AND RECOVERY

Alcohol dependence is a chronic disorder and affected persons can experience repeated cycles of treatment, abstinence, and relapse. Studies have shown however, not all recoveries from alcohol dependence occur with treatment. The data from the 2001–2002 NESARC found that nearly half of those diagnosed with an alcohol use disorder, prior to 1 year before the interview, were in various stages of recovery ranging from abstainers to asymptomatic risk drinkers. Only one quarter of those in recovery ever sought help for their alcohol problems. Additionally, a 3-year follow-up of those in recovery (in 2001–2002) showed that nearly half of asymptomatic risk drinkers had a recurrence of alcohol use disorder symptoms, as did 27% of low-risk drinkers and 7.3% of abstainers.

Investigators have examined the characteristics of those who seek treatment. Findings indicate that being male, younger age, having a previous treatment experience, and greater psychosocial problems are associated with treatment-seeking behavior. Contextual factors, like having a social network that discourages drinking and encourages help seeking, are also associated with treatment-seeking behaviors. Multiple treatment-seeking episodes are an indicator of severe alcohol dependence. Findings from the Combining Medications and Behavioral Interventions (COMBINE) study characterized subjects without previous treatment as having a later age of onset of alcohol problems and less psychological and physical distress.

In addition to comorbid psychiatric disorders, several other factors correlate with relapse among alcohol-dependent persons. Adamson et al. reviewed an extensive English-language literature on treatment outcomes from 1977 to 2005. This study identified gender as a significant predictor of treatment outcomes, with female gender being associated with better outcomes. Conversely, age, marital status, education, and ethnicity were generally poor predictors of treatment outcomes. Social functioning, measured by employment and higher socioeconomic status, predicted better outcomes. Substance use–related factors were consistent predictors of treatment outcomes. In particular, alcohol-related self-efficacy and motivation to change were consistently associated with better treatment outcomes, while baseline alcohol consumption, dependence severity, treatment history, duration of alcohol misuse, and craving/impaired control were moderately associated with poor treatment outcomes. The authors speculate that the associations between several of the alcohol-related variables were dependent on the measures used. There was vast variability in those studies reviewed related to the types and number of subjects, instruments used, and duration of follow-up.

This literature shows that recovery from alcohol dependence can occur without formal treatment. However, male gender, younger age, previous treatment experience, and greater psychosocial problems predict treatment seeking for alcohol problems. Alcohol dependence for some affected persons is a chronic, relapsing disorder.

TYPOLOGICAL CLASSIFICATIONS OF ALCOHOL-DEPENDENT PERSONS

While alcohol dependence is generally defined as a single clinical diagnostic entity, persons diagnosed with as alcohol dependent are heterogeneous. Drinking patterns, age of onset, co-occurring physical and psychiatric disorders, severity of symptoms, and the course of alcohol dependence vary considerably across affected individuals. Further, different demographic, family history, and other environmental factors contribute to this heterogeneity of persons with alcohol dependence. These differences affect treatment-seeking behavior and treatment outcomes by moderating or mediating clinical manifestations. The typological classification of alcohol dependence can be clinically useful by providing predictive value regarding the life course of alcohol dependence. Efforts to classify or group alcohol-dependent persons go back to the late nineteenth century, but earlier classifications were mostly based on drinking styles and the characteristics (e.g. chronicity and severity) of alcohol dependence. These approaches generally lacked predictive validity, while multidimensional approaches provided a more accurate description of the heterogeneity in alcohol-dependent persons.

Cloninger and colleagues first subtyped alcohol-dependent persons using multidimensional factors among 862 Swedish men adopted by nonrelatives at an early age. They found that both the genetic and the environmental backgrounds of the adoptees modified

their risk for alcohol abuse. Two forms of alcohol dependence were identified. Type 1 was characterized by mild or severe alcohol abuse and no paternal criminality. Type 2 was associated with severe and violence-related alcohol dependence. Broken down by heritability, Type 1 alcohol dependence tended to be influenced by environmental factors, while Type 2 was highly heritable from father to son. The genetic base of the Cloninger typologies has some support, but additional tests done in samples from Australia, the United States, and Europe resulted in mixed findings. Sannibale and Hall examined Cloninger's typology on 300 alcohol-dependent men and women in Australia. The Cloninger's typology failed to classify two types of problem drinkers and it did not predict gender differences in symptoms of alcohol dependence, family history or personality.

In the United States, Babor and colleagues conducted a cluster analysis of 321 male and female patients hospitalized for the treatment of alcohol dependence. The analysis was based on 17 defining characteristics including premorbid risk factors, alcohol and other drug use patterns, the chronicity and consequences of alcohol dependence, and comorbid psychiatric disorders. They derived two types of alcohol dependence, Type A and B. Type A was similar to the Cloninger's Type 1, and was characterized by a later onset of the disorder, fewer premorbid risk factors, and less psychopathology. Type B, similar to Type 2 was characterized by high-risk factors, early age of onset of alcohol dependence, familial alcoholism, and a more severe form of alcohol dependence. Babor et al.'s typology was replicated by outpatient samples of alcohol-dependent males and COGA samples. The relative proportion of Type A alcoholism is higher in the outpatient samples than in the inpatient samples. While Type A and Type B were similar to the Cloninger's classifications conducted on male only, the Babor's sample included both men and women. However, gender differences were not examined. The study of adolescents with alcohol use disorder found gender differences in two subtypes. Young women were more inclined toward affective disturbance, while young men tended toward conduct disorder.

Epstein and colleagues compared typological systems from five treatment studies, including (1) early versus late age of onset, (2) alcohol dependence with or without ASPD, (3) Cloninger et al.'s Type 1 and 2, and (4) Babor et al.'s Type A and B. They found that Type 1 and 2 classifications had poor construct validity due to symptom overlap. Stronger associations were found for early/late onset with Type 1 and 2 than with the Type A and B classifications; ASPD/Non-ASPD was associated with Type A/B classifications. Epstein and colleagues' study showed that while dichotomous subtypes can be easier to use in clinical situations and are conceptually more elegant, they may not be sufficiently complex to describe and adequately capture heterogeneous samples. Many older studies dropped cases that did not conveniently fit into two clusters or changed the cluster solution parameters in order to include the maximum amount of cases. Consequently, two-group solutions do not fully capture either clinical or general population samples. Depending on the variables of interest and the number of subjects examined, more recent studies have often identified three to five subtypes of alcohol dependence. The variability in the number of subtypes could be influenced by the data reduction technique used (cluster analysis, factor analysis, etc.), analysis not governed by proscribed rules, sample characteristics and sample sizes, the availability of clinical information, and the theory underlying the original analysis.

The indeterminate nature of cluster-derived typologies (and a limit of the statistical procedure) is best exemplified by a reanalysis of the Babor et al.'s data by Del Boca and Hesselbrock. The results showed four clusters as functional solutions that distinguished alcohol-dependent persons along gender and several clinically important dimensions. The largest subtype, containing approximately one-third of the cases was characterized as relatively Low Risk and Low Severity, including a mild form of alcohol dependence, late onset without family history, and low comorbid psychopathology. The High Risk/High Severity cluster included 22% of the female and 22% of the male patients, characterized by a severe form of alcohol dependence, early onset of alcohol use and dependence, positive family history of alcohol dependence, high alcohol involvement, conduct problems, polydrug use, depression, and ASPD. There were no gender differences in terms of the proportions or characteristics of subjects among both the mild and the severe forms of alcohol dependence. The two remaining clusters can be characterized as having moderate forms of alcohol dependence, labeled as Internalizing and Externalizing subgroups. There were gender-specific differences in both the Internalizing and the Externalizing subgroups. The Internalizing subtype included a higher proportion of women than men. This subgroup was characterized as depressed, anxious, and having severe alcohol dependence. They had medical or physical problems resulting from alcohol use, but a moderate family history risk. The fourth group, Externalizing subtype was predominantly male, was characterized as having a moderate family history risk, high levels of alcohol use, social consequences, and antisocial personality, but no depression or anxiety disorder.

Windle and Scheidt identified four cluster groups among inpatient subjects that have some similarity to those of Del Boca and Hesselbrock, including mild course, polydrug use, negative affect, and chronic/antisocial. Lesch and Walter also identified four alcohol

dependence types based on drinking patterns, severity, associated behavior, family history, and other risk factors in the sample of alcohol-dependent persons in Austria. Unlike US typologies, Lesch and Walter include motivations for drinking as defining characteristics. The Type 1 alcoholics, who drink and seek treatment for withdrawal, are characterized by a severe form of alcohol dependence and a positive family history without criminality. Type 2 alcoholics, drink to self-medicate for anxiety and conflict, and are characterized by low severity and no family history of alcoholism. Type 3 alcoholics who also self-medicate for depression are characterized by moderate severity, comorbidity, and a family history of psychiatric disorder, while Type 4 is characterized by premorbid brain injury, poor tolerance, and severe psychiatric, somatic and social problems.

Typological classifications have also been examined in large community samples. Johnson and his colleagues analyzed 911 Caucasian men in the ECA Survey and identified three subtypes along a severity dimension of alcohol dependence. The severe subtype was substantially associated with genetic influences, while the mild and dissociative subtypes were not. Furthermore, subjects in the severe subtype had significantly greater comorbid drug dependence and were more likely than other types to have sought treatment for alcohol problems. They suggest that these subtypes may be useful in identifying vulnerability genes in genetic linkage/association studies and help to identify environmental influences in behavioral and epidemiological studies. Johnson and colleagues reported similar findings among 3449 caucasian men and women with DSM-IV alcohol dependence who participated in the National Longitudinal Alcohol Epidemiologic Survey (NLAES).

More recently, Moss and colleagues identified five clusters among alcohol-dependent subjects in the NESARC study. Cluster 1 was characterized as a young adult subtype, associated with the beginning of their alcohol dependence career; Cluster 2 was a functional subtype, with late onset, low comorbidity, and low risk. Cluster 3 was an intermediate, familial subtype with late age of onset, high risk, moderate externalizing disorder, and high comorbid depression and anxiety disorder. Cluster 4 was labeled as a young antisocial subtype, characterized by an early age of onset, multigenerational family history, antisocial personality disorder, and the presence of depression, obsessive compulsive disorder (OCD), and substance abuse. Cluster 5 was labeled as a chronic severe subtype, characterized by late onset, moderate ASPD, the highest number of family history positives, and the highest level of psychiatric comorbidity.

While alcoholic typologies appear to capture complex symptom patterns, risk factors, and related conditions, it is difficult to synthesize these findings to be clinically useful. The variability of typology studies in the number and types of samples and the measurement and analytic approaches used make the application of their findings to clinical situations difficult.

A major limitation of multivariate typologies in the clinical setting is that most typologies contain too many defining characteristics, thus requiring a lengthy clinical assessment. Few treatment facilities are willing to devote additional time or personnel to obtaining the information necessary to permit reliable typological categorization of patients. Consequently, in order to increase their clinical utility, most typologies need to identify a limited number of critical indicators that can be readily identified, even if other features may have some theoretical importance. Regardless, the subtyping of alcohol-dependent persons may provide important information about the long-term course of alcohol dependence.

While many studies of alcoholic typologies do not have long-term follow-up or treatment outcome data, subjects in the Del Boca and Hesselbrock's study completed follow-up interviews. At 1-year and 3-year follow-up, the High Risk/High Severity and Externalizing groups reported poor alcohol-related outcomes. Twenty-five year mortality was also examined. A standard mortality ratio (SMR) was calculated for each cluster by gender. For men, the High Risk/High Severity cluster had the highest SMR despite being much younger than other cluster groups at admission, followed by the Externalizers. The Low Risk/Low Severity group and Internalizers had similar and lower SMRs. The number of women was too few to produce meaningful results.

The clinical application of alcoholic typologies based on two-group classifications (i.e. Type A/B and Type 1/2) in treatment studies have also been examined with mixed results. Litt and colleagues examined the usefulness of typological classification on predicting treatment outcomes. Seventy-nine empirically derived Type A and Type B alcohol-dependent males were randomly assigned to either coping skills training or interactional group psychotherapy. Interactional therapy was effective with Type A patients, while coping skills therapy was more effective with Type B patients. However, in a subsequent study with a much larger sample, the Type A/B classification did not produce a treatment matching effect with different forms of psychotherapy.

Typology-based pharmacological treatment studies of alcohol dependence have also produced mixed results. Dundon and colleagues found that Type A and B alcoholics had a differential response to pharmacotherapy with sertraline. Among Type A alcohol-dependent persons, those who received sertraline had better outcomes compared to those who did not while the

medications had no effect among Type B persons. Separate studies in Germany and Spain classified patients who received naltrexone treatment into Cloninger's Type 1 and 2. In both studies, naltrexone was no more effective than placebo among Type 1 patients with regard to the time to relapse. However, among Type 2 patients, naltrexone was effective in extending the time to relapse as compared to placebo. In contrast, a multisite study of fluvoxamine conducted in England, Australia, the United States, and Europe found that Type 2 patients were doing worse on fluvoxamine than on placebo 1 year after the treatment. No differences between fluvoxamine and placebo were observed among Type 1 patients. In a study of outpatients seeking treatment for alcohol dependence, the response to ondansetron was better predicted by the age of onset of alcohol dependence rather than Type A/B classifications.

The clinical literature thus far suggests an importance for typological classifications of alcohol dependence for clinical purposes, but it is not clear whether the Type 1/2 or A/B classifications are the most appropriate. The expanded 3–5 cluster typologies may be more clinically accurate for alcohol dependence, but their application in treatment studies is also more complex. Further, possible gender differences in response to pharmacotherapy should be considered in future studies.

CONCLUSIONS

This chapter reviewed alcohol dependence and several related conditions in adulthood. An early age of onset of alcohol use is associated with the early development of alcohol dependence (typically in early adulthood) and a severe course of alcohol dependence. While alcohol-related health conditions tend to be the result of chronic heavy drinking, alcohol-related psychiatric comorbidity could be both a risk factor for, and a consequence of, heavy drinking. Regardless of the nature of the association, psychiatric comorbidity consistently has a negative effect on the course of alcohol dependence.

Alcohol dependence in adulthood is a very heterogeneous disorder in terms of its etiology and clinical phenomenology. The nature of the associations among various alcohol-related conditions are also complex. There have been many attempts to identify more homogeneous subtypes of alcohol dependence. This chapter included a discussion of multivariate typological classifications of alcohol-dependent persons that take into account risk factors, alcohol use patterns, and related conditions. While no definitive typological classification of alcohol dependence is consistently found across clinical and community samples, these classification schemes appear to predict treatment responses, long-term outcomes, and mortality. More research efforts are needed to determine the number and types of classes that fully capture all cases of alcohol use disorder and are clinically useful.

Glossary

ASPD antisocial personality disorder.

Age of onset refers to the age that an individual first experiences a condition or symptom(s). In the study of addictions, the term is used for the age of first use of a substance, regular use, and the first symptom of dependence or abuse.

COGA Collaborative Study on the Genetics of Alcoholism. Funded since 1989 by the National Institute on Alcoholism and Alcohol Abuse (NIAAA) and more recently with contributions from the National Institute on Drug Abuse (NIDA), with the goal of identifying the specific genes underlying the vulnerability to alcohol dependence. The COGA investigators have collected extensive clinical, neuropsychological, electrophysiological, biochemical, and genetic data, and established a repository of immortalized cell lines from these individuals, to serve as a permanent source of DNA for genetic studies.

DSM the Diagnostic and Statistical Manual of Mental Disorders (DSM) is published by the American Psychiatric Association (APA) and provides a common language and standard criteria set for the classification of mental disorders. It is used in the United States and in varying degrees around the world by clinicians, researchers, psychiatric drug regulation agencies, health insurance companies, pharmaceutical companies, and policy makers. DSM has been revised several times since 1968, and currently DSM-IV has been used by clinicians and researchers. DSM-V is being field tested and is expected to be available in 2012.

The National Institute of Mental Health Epidemiological Catchment Area Survey (ECA) a comprehensive community-based survey of mental disorders and use of services by adults, ages 18 and older from 1980 to 1983. The survey was conducted in five communities in the United States through direct interviews or by proxy with 18 571 household and 2290 institutional residents using a standardized structured interview, the National Institute of mental Health Diagnostic Interview Schedule (NIMH-DIS).

NESARC the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) was designed to determine the magnitude of alcohol use disorders and their associated disabilities in the US general population. It is a longitudinal survey with its first wave of interviews fielded in 2001–2002 and a second wave in 2004–2005. The NESARC collects data on background characteristics, alcohol

and drug use, related conditions including psychiatric conditions, and family history information.

NSDUH the National Survey on Drug Use and Health (NSDUH) is conducted annually by the Substance Abuse and Mental Health Services Administration's Office of Applied Studies (SAMHSA; OAS). The survey provides information on the prevalence, patterns, and consequences of alcohol, tobacco, and illegal drug use and abuse in the general US civilian noninstitutionalized population, age 12 and older.

Standard Mortality Ratio (SMR) the ratio of observed deaths to expected deaths according to a specific health outcome in a population and serves as an indirect means of adjusting a rate.

Telescoping effect refers to the accelerated progression of the course of substance use and dependence (i.e. from the age of first use/regular use to dependence, treatment entry, etc.)

World Health Organization (WHO) the directing and coordinating authority for health within the United Nations system. It is responsible for providing leadership on global health matters, shaping the health research agenda, setting norms and standards, articulating evidence-based policy options, providing technical support to countries, and monitoring and assessing health trends.

OUTLINE

INTRODUCTION

Positive healthy behaviors can not only extend longevity but also reduce the risk of losing mobility and independence in later life, and there is already a body of evidence to show that lifestyle behavior differs according to age, with older people making up a large but unique target population for interventions. However, substance abuse – the use and misuse of illicit and/or licit substances – does occur in older age. Problems arise from drinking excessive levels of alcohol, smoking tobacco, misuse of prescribed medications or over-the-counter medication, and illicit drug use. While some substance use decreases with age (e.g. alcohol) other substance use is more common in later life due to social and generational effects (i.e. smoking was more acceptable when many older people began). Also, with increasing health problems in later life, prescription drug use is more common and this can become problematic due to confusion and/or dependence-forming properties. Lastly, use of illicit drugs is relatively uncommon in later life, but their addiction and criminogenic effects can present a significant problem for older individuals. Substance abuse is associated with notable social, psychological, physical, and economic consequences. While older age substance abuse is often less obvious, misdiagnosed, undetected or under-detected, or under-reported, a recent survey predicts that the number of Americans aged 50 or older who are addicted to drugs or alcohol will double by the

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00012-7

year 2020. The aging of populations worldwide means that the absolute number of older people with substance abuse problems is on the increase and a real danger exists that a "silent epidemic" may be evolving.

The question of what constitutes old age is a vexed one. The usual cutoff point for old age in the West is 65 years of age. The United Nations defines the older population as those over 60 years, but recently it has modified its definition for older people in Africa to include those over 50 years in order to take into account environmental conditions. There is little consensus within the academic literature regarding the definition of an older person and although this term is widely used, definitions vary from 50 years upwards. In order to be as inclusive as possible with the literature on older age and substance abuse individuals aged 50 years or more are included.

ALCOHOL

Extent of Use

General population figures indicate that alcohol use decreases with age. However, since 2001, surveys have indicated a small but steady increase in the amount of alcohol consumed by the middle and older age groups. Men and women aged 65 and over also drink more frequently than those in younger age groups.

Drinking habits of middle-aged and older adults in America are broadly similar to the use of alcohol in Canada and Brazil with 19% of males aged 50–64, and 13% of females drinking at risky levels. In those aged 65 or over, 13% of males and 8% of females report at-risk alcohol use (more than two drinks per day). In the 50–64 age group, 23% of males and 9% of females also report binge drinking (defined as five or more drinks on the same occasion), and 14% of men and 3% of women aged 65 years and over report binge drinking. Older women may be especially at-risk for alcohol problems because they are more likely to outlive their spouses and face other losses that may lead to loneliness and depression. Physiologically, women are also at greater risk as they have a greater predisposition to have less lean muscle mass than men, making them more susceptible to the effects of alcohol. Both men and women experience losses in lean muscle mass as they age, but women have less lean muscle mass than men throughout adulthood and, therefore, are less able to metabolize alcohol throughout their lives, including into older adulthood. In addition to gender, having a college degree, being separated, having a middle or high income, smoking and drug use are all associated with at-risk and binge drinking. These findings have been replicated in other studies of older people from both developed (USA, France, Korea, Germany) and developing (Brazil) countries.

In the United Kingdom, 16% of men and 5% of women aged 65 and over drink more than the daily recommended limits (4 units day^{-1} for men and 3 units day^{-1} for women) while 15% of men and 7% of women aged 65 and over and 23% of men and 8% of women aged 60 and over drink more than the recommended weekly limits (21 units $week^{-1}$ for men and 14 units $week^{-1}$ for women). Also, in the United Kingdom, 31% of 50–59 year olds and 22% of 60–69 year olds report hazardous drinking behavior in the preceding 12 months, as measured by the Alcohol Use Disorders Identification Test (AUDIT). The 2007 Eurobarometer survey estimates that 27% of European people aged 55+ years had episodes of binge drinking (5+ drinks of 50 g alcohol on a single occasion) at least once a week during the previous 12 months. Those aged 50–65 years have the highest weekly expenditure on alcohol. There is also a substantial prevalence of alcohol problems in older hospital patients and in nursing homes with the possibility that more than one quarter of nursing home residents may have symptoms of active problem drinking.

Effects of Use

Negative

Excessive alcohol consumption is strongly associated with serious social, psychological, physical, and economic costs for the individual and society. As people age, physiological changes that occur as part of the aging process mean that older people are more sensitive to the effects of alcohol and experience problems at lower levels of consumption. The average person aged 65 years and over also takes at least two medicines per day some of which can be dangerous when mixed with alcohol. Combined use of alcohol and medication is estimated to affect up to 19% of older Americans although there is some evidence that older people may cease or reduce drinking as a result of changes in medication use or physical illness. Drinking alcohol for medicinal purposes is also common and some people, especially older women, may find it easier to discuss their alcohol consumption in the context of medicinal use. Older adults with more health problems and who rely on alcohol to manage pain are at elevated risk for drinking problems. The presentation to health professionals of older people with alcohol problems may be atypical (such as falls, acute hip fracture, neglect, malnutrition, depression, or confusion which can be mistaken for Alzheimer's) or masked by comorbid physical or psychiatric illness which makes detection all the more difficult. Some medical conditions (such as high blood pressure, ulcers, and diabetes) can worsen with alcohol

use. For people aged over 60 years, drinking more than seven drinks per week or more than three drinks per occasion has been associated with impairments in the instrumental activities of daily living. Men aged 55–64 years and women aged 65–74 years have the highest death rates from liver disease, while the highest rates of deaths each year, directly attributable to alcohol, occur in the 55–74 age group.

Positive

In moderation, alcohol consumption can contribute to older peoples' quality of life. Benefits of low-to-moderate alcohol consumption for older people include a lower risk of Alzheimer's disease, dementia, and functional decline, a reduced risk of stroke, protection against heart disease and respiratory disease and lower overall mortality. Older men and women who consume small to moderate amounts of alcohol are more likely to maintain mobility than nondrinkers. Light to moderate alcohol use by older women has also been associated with better self-perceived health status and lower rates of hospitalization. In middle-aged and older men and women, moderate levels of alcohol consumption are associated with better cognitive health than abstinence and moderate consumption of alcohol may increase bone mineral density in men and postmenopausal women. However, a consumption increase is unlikely to produce any net benefit in terms of cardiovascular mortality when lifestyle factors are taken into consideration – at least in older drinkers. Recent estimates are such that the potential health benefits of alcohol are significantly outweighed by the harm caused.

Course

Early-onset drinkers or "survivors" are those with a continuing problem with alcohol which developed in earlier life. It is thought that two-thirds of older problem drinkers have had an early-onset of alcohol misuse. These drinkers are likely to need more intensive support than brief interventions. Late-onset drinkers or "reactors" begin problematic drinking later in life, often in response to traumatic life events such as bereavement, loneliness, pain, insomnia, or retirement. This population is more likely to be female. As "reactors" also have higher life satisfaction, less physical and psychological comorbidity, and fewer alcohol-related problems than "survivors," they are often difficult to identify and diagnose. Evidence also suggests that as a population late-onset drinkers are more motivated to change their drinking behavior, more compliant in treatment and have better treatment outcomes. Intermittent or binge drinkers are defined in terms of consumption thresholds of six standard drinks for females or eight for males, in a single day. Identifying heavy episodic consumption in this population is made difficult in part because the usual cues (employment-related difficulties and driving offenses) are more rare in the older population – many of whom do not work or drive. Like late-onset drinkers, this group will be likely to respond well to alcohol treatment or interventions.

Although there is growing recognition of this public health problem and instruments to detect problem drinking generally perform well in older populations, problems have been identified when screening and intervening for alcohol misuse including inaccurate self-report, staff embarrassment, poor use of the screening tool by professionals, and inaccurate patient history. Some of these factors may be more influential when screening an older population given a widespread attitude that alcohol is a problem particular to younger age groups. Greater social stigma attached to older people's drinking may exacerbate under-reporting or nonreporting of alcohol problems or levels of drinking particularly among older women, who have been found to be less likely to present for treatment for alcohol problems than older men. Professionals can be reluctant to ask older people about alcohol use due to awkwardness or stereotyped views about older people and people who have alcohol problems; and alcohol problems are often presented in nonspecific ways among older people. Even when clinicians have been encouraged to screen for problem alcohol use, they under-deliver health-promoting advice to older people, while nurses report that they do not engage with older people as they worry about depriving them of the social benefits of drinking. Only a small proportion of older people with alcohol-related problems are referred on for rehabilitation as health care workers are less likely to refer older people for specialist treatment than they are to refer younger people.

Limited evidence exists for the most efficacious approaches to prevent and/or intervene for alcohol problems in older people. Many strategies are neither age-specific nor sensitive to what is most clinically effective in accommodating the unique biological and social conditions of older persons. However, older people can benefit as much from treatment for alcohol misuse as younger age groups, and older people with dependence have been found to respond better to treatment than younger age groups. Those whose alcohol problems are of late-onset have fewer health problems and are more receptive to treatment than those with early-onset problems associated with previous family history; they are also more likely to recover spontaneously. Older adults have better attendance at, and adherence to, therapy and medications than younger age groups.

Older people are, however, one of the least well-informed groups about alcohol units and there is little evidence regarding effectiveness of education campaigns.

Brief interventions and cognitive behavioral approaches have been shown to be effective at reducing alcohol consumption among older adults. Simple brief interventions, typically involving a structured advice session of a few minutes with a trained practitioner (not necessarily a specialist), are effective in reducing hazardous drinking. Extended brief interventions, involving 20–30 min of structured therapy possibly with follow-up sessions, are efficacious with those for whom a short brief intervention is not successful, or who have experienced harm in relation to drinking alcohol. Brief interventions are seen as an acceptable and effective treatment in reducing hazardous drinking among older adults. Inpatient (rather than outpatient) detoxification is recommended for older people who are severely alcohol dependent although information on the use of abstinence medication in older people is limited. Interventions that involve or treat family members or encompass an individual's support network have been endorsed, particularly as a means of countering relapse for older people with alcohol problems.

Rather than a single treatment of choice, a range of treatment options may be beneficial at different levels of drinking: low-risk, hazardous, harmful, moderate dependency, and severe dependency. Groups with complex needs are likely to require more intensive or prolonged interventions, even at lower levels of alcohol use and dependence. A stepped care approach is recommended as a practical and efficient alternative to one-size-fits-all recommendations.

Some experts suggest that recommended limits for intake should be redefined for older people. In the USA, the National Institute on Alcohol Abuse and Alcoholism recommends that people over 65 years of age should consume no more than one standard drink per day, seven standard drinks per week, and no more than two drinks at any one time. Among the member states of the European Union only Italy has an alcohol consumption guideline for older adults. The recommendation is no more than one standard drink per day.

TOBACCO

Extent of Use

One out of five adults over the age of 50 years smokes cigarettes. Today's generation of older Americans had smoking rates among the highest of any USA generation. In the mid-1960s, about 54% of adult males were current smokers and another 21% were former smokers; in 2008, about 23% of adult males were smokers and another 24% were former smokers. In 2008, over 17 million Americans over the age of 45 smoked, accounting for over 22% of all adult smokers. Nine percent of Americans over 65 years of age currently smoke. Older people have usually smoked for longer than younger people and have been and continue to be heavy smokers. Older smokers also smoke more than younger people and are more likely to smoke brands of cigarettes that have high nicotine levels. In the United Kingdom, the highest rates of smoking are in the 20–24 age group, with 30% of people this age being recorded as smokers. The prevalence of smoking then declines with age to 13% of people aged 60 and over smoking. The difference between the age groups has historically been smaller and has increased as a result of higher smoking cessation rates among older people. For example, in 1974, 34% of people aged 60 and over smoked. By 2008, this had more than halved to 13%, whereas the decrease for people aged 20–24 over the same time period is from 48 to 30%. In the United Kingdom, the over 65s, supported by National Health Service (NHS) smoking cessation services, are giving up smoking more quickly than any other age group. Unlike other drugs, tobacco is used openly and therefore there should be no difficulty with recognizing its use. However, in an Australian study of hospital patients over the age of 65 years, 12% were smoking a median of 17 cigarettes per day (range 1–50), only 38% of whom had been identified as smokers by ward doctors.

Effects of Use

Tobacco is the most commonly used psychoactive substance in older people and accounts for more medical disability and mortality than any other substance of potential misuse. Older smokers are more likely to have chronic diseases than nonsmokers with their smoking causing further deterioration in their health. Tobacco use has been shown to cause about 25 life-threatening diseases and smoking is a major risk factor in eight of the top sixteen causes of death in people aged 65 years and older. It is well documented that smoking is directly responsible for more than 90% of chronic obstructive pulmonary disease (COPD, or emphysema and chronic bronchitis) deaths and approximately 80–90% of lung cancer deaths in women and men, respectively. Smoking is also a major risk factor for coronary heart disease, stroke, and lower respiratory tract infections – all leading causes of death in those over 50 years of age. Older smokers are at greater risk from smoking because they have smoked longer (an average of 40 years), tend to be heavier smokers, and are more likely to suffer from smoking-related illnesses. They are also significantly less likely than younger smokers to believe that smoking harms their health. COPD prevalence rates are highest among those 65 years of age and older and the disease consistently ranks among the top

10 most common chronic health conditions and sources of daily activity limitation. COPD is the fourth leading cause of death and is predicted to become the third by 2020. Men aged 65 years and over who smoke are twice as likely to die from a stroke, and women smokers are about one and a half times as likely to die from a stroke, as their nonsmoking counterparts. The risk of dying from a heart attack is 60% higher for smokers than nonsmokers among those aged 65 years. Smokers are more than twice as likely as nonsmokers to develop dementia of any kind and Alzheimer's disease. Smokers also have two to three times the risk of developing cataracts, the leading cause of blindness and visual loss, as nonsmokers. Smoking reduces a person's normal life expectancy by an average of 13 to 15 years, thereby eliminating or shortening retirement years for most smokers. The complications of smoking occur later in the period of use and it may therefore appear that a person has smoked for many years without apparent ill effect.

Course

Although quitting smoking has proven health benefits, even at a late age, older smokers (50–74) are less likely to have tried to quit than smokers aged 21–49. When an older person quits smoking, circulation improves rapidly, and the lungs begin to repair damage. In one year, the added risk of heart disease is cut almost in half, and risk of stroke, lung disease, and cancer diminish. Many older adults say they do not quit smoking because doing so offers no benefit at an advanced age. However, there is strong evidence that smoking cessation even late in life not only adds years to life, but also improves quality of life. Treatments for quitting smoking have been found to be effective and could decrease health care costs. Using a tobacco treatment plan doubles the quitting success rate. Effective treatments combine counseling and medications. Older people have been shown to have greater success in stopping smoking than younger people with 60% of those aged 60 and over successfully quitting in 2007/08, compared with just 38% of those under 18. Smoking cessation is beneficial at all ages and has immediate and long-term benefits for those with and without smoking-related illnesses. About 75% of years of potential life lost in smokers occur after the age of 65. Former smokers live longer than continuing smokers as smoking cessation at age 50 reduces the risk of dying within the next 15 years by 50%.

Smoking remains prevalent in older people in the United Kingdom and similar countries. The adverse health effects of current smoking continue to accumulate in old age and stopping smoking in old age confers benefits on function, morbidity, and mortality. Many older people wish to stop smoking and many are successful, although cognitive impairment – more prevalent in this population – is a barrier to successful smoking cessation.

Smoking cessation interventions have been shown to be effective. Although self-help strategies alone marginally affect quit rates, individual and combined pharmacotherapies and counseling either alone or in combination can significantly increase cessation. Pharmacotherapies include all forms of nicotine replacement therapy (NRT) which can help people quit smoking, almost doubling long-term success rates. All forms of NRT make it more likely that a person's attempt to quit smoking will succeed. There is no evidence that one form of NRT is better than any other and NRT works with or without additional counseling. Using effective smoking treatments is strongly encouraged for all populations, especially those with high and heavy rates of smoking, such as psychiatric and substance abuse populations. Smokers of all ages benefit from cessation of smoking. Although most older smokers, like younger smokers, prefer to quit on their own, there are few interventions targeted at older smokers. A number of studies indicate that older smokers face age-specific obstacles to quitting, such as decreased self-efficacy due to greater number of lifetime quit attempts; longer smoking history and a tendency to be heavier, addicted smokers; and skepticism about the benefits of quitting. Moreover, a common misconception among lay and professional populations is that it is "too late" for older smokers. These data illustrate the specific smoking behavior of older people, suggesting that cessation interventions ought to be tailored to these characteristics. Indeed tailored interventions tend to be rated more highly and are also read and reread more than nontailored interventions. Quit rates are also higher among smokers who received a tailored intervention. Doctors and other health care staff should make use of patient contact to encourage older smokers to quit.

PRESCRIPTION/OVER-THE-COUNTER MEDICATION

Extent of Use

Older people are frequent and regular consumers of prescription medication (including diuretics, benzodiazepines, opioid analgesics, hypnotics, and antidepressants) and over-the-counter medication (such as laxatives, analgesics, and antihistamines). Persons aged over 65 years use about one-third of all prescribed medication. Older people receive more prescribed medications than younger people and are far more likely to be prescribed benzodiazepines on long-term prescriptions than younger people. This "medical" use of

dependence-creating pharmaceuticals is often related directly to the aging process and increased physical morbidity. Older women are more likely to be prescribed, and to misuse, psychoactive medications than men and are also at a higher risk of prescription medication misuse than other age groups. In the USA, up to 11% of older women misuse prescription drugs and prescription drug abuse is present in 12–15% of older individuals who seek medical attention. Inappropriate prescribing is common among community-dwelling older people and persists over time. Surveys of older community-based individuals indicate from 17 to 20% are receiving psychotropic medications that are highly addictive. Almost half indicate use beyond the prescribed levels of these medications. One quarter of the prescription medications sold in the USA are used by older people – often for problems such as chronic pain, insomnia, and anxiety. Prescription/over-the-counter medication abuse is associated with female gender, social isolation, recent divorce, widowhood, lower educational level, lower income, poorer health status, depression, anxiety, and history of substance abuse. An Australian study of hospital patients found 14% were problem users of benzodiazepines and had taken these drugs for periods ranging from 6 months to 20 years. Only 3% had been identified by ward doctors. Nonmedical use of drugs among adults older than 50 years is set to increase to 2.7 million by the year 2020.

Prescription of medicines is a fundamental component of the care of elderly people, and optimization of drug prescribing for this group of patients has become an important public health issue worldwide. Several characteristics of aging and geriatric medicine affect medication prescribing for elderly people and render the selection of appropriate pharmacotherapy a challenging and complex process. Some syndromes related to age, especially cognitive impairment, affect the ability of elderly people to engage with health services. For example, elderly people with dementia have increased difficulty with taking drugs, and dementia impedes their ability to make autonomous decisions about their medicines. In addition, frail elderly people have age-related impairments in the hepatic metabolism and renal clearance of medications, and enhanced pharmacodynamic sensitivity to specific drugs.

Elderly patients are also at high risk of having drug interactions, but the prevalence of these interactions is not well documented. Several types of interactions exist: drug–drug, drug–disease, drug–food, drug–alcohol, drug–herbal products, and drug–nutritional status. Factors such as age-related changes in pharmacokinetics and pharmacodynamics, frailty, individual variability, reduced homoeostatic mechanisms, and psychosocial issues need to be considered when drug interactions are assessed. Software can help clinicians to detect drug interactions, but many programs have not been updated with the evolving knowledge of these interactions, and do not take into consideration important factors needed to optimize drug treatment in elderly patients. Any generated recommendations have to be tempered by a holistic, geriatric, multiprofessional approach that is team based.

Effects of Use

Problems associated with prescription/over-the-counter medication abuse in older people are particularly likely to go unrecognized. The older abusers have a high rate of psychiatric problems due to addiction. Unlike younger addicts older misusers are more likely to have physical and neurological complications due to the addiction. Older adults are likely to experience more problems with relatively small amounts of substances because of increased sensitivity, slower metabolism, and a smaller volume of distribution. Age-related cognitive impairment may interfere with the ability of the older adult to self-monitor intake or interpret feedback from health care providers.

Course

Screening instruments for prescription drug abuse have not been validated in the older population. Benzodiazepines, opiate analgesics, and some skeletal muscle relaxants may result in physical dependence; however, tolerance, withdrawal syndrome, and dose escalation may be less common in the older patient. Lower doses may decrease the risk of abuse and dependence; however, fear of abuse often results in a failure to treat adequately symptoms such as anxiety, pain, and insomnia.

The treatment of disorders of prescription drug use in older adults may involve family and caretakers and should take into account the unique physical, emotional, and cognitive factors of aging. The use of nonaddicting pain treatment modalities, such as physical therapy, occupational therapy, acupuncture, nonaddicting medication, and support groups focusing on management of pain and disability are indicated in the context of cognitive behavioral therapy.

ILLICIT DRUGS

Extent of Use

The use of illicit substances does occur among older people but the research evidence concerning prevalence is equivocal; the Epidemiological Catchment Area

Survey (ECAS) reported a rate of illicit drug use of less than 1% in people over the age of 60 (1988), while in 1994 a study of US veterans reported a rate of 22% in those aged 55 and over. In the United Kingdom there has been a significant increase in the proportion of drug users aged 50 and over in contact with specialist drug treatment services (from 1.7% in 1998 to 3.5% in 2005). There is also a similar trend among those in contact with agencies that provide clean injecting equipment to drug users (syringe exchange schemes) with the median age of injectors in contact with such services increasing by almost 8 years over a 13-year period from 27.0 in 1992 to 34.9 in 2004. The UK's drug treatment services and syringe exchange schemes typically cater for drug-dependent people who are usually users of opiates (mainly heroin) or stimulants (cocaine, crack cocaine, and amphetamine) or who inject drugs. The European Monitoring Centre for Drugs and Drug Addiction has highlighted aging populations of opiate users in a number of European countries. In Great Britain, changes in the age of people taking illicit substances are monitored through the British Crime Survey (BCS). Against a backdrop of significant falls in the rate of last-year prevalence for the use of any illicit drug (predominantly cannabis, cocaine, ecstasy, amyl nitrate, and amphetamines) for the youngest age groups (16–29 years) between 1996 and 2008/09, the BCS shows that illicit drug use among those aged 30–59 years has increased. No data on illicit drug use among people aged over 60 is available from the BCS because it does not collect this information due to the perceived "very low prevalence rates for use of prohibited drugs" among people aged 60 and over, reflecting the prevalent attitude that older people do not use drugs. Like their younger counterparts, older adults do use illicit drugs and although illicit drug use is less common in this age group, its prevalence is increasing. Estimates from the USA suggest that the number of persons aged over 50 needing treatment for illicit drug problems may increase by up to 300% between 2001 and 2020. As methadone and other maintenance programs become more effective at retaining patients in treatment and reducing overdose deaths, the number of older patients will gradually increase although this is subject to the ongoing availability of such programs.

Effects of Use

Illicit drug use by older people presents unique problems as biological systems and processes alter naturally across the life course. However, the effect of concurrent drug use on some of these systems is not well understood. The natural progression of certain diseases means that symptoms manifest only in older age and the lives of older drug users are likely to be characterized by considerable levels of morbidity. The brain changes in a variety of ways across the lifespan, and how these changes alter drug–brain interactions and what implications these changes have for older drug users are not yet clear. In addition, chronic use of some drugs may exacerbate changes normally associated with aging; people dependent upon cocaine, for example, exhibit an increased number of age-related white matter (brain) lesions, which in turn are thought to be associated with cognitive abnormalities. Pharmacokinetics – the processes by which a substance is absorbed, distributed, metabolized, and eliminated from the body – also changes with age. Reductions in lean body mass and total body water content, coupled with reduced drug elimination by the kidneys, may increase elevated drug serum levels, and even moderate use of drugs may have significant effects. Long-term drug use further increases the risk of certain morbidities already prevalent in older age such as myocardial, pulmonary, and cerebral infarctions, which are associated with cocaine use. The natural progression of other diseases, for example, cirrhosis and other liver diseases (associated with hepatitis C infection contracted through the sharing of contaminated drug injecting equipment and/or excessive alcohol use), means that symptoms tend to manifest only in drug users of older age. Concurrent aging and drug use therefore create a unique set of problems for older people that are not yet fully understood.

Course

Historically, global populations have not witnessed a large number of older illicit drug users and this has resulted in a perception that older people do not use these substances. However, cross-sectional studies fail to account for period and cohort effects and the likelihood that older people in the past did not use drugs because they did not use them when they were younger. Older people of today are using drugs because they did so when younger, and have done little to change their consumption as they have aged. Whether there exists a second group of older users of illicit drugs – those who were abstemious when young but who commenced use in later life – remains unknown, because the lack of awareness of drug use among older populations has largely precluded any investigation of this issue and this has been compounded by the fact that the tools used to screen for drug use have not been validated for use in older populations. The advent of effective treatment and harm minimization initiatives for drug-dependent individuals in the past 30 years or so, in addition to general advances in medicine, has increased the average life expectancy of a drug user, and the trends described here demonstrate their survival into older

age. Despite positive evidence of the effectiveness of treatments for other substances, there is little substantive literature regarding the effectiveness of treatments for older illicit substance users.

CONCLUSION

Substance abuse does occur in older age and is associated with notable social, psychological, physical, and economic consequences. Older age substance abuse is often less obvious, misdiagnosed, undetected or under-detected, or under-reported. Screening tools aimed at identifying people at-risk of substance abuse are not designed with an older population in mind although older people seem to respond well to treatment. Older people are likely to perceive great social pressure not to be seen as a substance abuser, and this is likely to have an impact on self-reported statistics. The aging of populations worldwide means that the absolute number of older people with substance abuse problems is on the increase and a real danger exists that a "silent epidemic" may be evolving. The likely silence of many older people means that the epidemic could be greater than even this account suggests.

Glossary

Abstinence a voluntary restraint from indulging in bodily activities that are widely experienced as giving pleasure.

Alcohol units a simple way of remembering alcohol strengths. There is one unit of alcohol in one half-pint of ordinary strength beer, larger or cider (284 ml, 3.5% ABV); one pub measure of spirits (25 ml, 40% ABV); one standard glass of wine (125 ml, 8% ABV); one small glass of sherry (50 ml, 20% ABV). Also referred to as standard drink.

Binge drinking defined as episodic excessive drinking. There is currently no worldwide consensus on how many drinks constitute a "binge," but in the United States, the term is often taken to mean consuming five or more standard drinks (male), or four or more drinks (female), in about 2 h for a typical adult. In the United Kingdom, binge drinking is defined as drinking more than twice the daily limit, that is, drinking eight units or more for men or six units or more for women.

Comorbidity the presence of one or more disorders (or diseases) in addition to a primary disease or disorder, or the effect of such additional disorders or diseases.

COPD Chronic Obstructive Pulmonary Disease

Criminogenic producing or tending to produce crime or criminality.

Dependent drinking when a person feels that they are unable to function without alcohol.

Detoxification the physiological or medicinal removal of toxic substances from a living organism, including, but not limited to, the human body and additionally can refer to the period of withdrawal during which an organism returns to homeostasis after long-term use of an addictive substance.

Harmful drinking when a person drinks over the recommended weekly amount and has experienced health problems directly related to alcohol.

Hazardous drinking when a person drinks over the recommended weekly limit or binge drinks. Individuals may not yet have any health problems directly related to alcohol but are increasing the risk of experiencing problems in the future.

Illicit not sanctioned by custom or law; unlawful.

Licit permitted by law; legal.

Mortality susceptible to death.

Pharmacokinetics the processes by which a substance is absorbed, distributed, metabolized, and eliminated from the body.

Psychoactive affecting the mind or mental processes.

Reactors or late-onset drinkers begin problematic drinking later in life, often in response to traumatic life events such as bereavement, loneliness, pain, insomnia, or retirement.

Relapse when a person is affected again by a condition that affected them in the past.

Substance abuse the use and misuse of illicit and/or licit substances.

Survivors or early-onset drinkers a continuing problem with alcohol which developed in earlier life.

Relapse and Lapse

*Gillian Steckler**, *Katie Witkiewitz*[§], *G. Alan Marlatt*[†]

[*]Washington State University, Vancouver, WA, USA, [§]University of New Mexico, Albuquerque, NM, USA, [†]University of Washington, Seattle, WA, USA

OUTLINE

Many find that quitting a problem behavior is difficult and that maintaining the behavior change is even more of a challenge. The initial transgression of a problem behavior after a quit attempt, herein defined as a "lapse," could eventually lead to continued transgressions of the problem behavior to a level that is similar to the prequit level of behavior, which is often defined as a "relapse." For example, 40–80% of patients receiving treatment for alcohol use disorders have at least one drink, a "lapse," within the first year of after treatment, whereas fewer than 20% of patients return to pretreatment levels of alcohol use. Most psychological disorders and problem behaviors have very high rates of lapses, with many individuals having multiple "lapses" after treatment or a quit attempt. Thus, it is quite difficult to define the point at which "relapse" occurs and various definitions of relapse can result in practical differences in the interpretation of treatment effectiveness and patient prognosis. Based on the inconsistencies and difficulties in defining relapse, many researchers have proposed to define relapse as a process, rather than a discrete event.

Drawing from this conceptualization of relapse, one of the primary goals of problem behaviors research has been to characterize the relapse process using observable/measurable client characteristics as predictors or determinants of the relapse process. The purpose of this research is to gain a better understanding of predictors in the relapse process to implement relapse prevention. Relapse prevention (RP) is a psychotherapeutic approach that aims to teach clients skills in recognizing and avoiding high-risk situations for relapse through a cognitive-behavioral approach developed by Marlatt. Marlatt's cognitive-behavioral model of relapse prevention has been described as one of the most impressive and functional approaches in the field of addiction treatments.

The goal of this article is to review research on those factors that may predict the relapse process, as well as a review of the relapse prevention approach. We will

also suggest future clinical treatments and research questions pertaining to relapse prevention.

MODELS OF RELAPSE

The majority of people who have gone through treatment for substance addiction will experience some kind of "triggering" event, leading to an initial fall back to the undesired behavior (e.g. substance use), known as a lapse. Research has indicated that the majority of individuals who receive treatment for a substance use disorder will experience a lapse. Among those people who lapse, many are able to follow this with a "prolapse," defined as getting back on track in the direction of positive behavior change. This can be followed by remission, a relatively brief period of time without indulging in the behavior, which is often followed by another lapse cycle.

Cognitive-Behavioral Model of Relapse

Marlatt's cognitive-behavioral model of relapse has been an influential theory of relapse to addictive behaviors. The model defines the relapse process as a progression centered on "triggering" events, both internal and external, that can leave an individual in high-risk situations and the individual's ability to respond to these situations. In this process, after experiencing a trigger, an individual will make a series of choices and thoughts that will lead to being placed in a high-risk situation or not. There are two major types of high-risk situations, those with intrapersonal determinants, in which the person's response is physical or psychological in nature, and interpersonal determinants, those that are influenced by other individuals or social networks.

Starting from the point of confronting and recognizing a high-risk situation, Marlatt's model illustrates that the individual will deal with the situation with either an effective or ineffective coping response. Effective coping skills can lead to increased self-efficacy, and a decreased probability of a lapse. However, if one lacks skills, then the model predicts a decrease in self-efficacy and an increase in positive outcome expectancies for the effects of using the substance. This is a likely predecessor of giving into temptation in the initial use of a substance.

If an individual uses a substance after experiencing a remission, he/she may be vulnerable to the abstinence violation effect (AVE), which refers to an individual's response to the recognition that he/she has broken a self-imposed rule by engaging in substance use or other unwanted behavior. This response often creates a feeling of self-blame and loss of perceived control due to breaking a self-imposed rule regarding substance use. According to AVE research, those who do chose to respond to their behavior with blame and a sense of lost perceived control are more likely to relapse than those who respond by attributing lapse to preventable events and not feeling as though they failed completely. So long as an individual maintains a perceived sense of self-control, he/she has a better chance at evading further lapses. AVE has been studied and supported for the cessation of sex offenses, heroin, marijuana, and other illicit drug use.

Despite the empirical support for many components of the cognitive-behavioral model, there have also been many criticisms of the model for being too static and hierarchical. In response to these criticisms, Witkiewitz and Marlatt proposed a revision of the cognitive-behavioral model of relapse that incorporated both static and dynamic factors that are believed to be influential in the relapse process. The "dynamic model of relapse" builds on several previous studies of relapse risk factors by incorporating the characterization of distal and proximal risk factors. Distal risks, which are thought to increase the probability of relapse, include background variables (e.g. severity of alcohol dependence) and relatively stable pretreatment characteristics (e.g. expectancies). Proximal risks actualize, or complete, the distal predispositions and include transient lapse precipitants (e.g. stressful situations) and dynamic individual characteristics (e.g. negative affect, self-efficacy). Combinations of precipitating and predisposing risk factors are innumerable for any particular individual and may create a complex system in which the probability of relapse is greatly increased.

The revised dynamic model of relapse also takes into account the timing and interrelatedness of risk factors, as well as provides for feedback between lower- and higher-level components of the model. For example, based on the dynamic model it is hypothesized that changes in one risk factor (e.g. negative affect) influences changes in drinking behavior and that changes in drinking also influences changes in the risk factors. The dynamic model of relapse has generated enthusiasm among researchers and clinicians who have observed these processes in their data and their clients.

DETERMINANTS OF RELAPSE

Self-Efficacy

Self-efficacy is an important intrapersonal determinant of relapse and has been shown to be a predictor of outcomes across all types of addictive behaviors, including alcohol use, gambling, smoking, and drug use. Although essential in relapse prevention, measuring

self-efficacy is a challenge, since assessing it is limited within constrained contexts, rather than having the ability to measure it in individual high-risk situations. It is also difficult to use measures of self-efficacy as predictors of relapse because self-efficacy has been shown to be very highly correlated with other intrapersonal determinants of relapse.

When one group of researchers monitored individuals who had been diagnosed with substance dependence and a major depressive disorder, a significant association was established between self-efficacy, life stress, and periods of time to lapse for those who lapsed during the first 6 months in treatment. The study also found that individuals with high self-efficacy levels were able to maintain abstinence from drugs and alcohol for longer periods of time than those displaying lower levels of self-efficacy. Nearly every participant in the study who reported lower levels of self-efficacy experienced a lapse during the early stages of treatment. In addition to self-efficacy, the researchers found that acute stressors nearly tripled the risk of relapse, leading to poorer long-term outcomes for those in treatment.

Chronic stressors may also overlap between self-efficacy and other areas of intrapersonal determinants, like emotional states, by presenting more adaptational strain on the treatment-seeking patient. Chronic stressors are likely to result in depletion of coping skills and resources, which may reduce self-efficacy and leave the individual more vulnerable to high-risk situations. The combination of chronic stress, reduced self-efficacy, and negative emotional states greatly increases the probability of using a substance in a high-risk situation. Like the previously mentioned study, another group of researchers found that it is possible that a decrease of self-efficacy is likely to be influenced by inferior coping strategies, craving, negative affect, depletion of self-regulatory resources, and lack of knowing efficient coping skills. Specifically, these researchers found that the day before an initial smoking lapse, the level of individual self-efficacy plummeted to particularly low levels. At the same time that self-efficacy is falling, coping mechanisms to resist the urge to use may also drop, increasing negative affect and, in turn, increasing the risk of a relapse.

Outcome Expectancies

Outcome expectancies can be defined as an individual's anticipation or belief of the effects of a behavior or future experience. These expectancies greatly influence the behavioral response, depending on the strength and attractiveness of the expected outcome to the individual. Whether or not the substance in question is real, or even a placebo, the expectancy of the effects of the drug plays a major role in personal experience of a drug. Outcome expectancy theory proposes that individuals have expectancies about the drugs they use and that these expectancies are the result of both direct (e.g. memories of using at a party) and indirect (e.g. perceptions of a drug that has been derived from the media) experiences.

Outcome expectancies can be either positive or negative. Positive outcome expectancies, beliefs an individual holds that make a substance or behavior more attractive to the individuals (e.g. "That drink would make me feel relaxed"), are associated with poorer treatment outcomes and are an important component of motivation to drink. On the other hand, an individual's negative expectancies (e.g. "If I use heroin, I will feel awful later on") can motivate the individual to restrain, leading to improved outcomes and lesser risk of relapse.

According to Gwaltney, a clinical-health psychologist focused on smoking cessation, lapses are likely to occur when self-efficacy regarding abstaining is particularly low and when positive outcome expectancies for smoking are exceptionally high, with the influence of expectancies on lapse-behavior dependent on self-efficacy. Gwaltney and colleagues propose that the interconnectedness of outcome expectancies and self-efficacy can be attributed to the fact that they are both influenced by increases in negative affect or craving levels, in turn, increasing positive outcome expectancies and decreasing self-efficacy. While expectancies are related to outcomes, there is little evidence to support the notion that targeting outcome expectancies alone will change overall substance use or behaviors once the individual has left treatment.

Craving

Craving may be the most studied and most poorly understood concept in the field of addiction. Individuals with stronger cravings at admission into treatment are more likely to relapse. However, craving itself has not been shown to be a very strong predictor of lapse episodes. Interestingly, 78% of those who crave alcohol at admission to treatment do not show a diminished level of craving once discharged from treatment. It has been proposed that craving may not be a particularly strong predictor of lapse itself, but that the correlates of craving, including negative affect and decreased self-efficacy could be stronger predictors. Other factors that could be related to craving include perceived availability of a substance during a time of abstinence, symptoms of withdrawal, anticipated physical effects, and outcome expectancies of the drug, and fundamental conditioned responses to drug effects.

Numerous human and animal studies over the past 10 years have added more questions than answers to

the craving literature. For example, recent clinical studies have shown that craving for cocaine during treatment predicts post-treatment cocaine use and that cocaine use is highly correlated with cocaine craving in a person's natural environment, whereas other studies of cocaine craving have not found a significant association between craving and use. Similarly, one group of researchers found that cue-provoked craving predicted smoking lapses, whereas another researcher concluded that there was no compelling evidence to support the association between cue-induced craving and smoking lapses. Cross-substance craving could also be an important predictor of relapse as seen in a recent study which showed that smoking and craving for nicotine were associated with episodes of heroin and cocaine use, as well as craving for heroin and cocaine.

One recent method for managing craving and its correlates incorporates cognitive and behavioral coping skills through urge-surfing and mindfulness-based relapse prevention techniques. Researchers have found that mindfulness-based instructions are associated with significantly less alcohol and drug use after treatment, which is mediated by reductions in craving after the mindfulness-based intervention.

Motivation

Motivation may relate to the relapse process in two distinct ways, the motivation for positive behavior change and the motivation to engage in the problematic behavior. Using the example of alcohol use, we could define the first type of motivation, *motivation to change*, as the stimulus for action toward abstinence or reduced use of alcohol, and the second type of motivation, *motivation to use*, as the stimulus for engaging in drinking behavior. This distinction captures the ambivalence that is experienced by individuals attempting to change their addictive behavior. The ambivalence toward change is often highly related to both self-efficacy (e.g. "I really want to quit drinking, but I do not think that I'll be able to say no") and outcome expectancies (e.g. "I would quit drinking, but then I would have a really hard time meeting people"). With regard to the *motivation to change*, the trans-theoretical model of behavior change provides a framework for understanding motivation to change, defined by five stages of behavior change: pre-contemplation, contemplation, preparation, action, and maintenance. During pre-contemplation, there is very little motivation to change, but as the individual moves toward contemplation there is an increase in ambivalence and "change talk." Interventions that focus on resolving ambivalence (e.g. evaluating the pros and cons of change vs. no change) may increase intrinsic motivation by allowing the client to explore their own values and how they may differ from actual behavioral choices (e.g. "I want to be an effective employee, but I often spend my daytime hours hungover and my evening hours getting drunk."). One such intervention, called Motivational Interviewing (MI), was developed as a treatment technique for enhancing motivation and encouraging positive behavior change. Originally developed for patients presenting with alcohol use disorders, MI has demonstrated efficacy for reducing alcohol consumption and frequency of drinking in this population. Additionally, MI has been successfully adapted and applied to work with a variety of other health behaviors including weight reduction, use of illicit substances, smoking, and HIV risk reduction.

Motivation to use in any given situation is based on the reinforcement value of the outcome in that situation. Similar to outcome expectancies, craving, and self-efficacy, changes in motivational levels may serve as a marker or lapse risk preceding a lapse. This has been illustrated by observed abrupt drops in motivation levels in the weeks before relapse. Although research shows that these drops occur, little research has been conducted in developing measures that look at changes in motivation levels for smokers who have already attempted to quit smoking; most previous measures have been focused on motivation to quit smoking before the smoker has attempted.

Recent measures have been developed and are currently undergoing further analyses to measure abstinence-related motivational engagement (ARME). In previous studies, measures to assess motivation as a predictor in quitting a behavior and staying abstinent have generally been evaluated through single broad motivational items (e.g. on a Likert scale, "How motivated are you to quit smoking?"). Some researchers believe that this approach focuses too much on the desire to remain abstinent, rather than the motivation to put forth the necessary efforts it will require to remain abstinent. In contrast to the former, single-item measures of motivation to stay abstinent, the 16-item ARME scale reflects four themes of an individual's motivation to not use: cognitive effort, focusing, and thinking of staying abstinent; priority in comparison to other issues in the individual's life; vigilance and preparing for high relapse risk situations; and excitement and enthusiasm to remain abstinent. Although this information is new, initial studies for ARME to be used in targeting smoking relapse prevention therapies and predicting cessation results is promising.

Coping

The cognitive-behavioral model of relapse focuses on effective coping as central to RP. Coping skills have been characterized as either cognitive (e.g. urge-surfing) or behavioral (e.g. calling an abstinent friend) and as

either approach (e.g. calling a friend) or avoidance (e.g. avoiding a non-abstinent friend) coping. The behavioral approach has shown to be important in preventing alcohol lapses, while in another study, the cognitive approach was related to lower rates of heroin use relapse.

A 2004 study suggests that individuals with higher approach scores were more likely to be more engaged in treatment, were more willing to disclose lapses, and did as well at improving relapse knowledge as the avoidance-oriented group. The study also proposed that approach-oriented participants may see themselves as more responsible for their actions, including lapse, while avoidance-based coping may focus more on their environment than on their own actions, leading more favorably toward the approach coping method. In a 2007 study, avoidance coping strategies suggested a higher probability of alcohol use, specifically when there is a lack of social or familial support.

There is also support for avoidance-based coping strategies in RP, which are consistent with cognitive-behavioral treatments. While testing for the validity of a new measure for approach and avoidance coping, researchers utilized the Approach and Avoidance of Alcohol Questionnaire (AAAQ). The questionnaire was given to a group of alcohol-dependent individuals, results showing that higher approach scores could be correlated with heavier, more frequent, and more recent drinking, while higher avoidance scores were associated with fewer drinks in the past week and more time elapsed since their last drink.

There are arguments for approach- and avoidance-based coping in RP, but in general, coping skills and their different approaches are useful for changes in substance use, and can also be beneficial in management of stress, sex abuse, and craving. Importantly, it was also found that changes in coping during and after coping skills training programs (including RP-type interventions) did not mediate treatment outcomes. In other words, coping skills are related to outcomes, but changes in coping skills are not a powerful mechanism of treatment change after coping skills interventions.

Emotional States

Substance abuse relapse has been linked to negative affect in a number of studies and negative emotional states were identified as the most salient risk factor for relapse in Marlatt's early work in relapse prevention. Recently, researchers asked whether lapses result in an individual feeling more depressed or angry or anxious. Do changes in negative affect cue an individual to resume drinking? Or perhaps both processes are working concurrently.

Results of the questions posed in research yield support for a dynamic association between negative affect and alcohol use such that changes in alcohol use predicted subsequent changes in negative affect and changes in negative affect predicted subsequent changes in alcohol use. Results also suggest that reducing negative affect after alcohol treatment can increase an individual's chance of staying sober, or returning to sobriety after a brief lapse.

Placing significance on successful affect regulation to prevent relapse is a main theme in addiction treatment. For Alcoholics Anonymous (AA), individuals learn skills in coping, motivation, self-efficacy, social changes, and spirituality; however, anger is exclusively tagged as a high-risk emotion for relapse to alcohol. While examining anger as a predictor of relapse, researchers of a 2010 study found that anger levels at intake were found to be significantly higher than those of the general population. The mean score measuring anger for the group was in the 98th percentile, dropping to the 89th percentile 15 months preceding initial intake. It is worth noting that those who score above the 75th percentile are likely to experience anger intense enough to interfere with relationships, psychological and physical disorders, and psychosocial functioning. These factors stemming from a negative emotional state are prone to having a negative effect on self-efficacy, motivation, positive outcome expectancies, coping skills, and interpersonal determinants of lapse. Although emotional state is not a significant lone predictor of lapse, the findings suggest that treating depressive, negative affect symptoms after a lapse may be crucial to cessation.

Interpersonal Determinants

Interpersonal determinants include the social support system, level of perceived emotional support, and peer pressures to use substances. Without a proper support group, which should consist of high levels of high-quality support, an individual is likely to relapse. Positive, high-quality support networks are highly predictive of long-term abstinence rates. Sources of support are most commonly found in family, a spouse, friendships, and coworkers.

While many families can find addiction difficult to deal with, negative family behaviors such as withdrawing from a family member with a substance use disorder or avoiding dealing with the substance use is actually associated with more drinking. As challenging as it may be, good family functioning and adjustment are related to more positive substance use outcomes. This is also connected to spousal relationships. Although positive spousal behaviors are associated to more positive substance use outcomes, negative behaviors have a contrary effect. In a marital relationship, predictors for positive substance use outcomes include marital happiness, having a better-functioning marriage before

treatment, and being a married male. Predictors of negative outcomes include marital dissatisfaction, marital events, and negative spousal factors and behaviors.

In general, encouragement from friends and coworkers is also related to positive substance use outcomes. In addition to encouragement, other positive factors include surrounding oneself with more nondrinking friends and abstinent coworkers. On the other side of this, having more drinking or using friends, having just one friend who uses the same drug, and having a social network with higher stress levels are indicators of negative outcomes.

In addition to familial, marital, friend, and coworker relations, research also suggests that community-based support services, such as recovery communities, enhance outcomes for those struggling with cessation once treatment has been completed. In these peer-support communities, members of the group share their experiences and help one another cope with the issues, including minor lapses while maintaining a healthy, abstinent social network and enhancing their chances at recovery and abstinence. If a major lapse occurs, recovering peers are not expected to treat the individual; rather, he/she will be readmitted into treatment and invited back to the community when the level of recovery is appropriate.

Unfortunately, the relationship between substance treatment outcomes and interpersonal determinants is not clear-cut. Interpersonal relationships and support systems are highly influenced by intrapersonal processes such as emotion, coping, and expectancies, which is why some have suggested an extension of the Witkiewitz and Marlatt model of relapse which posits ways in which interpersonal behavior may influence their social network and vice versa.

RELAPSE PREVENTION

RP aims at educating the patient about the relapse process, likelihood of relapse, and how to provide ways to make it through attempts at giving up the problem behavior. Educating a treatment-seeking individual includes ongoing assessment of specific high-risk situations that may jeopardize an individual's attempt to maintain a treatment goal. These high-risk situations are identified through assessment of interpersonal, intrapersonal, and environmental factors, as an assessment of withdrawal and craving (physiological risks for relapse). Although these high-risk scenarios cannot always be planned for, educating the patient is aimed at helping him/her prepare for a high-risk situation through behavioral skills training and cognitive interventions aimed at limiting the occurrence of a lapse episode. Once high-risk situations are acknowledged, patients learn to identify and modify coping skills used, in turn, reinforcing self-efficacy. The application of new, superior coping skills greatly increases the likelihood of not only achieving, but also maintaining abstinence from the externalized behavior.

Effectiveness and Efficacy of Relapse Prevention

A meta-analysis of RP based on 26 controlled trials suggested RP was particularly effective for decreasing alcohol and multiple substance relapse, with somewhat weaker effects for smoking cessation. Relapse prevention is not only effective for alcohol and drug studies, it is also effective in the treatment of depression, sexual offenses, erectile dysfunction, obesity, eating disorders, panic disorders, obsessive compulsive disorder, schizophrenia, bipolar disorder, gambling, cocaine abuse, and marijuana use.

In these cases, RP has been proven to be more effective than no treatment at all, and equally effective as other treatments (e.g. supportive and interpersonal therapies). RP may also provide continued improvement over a longer period of time when compared with other treatments. In recent meta-analyses, the effectiveness of cognitive-behavioral RP therapy across studies were examined, while controlling for cross-study differences in target substance use, sex of the patient, format of treatment (group vs. individual), concurrent treatment, duration of the intervention, and long-term effects. Results of the study indicated cognitive-behavioral interventions (including RP) may be best suited for marijuana use disorders, with women, when provided in a brief format, and when used in combination with psychosocial treatments. These researchers have also found that the intervention proved equally effective when presented in a group or individual format.

PHARMACOTHERAPY APPROACHES TO RELAPSE PREVENTION

Nicotine-Replacement Therapies and Prescription Smoking Cessation Aids

Nicotine-replacement therapy (NRT) aids in the cessation of cigarette smoking by reducing physiological withdrawal symptoms (e.g. depression, trouble sleeping, irritability, anxiety) and craving, thus reducing motivation to smoke and increasing the likelihood of remaining abstinent. The amount of nicotine in NRTs is enough to increase levels of dopamine and norepinephrine, which are thought to provide the pleasurable effects of smoking cigarettes, as well as reduce withdrawal symptoms and craving. Prescription smoking cessation aids, including bupropion and varenicline,

act as dopamine reuptake inhibitors, associated with increases in extracellular dopamine and norepinephrine levels. These chemicals mimic nicotine reinforcement while alleviating symptoms of withdrawal, making nicotine withdrawal and craving easier to manage.

Cessation Aids for Alcohol Dependence

The most common cessation aids for alcohol dependence are acetaldehyde dehydrogenase (ALDH) inhibitors, and opiate antagonists. Disulfirum is an ALDH inhibitor that, when mixed with alcohol, causes a buildup of toxic acetaldehyde resulting in flushing, headache, nausea, vomiting, chest pain, weakness, blurred vision, sweating, choking, respiratory difficulty, as well as mental confusion and anxiety. It is primarily used because of its unappealing reaction when introduced to alcohol, but also increases dopamine concentrations causing some individuals to report a decrease in alcohol craving. Disulfirum has become a key component in preventing lapse and relapse for many patients due to alcohol avoidance. Other alcohol-cessation drugs, such as naltrexone, block opioids from the "rewarding" pathways of the brain, neutralizing positive responses, making drinking less gratifying, and making it easier to stop using alcohol. Due to fewer reward responses, craving is reduced and patients are less likely to relapse to heavy drinking. Acamprosate is the latest drug to be approved by the FDA for alcohol dependence treatment. Results of numerous studies suggest that acamprosate may function by relieving some of the withdrawal symptoms of alcohol dependence and lessening the likelihood of lapse and relapse. Results show consistent improvement in abstinence rates and duration of abstinence when combined with psychosocial interventions.

Illicit Drug Cessation Aids

The most successful pharmacotherapies for the prevention of illicit drug relapse have been opioid substitution treatments developed for opiate dependence, including methadone and buprenorphine. Opioid substitution treatments provide a safer alternative to heroin and other opioids (e.g. oxycodone or hydrocodone, which are legal and prescribed for pain, yet widely available on the street for recreational use). At lower, prescribed doses, cessation aids give addicted individuals the opportunity to abstain from opioids without experiencing the severe withdrawal symptoms that often lead one to lapse and relapse.

The knowledge of pharmacotherapy for addiction is constantly growing and many new cessation drugs are being investigated. Importantly, all of these pharmacotherapies have potential side effects and are not effective for everyone. Furthermore many studies have shown that many of the medications described above are most effective when combined with psychotherapy.

Glossary

Abstinence violation effect (AVE) an individual's response to the recognition that he/she has broken a self-imposed rule by engaging in the problem behavior, creating a feeling of self-blame and loss of perceived control. Individuals who respond in this manner are more likely to relapse than those who attribute lapse to preventable events that are controllable.

Craving an intrapersonal determinant of relapse of addictive behaviors; wanting more of something (e.g. alcohol, a drug).

Lapse the initial transgression of a problem behavior after a quit attempt.

Relapse continued transgressions of a problem behavior to a level that is similar to the prequit level of behavior; a process, rather than a discrete event.

Self-efficacy the belief in one's capabilities to achieve a goal or an outcome or the belief in one's ability to succeed in specific situations; an intrapersonal determinant of relapse and shown predictor of outcomes across addictive behaviors.

CHAPTER

14

Natural Recovery

Tony Toneatto

University of Toronto, Toronto, ON, Canada

OUTLINE

INTRODUCTION

Traditional conceptual models of addictive behavior have stressed their chronic, progressive, and unremitting nature. Among many expressions of this perspective, the disease model of addiction, whether reflected in the self-help emphasis on the spiritual aspects of addictive disease, or the more recent, neuroscientific view of addiction as a "brain disease," the assumption is that addiction is mediated by basic deficiencies in brain, mind, or spirit. In the absence of treatment, and left to its own natural course, death, disability, and deterioration are the inevitable outcomes. Without the active intervention of professionals, within the context of formal treatment, the assumption is that a durable recovery would be highly unlikely. Such views of addiction and its resolution have also generally been held by the general public. This model of addictive behavior and recovery, based on the study of individuals with severe dependence or who have been in formal treatment programs, and an emphasis on lifelong abstinence, leaves little space for alternative approaches and outcomes. As a result, a bias arguing against the possibility of natural recovery from addiction has resulted. This chapter will review the recent empirical literature describing what is known about individuals who recover from addiction without formal psychological treatment. Although the majority of the research has focused on the abuse or dependence on alcohol, studies of natural recovery among other psychoactive dependencies and pathological gambling will also be cited.

The assumptions of the disease model have been seriously challenged in the past several decades with an accumulating body of empirical research demonstrating that recovery from addiction may commonly occur in the absence of formal treatment and that such recoveries do not always lead to abstinence. Viewing addiction problems on a continuum of severity ranging between mild and severe dependence opens the possibility that there may be multiple approaches to resolution of addiction and goals other than total abstinence.

Natural recovery (or spontaneous remission, natural remission, untreated remission, spontaneous recovery, maturing out, self-change, auto-remission), the notion that the resolution of a serious addictive problem could occur in the absence of professional treatment and an adherence to abstinence, is one of the "taboo" topics in addiction treatment. Indeed, the presence of an addiction could only be verified if the individuals could not stop on through their own efforts. If one could cease an

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00014-0

addictive behavior, then it is unlikely that they were addicted in the first place. Such tautological reasoning served as "blinders" to the empirical literature by demonstrating the successful recovery by individuals who would be considered to be dependent on psychoactive substances by any diagnostic criteria. Although reports of recovery that did not conform to the received opinion had been available in the research literature, these did not significantly alter the basic view that addiction was a chronic, progressive disease that would ultimately lead to destruction and death unless remediated through professionally mediated interventions. The conviction with which this attitude has been held by generations of clinicians and researchers is perplexing when it is considered that the vast majority (over 80%) of individuals with nicotine addiction, for example, have recovered without formal treatment and that the rates of lifetime addiction are not matched by similar rates of lifetime treatment seeking.

The natural recovery research has also challenged the conventional notion that the control of the addictive process lies largely outside the volitional control of the individual. Overcoming addiction, within the traditional perspective, requires that the individuals surrender personal control over the addictive process to the influence and variables beyond them (e.g. a medication, Higher Power, God, therapist, physician, group process) and that the individuals' control lies primarily in the insight that such surrender is necessary. Without the intervention and assistance of a transcendental influence, the individuals cannot make therapeutic progress and durable recovery is thus unlikely. This assumption has been strongly challenged by the extensive natural remission and problem-solving therapy (i.e. cognitive-behavioral therapy) literature which has unequivocally and empirically demonstrated that individuals with substance dependencies do remain able to choose among a range of alternative resolution strategies (e.g. 12 Step programs, medication, residential treatment, outpatient therapy) including recovery without treatment even in the midst of an addictive process. While the severity of the addiction may make it less likely for an individual to choose natural recovery, such a choice remains a possibility and is often the first choice. It has been argued that formal addiction treatment is only sought if efforts to stop on one's own are unsuccessful.

In summary, although early studies of untreated recovery were controversial for their conflict with the traditional concept of addictive processes, the consensus today suggests that not only may natural recovery be the most common pathway to the resolution of an addiction, but that this process occurs across all addictive behaviors, substance-based or behavioral (e.g. pathological gambling). Self-recovery has been demonstrated for several psychoactive substances, including alcohol, cigarettes, cannabis abuse and dependence, cocaine, and other drugs. Individuals with behavioral addictions, such as problem gambling, have also been shown to recover without formal treatment. The Institute of Medicine (1990) has identified and supported natural recovery as an empirically supported route to recovery.

VALUE OF NATURAL RECOVERY RESEARCH

Apart from the scientific interest in studying untreated remission as a valid pathway to addiction recovery there are several clinically relevant reasons for studying this phenomenon. Firstly, what constitutes truly effective treatment is yet to be defined. Formal, professional treatment continues to evolve and no treatment is reliably and durably effective. The results of Project MATCH have demonstrated how difficult it is to successfully match treatments to individuals. In the absence of a therapeutic "cure" for addiction it behooves the clinical addiction research community to continue to deepen our understanding of the variables that lead to the resolution of an addiction problem. Furthermore, treatment seeking occurs for only a small proportion of all those who develop a clinically significant addiction. Indeed, the vast majority of addicted individuals never seek treatment. Recent comprehensive reviews of natural recovery have shown that addicted individuals may avoid treatment because they fear the associated stigma (a variable that may help account for the reluctance of some minority groups and women to seek treatment), believe their problem is not sufficiently severe to merit professional treatment, or have a preference to resolve their addiction problem on their own, relying on their personal resources. Thus, knowledge of the processes that mediate this increasingly common pathway to addiction recovery may improve interventions for individuals who wish to resolve without professional treatment.

In addition to the necessity of continuing to understand recovery, regardless of how it occurs, and of deriving a coherent scientific theory of untreated recovery, the elucidation of the variables that facilitate and maintain such behavior change may have important implications for the delivery of professional treatment, prevention strategies, and public policy. Clinicians can integrate the insights derived from the natural recovery literature into their formal interventions; prevention and awareness strategies can be developed based on the change processes that have been shown to trigger natural recovery; public policy can make this information available to a wider population of addicted individuals through a variety of means (e.g. web-based).

RATES OF NATURAL RECOVERY

Several studies in recent decades have repeatedly demonstrated that significant numbers of individuals with substance dependencies recover without ever receiving formal treatment. That such recoveries occur is no longer surprising or controversial. Epidemiological surveys of American adults found that almost three-quarters of those with alcohol dependence who had remitted in the previous year had done so without receiving professional help. These rates were similar to the rates among older adults (aged 51–65). Other research has found that as many as one out of five college students with a history of adolescent binge significantly reduced their alcohol consumption of drinking while still in college and without treatment.

The duration of the recoveries reported in these studies were neither transient nor unstable. An average of about 6 years has been reported across different psychoactive substances indicating that these recoveries are durable and sustained. Since a period of about 5 years is considered a stable recovery, with or without treatment, the length of recovery reported in spontaneous recovery studies suggest that these recoveries are not a mere respite from an ongoing addictive process. However, it should be noted that some studies have shown that the recovery from the primary substance does always mean that the individual is abstinent from all psychoactive substances and may thus be associated with the continued use or abuse of another substance (e.g. of alcohol in a sample of naturally recovered cocaine and heroin users).

REVIEW OF THE NATURAL RECOVERY LITERATURE

In their seminal review of 38 natural recovery studies (comprising 40 samples) dating back several decades, from 1960s to 1998, Sobell, Ellingstad, and Sobell (2000) found that the methodological quality of the research was generally poor. In general, early studies failed to describe their samples adequately, did not describe pre-recovery substance histories and severity in sufficient detail, failed to assess factors associated with the maintenance of recovery, ignored the complicating factor of concurrent psychiatric psychopathology, did not corroborate subject self-report, or assess family history of addiction. The vast majority (75%) of earlier studies addressed the spontaneous recovery from alcohol (not unusual since this substance is the most abused in western culture), followed from heroin (22.5%) and cocaine (7.5%). Advertisements (38.5%) were the most common way these subjects were recruited, followed by snowballing techniques (28%) and surveys (23%). The samples surveyed were generally male (69%), unmarried (64%), and unemployed (45%) with a mean age of 34.4 years at the time of their recovery.

Recently, Carballo et al. (2007) updated the Sobell et al. (2000) review. Twenty-two natural recovery studies were published in the 7 years following Sobell et al. (2000). Similar to the earlier review, the Carballo et al. study (2007) found that the majority of the 22 studies addressed natural remission from alcohol (82%) followed by cannabis (32%), heroin (23%), and cocaine (23%). Surveys (45%) and media solicitation (41%) remained the most common ways to recruit subjects. The demographic profile across both reviews was quite similar. Men continued to be the majority of individuals recruited into natural recovery studies, with a mean age in the early 40s, likely reflecting the higher prevalence of addiction among men. The Carballo et al. (2007) review found that the length of the addiction prior to natural recovery was approximately 13 years (compared to 11 years in the Sobell, et al. (2000) review). The mean length of the natural recovery was 8 years in the Carballo et al. (2007) review compared to 6.3 years in the earlier review. Abstinent outcomes continued to be reported by over half the sample in both reviews (57% versus 60%, respectively). Family-related reasons (54.5% of studies) with health (50%) followed by financial concerns (50%) were the most common explanations for the decision to recover from the addiction in the Carballo et al. (2007) review while health-related reasons were cited as the most important factor in the older review. The most common factors maintaining natural recovery reported in the Carballo et al. (2007) were social (54.5% of respondents) and family support (45.5% of respondents), similar to the 2000 review. About a third of the respondents reported avoidance of the addictive substance, self-control, and spirituality as important maintenance factors.

In their assessment of the quality of the natural recovery research since 2000, Carballo et al. (2007) noted that socio-demographic variables at the time of the recovery continued to be underreported (compared to these variables at the time of the interview, which generally tended to be well-reported). In other words, a clear understanding of the sample at the time of the recovery was generally lacking. Insufficient research examining the relationship between natural recovery from multiple substances has been conducted and remains a neglected area of research. Naturally recovered individuals tended to have had a less severe addiction with less severe consequences than did treated populations, a finding that has been repeatedly substantiated empirically.

The study of natural recovery from nonalcohol substances remain in the minority. The association between natural recovery and psychiatric comorbidity remains unclear although in a recent study alcohol natural recovery was equally prevalent among nonpsychiatrically comorbid or comorbid individuals suggesting that the presence of Axis I disorders was not a negative prognosis for untreated recovery from alcohol dependence. However, this should not be interpreted to mean that all natural recovery samples are similar. For example, three subgroups of naturally recovered populations have been delineated: low dependence/few alcohol problems/low social support; high dependence/several alcohol problems/moderate social support; low dependence/high social support/few alcohol problems. Such complexity precludes any simple description of naturally recovered populations.

PROCESS OF NATURAL RECOVERY

Having established the frequent occurrence of natural recovery, an issue of great interest is the trigger or reason for such transformations and the variables that may maintain such recovery. There appears to be a growing consensus that a cognitive process mediates natural recovery. In response to the debilitating effects of addictive behavior on their physical and mental health, relationship with significant others, and financial status, individuals undergo a process of rational re-evaluation of their substance use, weighing the advantages and disadvantages of continued use. Over time, the outweighing of the positives of substance use through the accumulation of negative consequences leads to a reconsideration of the benefits, value, and advantages of continued substance use. When the decisional balance tips irrevocably toward aversive effects, the individual is more likely to decide to make efforts to cease use. There are several models of cognitive change that are applicable to this decision-making process such as the Trans-theoretical Model of Change and Conflict Theory. However, little is known about what contributes to the defining decisional moment that leads to stable behavioral change.

This cognitive process mediating natural recovery is to be distinguished from recoveries triggered by the occurrence of discrete, highly salient, negative consequences, such as a stressful life event (e.g. severe illness, loss of relationship, major injury), that leads to a rapid decision to cease use. While these types of events certainly play a role, cognitive reappraisals appear to be the more common process and have been observed in the recovery from cocaine, heroin, and alcohol addiction as well as behavioral addictions such as problem gambling. In a qualitative analysis of recovery narratives among alcohol, cocaine, and heroin subjects, the following 11 major categories of reasons for recovery were identified: cognitive evaluations/assessments, behavior monitoring/action statements, problem-related reasoning, dramatic events, references to others/statements of support, health, religious attributions, time-frame, affect-related statements, alcohol-related statements, references to illicit/licit drugs. The most common reasons allude to an ongoing examination of the effects of the addictive behavior on the individuals' functioning. Evidence for a role of cognitive re-evaluation (versus discrete events) has implications for community-level interventions in which evaluation of the pros and cons of substance use is facilitated as a means of shifting the individual's attitude toward the substance in the direction of the cessation or reduction.

MAINTENANCE OF NATURAL RECOVERY

The maintenance of natural recoveries has received less empirical study. The few studies that have investigated this aspect of recovery have identified the critical role of social support from significant others. This finding replicates what is already known about the maintenance of recovery among treated samples. In the case of natural recovery from drug abuse, there is also a "geographic" change in which the individual avoids social and physical environments associated with drug use. The role of social capital, defined as the resources, available to an individual as a result of the availability of a network of mutual relationships, in the maintenance of untreated recovery can provide sources of social control, family support, and extra-familial benefits. Taking into consideration the individual's social capital necessarily directs our attention to the broader social context of recovery and the role that structured social relations play in overcoming drug-use related problems without treatment. How nonaddicts respond to the individual recovery and whether such responses can facilitate the recovery requires additional study. In a study of naturally recovered opiate addicts, the importance of social and familial relationships, gratifying leisure activities (e.g. hobbies), and employment in the maintenance of behavioral change were identified as critical to the maintenance of recovery. A conventional lifestyle that brings structure to one's life was considered crucial in establishing a successful recovery. It has been suggested that natural remission from drug dependence, in contrast to alcohol dependence, often requires a radical modification of their social network and way of life. Naturally

recovered alcohol abusers are more likely to return to a previously existing conventional lifestyle.

METHODOLOGICAL ISSUES

Natural recovery studies have been divided into two major types: those that investigate the variables associated with the onset and maintenance of natural remission (and which may include control groups) and those that estimate the prevalence of natural remission. The two classes of studies are complementary as the latter research provides the estimate of how widespread natural recovery is while the former elucidates the psychosocial variables that contribute to natural recovery. In recent years, general population studies have reduced their reliance on solicitation techniques based on snowballing or media thereby reducing the biases of self-selection. Studies that have relied on media recruitment may recruit individuals who are different than those who do not respond to media solicitations (e.g. less dependent). The variability of what is considered an alcohol problem (e.g. dependence, abuse, self-report) (not described in 40% of the studies reviewed by Sobell et al. (2000)) remains a serious weakness of the earlier literature. This variable is an important descriptive variable since, for example, natural remission may be correlated with the severity of the alcohol problem. This was demonstrated in a study where those with only one alcohol-related problem had elevated rates of natural remission (87.5%) compared to those who reported six alcohol-related problems (53.7%).

The definition of what constitutes treatment has varied across studies. This issue has been further complicated by the fact that the benefits of formal treatment may not always be correlated with the number of sessions attended. There is strong evidence that even very brief professional contacts, as may often occur in the offices of physicians, can have a significant impact on patients' behavior. In some studies of natural recovery, some subjects have even reported receiving formal treatment but have adamantly maintained that these treatments did not affect their recovery. In other cases, especially when natural recovery over the life span has been examined, formal treatment may have occurred years prior to recovery. Thus, studies that allow very minimal treatment contact, including self-help groups (i.e. two meetings), may describe a different sample of natural recovery than do studies that rigidly exclude any treatment contact whatsoever, including attendance at self-help groups. Many studies unfortunately combine individuals with a treatment history with those without such a history. In recent years, a stricter, more conservative definition of treatment has been employed and data separated for those with a positive history from those with no history. Naturally recovered samples with a history of formal treatment are not equivalent to those with no, or very minimal, histories of professional treatment. Typically, those with a history of treatment have more severe addiction problems than those without any treatment history.

NATURAL RECOVERY FROM PROBLEM GAMBLING

Although identified as an impulse disorder in DSM-IV the key symptoms defining this disorder and the recommended treatment approaches bear a very strong resemblance to substance use disorders. Not uncommonly, gambling is considered an addictive disorder among the professional community and the general public. Since the prevalence data suggest that the population of individuals who have a mild to moderate gambling problem may be much larger than those with a more severe problem, natural recovery as a common and preferred pathway to recovery requires additional study.

There have been a number of studies that have investigated the natural recovery from pathological or problem gambling. Not surprisingly, natural recovery from problem gambling appears to be highly comparable to that observed for substance use disorders. Several sources of evidence suggest that recovery from a gambling problem may not always be mediated through contact with the formal treatment system but rather reflect natural recovery processes paralleling those found with untreated recovery from substance dependencies. As has also been the case with substance use disorders, epidemiological studies of gambling prevalence frequently identify significant numbers of "former gamblers." For example, over a third of lifetime gamblers surveyed reported no problems in the previous year but did not report having received treatment. Similar results have been reported in American and Australian population surveys. In addition to the epidemiological evidence, the number of treatment-seeking gamblers is often considerably below what would be expected based on the point prevalence data. The National Gambling Impact Study Commission (1999) has estimated that less than 3% of pathological gambling had participated in formal treatment. Clearly, a substantial number of problem gamblers do not resolve this impulse disorder through formal treatment.

Similar to untreated recovery from addictions, natural recovery from problem gambling appears to involve a cognitive evaluation process focused on the detrimental impact of gambling on the individuals' core values as well as an accumulation of gambling-related negative consequences. Negative emotional

states, financial crisis, interpersonal distress, and conflict have been identified as frequently mentioned reasons for resolving the gambling problem in several studies. Change strategies reported by naturally recovered problem gamblers included staying from social situations and environments where powerful gambling triggers may be present, avoiding gambling locations, instituting desirable lifestyle change, and remaining aware of gambling-related negative consequences. Stimulus control, development of gambling-incompatible lifestyle, reduced access to money, and awareness of gambling-related negative consequences have been identified in many studies as the most common change maintenance strategies following recovery. The majority of naturally recovered gamblers, unlike what has been reported in the substance use literature, choose abstinence. Untreated, naturally recovered gamblers appear to have a less severe gambling problem than do treated gamblers. Gambling severity was found to predict treatment entry with less severe problem gamblers more likely to prefer natural recovery. Treated gamblers were found to have had a longer problem gambling duration, greater gambling severity, more numerous symptoms of gambling (e.g. feelings of despair, panic, suicide), and more gambling-related negative consequences (e.g. family, health) compared to the untreated but recovered gamblers.

In summary, the severity of problem gambling may be the main variable distinguishing those who choose to recover from gambling without treatment. Most studies of gambling natural recovery, like those of substance dependence, identify a crisis in self-image or values as accompanied by multiple gambling-related negative consequences as precipitating a re-evaluation process of the role of gambling in their lives.

CONCLUSIONS AND FUTURE DIRECTIONS

Untreated recovery from addictive behavior has been demonstrated to be a common pathway across all addictions. The results of a diverse set of methodological approaches have shown this recovery process to be robust. Several approaches to identifying naturally recovered individuals (e.g. population surveys, media solicitation, surveys, snowballing techniques) have shown substantial rates of recovery from alcohol and other drug problems without ever receiving formal treatment or attending self-help groups. Such recoveries have been shown to generally be triggered by cognitive appraisals of the cost and benefits of substance use. That is, addicted individuals reach a point in their addiction career in which they can no longer continue or justify addictive behavior. While specific events may be associated with the final decision to quit or reduce significantly, it is clear that a parallel cognitive process has been active for which the triggering event has been the definitive one. Such cognitive processes are likely present in all individuals caught in the addictive cycle and can ultimately lead to recovery as the benefits or advantages of substance use outweigh the decided disadvantages and risks.

Most evidence suggests that naturally recovered individuals are less severely dependent than those who recover with formal assistance. A review of the natural recovery research literature came to the following conclusions regarding the study of natural recovery (and applicable to the study of natural recovery from problem gambling as well). It was suggested that future research should focus on the following: ethnic subgroups (e.g. Asian), high-risk groups (e.g. aboriginals) and other minorities, individual differences characterizing those who recover without treatment, and gender differences. Major reviews of the natural recovery literature have also called for the study of subgroups within naturally recovered samples acknowledging that this population is not heterogeneous. Thus, future research should continue to explore individual differences in natural recovery in order to determine which subpopulations of substance dependence are likely to adopt natural recovery. Such information will be critical in developing targeted prevention and public health programs to reduce the incidence of substance abuse and dependence.

Gender Differences

Susan Nolen-Hoeksema
Yale University, New Haven, CT, USA

OUTLINE

GENDER DIFFERENCES IN ALCOHOL USE AND RELATED PROBLEMS

Dozens of studies done across many countries and cultures of the world have established that men are more likely to drink alcohol than women, men drink a greater volume of alcohol than women if they drink at all, and men are more likely to show behavioral problems as a result of alcohol use than women. For example, analyses of data from 35 countries by the GENACIS project (Gender, Alcohol, and Culture: An International Study) show that drinking and high-volume drinking were consistently more prevalent among men than among women, whereas lifetime abstention from alcohol was consistently more prevalent among women. Among drinkers, women in all age groups were consistently more likely than men to have stopped drinking. The size of the gender ratios, and the absolute amount of drinking, varied considerably across country. For example, rates of heavy episodic drinking ranged between 91 and 62% of male and female drinkers, respectively, in Ireland and to 22 and 11% of male and female drinkers in Israel. Still, men evidenced more drinking and related problems than women in all age groups in almost all countries.

Gender differences in alcohol misuse disorders are also consistently found. In the United States, the National Comorbidity Survey (NCS), which surveyed over 8000 adults under 55 years of age, estimated that, at some time in their lives, 12.5% of men and 6.4% of women will meet the criteria for alcohol abuse, and that 20.1% of men and 8.2% of women will meet the full criteria for alcohol dependence. Similarly, the National Longitudinal Alcoholic Epidemiologic Survey (NLAES), which had a nationally representative sample in the United States of 42 862 adults 18 years of age and older, and used DSM-IV criteria to diagnose alcohol dependence, found a lifetime prevalence for alcohol dependence of 18.6% for men and 8.4% for women. Although most cross-national studies have examined gender differences in problems related to drinking rather than diagnosed alcohol misuse disorders per se,

http://dx.doi.org/10.1016/B978-0-12-398336-7.00015-2

in those that have examined diagnoses, males are more consistently more likely than females to meet criteria.

Some studies suggest that, in recent decades, the gender difference in drinking and alcohol-related problems has decreased. For example, retrospective data from the NCS suggest that there has been a convergence in recent decades between men and women in their probabilities of alcohol use and problems, with both genders showing earlier onset of drinking and symptoms of alcohol use disorders in more recent cohorts than in cohorts born a few decades ago. Cross-sectional data from surveys of high school students in the United States from 1975 to 2001 suggest that the gender gap in the prevalence of binge drinking (five or more drinks in a row) decreased from 22.6% in 1975 to 12.3% in 2001. The typical explanation for this convergence is that females are drinking more and having more related problems in recent years, due to decreases in social pressures against drinking by females. Analyses of data from a longitudinal study of women from 1981 to 2001 provide mixed support for this explanation, at best. Researchers found increases over time in the percentage of women who drank at all. There were also increases over time, however, in abstinence and declines in heavy episodic drinking among women. Moreover, although the size of the gender gap in alcohol use and related disorders may be decreasing, women still consume significantly less alcohol and are less likely to manifest alcohol-related problems than men.

The comorbidity between alcohol misuse disorders and diagnoses of depression, anxiety disorders, eating disorders, and borderline personality disorder is higher for women than for men. The comorbidity between alcohol misuse disorders and antisocial personality disorder is greater for men than for women.

SOCIAL CONTEXT FOR MEN'S AND WOMEN'S DRINKING

For both men and women, drinking is often a social activity, but the social context for drinking differs somewhat for men and women. For men, drinking often occurs in the context of peer or work relationships (i.e. going to a bar with buddies or coworkers to relax and have a few). This social activity appears to strengthen these relationships and serve as a means of social support. Although women also drink with friends and coworkers, heterosexual women's levels of drinking are particularly strongly tied to husbands' or male partners' levels of drinking. Women problem drinkers are more likely to be married to male problem drinkers than male problem drinkers are to be married to women problem drinkers. This may be due to the fact that there are more male problem drinkers than there are women problem drinkers. But when a husband's and wife's drinking patterns are discrepant, there is more general discord in the marriage. A movement toward more similar drinking patterns in a couple may be reinforced by the resolution of marital discord. A fascinating twin study provided evidence that marriage does affect how women drink: Andrew Heath and colleagues found that genetic factors were more strongly related to women's drinking patterns if they were unmarried than if they were married, suggesting that marriage exerted a significant effect on women's drinking patterns over and above the effect of their genetic heritage.

BIOLOGICAL CONTRIBUTORS TO THE GENDER DIFFERENCE

The universality of the gender difference in alcohol use and problems suggests that biological factors may play a role. Differences in the effects of alcohol on intoxication in women and men, and genetic factors, have been argued to contribute to the gender difference in alcohol and related problems.

Effects of Alcohol in Men and Women

After an equivalent dose of alcohol, women have higher blood ethanol levels than men. This may lead women to drink less and thus to show fewer alcohol-related behavioral problems and be less likely to develop tolerance to alcohol than men. Women's higher blood ethanol levels at a given dose may occur because women are generally smaller than men, or because women's body water content is smaller than men's per kilogram of body weight, leading to greater amounts of alcohol being passed through the stomach and into the blood stream in women compared to men. Also, gender differences in the metabolism of alcohol may lead to gender differences in blood alcohol concentrations following a given dose. In the stomach, alcohol is metabolized with the enzyme gastric alcohol dehydrogenase (ADH), which helps to breakdown the alcohol. Gastric ADH activity is lower in women than in men; one study found that for a given alcohol dose, men's ADH levels were two times higher than women's, and in turn, women's blood alcohol levels were higher than those of men.

Genetic Risk

Family history, adoption, and twin studies all suggest that genetic factors play a role in alcohol use problems and disorders. Some studies have suggested that this role is greater for men than women, although not all do. For example, some twin studies find stronger effects

of genetic factors in the risk of alcohol use disorders in men than women, although others find no gender difference or even a modestly higher heritability for women than for men. A review of twin studies of the genetic influences on alcohol consumption patterns (rather than alcohol use disorders) by Andrew Heath concluded that genetic factors are as important in women as in men for measures of frequency and quantity of consumption, typical weekly consumption, and frequency of excessive drinking, usually defined as having five or more drinks in one drinking bout.

Inconsistent results across studies may be due to methodological differences. Several studies have had relatively small samples of women with alcohol-related problems, due in part to the lower prevalence of these problems in women, and thus have had low statistical power to test hypotheses. Others have relied on records of hospitalization for alcohol use disorders or other social indicators of severe alcohol problems (e.g. drunk-driving arrests) to identify alcohol-related problems in study participants. Such methods detect only the most severe alcohol-related problems, which are more likely among men. Other studies have focused on treatment-seeking individuals, when women are less likely to seek treatment for alcohol-related problems than men.

Summary of Biological Contributors

Although genetic factors could contribute to greater involvement in alcohol for men than women, the evidence is inconsistent. More likely, the greater effects of a given dose of alcohol on women's blood alcohol levels and intoxication compared to men's likely play a role in women drinking less than men.

PSYCHOSOCIAL CONTRIBUTORS TO THE GENDER DIFFERENCE

Cross-cultural differences in the amount of alcohol use in men and women and the size of the gender difference suggest that psychosocial factors may also play a role. The gender difference in alcohol use has been attributed to differences in social norms for alcohol use in men versus women and gender differences in the presence of psychological risk factors for alcohol misuse.

Gender Norms and Roles

Social norms in most cultures permit alcohol use more for men than for women. For men, drinking can serve as a demonstration of their masculinity, their nonconformity, their willingness to take risks, and their superior status. Women who drink, however, are viewed in some cultures as less moral and responsible, more sexually promiscuous, and more sexually vulnerable. Women's drinking is often seen as a threat to their roles as mothers and as the purveyors of "family values." Women are aware of these norms and, to a large extent, enforce them. In a US national survey, 65% of the women said they strongly disapproved of a woman getting drunk, while 58% disapproved of a man getting drunk. In studies in which participants read vignettes about men or women drinking alcohol or cola in the context of a heterosexual date, women drinking alcohol are rated by participants as more sexually available and aggressive than women drinking cola, but no differences in judgments are made about the males in the vignettes. Recent studies using implicit measures instead of self-reports also find that men view women as more sexually available if they are drinking than if they are not.

Ethnographic studies suggest that in cultures in which gender roles are more traditional and pronounced, the gender differences in drinking behavior are greater. Similarly, in US ethnic minority groups that more widely accept traditional gender roles, such as Hispanics and recent Asian immigrants, the gender gap is greater than among European Americans, due largely to high percentages of minority women who completely abstain.

Further, women who endorse traditionally feminine traits (nurturance, emotional expressivity) report less quantity and frequency of alcohol use and adolescent girls and young women who hold more traditional gender role attitudes are less likely to drink at all. On the other hand, males who hold traditional beliefs toward male and female roles are more likely to use alcohol and to show heavy drinking and drinking problems. A study by Rebecca Huselid and Lynne Cooper found that gender-role attributes and ideologies statistically accounted for the relationship between gender and measures of alcohol use. Gender roles completely mediated the gender differences in drinking to intoxication, and partially mediated gender differences in quantity consumed, frequency of heavy drinking (five or more drinks per occasion), and drinking problems. Thus, the theories that differences in social norms and gender roles contribute to the gender differences in drinking behavior have been supported in a variety of studies.

Impulsivity, Sensation-Seeking, Behavioral Undercontrol, and Antisociality

Four personality characteristics that overlap conceptually and cluster together empirically – impulsivity, sensation-seeking, behavioral undercontrol, and antisociality – are consistently related to heavy alcohol

consumption and alcohol-related problems. Males generally score higher on ratings of all these characteristics than females. Thus, the gender difference in alcohol use and problems may be due to gender differences in these personality risk factors.

Further, there is some evidence that this cluster of characteristics is more strongly related to alcohol-related problems in men than women, although the evidence is mixed. For example, some cross-sectional and longitudinal studies have shown that behavioral undercontrol predicts heavy drinking and alcohol-related problems more in men than in women. In contrast, a large twin study found that behavioral undercontrol was equally correlated with lifetime history of alcohol use disorders in men and women, and that behavioral undercontrol accounted for significantly more of the genetic risk for alcohol use disorders in women than in men.

The Dunedin study, which followed youth from early childhood through young adulthood, found that ratings of antisociality when the participants were young adolescents predicted symptoms of alcohol dependence at age 21 for both the male and female participants. Similarly, both males and females who had been diagnosed with conduct disorder between 11 and 18 years of age were more likely than those not diagnosed with a conduct disorder to have symptoms of alcohol dependence at age 21. Antisociality may be more consistently related to alcohol use and problems in males and females than behavioral undercontrol because it results in more severe dysfunction and encompasses a broader syndrome of adolescent problem behavior that includes other drug use, sexual activity, and delinquent and aggressive behavior.

Drinking Motives and Expectancies

People vary in their motives for drinking and expectancies about the effects of alcohol, and these motives and expectancies predict alcohol use and problems. Drinking to cope with distress or depression or to escape from concerns is associated with heavier drinking and more drinking-related problems. Men are more likely than women to report drinking to cope with negative affect or to avoid problems, and drinking to cope or avoid is more strongly related to alcohol use in men than in women. More generally, drinking to cope with stress may be part of a larger avoidant coping style, which is more common in men than women.

Similarly, men are more likely than women to have positive expectancies that alcohol will reduce tension or negative affect, and these expectancies are related to greater drinking. In contrast, laboratory studies show that women are more likely than men to expect alcohol to interfere with their ability to cope with difficult situations, and to avoid alcohol when they must deal with stressful situations.

Summary of Psychosocial Contributors

Drinking, particularly heavy drinking, is more socially accepted for men than for women, and more a part of the male gender role. These social norms and roles appear to account substantially for the gender difference in drinking and related problems. In addition, men tend to carry psychological risk factors for problematic drinking more than women, including impulsivity, sensation-seeking, behavioral undercontrol, antisociality, and drinking to cope with stress.

CONSEQUENCES OF MEN'S AND WOMEN'S DRINKING

The physical health and social consequences of drinking may differ for men and women, contributing to the gender differences in drinking behavior.

Physical Health Consequences

Among people who develop alcohol use disorders, the progression from first use to these problems appears to be faster for women than for men, a phenomenon known as *telescoping*. For example, retrospective studies of alcoholics suggest that women progress from first getting drunk regularly (e.g. weekly) to a diagnosis of alcoholism more quickly than men do.

Perhaps because of the increased bioavailability of alcohol in women compared to men, women may suffer more physical diseases as a result of alcohol use compared to men. A meta-analysis of 38 studies found that women are more likely than men to report health problems when they have a history of heavy drinking, alcohol abuse, or alcohol dependence. Similarly, another study found that women's risk of death increased by 160% if they were heavy drinkers (defined as six or more drinks per day) compared to if they were light drinkers (more than one drink per month but less than one drink per day), whereas heavy drinking increased men's mortality risk by only 40% over light drinking.

Moderate alcohol use is associated with lowered risk of myocardial infarction or cardiac death in men and in postmenopausal women, but excessive alcohol consumption is associated with a significantly increased risk of cardiac diseases, including cardiomyopathy, dysrhythmia, and hypertension. Women may show cardiac harm at lower levels of drinking than men. Analyses of a survey of 43 763 men and women showed that among women, even moderate drinking (defined as

more than two drinks per day during their heaviest drinking period in the last year) was associated with a significant increase in risk for heart disease. Among men, heavier drinking (more than five drinks per day in their heaviest drinking period in the last year) was associated with an increased risk for heart disease.

Women who are dependent on alcohol have 50–100% higher rates of premature death than do men who are dependent on alcohol. Women dependent on alcohol show comparable rates of diseases associated with alcohol dependency as do men dependent on alcohol, such as ulcers, gastrointestinal hemorrhage, fatty liver, hypertension, obesity, anemia, and malnutrition, even though the women tend to have shorter durations of drinking.

Women with diagnosed alcohol use disorders are more likely than women without alcohol use disorders to experience sexual dysfunctions, cessation of menstruation, irregular menstrual cycles, and early menopause. Alcohol use is a risk factor for breast cancer in women.

Heavy drinking by pregnant women is associated with fetal alcohol syndrome, which is characterized by growth deficiency, altered structural development, and central nervous system dysfunction due to the exposure of a fetus to alcohol in the womb. Even low to moderate levels of drinking during pregnancy have been associated with subtle abnormalities in reproductive outcomes such as birth weight, gestational age, rate of miscarriage or stillbirth, congenital abnormalities, and social and cognitive development. Many women stop drinking when they are pregnant and do not resume heavy drinking after they give birth, in part because of the demands of parenting small children.

In men, alcohol reduces testicular function, but whether it affects reproductive outcomes or infant development is unclear. Both animal and human studies have produced inconsistent results on whether paternal drinking around the time of conception has effects on fertility or fetal outcomes.

The greater physical health effects of drinking on women compared to men may lead more women to stop drinking or to drink more lightly than men, particularly when pregnant and in older age.

Violence and Sexual Assault

The risk of sexual assault and violence to women is substantially increased when they are under the influence of alcohol. A longitudinal study found heavy alcohol use predicted later physical assault victimization for women but not men. Women who abuse alcohol (or other drugs) are at particularly high risk for sexual or physical assault. More generally, being under the influence of alcohol appears to increase a woman's risk of assault by her male partner. One study of over 1000 women who had been sexually assaulted found that over half the assaults involved alcohol; in almost all cases, the man had been drinking, and in the majority of cases the man and woman had both been drinking. Women may become more physically abusive when they are drinking, but women's assaults most often come in the context of drinking by both the woman and the man, leading to mutual aggression toward each other.

Risky Sexual Behavior

One of the fears concerning women drinking is that it will make them sexually promiscuous. General surveys of the population suggest that adults who use more alcohol are more likely to report more liberal sexual attitudes and to report participating in risky sexual behavior, such as unprotected sex, sex with multiple partners, or sex with partners at high risk for sexually transmitted diseases. Similarly, surveys of adolescents and young adults have found that those who use more alcohol report more risky sexual behavior. These links may not be due to the alcohol itself, however, but to a third variable of sensation-seeking, behavioral undercontrol, or impulsivity.

Indeed, some studies find that women become more conservative in their sexual behavior when they are drinking. Studies of adolescents' first dates with an opposite sex partner find that girls are less likely to agree to intercourse if they have drank alcohol on the date, suggesting that alcohol inhibits girls' willingness to engage in sex with males they do not know well. Boys, however, reported that they were more likely to engage in intercourse or heavy petting on a first date if they had been drinking.

In experimental studies, men and women are told they will receive an alcohol beverage or a placebo; this is crossed with the actual administration of an alcohol beverage or placebo, creating four groups. Men who believe they have consumed alcohol become more sexually aroused and forward in their interactions with women, regardless of whether they have actually consumed alcohol or not. Women, however, do not show consistent effects of expectations, and sometimes show suppression of sexual arousal and interactions with male partners.

Summary of Consequences

Both men and women may suffer physical health problems, violence and sexual assault, and engage in riskier sexual behavior when drinking, particularly when drinking heavily. There is some evidence that women experience more of these negative consequences, and at lower levels of drinking than men.

GENDER AND TREATMENT FOR ALCOHOL USE DISORDERS

The treatment of alcohol use disorders is challenging. Meta-analyses and reviews of existing treatments suggest that, as a whole, they help only about 17–35% of substance-dependent individuals abstain for up to 1 year.

Women with alcohol use disorders are less likely than men with alcohol use disorders to seek treatment. This may be due in part to the greater stigma against excessive alcohol use in women. Women also are more likely than men to have child care responsibilities, and transportation and financial problems that impede treatment-seeking.

Some studies find that women may respond better to women-only treatments than to mixed-sex treatments. In addition, treatments that address common comorbidities with alcohol use disorders in women, especially depression and posttraumatic stress disorders related to sexual assault, are associated with fewer relapses and higher treatment satisfaction.

CONCLUSIONS

Men appear to be more likely to carry a number of risk factors for alcohol use and alcohol-related problems. Some studies suggest that genetics may play a stronger role in alcohol use problems in men than women, although the literature is somewhat inconsistent. Women show higher blood alcohol levels and become more intoxicated at lower levels of alcohol intake, which may protect them from heavy drinking and building tolerance.

Drinking is more socially acceptable for men than women, and men are judged less harshly for heavy drinking and intoxication than are women. Men who endorse traditional gender roles are more likely to drink while women who endorse traditional gender-stereotyped traits are less likely to drink.

Men are more likely than women to have a number of individual difference characteristics associated with alcohol use and related problems. These include impulsivity, sensation-seeking behavioral undercontrol, and antisociality. Men are also more likely than women to drink to cope with distress and to have positive expectancies for the tension-reducing effects of alcohol, which contribute to more drinking.

The consequences of alcohol consumption are different for men and women. Women progress to alcohol use disorders given heavy drinking faster than men, suffer alcohol-related physical illnesses at lower levels of exposure to alcohol than men, and heavy alcohol use is associated with several reproductive problems in women. Women may also be more likely to suffer physical harm and sexual assault when they are using alcohol.

Both the absence of risk factors and the greater negative consequences of alcohol use may play roles in women drinking less than men and having fewer alcohol-related problems than men. Women may notice they are becoming intoxicated at a much earlier stage of intoxication than men and may be more likely to find these effects aversive or frightening, leading women to inhibit their alcohol consumption. This, in turn, may protect women from developing tolerance to high doses of alcohol, and alcohol-related social and occupational problems.

If alcohol consumption reduces women's reproductive capacity, and leads them to produce offspring that are less likely to survive and to produce their own offspring, then there would be selection pressures against alcohol consumption in women. Women who were more sensitive and averse to the early negative effects of alcohol on their functioning might be less likely to develop alcohol-related physical diseases and more likely to produce healthy offspring than women who were less sensitive and averse to the effects of alcohol.

Women with alcohol misuse problems are less likely to seek treatment than men with alcohol misuse problems. Decreasing barriers to treatment-seeking (e.g. providing child care) and women-specific treatments may increase women's help-seeking.

Glossary

Alcohol abuse DSM-IV diagnosis defined as persistent drinking behavior in the face of repeated social, interpersonal, and occupational problems due to excessive alcohol consumption.

Alcohol dependence DSM-IV diagnosis that includes the psychosocial problems involved in alcohol abuse, but can also involve physiological dependence on alcohol, such as tolerance and withdrawal symptoms. Also referred to as *alcoholism*.

Alcohol misuse maladaptive pattern of drinking that may qualify for diagnoses of alcohol abuse or dependence.

GENACIS project Gender, Alcohol, and Culture: An International Study; a multinational study of alcohol use and correlates.

Heavy drinking or binge drinking drinking a large amount of alcohol in a short period of time, often defined as five or more drinks in 2 h for men and four or more drinks in 2 h for women.

National comorbidity survey Large-scale survey of psychiatric problems in the United States.

CHAPTER

16

Minority Groups and Addictions

Arthur W. Blume

Washington State University, Vancouver, WA, USA

OUTLINE

Minority populations often have different health and mental health needs and outcomes than the majority. With regard to substance use, minority groups within societies have been found to have different substance use presentations and responses to treatment than the majority group in the same society. Group differences noted by researchers are generally attributable to cultural differences between minorities and the majority and to differential treatment in society.

DEFINITION OF A MINORITY GROUP MEMBER

The term minority group seems to imply a population subgroup numerically smaller in size than a majority group in a culture, but such a definition does not account for being politically disempowered. In reality, minority groups can be the largest group in a society numerically, but not wield dominant political power. Because of the unusual circumstances that occurred during the empire building colonization by European nations in many areas of the world, European colonialists have exercised significant political power in many societies in spite of being a numeric minority.

The majority group regardless of its numbers has the majority of political power and determines the cultural norms, practices, and worldview of a given society, whereas minority culture is a subgroup with a history of being disempowered in society that usually have significantly different cultural norms, practices, and worldview than the majority culture. A minority group member would be a person who self-identifies with (or is identified by others as belonging to) a minority group. Minorities, because of their different assumptions about the world than the majority, have sometimes been oppressed by the majority for their views.

The focus here is on minority groups defined by ethnicity/race, but it is worth noting that there are other minority groups in society defined by gender, sexual

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00016-4

orientation, and disability that also have different substance use presentations and treatment needs than the majority group within particular societies.

HISTORICAL CIRCUMSTANCES

The historical circumstances of minority populations within a particular society are often different than the majority within the same society. Because the historical contexts for minority groups differ from majority group members, they often have unique health and mental health issues not shared by the majority. Minority groups have experienced disempowerment and oppression at the hand of the majority in historical power struggles within many societies. The causes for majority–minority group conflict are many, but include historical feuds between groups, prejudice and racism, and economic motives.

Colonialism

Colonial expansion by Europeans into Africa, Asia, Australia, the Caribbean and Pacific Islands, and North and South America profoundly shaped minority experiences in these areas of the world. Europeans were eager to move to new territories opened to them by exploration to seek freedom and economic opportunities. During the mass migration of people, European settlers found the areas occupied by indigenous people. First encounters varied from peaceful to violent depending on circumstances, but soon armed resistance by some indigenous people to what they perceived to be an invasion of their historical territories became more prevalent.

The interaction of Europeans to indigenous people also included exposure to pathogens not previously experienced by either population. An exchange of infections occurred in both indigenous and Europeans, but the clear losers in the exchange of pathogens were the indigenous people who did not have immunity to serious and rapidly spreading diseases for which Europeans had developed some resistance. The most famous exchange of pathogens occurred in the Western hemisphere in what was called the Columbian Exchange when Indians and Natives were plagued by diseases such as measles, small pox, and tuberculosis for which they had no natural immunity. Some demographers and public health scientists have estimated that 80–90% of exposed indigenous populations died during these epidemics, leaving behind vast areas of abandoned or under populated areas that were often noted in historical accounts by European settlers. The decimation of many communities and civilizations left indigenous societies vulnerable to conquest. Illnesses together with the superior weaponry of European soldiers (in spite of being outnumbered) contributed to lopsided victories for the colonists.

With regard to substance abuse, European colonization brought the introduction of distilled spirits into indigenous cultures. Although many indigenous cultures had fermented grain and berries for special ritualistic use in religious practices and medicines, many groups had not developed distillation methods. For many communities, the introduction of potent distilled alcohol caused significant behavioral and health problems. Europeans also used alcohol as an everyday drink and for social occasions rather than religious or spiritual practices. Daily use was unfamiliar to many indigenous groups prior to exposure to European colonists. Within a generation or two, substance use patterns among indigenous communities shifted from special and occasional to regular and excessive, and to the use of potent distilled liquor rather than fermented beers and wine. The results were devastating to many communities. Some European colonists used the knowledge that indigenous communities were having difficulties with substance use to their political advantage. For example, distilled spirits were used by various colonial powers to influence treaty negotiations with indigenous people, impairing the judgment of tribal representatives. The result was loss of access to traditional territory and forced removal of various indigenous groups, as well as tribal infighting that further weakened indigenous communities as a result of substance use and community anger at the concessions made by various leaders.

Derivative Eurocentric societies were spawned from the legacy of European colonialism in many areas of the world. The indigenous populations within those Eurocentric cultures were subsumed into the role of minorities, even though in some cases they represented the numeric majority. Because indigenous cultures were generally conquered people, they almost without exception had little political power in colonial societies for years, and in some cases, the political imbalances continue today. The consequences of these imbalances have contributed to a number of risk factors for substance abuse among minority groups in these societies, including the experience of oppression and discrimination, trauma, poverty, and lack of access to quality health and mental health care. These risk factors for minority substance abuse will be discussed subsequently.

Slavery and Indentured Servitude

For many minority groups, being enslaved or used as indentured servants by the majority culture has been an important part of group identity in the society in which

they live. Slavery has been in existence for a significant portion of human history. Although slavery is often a function of a majority group enslaving members of a minority group, some minority groups have a history of slave ownership themselves. In the new world, European soldiers enslaved indigenous people to help them build their settlements. However, the diseases of the Columbian exchange so severely reduced the native population that in the estimation of European colonists there was not enough indigenous labor available to fill the labor needs. Hence, Europeans began the slave trade and imported African slaves into the new world, a practice that lasted for over 300 years in many societies.

Indentured servitude, on the other hand, is a practice in which a person agrees to labor for another person for a specified length of time in exchange for immigration into a society, transportation, food, shelter, use of land, or other possible material benefit. The idea was that a person who otherwise could not afford something would trade hard work for the item being sought. The reality was that indentured servitude was a way to enslave people for significant periods of time with the promise of an eventual material reward. Those who employed indentured servants often found ways to compound the debt by underhanded means, thereby extending the time of service exponentially. Many minorities could not afford immigration and would agree to indentured servitude as a means of immigrating into a society. Indentured servitude also has been used as a way to continue to deny economic and political power to minorities, especially those who were emancipated from slavery (e.g. sharecropping).

The consequences of slavery and indentured servitude have contributed to increased risk factors associated with substance abuse, including poverty, health and mental health problems, and lower educational attainment among minority groups over many generations. In societies where slavery existed for centuries, the intergenerational consequences of oppression have been difficult to remediate.

Assimilation Efforts

Majority groups sometime pressure minorities to conform to majority group expectations and norms. The European derivative societies that resulted from colonization engaged in this practice to a varying degree, often as a function of the perceived threat of a minority group to the majority culture and of the level of ethnic superiority practiced by the majority culture. The expectation that minorities will discard their minority culture in favor of embracing majority culture beliefs and practices is referred to as assimilation. The goal of assimilation is to extinguish cultural differences to achieve a homogeneous society. Minority groups are expected to discard their native language, traditional cultural practices, traditional spiritual practices, and any other beliefs or practices that are discordant with majority beliefs and practices. Some European derivative societies, including the United States, had written policies directing organized assimilation efforts during colonial periods.

In the United States, policies toward assimilation of American Indians and Alaska Natives were implemented in conjunction with military conquest campaigns. American Indians and Alaska Natives were promised rewards in treaties for giving up traditional practices. Many children were removed from families and sent to boarding schools that were in some cases hundreds of miles from their homes. In these boarding schools, speaking the native language or engaging in traditional practices was punished and education was designed to indoctrinate children into American society. In another government effort, native people were lured away from reservations into urban centers with promises of jobs in efforts to assimilate them into the larger society. The result of assimilation was a general disintegration of traditional culture and family structures in American Indian and Native Alaska communities. It has no coincidence that substance abuse became a problem for many of these communities during this time. Many American Indians and Alaska Natives refer to conquest and assimilation efforts as a "soul wound" which they directly attribute as the cause for a number of health and mental health problems including substance abuse.

Isolation

Some minority communities have experienced isolation as a consequence of historical circumstances. In some instances, isolation has been imposed on minority groups by the majority culture. Examples of imposed isolation include relocating indigenous people into special reserves that are often located in sparsely inhabited areas, the legal segregation of communities defined by skin color or ethnicity, and the internment of certain groups in times of war or threat of war. In other instances, isolation has been self-imposed by the minority communities, often as an effort to protect traditional practices. Self-isolation often results in enclaves of minority communities operating independently of the majority culture and interacting with the majority culture when it is absolutely necessary. Cultural isolation has contributed to a number of risk factors related to substance use such as poverty, poor access and quality of health and mental health services, poor education outcomes, and societal neglect.

CULTURAL FACTORS ASSOCIATED WITH SUBSTANCE USE PATTERNS AND TREATMENT OUTCOMES

Differences in Worldviews

One result of European colonization has been the development of pluralistic societies that have brought together a wide range of cultural worldviews. Basic tenets of European culture such as individualism, personal autonomy, and the linear flow of time are not shared by the minority cultures they conquered. Assimilation efforts, although comprehensive in many societies, did not succeed in eliminating all divergent worldviews. In addition, many societies have experienced significant post-colonial immigration with improvements in transportation. One source of significant migration in Europe, for example, has been by immigrants from former colonies, rapidly diversifying many European nations that historically had been rather homogeneous.

Differences in cultural worldviews have been identified as one key variable to consider when studying and treating addictive behaviors among minorities using substances. Because worldviews of minority groups often differ radically from majority culture, one cannot assume that majority culture approaches to investigating and treating addictive behaviors will work effectively among minority populations, and in fact, there is able evidence to the contrary.

Cultural differences between majority and minority cultures vary by society. It is hard to make generalizations about cultural differences for the many societies where European colonialism occurred, but there are often major differences across cultures. For example, in many European derivative societies, the view of time is linear and view of space is that it includes the observable and measureable world. In some minority cultures within those Eurocentric societies, time is viewed as cyclical and repeating and space is viewed as visible and invisible (the natural and supernatural coexist).

Some minority cultures hold more collectivistic views, although this is not true for all. The welfare of the community is more important than the welfare of the individual, and in fact, the two may be viewed as inseparable. Many minority cultures view family roles and structures as more important than individual identity. Some also may believe in fate and destiny over free will and free choice. Autonomy is not something that is either desired or sought in some minority cultures. In some minority cultures suffering is at the center of understanding existence whereas in many European derivative cultures suffering is something to be avoided or overcome.

Understanding cultural beliefs is essential for conducting competent addictive behaviors research in minority communities. Since much of addictive behavior research is formulated, implemented, and analyzed by majority group scientists, they often lack awareness and understanding of the cultural differences in minority groups that may impact their research. Important culturally bound constructs within a minority culture that are not similarly present in majority culture may be inadvertently ignored in research, and scientists, assuming construct equivalence, may mistakenly assume that important addictive behavior variables of interest in general population studies exist similarly in the minority culture. Another difficulty is that scientific methods common deployed with success in majority culture may conflict with minority culture beliefs and practices, contributing to distrust of addiction scientists among minorities and poorly conducted research.

Understanding minority cultural beliefs is also essential to providing effective treatment services to minority clients. It would be extremely difficult to develop the therapeutic alliance with a minority client without understanding the cultural issues that influence the thinking and behavior of the client. It would be difficult to aid a client without understanding the cultural roles and expectations for that client. It also would be difficult to develop an effective treatment plan without understanding the everyday challenges that a minority client may face in her or his society.

Acculturation and Enculturation

Acculturation and enculturation levels have been found to be important predictors of the therapeutic alliance and for treatment outcomes for minorities engaging in the addictive behaviors, and are critical variables to account for when developing effective treatment plans. Acculturation level is the degree to which a person from a minority group functions and interacts competently within the majority culture. High levels of acculturation are associated with high levels of competence in understanding and using majority culture beliefs and practices and engaging successfully in majority culture functions. Highly acculturated minorities often are proficient at use of majority language, have received advanced education in majority culture schools, employed by majority culture entities, and are able to function competently on a daily fashion in the majority culture. Low levels of acculturation, on the other hand, would be associated with little engagement in majority culture activities, little understanding of majority culture beliefs or practices, and sometimes little use of majority culture language. People low in acculturation often have not received education from a majority culture institution, therefore are often at a competitive

disadvantage for employment opportunities in majority culture.

Enculturation level is the degree to which a person from a minority group functions and interacts competently within her/his minority culture. High levels of enculturation are associated with high levels of competence in understanding and using minority culture beliefs and practices and engaging successfully in minority culture functions. Highly enculturated minorities are proficient at use of her/his ethnic language and are able to function competently on a daily fashion in the minority culture. Low enculturation would be associated with little engagement in minority culture activities, little understanding of minority culture beliefs or practices, and little use of minority culture language.

Researchers have found that having high levels of both acculturation and enculturation is a protective factor for minorities from addictive behaviors. Having high levels of both acculturation and enculturation has been referred to as bicultural competence for personal expertise in majority and one minority culture, or multicultural competence for personal expertise in majority and more than one minority culture. Many culturally relevant addictive behaviors prevention and treatment programs used with minority clients include skill training components to enhance bi- and multicultural competence in participants to improve outcomes.

Ethnic Identity

Ethnic identity is self-identified ethnic group membership. Ethnic identity evolves from highly personal beliefs that reflect personal experience and social interactions. Ethnic identity is highly variable even among people who look and think alike. It is important to note that members of minority groups do not always self-identity with being a minority on a daily basis, and in some cases due to assimilation or low enculturation, may actively resist being identified as a minority group member. The difficulty for such a person is when they are identified as a minority group member by others, especially if such identification happens in ways that are uncomfortable or hurtful. Such an event can create cognitive dissonance between personal beliefs about ethnic identity and societal beliefs about group assignment.

Ethnic identity has been used to identify appropriate addictive behavior treatment and prevention strategies. Some research suggests that an ethnic identity (like to like) match for choice of treatment and prevention methods may improve outcomes. Certainly, it is important for clinicians to recognize and respect the wide variations in ethnic identity that minority clients bring to therapy in order to enhance the therapeutic alliance. Research also highlights the importance in avoiding assumptions about ethnic identity.

Discrimination, Prejudice, and Racism

Research has found that minority groups face discrimination, prejudice, and racism routinely with detrimental effects. Discrimination involves treating a person differentially and in a way detrimental to the person because of bias toward that person's group membership. Prejudice involves biased attitudes about groups of people that are insulting or injurious to a minority group member that are often expressed or acted upon automatically and without awareness. The attitudes are often the result of stereotypes about a particular group that is pervasively held in majority culture. Stereotypes are broad swath generalizations about group members (in this instance, minority group members) unsupported by empirical evidence. Stereotypes are perceived as insulting by minority group members even though they are sometimes perceived as flattering by the majority culture (even though untrue). Stereotypes are the net result from divisive us versus them thought processes.

Racism is rooted in belief in biologically based group differences (often defined by skin color and phenotypes) that causes certain groups to be biologically and intellectually superior to another. Racism also includes stereotyping, but the assumptions are that stereotypes reflect real biological differences between groups. Racism generally contributes to beliefs in the superiority of majority culture because of innate racial hierarchies. Racism also often contributes to the belief that it is important to maintain distances between racial groups, often to maintain racial "purity," and generally results in hostile thoughts or actions against minority group members. Racism can be expressed overtly (highly visible and aggressive) or covertly (veiled and done passive-aggressively).

Minority group members frequently report the experience of discrimination, prejudice, or racism. Public health researchers have linked these regular experiences to increased stress, poor overall health outcomes, and increased substance abuse. As an example, researchers have found that minority group members often experience subtle stereotyped insults or put downs on a daily basis, referred to as microaggressions. Microaggressions can be verbal (e.g. an insulting comment), written (e.g. an offensive statement), or visual (an offensive image). Perpetrators of microaggressions often lack awareness that their comments or actions are disturbing and hurtful. Microaggressions are likely the result of implicit racial and ethnic bias that permeates a society (see following section). Psychologist Derald Wing Sue has written a great deal about the different kinds of

microaggressions found in American culture and their consequences for people of color.

SPECIAL CONSIDERATIONS FOR RESEARCH AND CLINICAL PRACTICE

Cultural researchers have found consistent evidence for implicit bias against minorities in society. From hiring practices to leadership styles, experimental research has demonstrated bias in interpreting behavior and making hiring decisions that favor majority culture members. In addition, social psychologists have found substantial evidence documenting implicit bias that affects perceptions of others, attitudes, and decision-making in people without their awareness. Even minority group members have been found to often have implicit negative bias against their own groups. The balance of evidence suggests that bias against certain minority groups is present and pervasive in all members of society regardless of group membership, and because of that bias we cannot trust our objectivity.

Assessment

Scientists are creatures of culture as are all humans. Although researchers strive to be completely objective, it is simply impossible to divorce one's self from one's socialization. In spite of empirical training, culture impacts the development of theoretical models to study research questions, decisions about how to investigate research questions, and interpretation of results.

Most of the gold standard measures used in the research of addictive behaviors have been developed in the context of implicit majority culture bias. They are constructed from models that typically reflect "Western" ways of thought that include basic assumptions about the world that may not be accepted by certain minority groups. Many behaviorally oriented measures use majority culture language or were first developed in majority culture language and translated. Sometimes the language also reflects worldview biases. Many gold standard measures of addictive behaviors have been developed with majority culture assumptions that likely do not apply to certain minority cultural worldviews. Construct equivalence across cultures has been assumed in the development and use of these measures, but the reality is that vast cultural differences make the assumption of construct equivalence flawed. In addition, many of the quantitative measures have been inadequately normed for many minority cultures and therefore contribute to questionable interpretation of results.

Diagnosis

Since assessment tools are generally biased, the ability to make an accurate diagnosis is impacted. Indeed, public health researchers have noted that mental health diagnostic assessment tend to overpathologize minority respondents through artificially inflated symptom scores due to measurement error or by misinterpreted results. In addition, minority group members have been found to describe symptoms differently than typically observed in majority, causing health care professionals to miss important information about symptoms and contributing to missed diagnoses and prescribing errors. As an example, there is no exact translation of the English word binge into Spanish, so clients whose first language is Spanish will not naturally use the term to describe substance use behavior. Treatment professionals should be aware that some minority members may describe their addictive behaviors and subsequent consequences differently than majority group members.

Minority cultures also may have culturally bound conditions that treatment professionals may not know. Sometimes a culturally bound condition is linked to the addictive behavior being assessed and treated. It is important for treatment professionals working with minority clients to understand culturally bound conditions and their association to addictive behaviors in their clients. Some cultures view addictive behaviors as symptoms of a more pervasive culturally bound condition. As an example, some American Indians and Alaska Native groups will refer to problems with substance abuse (and other health and mental health concerns) as a result of a soul wound that has resulted from collective trauma experienced across the generations as a result of colonial conquest and assimilation efforts. Under those circumstances, a minority client will believe that treating the culturally bound condition will impact not only the addiction but also perhaps multiple health and mental health problems simultaneously. In other words, culturally bound conditions would be considered systemic and the primary condition to be treated, whereas the addictive behavior would be considered a symptom of the underlying condition.

Stereotype Threat

Research by Claude Steele and others have found that minority group members may experience stress that can negatively impact outcomes when they are engaged in a performance task involving a stereotyped behavior for their group. This phenomenon is referred to as stereotype threat. For example, if a stereotype exists in majority culture that suggests a member of a minority group will perform poorly on a test or task, the expectation by

society of poor performance places undue stress and anxiety on the minority group member that can actually contribute to poor performance. When assessing and treating the minority group members for addictive behaviors, clinicians should be aware of the possibility of stereotype threat that might contribute to poor performance and outcomes in treatment. A savvy professional will want to determine if stereotype threat is impeding progress.

Ethics and Research among Minorities

Researchers have made a number of missteps when investigating addictive behaviors among minority communities. Perhaps the most notorious of studies is referred to as the Barrow Alcohol Study, which has been written about extensively. The study was conducted in Barrow, Alaska, in the late 1970s. The study was requested by public health officials in the Barrow area that had concerns about alcohol abuse among the Inupiat people of Alaska. The public health group sought help from investigators in Pennsylvania with no experience in working with Native Alaska populations. The investigators developed and implemented the study methods without any consultation with Inupiat community members. Data collection focused solely on drinking behavior of some members of the Inupiat community without providing appropriate context for the drinking behavior by including non-native members of the Barrow community as a comparison group in the study. The measures used were not normed or tested in the Inupiat community prior to the study, and included measures not representative of the worldviews of Inupiat people. The results of the study were released to the press without community input or knowledge, and resulted in an embarrassing and damaging story that appeared in national media venues including the *New York Times*. The press release was meant to coerce the Inupiat community into changing drinking behavior, but instead resulted in Inupiat community outrage and increased distrust of majority culture researchers by American Indians and Alaska Natives in Barrow and beyond.

Researchers of addictive behaviors investigate issues of a highly sensitive nature given the stigma attached to addictive behaviors in many societies. Because of the history of societal disempowerment and oppression, and a track record of poorly conducted research that have shamed communities, there is a burden for proof on addictive behavior researchers to demonstrate extra care in conducting research with vulnerable minority communities. In addition, ethical violations have made conducting minority research a difficult enterprise because distrust of scientists is deservedly high.

Ethics and Clinical Practice among Minorities

Multicultural competence is an important skill to develop to effectively treat the addictive behaviors of minority group members. Some clinically oriented professional organizations have instilled training requirements for multicultural cultural competence into graduate training programs (e.g. the American Psychological Association) because of the research findings suggesting its importance for improved clinical outcomes. Treatment programs for addictive behaviors that serve minority communities may expect their therapists to receive additional training in multicultural methods and often opt to include culturally relevant approaches to treatment in the programs. In some instances, progressively minded service providers have established collaborative relationships with traditional healers and elders form the minority community being served. The result is holistic care that includes the best practices from minority and majority culture.

An appropriate match of client to therapist by common ethnicity has long been considered an important factor for a positive treatment outcome. The research evidence is mixed concerning the efficacy of ethnic identity match for improved outcomes in psychotherapy. What appears to be more important is an appropriate match of therapy and therapist to the acculturation level of the client to improve the therapeutic alliance. For a client low in acculturation, it might be more important to have an appropriate ethnic match than for a client high in acculturation level. Many culturally relevant therapies for addictive behaviors employ the use of acculturation match to potentially improve treatment outcomes.

Empirically Based Substance Abuse Practices for Minorities

Addictive behavior research has used complex experimental methods including randomized controlled clinical trials to validate the efficacy of particular interventions within the general population. However, it is difficult to know if a particular intervention will work similarly with minority groups as it did in general population studies. Many intervention efficacy studies have not had sufficient sampling of some minority groups to be able to determine the efficacy for those group members. Minority group members frequently respond differently to interventions than majority group members. Having insufficient data concerning minority group responses in efficacy trials lead the American Psychological Associations' Task Force on Empirically Validated Therapies to conclude that, "…the efficacy of empirically validated therapies has not been established

with ethnic minority populations." Although a number of highly regarded and empirically supported interventions for addictive behaviors have been used with various minority group participants, there has generally been insufficient research in the area to draw any conclusions about whether established empirically based practices will work effectively and consistently among minority communities.

In the past, researchers have used a utilitarian approach concerning the use of empirically supported interventions, reasoning that what is good for the majority would likely be good for minority groups as well. Initial efforts to transport empirically supported therapies into some minority communities did not attempt to account for cultural differences of the community being served. In discovering that minority participants often did not respond in the same way to the interventions as would be expected in the general population, methods were revised and the process became to modify empirically supported interventions to be more culturally relevant by adding new components consistent with the beliefs and practices of the community. These efforts have met with limited success, and even among those that showed promise, it was unclear which components may have been most effective, the original intervention or the culturally relevant add-ons. In reality, in order to tailor interventions for effective use within minority communities, it would be important to include community stakeholders during initial development of an intervention, rather than in an advising role to assist scientists in making an existing intervention more culturally relevant to the community being served. Today, many researchers working with minority communities to develop effective interventions on addictive behaviors understand it is important to seek early community participation to make certain the intervention is developed with community in mind from the beginning rather than borrowed and revised as an afterthought.

Model for Community-Based Participation

Researchers have to overcome challenges between bridging the culture of science to the culture of the minority community being studied. Since minority community worldviews, beliefs, and practices can differ sharply from the assumptions and expectations of researchers, there is a high potential for mistakes that damage collaborative relationships.

Because of frequent missteps that scientists have made in working with minority groups, as well as serious concerns about the lack of information about what will effectively intervene on addictive behaviors with many minority communities, a new model of scientific inquiry referred to as the Community Based Participatory Research (CBPR) Model has been developed and used with great success. The CBPR model proposes a collaborative relationship between the community being investigated or served and addiction professionals. In the CBPR model, researchers serve as expert advisors to the community on what is known to be best scientific practices as particular studies or services are being developed, implemented, and analyzed. However, community stakeholders will define who will participate, what will be investigated and how the investigation will proceed, and how the results will be disseminated. Addiction scientists advise community stakeholders using professional expertise and scientific judgment in their roles of consultant-scholars, but the ultimate decisions about methods lie with the one's being impacted most directly by the research. High on the list for reasons to use such an approach include conducting research with enhanced cultural sensitivity and increased oversight of methods that will protect the community from harm and embarrassment. Using the CBPR to guide research of addictive behaviors in minority communities has increased trust of minority communities in researchers, provided tangible and more immediate benefits for minority groups, and improved scientific methods for understanding addictive behaviors among minority group members.

HEALTH DISPARITIES AND ADDICTIVE BEHAVIORS

Researchers have found consistent evidence for addictive behavior health disparities among some minority groups. Patterns for health disparities vary across societies. Minority group disparities have been found both in the prevalence of certain types of addictive behaviors and in the accessibility of treatment services. Some but not all minority groups have been found to have significantly higher rates of addictive behaviors than those reported in general population. In addition, some minority groups have significantly lower utilization rates of addiction treatment services than would be predicted by the prevalence rates of the group, and some groups have significantly less utilization of treatment services than observed in the general population.

The contributors to health disparities are many. Greater rates of addictive behaviors are often linked to conditions to which many minority groups are exposed, such as oppression and poverty. Prevention efforts have not been historically targeted within some minority communities with the same intensity as in the general population. There is evidence that specific minority groups have been targeted for intense and culturally specific alcohol and tobacco advertising

and marketing campaigns. In some minority communities, the density of liquor markets, bars, and convenience stores selling legal psychoactive substances have been found to be significantly higher than surrounding majority culture neighborhoods. Financial burdens linked to poverty or unemployment often reduce accessibility to treatment, as does lack of health care insurance that covers addiction treatment services. Access is also restricted in rural locations, by number of local treatment providers, and by accessibility of transportation to treatment facilities. Unfortunately, it is often true that treatment services in remote locations or near impoverished neighborhoods, or provided to people with limited means or the uninsured, are also not always of the quality provided in more affluent and urban areas.

CONCLUSION

Minority clients have unique needs that require approaches that respect cultuniral beliefs and values. Historical circumstances have frequently created disadvantages for minorities and many of these disadvantages remain problematic today. These difficult circumstances have contributed to disparities in the prevalence of and care for addictive behaviors. In the past, addictive behavior researchers made missteps that harmed minorities and produced inadequate data. Addiction professionals have improved their research and clinical practice by enlisting community stakeholders as collaborators. Use of the CBPR model has created opportunities not only to serve minorities more effectively, but also to develop creative and culturally relevant new interventions for addictive behaviors.

Glossary

Acculturation level the degree to which a person from a minority group functions and interacts competently within the majority culture.

Assimilation the expectation that minorities will discard their minority culture in favor of embracing majority culture beliefs and practices.

Bicultural competence being highly competent in both majority and traditional minority cultural practices.

Columbian exchange the natural exchange of human pathogens that occurred upon first contact between old world and new world citizens during the colonial period. Diseases like small pox and tuberculosis spread rapidly through new world populations because of no natural resistance and syphilis spread rapidly through European populations for the same reason.

Community-Based Participatory Research a model that includes minority community stakeholders as equal partners with researchers in the development, implementation, and dissemination of research studies.

Construct equivalence the assumption that a particular item, factor, or variable of interest is the same conceptually across cultures and can be measured in the same way (e.g. intelligence).

Culturally bound conditions syndromes or illnesses that are defined by a group but may have no equivalent outside of that group.

Culturally specific constructs items, factors, or variables that are culturally important to understand the behavior of a group but may not exist or be relevant outside of that culture.

Discrimination treating a person differentially and in a way detrimental to the person because of bias toward that person's group membership.

Ethnic identity how a person defines her or his identity by ethnicity. The ethnic identity of a person may not agree with the ethnic identity assigned by the culture to the person, and ethnic identity can reflect multiple culturally heritages.

Empirically supported interventions interventions empirically tested by use of a randomly controlled trial experimental design and found to be significantly more effective than no intervention at all or treatment as usual.

Enculturation level the degree to which a person from a minority group functions and interacts competently within her/his minority culture.

Health disparity significantly higher prevalence of a health problem among a group than would be predicted by rates among the general population or significantly less access of care than would be predicted by the prevalence of a health problem in the group.

Implicit bias since inherent bias permeates a culture, people socialized within that culture often believe and act on biased assumptions without awareness of their biases.

Intergenerational trauma the belief by many minority people that historical incidents of oppression have created trauma so severe that it has been passed intergenerationally among the group.

Majority group the group that prescribes the appropriate belief system and behavior for a particular society. Although the majority group generally has the largest concentration of political power in a society, it is not always the numerically largest subgroup.

Microaggression often subtle insults, expressions of stereotypes, or put downs based upon group bias that may occur without the awareness of the perpetrator.

Minority groups subgroups in society that often have different assumptions about the world than the majority and sometimes have been oppressed because of these views. Minority groups can be the largest group in a society numerically, but not wield dominant political power.

Multicultural competence being highly competent in multiple cultures including the majority culture. Multicultural competence is a term recognizing that ethnic identity may involve more than two cultures.

Prejudice biased attitudes about groups of people that are insulting or injurious to a minority group member that are often expressed or acted upon automatically and without awareness.

Racism belief in biologically based group differences (often defined by skin color and phenotypes) that causes certain groups to be biologically and intellectually superior to another.

Stereotype threat minority group members experience stress that can negatively impact outcomes when engaged in a performance task that may involve a stereotyped behavior for their group.

Therapeutic alliance the ability of client and therapist to work together collaboratively on client-oriented treatment goals.

CHAPTER

17

Medical Toxicology of Drugs of Abuse

Teresa Cunha-Oliveira, Ana Cristina Rego*, Félix Carvalho$, Catarina R. Oliveira**

*CNC, University of Coimbra, Coimbra, Portugal $University of Porto, Porto, Portugal

OUTLINE

INTRODUCTION

Drug addiction seriously affects public health and represents a social burden worldwide. The abuse of drugs has become a complex issue, mainly due to the development of synthesis and purification procedures that enable an increase in the effective quantities of the active compounds consumed and to the invention of the hypodermic syringe in the mid-nineteenth century, which allowed the direct injection of purified active compounds into the bloodstream. This also contributed to the increase of infections among drug addicts.

Among psychoactive drugs, alcohol (ethanol) is the most common in the world. Its harmful use is responsible for 3.8% of all global deaths. Besides alcohol, the most abused drugs in the world are cannabis (used annually by 2.9–4.3% of the world population aged 15–64), amphetamines (0.3–1.2%), cocaine (0.3–0.4%), and opiates (0.3–0.5%), as described in the World Drug Report 2010, from the United Nations Office on Drug and Crime. Although less consumed, opiates are illicit drugs that lead more people to seek treatment, due to the severe withdrawal effects and the increased risk for infections.

This chapter summarizes and compares the characteristics and toxicological properties of the main drugs of abuse, namely alcohol, amphetamines, cocaine, heroin, and cannabis.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00017-6

CHARACTERISTICS OF PSYCHOACTIVE DRUGS

The term "drug of abuse" is usually applied to a psychotropic drug that is used in a manner that deviates from the approved medical or social patterns within a given culture at a given time.

Drugs with psychoactive effects can be divided into several groups, according to their specific actions. The most common illicit drugs of abuse are the psychostimulants (e.g. amphetamines and cocaine), depressants (e.g. alcohol (ethanol) and opiate narcotic analgesics), and hallucinogens (e.g. mescaline and lysergic acid – LSD). The properties of these groups of drugs are summarized in Table 17.1.

Some drugs of abuse induce effects that are common to more than one group. For example, ecstasy (or 3,4-methylenedioxymethamphetamine – MDMA) belongs to the class of amphetamine-type psychedelic drugs, which share stimulant and hallucinogenic effects. These drugs are also known by empathogens or entactogens, because they induce feelings of empathy and entactogeny. Another example is cannabinnoids, which share properties of all the groups described above.

Drug abuse is frequently associated with toxic effects that evolve under regular use, overdosage or the withdrawal syndrome that manifests during abstinence from the drug. It affects a number of body systems, leading to signals and symptoms of organ dysfunction, such as:

- Central nervous system (CNS) symptoms that may range from headaches and altered mental status to coma and seizures.
- Cardiovascular alterations that include changes in blood pressure, heart rate, as well as arrhythmias and organ ischemia.
- Respiratory changes that include respiratory arrest, pulmonary edema, and pneumothorax.
- Metabolic effects, including alterations in body temperature, electrolytes, and acid–base disturbances.
- Hepatic damage, from hepatitis to severe hepatotoxicity and liver failure that may require liver transplantation.
- Renal damage, with symptoms derived from decreased filtration rate to acute kidney failure.
- Reproductive consequences that may range from impaired fertility to teratogenesis, intrauterine growth retardation, premature births and neonatal syndromes, and attention deficit hyperactivity disorder (ADHD).
- Infectious complications from intravenous drug use, including viral infections such as HIV and hepatitis B, and bacterial infections such as bacterial endocarditis, osteomyelitis, and abscesses.

The clinical toxicology of drugs of abuse depends on the administration pathway, which affects its bioavailability

TABLE 17.1 Classification and Principal Effects of the Main Drugs of Abuse

	Effects			
Class	**Acute**	**Chronic**	**Withdrawal**	**Drugs**
Sedative/hypnotics	Euphoria, relaxation, CNS depression, nausea, vomiting, impaired motor function, impaired sensory function, impaired cognition	Craving, tolerance, physical dependence	Severe shaking, sweating, weakness, agitation, headache, nausea, vomiting, tachycardia, seizures	Alcohol (ethanol)
Psychostimulants	Euphoria, tachycardia, hypertension, hyperthermia, increased mental alertness, seizures	Psychosis, paranoia, reduced appetite, weight loss, heart failure, nervousness, insomnia	Severe depression (sometimes), headache	Cocaine, amphetamine and derivatives (e.g. methamphetamine, ecstasy, cathinone, mephedrone)
Opioid-type depressants	Pain relief, euphoria, drowsiness/nausea, constipation, confusion, sedation, respiratory depression and arrest, hypothermia, unconsciousness, seizures, coma, death	Depressed sexual drive, lethargy, general physical debilitation, infections, hepatitis, tolerance, addiction	Anxiety, insomnia, nausea, vomiting, diarrhea, anorexia, tachycardia, lacrimation, sweating, severe back pain, stomach cramps, muscle spasms	Opium, morphine, heroin, desomorphine
Hallucinogens	Altered states of perception and feeling	Persisting perception disorders (flashbacks)	No typical symptoms	Mescaline, LSD, psilocybin, ecstasy

(affecting the onset and extent of the psychotropic effects), the biodistribution (and therefore the exposure of target organs), and biotransformation or metabolism, which occurs mainly in the liver (affecting the nature and concentration of toxic compounds in the organism).

The reaction of the toxic compounds with their target molecules may result in their dysfunction or destruction, or in the generation of new toxic compounds. In consequence, cellular exposure to toxic compounds may result in cell dysfunction and cell death, if cell repair and adaptation are overcome. Beyond the inherent toxicity of drugs of abuse, the toxic effects may be affected by adulterants and other impurities, or even by interactions among different drugs in the frequent events of polydrug abuse.

ADULTERANTS AND CONTAMINANTS

A critical problem associated with drug abuse is the fact that the drugs available in the streets are illegally synthesized, usually under poor conditions. Deficient purification and low quality of the reagents used often leave some impurities in the final products. Frequently, adulterants are also intentionally added to the drugs to increase profit or to modulate the experienced effects.

Heroin is a semisynthetic drug, obtained from acetylation of morphine. *Street* heroin may contain different amounts of heroin and other components, depending on its origin and on the method of illicit synthesis. Usually, *street* heroin is illegally synthesized from morphine purified from opium extracts, which is often contaminated with other alkaloids. These alkaloids may also suffer synthetic acetylation during heroin manufacture. Depending on the purification procedure, *street* heroin may contain some impurities, such as morphine and 6-monoacetyl morphine (6-MAM) (heroin metabolites) or codeine and acetylcodeine. Heroin in seized samples often contains various inert diluents (starch, lactose, fructose, sucrose, mannitol, powdered milk) and active adulterants (caffeine, paracetamol, strychnine, acetylsalicylic acid, barbiturates, quinine, and amphetamines).

Street cocaine can be mixed with several diluents or adulterants, such as amphetamines, antihistamines, benzocaine, inositol, lactose, lidocaine, mannitol, opioids, phencyclidine, procaine, sugars, tetracaine, and sometimes arsenic, caffeine, quinidine, and even flour or talc.

MDMA is also frequently adulterated. Occasionally, tablets that are sold as "ecstasy" do contain drugs other than MDMA, or even none at all. Other psychoactive substances found in tablets sold as "ecstasy" included mostly other amphetamines, such as 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxyethylamphetamine, paramethoxyamphetamine, 2,5-dimethoxy-4-bromoamphetamine (DOB), and 4-methylthioamphetamine (4-MTA). Other compounds such as caffeine, cocaine, heroin, ketamine, LSD, aspirin, synthesis intermediaries, among other drugs, have been found in ecstasy tablets and may contribute to its toxicological outcome. The online project http://www.ecstasydata.org/ receives ecstasy tablets sent by users for testing and publishes the results in their website with the aim of helping drug users with harm-reduction, medical personnel, and researchers.

POLYDRUG USE

An important factor affecting drug toxicity and medical complications is polydrug abuse. A relatively common combination of drugs is the *speedball*, which consists in concurrent administration (by injection) of cocaine and heroin. *Speedball* has been reported to cause more rewarding effects in rats than cocaine or heroin alone. The popularity of this drug combination may be explained by the reduction of the unwanted side effects of one drug by the other, since they have different mechanisms of action, or by the enhancement of the desired effect at the reward system.

Ethanol is frequently combined with other drugs of abuse. When ethanol and cocaine are co-consumed, the euphoric effects of cocaine are enhanced. However, this combination also increases the toxic effects of both drugs, because the drugs are combined in vivo to form a very toxic metabolite – cocaethylene. This is a very lipophilic compound and is able to cross the blood–brain barrier. The effects of cocaethylene are similar to those of cocaine but the metabolite has a longer half-life, prolonging the acute effects of cocaine.

Consumption of ethanol also increases the toxic effects of MDMA, enhancing hyperthermia, hepatotoxicity, and neurotoxicity.

TOXICOLOGICAL PROPERTIES OF SELECTED DRUGS

Characteristics of drugs of abuse such as induction of positive reinforcement, dependence, and withdrawal are generally associated with certain pharmacological properties. Psychoactive drugs with rapid absorption and delivery to the CNS, high bioavailability, low protein and peripheral tissue binding, small volume of distribution, short half-life, and high free drug clearance are generally predicted to produce positive reinforcement and lead to persistent self-administration. Drugs that induce physical dependence generally have a long half-life, low free drug clearance, and must achieve high enough concentrations for sufficient time to induce the development of compensatory homeostatic changes that permanently or temporarily change the organism's

response to the drug. These homeostatic changes are responsible for the development of tolerance and sensitization to the drug, and for the withdrawal syndrome that manifests in the absence of the drug. Withdrawal symptoms are most probably manifested for psychoactive drugs with a short half-life, high free drug clearance, and that rapidly exit the CNS.

The intensity and onset of a drug's effects are determined by the rapidity of its delivery to the CNS. Drug users learn to optimize the delivery of the drug to the brain and to maximize the bioavailability of the drug by adapting the methods and routes of administration. The most rapid CNS delivery is achieved by inhalation, due to the direct access of pulmonary blood to the brain. Smoking is a very effective route of administration, but requires highly volatile forms of the drugs, to assure resistance to degradation at the temperatures produced by burning. Intravenous administration provides the highest bioavailability but is associated with severe health complications, whereas oral administration is generally more convenient, but is associated with lower bioavailability and slower delivery to the brain.

Central effects of drugs of abuse are due to the interference of these drugs with the molecular and cellular pathways involving neuronal active endogenous compounds, including monoamine and other types of neurotransmitters, endocannabinoids and endorphins, taking advantage of structural and bioisostere similarities (Fig. 17.1). The molecular targets of these xenobiotics are transporters or receptors that mediate the physiological actions of those endogenous compounds, activating specific intracellular signaling pathways. However, drugs of abuse do not completely mimic the action of the endogenous compounds because the molecular machinery involved in their removal from the synapse is frequently inefficient for these xenobiotics, which implies the interference with neuronal activity for longer periods of time.

In the next sections, we discuss the toxicological properties of the most common drugs of abuse, the main medical complications found in drug abusers and the biomarkers of abuse. The data presented are mainly based on literature referred at the Further Reading section.

Alcohol (Ethanol)

Alcohol (ethanol) has long been used by mankind for social, medical, cultural, and religious purposes. For most users, alcohol consumption does not impair physical or mental health. However, acute or chronic alcohol intoxication has negative individual and social consequences. Ethanol is a straight-chain alcohol (Fig. 17.1) produced by fermentation of sugars present in agricultural products. It is present in alcoholic drinks, namely in beer (3–6% w/v), wine (9–12%), spirits (32–40%), or cocktails (15–25%). Alcohol is generally used to obtain euphoria and relaxation. The effective dose in humans is around 22–40 g and the effects generally persist for 1.5–3 h. The harmful use of alcohol is generally associated with chronic or binge drinking.

Routes of Exposure

Alcohol is generally used by the oral route to obtain its psychoactive effects. However, it may be used as an antiseptic for medical purposes, applied topically in the skin.

Pharmacokinetics

- Absorption

When taken orally, alcohol is rapidly absorbed in the small intestine into the bloodstream. The presence of food in the stomach may delay gastric emptying and slow absorption. The oral bioavailability of alcohol is generally higher than 80%. Peak blood concentrations typically occur between 30 and 90 min after ingestion.

- Biodistribution

Alcohol has low molecular weight, mixes well with water and is only weakly charged, easily crossing biological membranes and the blood–brain barrier. It has low-protein binding and a volume of distribution around 0.55 l kg^{-1}. On entering the bloodstream, alcohol is distributed throughout the body, mainly affecting the brain, liver, and kidneys.

- Plasma half-life

At high alcohol concentrations, the plasma half-life is about 4–5 h, whereas at low alcohol concentrations the clearance is slower and the plasma half-life increases.

- Metabolism

Alcohol is mainly metabolized in the liver by alcohol dehydrogenase into acetaldehyde. Alcohol dehydrogenase may also be present in the stomach and small intestine. Catalase and cytochrome P450 (CYP2E1) may also contribute to alcohol metabolism into acetaldehyde, and hepatic CYP2E1 expression is 5- to 10-fold increased in chronic alcohol users. Acetaldehyde is then converted into acetate by aldehyde dehydrogenases (these enzymes are found in many tissues of the body but are at the highest concentration in the liver). Acetate combines with coenzyme A, to generate acetyl-coenzyme A, which may enter metabolic pathways. A small percentage of ethanol is conjugated to give ethyl glucuronide and ethyl sulfate, which may be helpful as biomarkers of alcohol abuse.

- Excretion

About 5–10% of ingested alcohol is excreted unchanged in urine, breath, and sweat. Alcohol or its

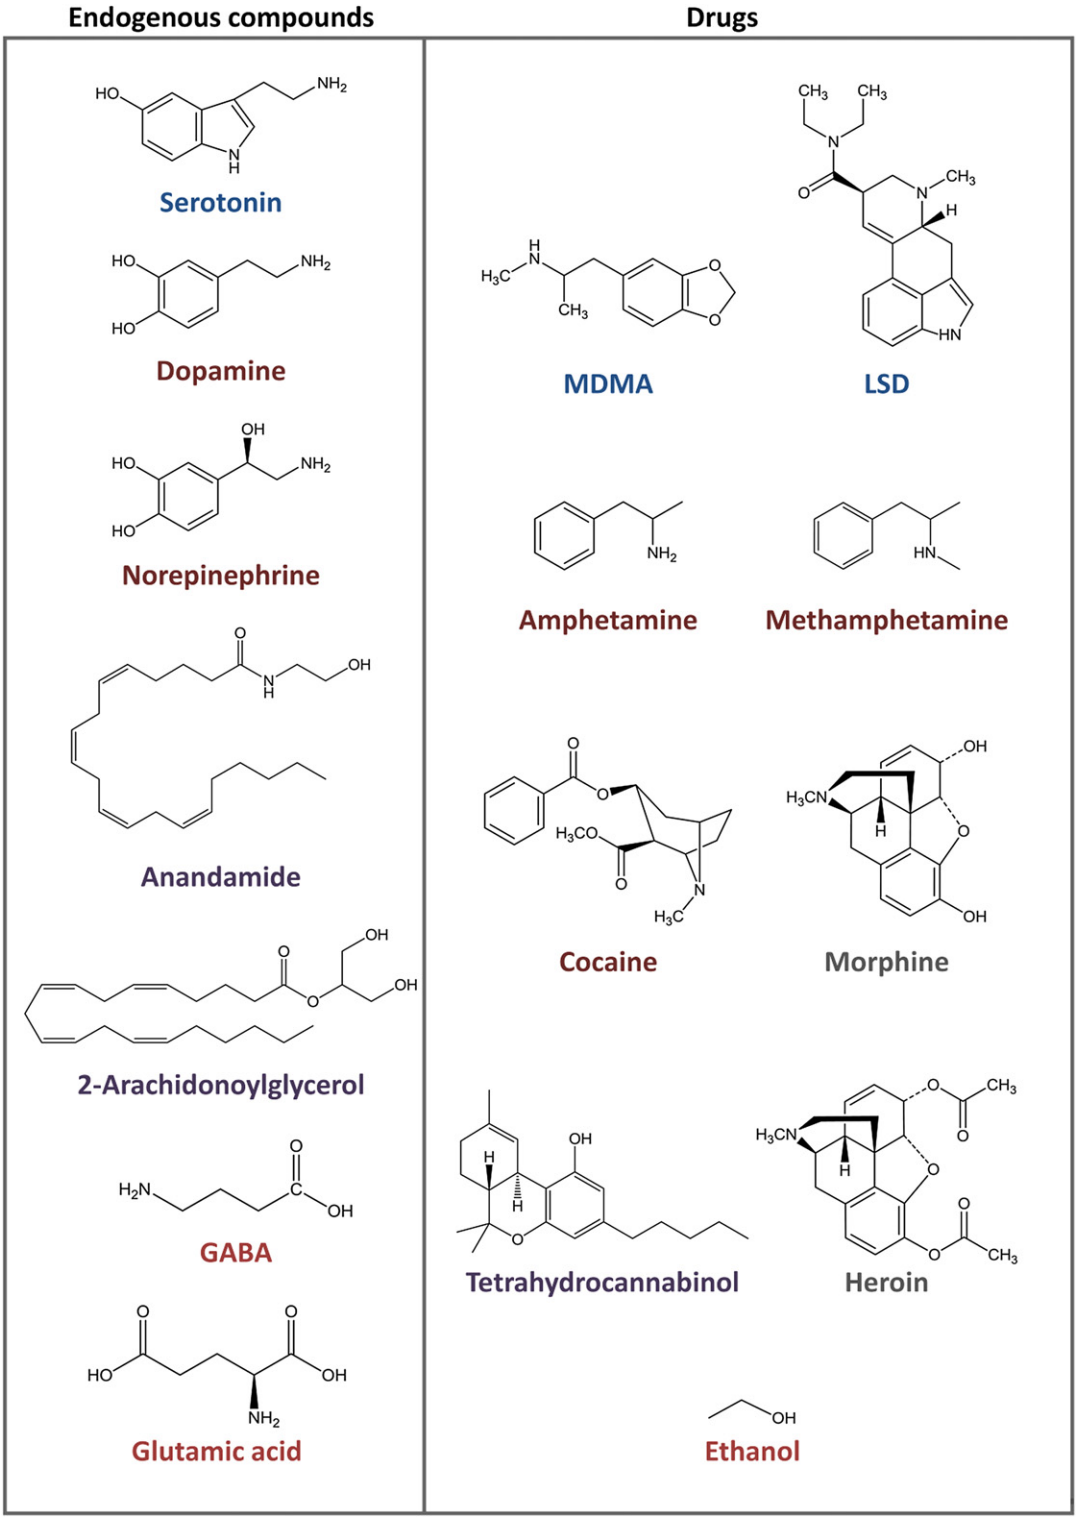

FIGURE 17.1 Chemical structures of some drugs of abuse and neuronal active endogenous compounds. The structures of MDMA and LSD resemble the structure of serotonin and thus interfere with serotonergic systems. Amphetamine, methamphetamine, and cocaine are structurally similar to dopamine and norepinephrine, affecting primarily the systems involving these monoamines. Tetrahydrocannabinol has similarities with the endogenous cannabinoids anandamide and 2-arachidonylglycerol and interferes with the receptors for these compounds. Morphine and heroin present chemical similarities to the active sites of endogenous opioid polypeptides such as enkephalins and endorphins (polypeptidic structures not shown here for simplicity). Ethanol shares structural similarities with the neurotransmitters GABA and glutamate and interferes with receptors for these amino acids.

metabolites are generally detected in urine up to 96 h. Alcohol use is generally tested by breath analysis, which is well correlated with blood alcohol concentration.

Pharmacology and Toxicology

- Pharmacodynamics/Mode of action

Although alcohol has long been believed to act nonspecifically by disordering lipids in cell membranes, it is now acknowledged that at physiologically relevant concentrations (5–20 mmol l^{-1}), alcohol interferes with neural activity by acting directly on neurotransmitter-gated ion channels. Ethanol enhances GABAergic neurotransmission by altering the conformation of inhibitory $GABA_A$ receptors and inhibits the excitatory N-methyl-D-aspartate (NMDA) receptors, acutely depressing neural activity, thus explaining the sedative effect of alcohol.

At the reward pathway, ethanol acts on $GABA_A$ receptors present on inhibitory neurons in the ventral tegmental area, and induces the release of opioid neuropeptides, leading to the disinhibition of dopamine release in the nucleus accumbens. Ethanol may also act in the nucleus accumbens, possibly by inhibiting NMDA receptors in corticostriatal synapses.

Long-term alcohol use leads to neuroadaptations at the ion channel sensitivity (subunit composition) or number. When alcohol is no longer present, the decrease in inhibitory and increase in excitatory receptor functions become unmasked, leading to the withdrawal syndrome, where neurons are in a hyperexcitable state.

- Toxicity

Ethanol is a general CNS depressant, inducing a degree of sedation dependent on the blood concentration achieved. On drinking a moderate amount of ethanol, users may experience a stimulating phase, due to the depression of the brain mechanisms that control behavior. At low-blood alcohol concentrations (0.01–0.1% w/v), the main brain areas affected are at first the cerebral cortex and then the forebrain, associated with the feelings of relaxation, well-being, loss of inhibition, pleasure, and emotional arousal. From concentrations of 0.01–0.3%, the cerebellum and the brain stem also become affected, leading to mood swings, anger, sadness, aggression, and depression. From 0.31% to higher blood alcohol concentrations, the entire brain becomes affected, leading to unconsciousness, coma, and possibly death. Accordingly, the level of alcohol-induced impairment is also dependent on blood alcohol concentration. At first, alertness is affected, followed by judgment, motor coordination, visual tracking, balance, temperature regulation, bladder control, breathing, and heart rate.

Chronic alcohol use induces liver damage, including fat accumulation, alcoholic hepatitis, and cirrhosis. Chronic alcohol intake also affects digestive functions, leading to gastritis and pancreatitis; cardiovascular function, by inducing cardiomyopathy, arrhythmias, and hypertension; brain damage, head, neck, and esophageal cancers; and also affects immune and endocrine systems. Undernutrition may also be observed in chronic alcohol users, particularly involving vitamin deficiencies.

Tolerance to alcohol develops rapidly, due to neuroadaptations and induction of metabolic enzymes. These adaptations underlie the withdrawal syndrome, which highly contributes to the burden of alcoholism. Alcohol withdrawal is characterized by the symptoms of autonomic nervous system hyperactivity. The initial symptoms are usually mild and include anxiety, insomnia, and tremors, beginning within about 3–6 h of last alcohol intake and usually lasting about 1–3 days. In 5–10% of patients, severe convulsions may also occur in the first 2 days of abstinence. About 10% of alcoholics may develop more severe withdrawal symptoms involving autonomic nervous system hyperactivity, including increases in blood pressure, pulse, breathing and heart rates, and body temperature. Excessive sweating and tremors generally occur. In extreme cases, severe alcohol withdrawal may be complicated by the presence of delirium tremens," which usually manifests within 48–72 h of abstinence. This condition involves agitation, confusion, disorientation, delusions, and vivid hallucinations, and may persist up to 96 h of drink cessation.

Fetal alcohol syndrome (FAS) is an important complication of alcohol abuse by pregnant women. Children with FAS present developmental anomalies such as deficits in the formation of the CNS and restricted physical growth, which may lead to cognitive, behavioral, emotional, and social deficits.

Blood concentrations found in ethanol-related deaths are in the range 2.2–5.0 g l^{-1} and a typical lethal dose varies between 276 and 455 g.

The median lethal dose (LD50) in rats ranges between 5.6 and 10 g kg^{-1} when consumed orally. In mice, the LD50 (oral) was reported to be 3.45 g kg^{-1}.

Methamphetamine (and Other Amphetamines)

Amphetamine was first synthesized in 1887 by Lazar Edeleanu at the University of Berlin. This drug is a synthetic derivative of the plant alkaloid ephedrine, extracted from plants in the genus *Ephedra*. *Ephedra sinica*, also known as Ma Huang, has been used in traditional Chinese medicine for 5000 years to treat several diseases, such as asthma and common cold. Amphetamines are illegally used to increase alertness, to relief fatigue, control weight, and for their intense euphoric effects. Amphetamines are still used in medical practice

to treat narcolepsy and ADHD and have been used as energy boosters by athletes, soldiers, fighter aircraft pilots, and long distance truck drivers.

Methamphetamine is a common amphetamine derivative, more potent than the parent compound. Methamphetamine hydrochloride is presented as a white to light-brown crystalline powder, or crystals that resemble ice, whereas methamphetamine base is a liquid. Methamphetamine is usually available in high purity forms, ranging from 60 to 90% purity. A typical dose ranges from 50 to 2000 mg day^{-1}, but in chronic binge users it may reach 5000 mg day^{-1}.

Another popular amphetamine derivative is MDMA, a ring-substituted amphetamine derivative with mild hallucinogenic properties. It was first synthesized and patented in 1912 by the German pharmaceutical company Merck under the name of "methylsafrylamin," as a precursor for therapeutically active compounds. In 1976, MDMA was used for the first time in the clinics as an adjuvant to psychiatric treatment, to increase patient self-esteem and facilitate therapeutic communication, which continued until the early 1980s, when MDMA was classified as a schedule one drug due to its high abuse potential, lack of clinical application, lack of accepted safety for use under medical supervision, and evidence that it could be neurotoxic. Also at the early 1980s, it became popular in the streets as a recreational drug and is still highly used nowadays, especially in dance parties (raves). MDMA is a white, tan or brown powder, primarily available in tablet form. The typical content of MDMA per tablet has been reported to range from 2 to 130 mg, although the average is between 30 and 80 mg. The typical pattern of MDMA use ranges from 1 to 2 tablets in a single episode, though binge administration of ecstasy tablets is also frequent among users.

Routes of Exposure

Methamphetamine users generally begin with intranasal or oral use and may progress to intravenous use, and occasionally smoking. "Ecstasy" is almost exclusively sold and consumed orally in the form of tablets (rarely capsules), which frequently contain symbols (logos) and are colored.

Pharmacokinetics

- Absorption

Amphetamines are rapidly absorbed after oral ingestion, with peak plasma levels occurring within 2.6–3.6 h. Peak plasma concentrations may range from 0.01 to 2.5 mg ml^{-1} for methamphetamine or 0.02–0.44 mg ml^{-1} for MDMA. The effects of methamphetamine usually persist for 4–8 h, but residual effects may last up to 12 h. MDMA effects may persist for 2–3 h.

- Biodistribution

Amphetamines concentrate in the liver, kidney, lungs, cerebrospinal fluid, and brain. They are highly lipid soluble and readily cross the blood–brain barrier. Amphetamines are weak bases with high p*K*a values between 9.4 and 10.1, low molecular weight, low protein binding (around 20%), and high volume of distribution (3.5–7 l kg).

- Biological half-life

The biologic half-life of orally administered methamphetamine is 10.1 h in average, ranging from 6.4 to 15 h, while that of MDMA is found to be in the range of 6–9 h, depending on the dose.

- Metabolism

The phase I metabolism of methamphetamine by CYP2D6 generates two pharmacologically active metabolites, amphetamine and 4-hydroxymethamphetamine. The major metabolic pathway for amphetamine involves aromatic hydroxylation by CYP2D6 to 4-hydroxyamphetamine, which is psychoactive, and deamination to phenylacetone. This compound is subsequently oxidized to benzoic acid and excreted as glucuronide or glycine (hippuric acid) conjugate. Smaller amounts of amphetamine are converted to norephedrine by oxidation. Hydroxylation of norephedrine produces an active metabolite, 4-hydroxynorephedrine, which is psychoactive.

MDMA is also a substrate for CYP2D6. The major pathways of MDMA metabolism are N-demethylation, O-demethylation, and deamination. MDMA is converted to the catechol, 3,4-dihydroxymethamphetamine (DHMA) and the N-demethylated psychoactive product, 3,4-methylenedioxyamphetamine, MDA, by CYP2D6, but other enzymes may also contribute (e.g. 1A2, 2B6, and 3A4). MDA is further metabolized to the catechol intermediate, 3,4-dihydroxyamphetamine (DHA). DHMA and DHA can undergo oxidation to the corresponding ortho-quinones, which can form adducts with glutathione and other thiol-containing compounds.

- Excretion

An oral dose of 30–54% of methamphetamine is excreted in urine as unchanged methamphetamine, and 10–23% as unchanged amphetamine. After intravenous use, 45% is excreted as methamphetamine and 7% as amphetamine. However, the amount of urinary excretion and metabolism is highly pH dependent, with alkaline urine significantly increasing the drug half-life. Detection time of amphetamine in urine is usually 1–4 days. Methamphetamine may be detected in urine 3–5 days after the last use. The urinary recovery of MDMA is approximately 60%, independently of the dose

administrated. DHMA is the main metabolite found in urine (>20%), with less than 2% of the dose excreted as MDA. MDMA or its metabolites may be detected in urine 1–5 days after the last use.

Pharmacology and Toxicology

- Pharmacodynamics/Mode of action

Methamphetamine increases synaptic levels of the monoamine neurotransmitters dopamine, serotonin (5-HT), and norepinephrine, and has α- and β-adrenergic agonist effects. Due to its structural similarity with dopamine (Fig. 17.1), amphetamine is a substrate for the dopamine transporter (DAT). Amphetamine also interferes with the vesicular monoamine transporter-2 (VMAT-2) function, impairing the active transport of the monoamines into synaptic vesicles, where they are stored. In addition, amphetamines can also deplete vesicular biogenic amine content by disrupting the pH gradient via a weak base effect that drives the transporter. Cytosolic dopamine is then released to the extracellular space via reverse transport through DAT. Amphetamine also inhibits dopamine synthesis by inhibiting tyrosine hydroxylase and may also slowdown catecholamine metabolism by acutely inhibiting monoamine oxidase.

MDMA is similar in structure and effects to methamphetamine (Fig. 17.1), but has significantly less CNS stimulant properties. MDMA has a high affinity for 5-HT2 receptors and may cause acute depletion of presynaptic 5-HT, depression of 5-HT synthesis, and retrograde destruction of 5-HT neurons. MDMA easily diffuses across the cell membranes and lipid layers and may be specifically accumulated inside serotonergic neurons through the serotonin transporter (SERT). MDMA also increases the levels of norepinephrine and dopamine. MDMA hallucinogenic properties depend on the stimulation of 5-HT2A-receptors, mainly in the pyramidal neurons of the neocortex.

Increase in synaptic dopamine in the brain reward pathway is associated with feelings of pleasure induced by amphetamines and other drugs of abuse.

- Toxicity

The increase in dopamine levels induced by amphetamines leads to an increase in its oxidative metabolism, which generates free radicals that may induce cytotoxicity. Dopamine mediates locomotor stimulation, psychosis, and perception disturbances, whereas changes in norepinephrine levels are associated with alerting, anorectic, locomotor, and sympathomimetic effects and 5-HT is responsible for delusions and psychosis. Toxicity of methamphetamine may lead to renal and liver failure, hyperthermia, cardiac arrhythmias, heart attack, cerebrovascular hemorrhages, stroke, seizures, and death.

The effects of methamphetamine are similar to those of cocaine, but start slower and last longer. In most methamphetamine-related deaths, blood concentrations found are in the range 1–43 mg l^{-1}.

D-amphetamine has similar effects to methamphetamine, but is less potent. LD50 of amphetamine was reported as 55 mg kg^{-1} (oral) and 180 mg kg^{-1} (s.c) in rats and 24.2 mg kg^{-1} (oral) in mice. LD50 for methamphetamine was reported as 70 mg kg^{-1} (ip) in rats, 43 mg kg^{-1} (ip) in mice, and 10 mg kg^{-1} (oral) in dogs. The lethal dose of methamphetamine in humans is usually within 140–1650 mg.

MDMA associated fatalities have been reported with blood levels of 0.04–8.5 mg l^{-1}. LD50 for MDMA was determined as 97 mg kg^{-1} (ip) in mice, 49 mg kg^{-1} (ip) and 160 mg kg^{-1} (oral) in rats, and 26–98 mg kg^{-1} (ip) in guinea pigs. The lethal dose of MDMA in humans is in the range of 150–1250 mg.

MDMA neurotoxicity is the most widely studied toxic effect and potentially the most significant long-term effect of this drug. Other complications of acute MDMA use include hyperthermia, arrhythmias and cardiovascular collapse, liver failure, renal failure, and hyponatremia. Another severe consequence is rhabdomyolysis, which is characterized by the breakdown of muscle fibers that result in the release of their myoglobin contents into the bloodstream, contributing to kidney damage.

The MDMA metabolite, MDA, induces higher levels of stereotypic behavior and is more neurotoxic than the parent drug. MDA destroys 5-HT-producing neurons, which regulate aggression, mood, sexual activity, sleep, and sensitivity to pain.

Cocaine

Cocaine was first isolated in 1855 by the German chemist Friedrich Gaedcke. This alkaloid is extracted from the plant *Erythroxylum coca*, which is cultivated in the South American countries Bolivia, Colombia, and Peru. The natives of these countries chew the coca leaves in magical ceremonies and initiation rites. Cocaine may be processed in water-soluble or -insoluble forms. Water-soluble forms include cocaine sulfate and cocaine hydrochloride. In medicine, cocaine is used as a topical local anesthetic for ear, nose, and throat surgery.

Cocaine hydrochloride is presented as a shiny white to light-brown crystalline powder, whereas cocaine base is generally a white to beige waxy solid. Cocaine is used recreationally to increase alertness, relief fatigue, and increase self-confidence, and is abused for its intense euphoric effects. Purity of cocaine hydrochloride ranges from 20 to 95%, and crack cocaine is generally 20–80% pure. Cocaine is often "cut" with sugars, other CNS stimulants, and local anesthetics. Common doses range from 10 to 120 mg.

Routes of Exposure

Cocaine sulfate and cocaine hydrochloride are used by oral, sublingual, intranasal, and intravenous routes, whereas coca leaves may be chewed. Drug smugglers, known as "mules" or "body packers," may swallow packages of cocaine, which may leak or rupture and cause massive intoxication.

Water-insoluble forms such as free base cocaine or crack are usually smoked. Crack cocaine is abused by inhaling the vapor from cigarettes (usually mixed with tobacco or marijuana) or after heating the drug in a glass pipe. Most drug abusers use cocaine by the nasal route. Cocaine hydrochloride can be "sniffed" or "snorted" in "lines" on a flat surface. This route leads to pulmonary complications.

Some drug abusers inject cocaine hydrochloride subcutaneously, intramuscularly, or intravenously, alone or with heroin ("speedball") or with other drugs

Cocaine can also be administered rectally, vaginally, and urethrally.

For clinical purposes, cocaine is used topically to take advantage of its local anesthetic effects.

Pharmacokinetics

- Absorption

Cocaine is rapidly absorbed following smoking, snorting, and intravenous administration.

Bioavailability is about 93.7% after intranasal use and 70% on smoking.

Injecting cocaine produces an effect within 15–30 s. After smoking crack or snorting cocaine the effects are almost immediate. In fact, through this way, cocaine enters the pulmonary circulation and reaches the cerebral circulation within 6 s, eliciting a rapid, short, but very intense euphoric effect. The effects of crack typically last 5–15 min, whereas after snorting the effects may last 15–30 min.

When orally ingested, the effects of cocaine begin to be observed in about 1 h and may persist for 1–2 h.

Typical blood concentrations after a single use are in the range of 0.2–0.4 mg ml^{-1}, but tolerant individuals may present up to 5 mg l^{-1}.

- Biodistribution

Cocaine is distributed within all body tissues, and crosses the blood–brain barrier. In large, repeated doses, it is probably accumulated in the CNS and in adipose tissue, due to its lipid solubility. Cocaine is found 91% bound to proteins and its volume of distribution varies between 1 and 3 l kg^{-1}. Cocaine crosses the placenta by simple diffusion and may accumulate in the fetus after repeated use.

- Biological half-life

Cocaine half-life is about 1 h, varying from about 0.6 h on smoking, 0.8 h after oral administration, 1.25 h after nasal administration, and 0.7–0.9 h after parenteral administration.

- Metabolism

Cocaine metabolism takes place mainly in the liver, within 2 h of administration. The rate of metabolism varies according to plasma concentration. There are three main routes of biotransformation: The major route is hydrolysis of cocaine by hepatic and plasma esterases, with loss of a benzoyl group originating ecgonine methyl ester (EME). The secondary route is spontaneous hydrolysis, which leads to benzoylecgonine (BE) by demethylation. Both EME and BE are then converted into ecgonine. A minor route is N-demethylation of cocaine by CYP3A4, leading to the active metabolite norcocaine, which crosses the blood–brain barrier.

Anhydroecgonine methyl ester can be produced when the drug is consumed in the free base form (as a result of thermal degradation of smoked "crack"). In the presence of alcohol another active metabolite, cocaethylene, is formed, which is more toxic than cocaine itself.

- Excretion

Unchanged cocaine is recovered at less than 2% in urine, although higher proportions may be seen in acidic urine; 26–39% of cocaine is recovered as BE and 18–22% as EME. After 4 h of use, most of the drug is eliminated from plasma. Cocaine metabolites persist in urine at detectable concentrations from 2 to 4 days of abstinence, but after chronic use they may be present for up to 10 days after the last use.

Pharmacology and Toxicology

- Pharmacodynamics (mode of action)

The main targets of cocaine are the CNS and cardiovascular system.

Cocaine interferes with the reuptake of monoamine transmitters, particularly dopamine, a neurotransmitter associated with pleasure and movement. Cocaine binds to the DAT blocking its function, which leads to increased extracellular dopamine and results in chronic stimulation of postsynaptic dopamine receptors, resulting in the euphoric "rush." Dopamine levels then fall, resulting in the dysphoric "crash." Cocaine also interferes with the uptake of norepinephrine and 5-HT, leading to accumulation of these neurotransmitters at postsynaptic receptors. Cocaine also acts as a local anesthetic, because it reversibly blocks the initiation and conduction of the nerve impulse, by binding to voltage-gated sodium channels.

Cocaine also increases catecholamine concentrations in the blood, leading to excessive stimulation of peripheral α- and β-adrenoreceptors.

- Toxicity

The neurotoxic actions of cocaine involve several brain areas and different mechanisms of action. Euphoria, confusion, agitation, and hallucination result from an increase in dopamine activity in the limbic system. Cortical effects lead to pressure of speech, excitation, and a reduced feeling of fatigue. Stimulation of lower centers leads to tremor and tonic–clonic convulsions. Brain stem effects lead to stimulation and then depression of the respiratory vasomotor and vomiting centers. Cocaine may induce hyperthermia due to increase in muscular activity and by a direct effect on thermal regulatory centers.

At low doses, cocaine induces vagal stimulation with bradycardia, whereas at moderate doses, adrenergic stimulation leads to a rapid increase in cardiac output, myocardial oxygen consumption, and blood pressure, then followed by a decrease. This may result in increased risk of myocardial infarction and spontaneous cerebral hemorrhage. At very high doses, a direct toxic effect of cocaine on the myocardium may result in cardiac arrest.

Cocaine abusers may present rhabdomyolysis, probably due to a direct effect of cocaine on muscle and muscle metabolism, tissue ischemia, or due to the effects of other drugs taken with cocaine, such as alcohol and heroin.

Prenatal brain toxicity constitutes another serious negative effect of cocaine, leading to structural, metabolic, and functional brain abnormalities.

Lethal doses of cocaine in humans are estimated at 20–2000 mg. However, cocaine addicts can tolerate doses up to 5 g day^{-1}. Toxic effects can be manifested with plasma concentrations of 0.50 mg l^{-1} or more and death has been reported with concentrations of 1–20 mg l^{-1}.

The LD50 of cocaine was determined as 17.5 mg kg^{-1} (iv) in rats, 91 mg kg^{-1} (ip) in mice, and 21 mg kg^{-1} (iv) in dogs.

Heroin and Morphine

Morphine and heroin are derived from opium, which is extracted from the opium poppy *Papaver somniferum*. There are reports of cultivation of this plant in the Mesopotamia since 3400 BC. Opium contains about 40 alkaloids that make up 10–20% of total opium substances. The most abundant opium alkaloids are morphine (8–17%), codeine (0.7–5%), thebaine (0.1–1.5%), papaverine (0.5–1.5%), and noscapine (or narcotine, 1–10%). Morphine is purified from opium extracts and converted into heroin by acetylation. Heroin is more lipid soluble than morphine and is easily transported across the blood–brain barrier, being two to four times more potent than morphine. Heroin was first synthesized in 1874 by Charles Alder Wright in England, but it was only discovered by the medical community when it was independently resynthesized, 23 years later, by Felix Hoffmann, who worked for Bayer. The use of heroin was thought to be a potential cure for morphine addiction until it was found that heroin is converted into morphine, when metabolized in the liver.

Morphine and heroin are generally white, crystalline powders. Illicit heroin may vary in color from white to dark-brown due to impurities or may appear as a black tar-like material. Depending on the demographic region, the street purity of heroin can range from 20 to 90%. Heroin may be "cut" with inert or toxic adulterants such as sugar, starch, powdered milk, quinine, and ketamine.

Heroin is often mixed with stimulants, such as methamphetamine or cocaine ("speedball"), and injected. It may also be coadministered with MDMA or crack cocaine.

Daily heroin doses may range between 5 and 1500 mg, with an average daily dose of about 300–500 mg, which may be divided by two to four daily injections.

Routes of Exposure

Morphine may be used by oral, intramuscular, intravenous, subcutaneous, rectal, epidural, and intrathecal administration. Heroin may be smoked (referred to in street jargon as "chasing the dragon"), snorted or injected intravenously ("mainlining"), and subcutaneously ("skin popping"). Black tar heroin is typically dissolved, diluted, and injected, while higher purity heroin is often snorted or smoked.

Pharmacokinetics

- Absorption

The absorption of heroin is 1.5 times higher than that of morphine, and it is 2–4 times more potent, and 200 times more soluble.

Tolerance makes interpretation of blood or plasma morphine concentrations extremely difficult. Postmortem analyses after heroin overdoses found blood morphine concentrations between 0.1 and 2.8 mg ml^{-1}.

- Biodistribution

The oral bioavailability of morphine is 20–40%, and 12–35% is bound in plasma, mainly to albumin, with approximately 5% bound to γ-globulin and 5% to α1-acid-glycoprotein. The blood/plasma concentration ratio is about 1.02 in healthy individuals. The bioavailability of smoked heroin is about 44–61%.

Morphine is relatively hydrophilic and therefore distributes slowly into tissues. The volume of distribution of morphine is generally within 1–5 l kg^{-1}. Heroin and 6-MAM cross the blood–brain barrier more easily than morphine. Morphine is transported into the brain by P-glycoprotein, present in brain capillary endothelium, and accumulates especially in the hippocampus where there is also a high concentration of opioid receptors.

- Biological half-life

Heroin has an extremely short half-life of 2–6 min. The half-lives of 6-MAM and morphine are 6–25 min and 1.5–7 h, respectively.

- Metabolism

Heroin is rapidly metabolized to 6-MAM and morphine. Heroin and 6-MAM are more lipid soluble than morphine and thus enter the brain more readily. Morphine is primarily glucuroconjugated at positions 3 and 6, to form morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), respectively. A small amount (5%) is demethylated to normorphine by CYP3A4 and to a lower extent by CYP2C8. M6G is an active metabolite with a higher potency than morphine. The half-life of M6G is 4 ± 1.5 h. About 90% of a single morphine dose is eliminated in urine in 72 h, 75% as M3G and less than 10% as unchanged morphine.

- Excretion

Positive morphine results in urine generally indicate use within the last 2–3 days, or longer after prolonged use. Detection of 6-MAM in urine is indicative of heroin use. High concentrations may indicate chronic use of the drug.

Pharmacology and Toxicology

- Pharmacodynamics (mode of action)

Morphine produces its major effects on the CNS primarily through μ-Receptors, and also at κ- and δ-receptors. μ-Receptors are almost always located presynaptically. Interaction of opioids with μ-opioid receptors located in inhibitory GABAergic interneurons in the reward pathway leads to inhibition of these neurons, resulting in disinhibition of dopaminergic neurons and increased synaptic dopamine concentrations associated with reward and repetitive drug use.

The brain region that contains the greatest concentration of μ-opioid receptors is the periaqueductal gray, but they are also found in the hippocampus, the superficial dorsal horn of the spinal cord, the external plexiform layer of the olfactory bulb, the nucleus accumbens (involved in reward and addiction), in some parts of the cerebral cortex, and in the amygdala.

μ1-Receptors are involved in pain modulation, analgesia, respiratory depression, miosis, euphoria, and decreased gastrointestinal activity; μ2-receptors are involved in respiratory depression, drowsiness, nausea, and mental clouding; κ-receptors are involved in analgesia, diuresis, sedation, dysphoria, mild respiratory depression, and miosis; and δ-receptors are involved in analgesia, dysphoria, delusions, and hallucinations.

Heroin has little affinity for opiate receptors. It behaves as a highly lipophilic transporter of morphine and induces more rapid and more intense CNS effects. Most of its pharmacology resides in its metabolism to the active metabolites, 6-MAM, morphine, and M6G.

Depending on morphine dose and the route of administration, effects begin within 5–60 min and may last 4–6 h. Following heroin use, the intense euphoria generally lasts from 45 s to several minutes. Peak effects may last 1–2 h, and the overall effects disappear in 3–5 h.

- Toxicity

The toxic and lethal doses depend greatly on the individual's tolerance to the drug, and thus the usual dose for an addict may be dangerous for the same individual after several days of abstinence, due to the rapid decrease in tolerance. A dose of 20 mg heroin may be lethal in non-tolerant subjects, whereas addicts may tolerate doses 10 times larger. Fatalities have been observed after a dose of 12 mg, resulting from respiratory depression.

Plasma concentration of morphine after lethal overdosage of heroin is generally in the range 0.1–2.8 mg l^{-1}, and the lethal dose is within 12–180 mg.

LD50 of heroin is around 21.8 mg kg^{-1} (iv) in mice and 23 mg kg^{-1} in rats, whereas for morphine the LD50 in mice is 226–318 mg kg^{-1} (iv).

Chronic heroin addicts frequently suffer from rhabdomyolysis, probably due to compression of muscle during prolonged immobilization, aggravated by the occlusion of vascular supply. Renal damage may progress to terminal renal insufficiency. Respiratory and cutaneous complications are also observed, probably due to immune deficiency, which may be related with a reduction in lymphocyte proliferation, spontaneous cytolytic activity, phagocytosis, and interferon production. Splenomegaly due to antigenic stimulation has been also described in heroin addicts.

Cannabis

Cannabis, also known as marijuana, is a term applied to preparations of the cannabis plant, especially of *Cannabis sativa*, intended for use as a psychoactive drug or for medicinal purposes. Cannabis is the most widely used illicit psychotropic drug in the world. The first descriptions of medical and toxic properties of the plant were part of the ancient Chinese herbal Pen-ts'ao, dating

TABLE 17.2 Characteristics and Pharmacokinetic Properties of Selected Drugs of Abuse

Drug	Ethanol	Amph	Meth	MDMA	COC	HER	MOR	THC
Class	Sedative/hypnotic, CNS depressant	CNS stimulant, sympathomimetic, appetite suppressant	CNS stimulant, sympathomimetic, appetite suppressant	Mild CNS stimulant, empathogen, entactogen, mild hallucinogen and psychedelic, appetite suppressant	CNS stimulant, local anesthetic	Narcotic analgesic	Narcotic analgesic	Cannabis/ marijuana

Note: For details see text.

from the first to second centuries AD. The popularity of cannabis recreational use by young people on both sides of the Atlantic was closely linked to the protest and rebellion associated with the 1960s generation. Cannabis contains more than 400 different chemical compounds, but the main psychoactive chemical compound is the delta-9-tetrahydrocannabinol (THC). Cannabis is used recreationally as a psychoactive drug under unprocessed or processed forms. In the streets, cannabis may be found in the form of leaves or small stems (known as marijuana, bhang, dagga, or kif), female flower heads (sensimilla), as resin (known as hashish, hash, charas, or polm), or oil (alcoholic resin extract). These forms have different levels of purity, ranging from 1 to 60% THC. In recent years, there has been a large increase in the consumption of home-grown cannabis – often using modern strains of plants yielding a high THC content. Cannabis is consumed in many different ways, most of which involve inhaling vaporized cannabinoids (smoke) from small pipes, paper-wrapped joints, or tobacco leaf-wrapped blunts. Cannabis may also be ingested orally in foods and drinks.

Clinically, cannabis may be used in the treatment of anorexia associated with weight loss in patients with AIDS, and to treat mild to moderate nausea and vomiting associated with cancer chemotherapy. Recreationally, marijuana is used for its mood altering effects, euphoria, and relaxation.

Routes of Exposure

The most common way of consuming marijuana and hashish is through inhalation. The inhaled smoke of one cigarette (joint) may contain 0.5–0.7 g of delta-9-THC, but a common dose generally contains 5–25 mg THC. Marijuana can be smoked directly or through small pipes or 'bongs.' The oral route is the usual route of administration for medical purposes. Cannabis may also be ingested orally in foods and drinks for recreational purposes.

Pharmacokinetics

- Absorption

Absorption by the oral route of administration is slow, with low, delayed peak THC levels. Bioavailability is reduced following oral ingestion (4–12%) due to extensive first pass metabolism.

Smoking marijuana results in rapid absorption, with a bioavailability of 8–50%. Peak THC plasma concentrations generally occur during the act of smoking. Typical peak plasma concentrations range from 100 to 200 ng ml^{-1} and drop below 5 ng ml^{-1} less than 3 h after smoking. The minimum plasma concentration of THC, which produces psychotropic effects, was reported as 25 ng ml^{-1}.

- Biodistribution

THC is highly lipophilic and thus widely distributed throughout the organism, with high concentrations accumulating in fatty tissues that are then slowly released into the circulation. The volume of distribution is about 4–14 l kg^{-1}.

- Biological half-life

The half-life of THC is about 3 days. Plasma concentrations of THC and its metabolite 11-hydroxy-THC decline in a few minutes, due to their redistribution to fatty tissues. After that the decline is slow, with a half-life of 30 h. The half-life may be increased in chronic users, from 2.9 to 5.0 days.

- Metabolism

THC is primarily metabolized by CYP2C9 and CYP2C19 to 11-hydroxy-THC, which has equipotent psychoactivity. The 11-hydroxy-THC is then rapidly metabolized to the 11-nor-9-carboxy-THC (THC-COOH), which is not psychoactive, and then to non-cannabinoid metabolites such as terpenes and alkenes. CYP3A4 in human liver catalyzes the oxidation of the 7- or 8-position of THC.

THC and its metabolites persist in human plasma for several days or weeks. Chronic marijuana smokers metabolize THC more rapidly than nonsmokers.

- Excretion

THC is rapidly and extensively metabolized with very little THC being excreted unchanged from the body. A majority of THC is excreted in the feces (~65%), with approximately 30% of the THC being eliminated in the urine, as conjugated glucuronic acids and free THC hydroxylated metabolites.

Metabolites can be detected in urine even 2–3 days after one exposure and, in cases of chronic use, after 4–5 weeks of abstinence.

Pharmacology and Toxicology

- Pharmacodynamics (mode of action)

THC binds to the cannabinoid receptors CB1 and CB2, and interferes with important endogenous cannabinoid neurotransmitter systems. CB1 exists mainly in the brain and in the nerve terminals innervating the gastrointestinal system, whereas CB2 is expressed mostly in immune cells.

Cannabis affects the CNS by activating CB1 receptors located on excitatory and inhibitory nerve terminals. Receptor distribution correlates with brain areas involved in physiological, psychomotor, and cognitive effects.

Repetitive use of cannabis is explained by the interaction of THC with presynaptic CB1 receptors located at

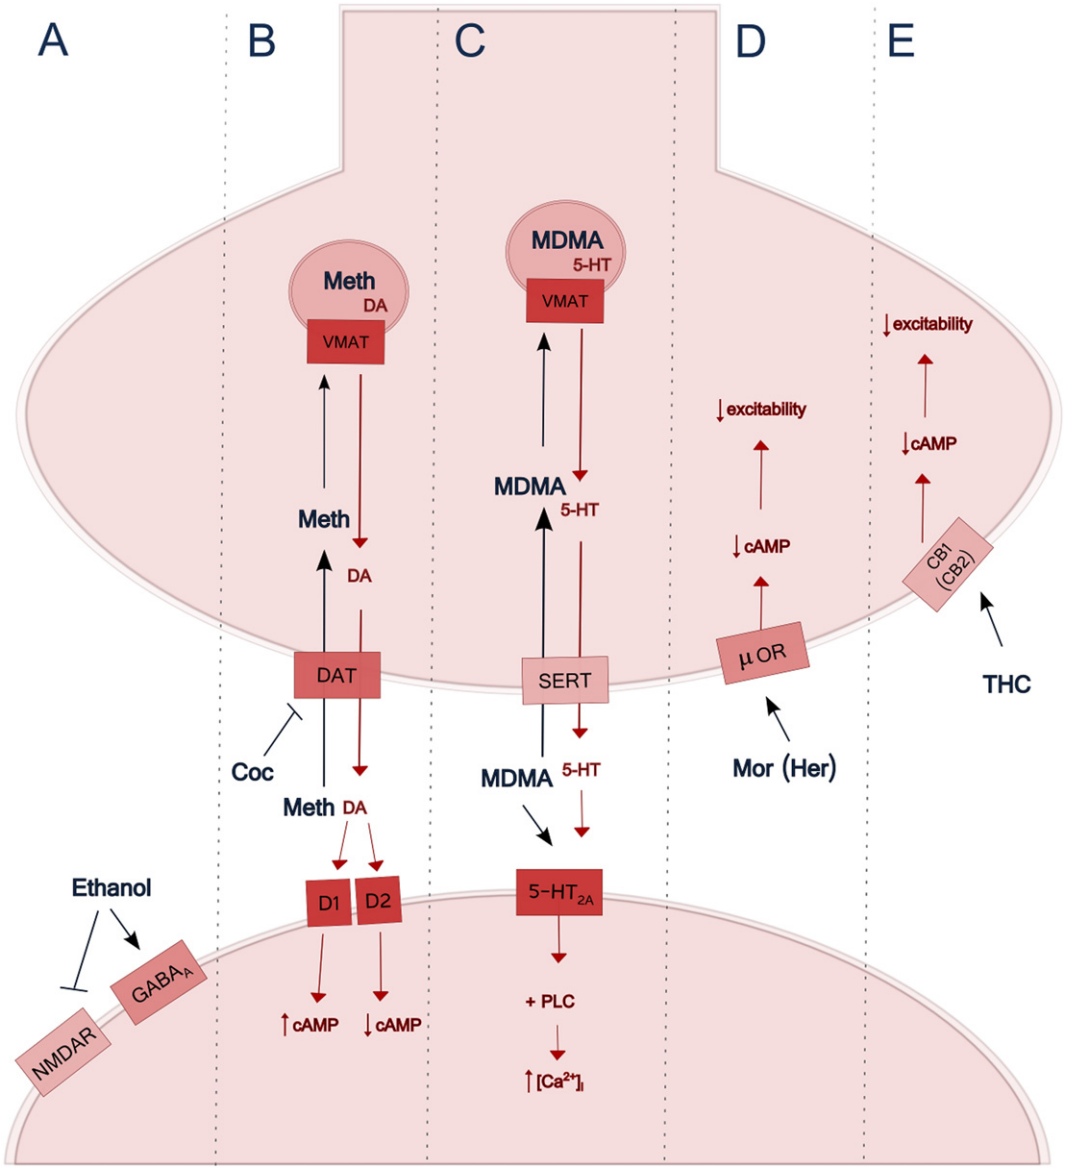

FIGURE 17.2 Molecular targets and main consequences of the actions of drugs of abuse in nerve terminals. **A)** Ethanol shares structural similarities with the neurotransmitters GABA and glutamate and interferes with $GABA_A$ and NMDA receptors, depressing neuronal activity. Methamphetamine (Meth), cocaine (Coc), and MDMA interact directly with monoaminergic nerve terminals. **B)** Meth is a substrate for the dopamine transporter (DAT), entering into the nerve terminal. There, it impairs the storage of dopamine (DA) in synaptic vesicles through VMAT, increasing DA cytosolic concentration and inducing the DAT reverse transport. Coc inhibits DA reuptake by the DAT. Both Meth and Coc lead to an increase in synaptic DA via direct effects in the DAergic nerve terminal, leading to increased activation of DA receptors. **C)** MDMA is a substrate for the serotonin transporter (SERT), being carried into serotonin (5-HT) terminals and leading to impairment of 5-HT storage in synaptic vesicles: This results in the release of 5-HT to the cytosol and reverse transport by SERT, thus increasing synaptic levels of 5-HT. MDMA is also an agonist of 5-HT2A receptors. **D)** Heroin is metabolized into morphine, which is a preferential agonist of μ-opioid receptors. **E)** Delta-9-tetrahydrocannabinol (THC), the psychoactive component of marijuana, activates cannabinoid receptors CB1 and CB2. Activation of μ-opioid and/or cannabinoid receptors leads to a decrease in adenylate cyclase activity, leading to decreases in electrical excitability and neurotransmitter release.

inhibitory GABAergic interneurons in the reward pathway, leading to decreased gamma-aminobutyric acid (GABA) release. This causes disinhibition of dopaminergic neurons and leads to an increase in synaptic dopamine concentrations, similarly to what happens with opioid drugs of abuse.

- Toxicity

THC produces alterations in motor behavior, perception, cognition, memory, learning, endocrine function, food intake, and regulation of body temperature. Long-term use of cannabis has been associated with the occurrence of psychotic episodes.

Activation of CB1 receptors causes profound coronary and cerebral vasodilation and hypotension. An increase in heart rate, usually accompanied by a mild increase in systolic pressure, is generally observed after THC use.

Lethal blood concentration of THC is within 0.180–0.315 mg l^{-1}, and the lethal dose is over 15 g.

In rats, LD50 (oral) of cannabis is within 730–1270 mg kg^{-1}, LD50 (iv) is about 40 mg kg^{-1}, and LD50 (inhalation) is 105.7 mg kg^{-1}. The LD50 in mice is 22 mg kg^{-1} (oral) and in monkeys is 130 mg kg^{-1} (iv).

CONCLUSIONS

Drugs of abuse, such as alcohol, amphetamines, cocaine, heroin, and cannabis have distinct toxicological properties and cause severe medical complications. Table 17.2 summarizes and compares the main chemical, pharmacological, and toxicological properties of these drugs, which share chemical similarities with neuronal active endogenous compounds and are thus psychoactive. All drugs of abuse affect neurotransmission, by interfering with neurotransmitter receptors and transporters. The molecular targets of these drugs of abuse in nerve terminals are represented in Fig. 17.2.

VMAT-2	vesicular monoamine transporter-2

Glossary

Bioavailability the proportion of drug absorbed into the systemic circulation.

Biodistribution the extent of distribution of a drug throughout the body.

Biotransformation chemical modification(s) made by an organism on a chemical compound.

First pass effect the loss of drug, following oral administration, due to hepatic metabolism, before it reaches systemic circulation.

Hyponatremia an electrolyte disturbance in which the sodium concentration in the plasma is lower than normal.

Median lethal dose (LD50) dose of a drug that kills half (50%) of the population tested (LD = lethal dose).

Plasma half-life a measure of the elimination rate, indicating the time it takes for the plasma concentration of a drug to reach half of its original concentration.

Parenteral route of administration independent of the gastrointestinal system.

Pharmacodynamics biochemical and physiological effects of drugs on the organism, including the mechanisms of drug action and the structure–activity relationship.

Pharmacokinetics study of the fate of substances administered externally to a living organism.

Rhabdomyolysis the destruction or degeneration of skeletal muscle tissue that is accompanied by the release of muscle cell contents (such as myoglobin and potassium) into the bloodstream.

Volume of distribution a measure of the volume in which the total amount of drug used would need to be uniformly distributed to produce the observed blood concentration.

Xenobiotic a chemical compound that is foreign to a living organism.

Tolerance and Withdrawal

Baine B. Craft, M. Kathleen B. Lustyk
Seattle Pacific University, Seattle, WA, USA

OUTLINE

TOLERANCE

As a construct, tolerance can be defined as a decrease in the magnitude of drug effects over the course of successive administrations of the same dose of drug. Stated another way, when a larger dose of a drug is needed to achieve a desired effect, tolerance has occurred. From a clinical perspective, tolerance is one of the seven potential symptoms or criteria used to diagnose substance dependence; however, dependence is not necessary for tolerance to occur.

Drug tolerance can be operationally defined as a shift in the dose–response curve to the right. As shown in Fig. 18.1, when the magnitude of the drug effect (*y*-axis) is plotted against the dose of the drug (*x*-axis), the dose response of a given drug follows a similar curvilinear trajectory irrespective of the dose. However, the dose at which a person achieves the desired drug effects is much less with first time use than the dose of drug needed with subsequent use. The difference in the dose needed to reach the desired magnitude of drug effect is explained by tolerance. This operational definition allows for tolerance to be mathematically quantified and empirically studied.

Tolerance can be defined more specifically as acute and chronic tolerance. Acute tolerance is the result of a single exposure to a substance whereby the drug effect decreases over time. Procedurally, the development and effects of acute tolerance have been studied when a single dose of a drug is administered or when a single dose of a drug is administered over a prolonged period of time during a single session. In ethanol studies, for example, acute tolerance occurs when the effects of ethanol, which cannot be explained by the half-life of the drug, decrease over time and exposure to ethanol during a single session. As a result of exposure to ethanol, more impairment in behaviors and cognitive performance occurs during the same ascending blood ethanol concentrations. However, once compensatory reactions that result in tolerance have occurred, fewer errors in behavioral and cognitive performance occur during descending blood ethanol concentrations.

Where acute tolerance is the result of a single session or administration of a drug over a brief amount of time (e.g. minutes or hours), chronic tolerance is due to several sessions of exposure to a drug across a longer amount of time such as days. Chronic tolerance more closely mimics the development of tolerance that is common in human drug dependence. For example, human substance abuse follows a typical pattern of relatively brief but repeated drug administration over days or weeks. Evidence from some studies suggest a relationship between acute and chronic tolerance such that associations with a particular drug that occur during acute tolerance facilitate the tolerance that occurs with chronic administration of a drug.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00018-8

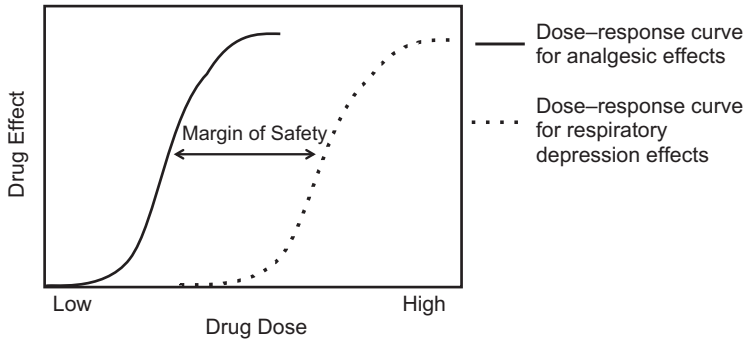

FIGURE 18.1 Margin of safety between therapeutic and harmful doses of opiates.

Research studies suggest that no single mechanism predicts tolerance. Rather, tolerance is due to various combinations of mechanisms, which may or may not be dependent upon the type of drug used. These mechanisms can be broadly categorized into biological and behavioral mechanisms or forms of tolerance. For example, research has shown that tolerance can result from changes in the metabolism of a drug, a decrease or increase in the responsiveness of neurotransmitter receptors, or as the result of learning. In addition, changes in the dose, type of drug consumed, or individual (i.e. genetic) factors can result in differences in the development of tolerance.

Biological Mechanisms

Biologically, tolerance is the result of adaptations or responses to changes in homeostasis. Homeostasis is a term coined by Walter Cannon in the early 1900s to mean internal stability despite environmental change. According to Cannon, environmental change could be either endogenous (i.e. within the individual) or exogenous (i.e. outside the individual). When confronted with the presence of an exogenous or endogenous chemical substance, the body responds in different ways to return to homeostasis. Moreover, both endogenous and exogenous factors can contribute to the homeostatic adaptations that result in tolerance. For example, a primary drug effect of alcohol use is hypothermia (i.e. a decrease in body temperature). Due to the hypothermic effect, a compensatory reaction occurs such that the body compensates for the presence of alcohol in the body by increasing body temperature through thermoregulatory mechanisms. While the compensation for changes in homeostasis is adaptive, it also underlies tolerance. In other words, tolerance is caused by compensatory reactions that oppose the primary drug effects.

Types of compensatory reactions include pharmacodynamics or metabolic adaptations, where pharmacodynamics refers to changes in the body in response to a drug. An example is when the tissue adapts to the drug. This adaptation can occur at the molecular level in the form of receptor binding site modification. If, for example, the effect of a drug is to increase the actions of a certain neurochemical, the body may respond by decreasing the number of active ligand-binding sites on the receptors for that neurochemical. More specifically, using positron emission tomography (PET), Michael Nader and his colleagues at Wake Forest University Medical School showed a reduction in dopamine D_2 receptor availability in response to cocaine abuse.

More complex adaptations at the molecular level can also occur such as those involving second messenger systems, which ultimately diminish receptor–ligand binding efficiency and/or the effects of receptor–ligand binding on cellular activity. For example, research with knockout transgenic mice lacking the opiate μ receptor shows that these animals are immune to the rewarding actions of morphine. Given that μ receptor actions are mediated by G-protein second messengers with various effects, myriad functional changes are possible due to tolerance at these sites. Resultantly, these biological responses compensate for the increased neurochemical activity brought on by the drug.

Given the properties of neural receptors, a drug-induced adaptation at the receptor level may result in cross tolerance or tolerance specificity. Cross tolerance occurs when one drug produces tolerance to another drug that acts via the same biological mechanism. For example, alcohol-dependent individuals may experience cross tolerance with benzodiazepines such that alcoholics may fail to obtain the anxiolytic effects from benzodiazepines. Both alcohol and benzodiazepines are central nervous system depressants with a primary site of action being the gamma-aminobutyric acid (GABA) receptor complex. By inducing changes that make ligand–receptor binding more efficacious, alcohol and benzodiazepines possess pharmacologic synergy and cross tolerance. While this may reduce the potential anxiolytic effects of benzodiazepines in the alcoholics, it does allow benzodiazepines to be used for alcohol detoxification. Because benzodiazepine dosage can be more tightly regimented than alcohol, step-down dosing

with benzodiazepines can ease the suffering experienced during rehabilitation from alcoholism.

Conversely, tolerance specificity is also possible. This occurs when specific neural adaptations to a drug result in tolerance to some drug effects but not others. For example, the primary effects of opiates on analgesia and euphoria are subject to tolerance whereas opiate effects on autonomic nervous system driven changes such as respiratory depression are not. These processes stand in stark contrast to sensitization, which can be thought of as the opposite of tolerance.

Sensitization occurs when drug effects become enhanced. Sensitization to the dopaminergic response in the nucleus accumbens has been observed in rats repeatedly exposed to amphetamines. That is to say, with repeated doses of amphetamines, the drug increases its ability to increase extracellular levels of dopamine in the pleasure circuit. Such findings have important clinical implications as they may help us understand an addict's progressive increases in motivation to seek out and use drugs. However, research attempts to demonstrate sensitization in multiple animal models and in humans are equivocal. As such, some researchers suggest that a model of drug abuse that includes processes of sensitization is of limited value. Interested readers are referred to the review of the topic by Paul Venzia cited in the reference section of this chapter.

With tolerance, metabolic adaptations can also occur. An example is drug dispositional tolerance. This can occur when the liver develops a more efficient clearance rate for the drug. For example, with repeated use of barbiturates, the concentration of microsomal liver enzymes responsible for metabolism of the drug increases. As a result, the drug can be more rapidly eliminated from the body. Other metabolic changes may involve drug absorption, distribution, and/or excretion, which can also result in dispositional tolerance.

Together, pharmacodynamics and drug dispositional tolerance counteract the desired effects of the drug resulting in the need for more of the drug to achieve the desired effect or high.

Behavioral Mechanisms

Using standard Pavlovian conditioning procedures, Dr Shepard Siegel and other researchers have demonstrated the powerful role of Pavlovian conditioning in the development of tolerance. Tolerance that results from learning or behavioral tolerance is a decrease in drug efficacy that is due to behavioral or associative mechanisms. This type of tolerance has been referred to as situation-specific or environment-dependent tolerance due to the influence of the situational or environmental cues on compensatory responses.

In situation-specific tolerance, the presence of a drug in the body is defined as an unconditioned stimulus, and the primary drug effect is the unconditioned response. After repeated pairings of the drug with neutral stimuli in a specific situation or environment (e.g. drug paraphernalia), classical conditioning occurs such that the previously neutral stimuli within the environment become conditioned stimuli that elicit a conditioned response. Conditioned stimuli (e.g. drug paraphernalia) that have been associated with a particular drug, when presented in the absence of the drug, elicit compensatory reactions; these reactions are called conditioned compensatory reactions (see Table 18.2).

Conditioned compensatory reactions serve to counteract primary drug effects. For example, using a rat model, if subjects were given alcohol in the presence of cues previously associated with alcohol (i.e. stimuli in the room), Siegel observed a conditioned compensatory reaction such that the cues caused an increase in body temperature. By increasing body temperature, the stimuli that had been paired with alcohol elicited a compensatory reaction to counteract the hypothermic effects of alcohol. However, if rats were exposed to alcohol in the absence of cues previously associated with alcohol (i.e. in a different room where they had not previously been given alcohol), a conditioned compensatory response did not occur, and subjects' body temperature did not increase. In the previous example, cues in the animals' environment elicited a conditioned compensatory reaction. These cues can be categorized as exteroceptive cues.

External or exteroceptive as well as internal or interoceptive are two types of cues that have been shown to result in conditioned compensatory reactions. Exteroceptive cues (e.g. visual, auditory, or olfactory) are observable and external to the organism, and when paired with a drug effect, these cues will result in a conditioned compensatory reaction. For example, in the rat model of heroin addiction, Siegel demonstrated that when rats experienced the administration of a drug in a distinctive environment, subjects' behaviors were less lethargic or more tolerant to morphine's sedative effects on behavior. However, when morphine was administered in novel or different environment than previously paired with morphine, subjects were less tolerant to the effects of the drug.

Interoceptive cues are internal or unobservable, but when paired with a drug effect (similar to exteroceptive cues), these cues will result in a conditioned compensatory reaction. For example, one type of interoceptive cues are drug-onset cues. Research has shown that when associated with a particular drug effect, the initial onset or effect of a drug can cause conditioned compensatory reactions. Animal studies of interoceptive cues resulting from pairings with ethanol have shown that

subjects with prior exposure to ethanol will display conditioned compensatory reactions when only a small dose of ethanol is administered. That is, increases in rat's body temperature were observed when a small dose of ethanol was administered to subjects with prior experience with ethanol.

A second example of interoceptive cues, self-administration cues, occur when individuals are preparing to administer a drug. Whether heroin or smoking a cigarette, individuals develop patterns of behavior that precede the administration of a drug. These behavioral patterns and the presence of drug paraphernalia before and during drug administration can serve as strong conditioned stimuli that elicit conditioned compensatory reactions. For example, the process of preparing a syringe or tying a tourniquet before using heroin or the process of packing or opening a pack of cigarettes can become conditioned stimuli that elicit conditioned compensatory reactions. While the cues in the aforementioned example may seem external, they are, however, internal as the behaviors being performed are initiated by the subject. These processes will be further discussed below as we focus on withdrawal.

Tolerance and Addiction

Due to the increased dose required to achieve a particular drug effect once tolerance has occurred, tolerance plays an integral role in the development of an addiction. These effects are particularly dependent on alterations in the neurocircuitry that allows for the pleasurable experiences of drug use. This circuitry involves dopaminergic neurons originating from a region in the lower brain called the ventral tegmental area (VTA). These neurons give rise to mesolimbic and mesocortical projections implicated in reward. Commonly abused substances such as nicotine, alcohol, and opiates affect the release of dopamine and/or the levels of dopamine within the complex circuitry known as the mesocorticolimbic dopaminergic system. Meso refers to the mesencephalon or midbrain, which as its name implies lies toward the middle of the brain. The mesencephalon is divided into the tectum, or roof, and the tegmentum, or floor. Within the ventral part of the tegmentum lies the VTA. One target of the dopamine fibers originating in the VTA is a limbic system structure referred to as the nucleus accumbens. The nucleus accumbens is a region located further up in the brain in an area called the ventral striatum.

Much research has shown that all drugs of abuse increase the release of dopamine in the nucleus accumbens. From animal studies, we learn that the increased release of dopamine is pleasurable as animals will exhibit high rates of intracranial self-stimulation to cause fibers in this region to release dopamine. That is, after having their brains implanted with an electrode that will provide a stimulating electric current when the animal presses a lever, animals will press the lever at extremely high rates; even to the point of physical exhaustion whereby they can no longer press the lever. Moreover, rats will choose to press the lever to receive the stimulation to their brains over eating palatable foods or engaging in copulatory behavior. It is also the case that the administration of dopamine receptor blockers to synaptic regions of this circuit reduce intracranial self-stimulation in the rat model. Thus, irrespective of the primary effects of an abused substance such as alcohol with its central nervous system depressant effect, substance use is rewarding or pleasurable because it increases dopamine within the mesocorticolimbic circuit. Because of the saliency of the pleasure experienced with activation of this circuit, researchers have termed this the pleasure circuit.

Advancements in neuroimaging have allowed for the investigation of the pleasure circuit in humans. For example, PET has been used to show increased dopamine release in the ventral striatum in response to alcohol and amphetamines. One property of the pleasure circuit neurobiology that is detrimental to the substance user is system down-regulation. Simply put, with repeated exposure to a substance, the pleasure circuit is less activated by the substance. At the cellular level, this down-regulation reflects tolerance, which is subjectively experienced as the failure of the substance to meet the expectations desired. To meet expectations, additional use is needed, which in turn results in more cellular adaptation and system down-regulation. At this point, the abuser has become dependent on the substance. For readers interested in more details on the cellular response to drug dependence, we recommend the 2007 review by Kauer and Malenka.

Amidst the receptor adaptation taking place within the nucleus accumbens, another pathway from the VTA to the dorsal striatum, which includes the caudate and putamen, comes into play further driving repeated substance use. This pathway, again using dopamine as the chemical messenger, is implicated in a simple form of instrumental or reward-based learning. This kind of learning is behind the behaviors we call habits. In one sense, drug addiction is habitual or compulsive use resultant from a loss of control over voluntary use. Research in monkeys supports this model of progression at the neural level with dopaminergic activation beginning in the nucleus accumbens (ventral striatum) with early cocaine administration and progressing upward to activate the dorsal striatum (caudate and putamen). This latter circuit has been termed the habit circuit.

The research of Rajita Sinha and her colleagues at Yale University reveals that in humans, this habit circuit is activated during stress. Thus, for a person with

a substance use disorder, stress becomes a trigger for a habitual response which in this case is substance use. The motivation for the habit or use is entrained at the cellular level. Given that the activator of this circuit is stress, motivation to use may be compounded by craving in those with substance use disorders. This is because craving can be a stressor in and of itself. Craving can result from withdrawal sensations between bouts of use. In response to craving, a person may habitually use to avoid the negative sensations resultant from withdrawal. Thus, the voluntary and conscious choice to ingest a drug such as enjoying a happy hour drink with colleagues following a stressful board meeting, may become a habitual response to stress over time. We discuss the role of stress and withdrawal in more detail later in this chapter.

Fortunately, inhibitory pathways from the prefrontal cortex (PFC) can modulate the function of the habit circuit. The PFC consists of many brain regions that are located behind the forehead. Inhibitory pathways from the PFC can be recruited to regulate habits. Many people possess what they call annoying habits. A good example is nail biting. Some people who bite their nails find that they often engage in the habitual behavior mindlessly. Operating on "automatic pilot," they can bite the nail down lower than the nail bed which can result in later discomfort. However, when they bring their conscious attention to their behavior, they find that they can temper the motivation to bite their nails. This is often true of other habitual behaviors as well. To refrain in this manner, one uses their PFC. The PFC is often called the brain "executive." This is because of its role in executive functions which are regulatory in nature. Some examples are emotion regulation, cognitive flexibility, planning, and impulse control. The latter is particularly relevant to the development of addiction. Using the neurotransmitter GABA, fibers from the PFC can inhibit neural activity in various subcortical regions including the dorsal striatum, a region within the habit circuit. Unfortunately, substance abuse has been shown to result in the loss of PFC gray matter and the development of functional hypofrontality. That is to say, the frontal regions of the PFC lose their ability to function fully. It follows then that a loss of PFC function would result in a loss of inhibition over the habit circuit and mindless habitual behavior be it nail biting or substance use. Moreover, the loss of PFC function could contribute to what addictions expert, G. Alan Marlatt, PhD, called the the problem of immediate gratification (PIG). When an addict has an urge or suffers craving, they may lack the executive function of impulse control thus succumbing to the urges and cravings and eventually relapse.

G. Alan Marlatt wrote extensively on the habitual nature of drug use and the powerful role of cue association in drug craving and potential drug relapse. In developing what is now a part of the canon for all clinical professionals, Relapse Prevention Therapy teaches people the skills aimed at dealing with triggers and high-risk situations that have a strong potential to produce urges and cravings that may lead to relapse. One way of dealing with PFC deficits is to tap metacognitive processes that introduce a kind of metal space between the cue or trigger and the urge or cravings. One metacognitive technique developed by Alan Marlatt and his colleagues Drs Sarah Bowen and Neha Chawla of the University of Washington Addictive Behaviors Research Center is the SOBER breathing space (SOBER breathing space is one of several mindfulness-based techniques described in detail in Mindfulness-Based Relapse Prevention for Addictive Behaviors: A Clinician's Guide by Sarah Bowen, Neha Chawla, and G. Alan Marlatt.). This technique teaches people how to mentally take a step back from their experience and engage in thought processes that explore their experience. True to the meaning of the term metacognition, the SOBER breathing space causes one to think about their thinking. SOBER is an acronym with the S meaning stop. In other words, stop right where you are and observe (the O) how you're feeling. You can ask yourself "What is this sensation?" You can give it a name "This is craving." Recognizing that all are too familiar sensations or feelings, you mentally shift your focus to your breathing, which is the B in SOBER. The idea is to follow your breath mentally. Breathing in, breathing out, you let your breath become the center of your attention. Next, you expand (the E) your awareness and gather a better of sense of the consequences associated with the habitual act. You can ask yourself "How would it feel to take that drink?" for example. Finally, you respond (the R in SOBER) mindfully and in the present moment returning to the conscious way you once engaged the behavior before it became a habit. Thus, this metacognitive strategy brings a mindfulness component to the classic cognitive-behavioral treatment strategy – Relapse Prevention.

In addition to what neurobiological and pharmacological science teaches about the etiology and effects of tolerance, behavioral economists have described tolerance as affecting the consumption of drugs relative to engaging in alternative behaviors. From this perspective, the science of behavior economics borrows from traditional economic theory and applies it to behavioral processes such that behaviors are viewed as having a relative utility or benefit. The consumer (i.e. the individual performing behaviors) is seeking to maximize the utility or benefit gained from each behavior in which they engage. While every behavior delivers a return, potentially with a variable rate of gain, each behavior also has a cost. Thus, according to behavior economics,

any behavior or patterns of behavior, including substance abuse, can be best described as being the result of the interplay between the cost of performing a behavior and the relative rate of gain from performing a behavior. Note that the cost of performing a behavior and the rate of gain returned from a behavior is not only monetary but also could be physical (e.g. effort) or psychological (e.g. stress).

For example, the price of a drug may be varied such that time, energy, social and familial relationships, and money must be paid in order to consume the drug. In fact, for many addicts, the cost of abusing a drug requires, for example, the majority of their time, energy, social and familial relationships, and money such that he or she does little else than seek out and use the drug. At the same time, the return from some drugs carries a rate of gain that has been described as being unparalleled to any other experience. For example, some heroin abusers describe the euphoria of drug effects as being more rewarding than any other experience (i.e. the effects are immediate and without any vagaries regarding its efficacy). In other words, unlike other behaviors in which a person engages where the return might be uncertain or vary (such as a social gathering), when it comes to drug use, there is no question as to the effects of the drug (i.e. the drug always works and it works quickly).

According to behavior economics, as the rate of gain from a behavior decreases and as the price of a behavior increases, as with tolerance, the way an individual allocates behaviors or chooses behaviors will also change. For example, with substance abuse, the effects of tolerance result in a change in the rate of gain from drug consumption as well as the price required to achieve the desired drug effect. Specifically, as an abuser uses their drug of choice and the biological and associative effects of tolerance are established, the rate of gain from the drug decreases. To increase the gain, more drug is needed and this is costly. Thus, the decrement in the return from drug coincides with an increment in the price of the drug needed to achieve the desired effect. Given the decrease in the rate of gain and resultant increase in price, tolerance should cause the drug seeking and drug use behaviors to decrease. However, whether or not the individual will continue seeking out and using drugs at the increased price is due to a variety of factors such as further changes in the price of drug use (i.e. elasticity of demand) and the temporal discounting of alternative behaviors (for a more detailed review see Vuchinich and Heather, 2003.).

Briefly, elasticity of demand describes changes in behaviors that result from fluctuations in the price of performing a behavior. In the case of substance abuse, the consumption of a drug is inversely related to the price of consuming the drug. In other words, there is flexibility or elasticity in the demand to consume substances such that some behaviors associated with drug use are more elastic than others. Whether the demand is inelastic or elastic depends on the price of the drug. When the price changes, as it does with tolerance, changes in the demand for a drug use can determine drug use. For example, research has shown that if the price of illicit drugs, cigarettes, or alcohol is low, the demand for the drug is inelastic. The effects of this inelastic demand on behavior is that the consumer will pay only small increments in cost (e.g. time, relationships, energy, money, etc.) in order to consume the drug. However, if the cost of the drug increases substantially such that the demand becomes elastic, the consumer won't pay the large cost but will instead choose to perform behaviors that are substitutes for the drug (e.g. seeking a drug or behavior that will serve as a substitute for the preferred substance) or alternatives to using the drug such as a nondrug alternative. A nondrug alternative can be defined as any behavior that could potentially serve as an alternative for drug use. For example, social, marital, and familial support has been shown to serve as alternatives to drug use such that if social support is available, a decrease in drug use will occur.

In most substance abuse situations, the increase in price that results from tolerance does not result in a decrease in consumption but rather the increase in price contributes to an increased consumption of the drug at a higher price. The elasticity of demand for drugs, despite increased tolerance, can be described as being the result of a decrease in value associated with nondrug alternatives due to temporal differences associated with drug use and nondrug use behaviors. Despite the value associated with nondrug alternatives such as spending time with family, the potential delay of gratification associated with such alternative behaviors stands in stark contrast to the immediate gratification of a drug. Moreover, as mentioned before, there are none of the vagaries about the drug's effectiveness; it always works. However, social and/or family gathering are not a guarantee for pleasure. Clinically, this is what the late addictions expert G. Alan Marlatt wrote of when he referred to the PIG. This choice for an immediate but smaller reward over a larger but delayed alternative can be described as being the result of temporal discounting.

In situations where temporal discounting occurs, the immediate return of using a substance outweighs the return from nondrug alternatives due to delay. For example, if two alternatives (i.e. a drug and nondrug alternatives) are presented simultaneously with no delay associated with the alternatives, an individual will choose the option that yields the highest rate of gain. However, when the delay to a reward is longer, as is typical of nondrug alternatives, the value

associated with that reward decreases or is discounted. Due to the temporal discounting of nondrug alternatives, individuals choose to engage in drug use because of the immediate reward associated with the drug, despite the increases in price that result from the development of tolerance to the drug.

WITHDRAWAL

The adaptive biological changes that underlie drug tolerance also underlie drug withdrawal. Withdrawal is a general term used to describe a cluster of symptoms that result from adverse biological reactions to the lack of drug in the system (Table 18.1). With tolerance, the system becomes habituated to having the drug present. When the drug is removed from the system, withdrawal effects (i.e. the adverse reactions) occur. Withdrawal effects are often the opposite of the drug effects. Thus, withdrawal symptoms are drug specific. For example, a person with a seizure disorder taking an anticonvulsant such as Phenytoin, is likely to experience seizure activity if the drug is stopped suddenly. This is because the goal of treatment with Phenytoin is to develop tolerance or physical adaptation so that a certain level of the drug is present in the system at all times. Thus, when the Phenytoin level drops, withdrawal occurs. Withdrawal effects in this instance are the opposite of the drug effects. As such, anticonvulsant effects give way to seizure.

With drugs of abuse however, withdrawal also results in a decrease of dopamine in the nucleus accumbens demonstrating a lack of drug specificity on withdrawal. The loss of dopamine within the pleasure circuit has negative consequences on one's ability to experience pleasure and as such may drive behavior to replenish dopamine through use. This is particularly likely during the initial or acute withdrawal phase, when symptoms are intense. Yet symptom intensity is not ubiquitous but rather depends upon the type of drug abused, the duration of abuse, and whether the person quits the drug suddenly or whether he or she steps down off the drug in a systematic fashion that allows for system titration. Still, the presence of withdrawal symptoms following cessation of the drug indicates that physical dependency to the drug has occurred.

A classic example of drug withdrawal is opiate withdrawal. Opiates exert varied effects due to their actions throughout the central nervous system. The primary therapeutic effects of opiates are analgesia and sedation. However, when rapid entry into the body occurs at a dose higher than therapeutic range, a profound and rapid high/euphoria is experienced. This is often referred to as the "rush." Through it's actions on the pain inhibitory pathway originating in the periaqueductal gray matter of the midbrain, opiates exert their analgesic effects. Actions on the preoptic area of the hypothalamus yield a warm flushing of the skin. Sedation is experienced via opiates actions on the mesencephalic reticular formation. The drowsy and clouded mental function are often referred to by users as "on the nod" and is accompanied by a feeling of heavy extremities and muscle relaxation. Also, opiates exert a whole host of effects on the autonomic nervous system (ANS) that can pose life threatening withdrawal symptoms when a person who is tolerant to opiates suddenly stops taking the drug. The primary effects of opiates on the ANS include slowed respiration, slowed heart rate, as well as inhibitory effects on smooth muscle including that which makes up the gastrointestinal (GI) system.

With abuse, each of these effects results in a compensatory reaction opposite to the primary effect of the drug (see Table 18.2). Thus, analgesia is countered by pain,

TABLE 18.1 Symptoms of Withdrawal

Psychological	Physical
Anxiety	Sweating
Irritability	Irregular heart beat
Restlessness	Muscle tension
Insomnia	Shortness of breath
Poor concentration	Headaches
Depression	Tremor
Emotional outbursts	GI upset including nausea, vomiting, or diarrhea
Social isolation	In severe cases: seizures, heart attack, stroke, hallucinations, delirium tremens (DTs)

TABLE 18.2 Primary Effects of Heroin and Associated Compensatory Reactions

Primary Effects	Compensatory Reaction
Analgesia	Pain
Euphoria	Depression Anxiety
Muscle relaxation	Muscle tension Muscle spasms
Sedation	Insomnia
Respiratory depression	Hyperventilation
Bradycardia	Tachycardia
Hypotension	Hypertension
Constipation	Diarrhea Nausea Vomiting

often experienced as aches in the muscles and bone. Sedation is countered by agitation, restlessness, and insomnia. Heart rate, respiration, and body temperature increase and GI disturbances arise such as diarrhea, cramping, nausea, and vomiting. When the addiction is severe, the withdrawal symptoms are at their worse. For example, hyperthermia can cause perspiration with subsequent skin cooling and goose bumps. This symptom of withdrawal led to phrase "going cold turkey" as the skin appears similar to plucked poultry skin with small bumps over the surface. "Going cold turkey" has come to mean the process of suddenly stopping any addictive substance. A second example of severe withdrawal symptomatology involves painful muscle contractions and twitching such as foot kicking. This symptom of opiate withdrawal gave rise to the phrase "kicking the habit" which again has been generalized beyond its initial clinical observation to refer to the general process of getting off addictive drugs. But it's the compensatory reactions to the primary effects of opiates on the ANS that pose serious health risks to those experiencing opiate withdrawal.

Of primary concern are the compensatory reactions affecting the cardiovascular system which include increased heart rate and blood pressure. Taxing the cardiovascular system in this fashion can have dire consequences such as heart attack. Cardiac effects may be further compounded by extreme electrolyte imbalances associated with withdrawal induced vomiting and diarrhea. Such concerns render severe opiate withdrawal a medical condition worthy of care by a healthcare provider.

The compensatory reactions that manifest themselves as opiate withdrawal symptoms are subject to conditioning. That is to say, they can be learned. As was discussed earlier, the primary effects of a drug can be termed as an unconditioned stimulus using Pavlovian terminology. The unconditioned response to a drug is the set of compensatory reactions. With repeated bouts of drug use, the neutral stimuli present and the time of use and/or used to administer the drug become conditioned stimuli which can produce the conditioned response. In this case the conditioned response is the set of compensatory reactions (see Table 18.2). Keeping with the model of opiate addiction, the administration of intravenous heroin, for example, involves heating the drug, drawing the solution into a syringe, and injecting the drug. Thus there are numerous paraphernalia items needed for drug administration such as a match or lighter, a spoon or small cup to hold the drug while heating, a tourniquet to ease the process of finding a viable vein, and a syringe. Any or all of these items can become conditioned stimuli over time. Moreover, heroin users often find their use to be ritualistic. That is, they do their drug in a particular location often in secrecy as heroin use is illegal. They may douse the sound of heating the drug with music and camouflage the smell by burning incense. All of these contextual variables can become conditioned stimuli as well.

Following with the learning model then, as the addict prepares their drug and engages in their ritual, the conditioned stimuli produce the conditioned response, which is the set of compensatory reactions. This means that even before the addict administers the drug, they are in withdrawal. Thus it follows that they are feeling warm, their heart is racing, they are hyperventilating, and they feel achy. Because the compensatory mechanisms are occurring prior to drug administration, the addict will find that they can safely administer a larger dose of heroin and in fact they will need in order to experience a high. This is because the compensatory responses have increased their tolerance to the drug. But this tolerance is situational. If the addict were to use in a different environment, with different music playing, and different incense burning, the compensatory responses may not occur as intensely. If that were the case, and the user administered the same dose of drug that they usually do when they engage in their ritual in their usual context, they will likely overdose.

In the case of heroin, this overdose phenomenon is easily explained by considering the small margin of safety between the analgesic effects of the drug and the respiratory depression effects. To explain, the margin of safety is a pharmacological principal that describes the range between the therapeutic and lethal doses of a drug. As shown in Fig. 18.1, the amount of drug needed to acquire the analgesic effects of opiates (i.e. the therapeutic effects) is less than the dose that would cause respiratory depression. However, with tolerance, the dose–response curve for the analgesic effects shifts to the right, shrinking the margin of safety. Thus, the addict that is tolerant to opiates will find themselves reaching a point where a larger dose is not realistic without overdosing and killing themselves. Their search for their high, which drives their use, may never be satisfied. Instead, they use to avoid the withdrawal symptoms that occur as the drug leaves the system. Bringing the situational tolerance back into the picture, when the heroin addict engages in their drug use with their ritual, the compensatory reaction of hyperventilation makes it safe for them to take a dose of drug that may "step over" the margin of safety as depicted in the figure. The hyperventilation counters the respiratory depression effects of the drug. Now, if the addict engages in use in a novel environment without their ritual, and the compensatory hyperventilation does not occur, then the dose that steps over the margin of safety will be lethal.

When we consider that withdrawal is caused by the presence of compensatory mechanisms and that compensatory mechanisms bring about tolerance, we can see that these responses are opposite sides of the proverbial coin. On one side we have withdrawal and on the other side we have tolerance. With tolerance comes compensatory reactions which in and of themselves are withdrawal. Withdrawal occurs because of the compensatory reactions, the effects of which the addict is motivated to reduce. Thus, anything that triggers the compensatory reactions will likely drive the addict to use. One well-studied trigger is stress.

Stress and Withdrawal

A grand irony in addiction science is the fact that substances with anxiolytic effects (e.g. alcohol) actually turn on the neurochemical stress system. Specifically, drugs of abuse activate the hypothalamic–pituitary–adrenal axis (HPAA), which in turn sensitizes the pleasure circuit during early use. The research of George Koob and his colleagues at Scripps Research Institute in California points specifically to an intricate system of neural dysregulation involving both the pleasure circuit and stress circuit. In fact, research has shown that nonabstinent alcohol-dependent individuals and alcoholics undergoing acute withdrawal have high levels of cortisol, which is the end-product of the HPAA. Briefly, cortisol is a glucocorticoid released by the adrenal cortex in response to adrenocorticotropic hormone (ACTH) from the anterior pituitary located at the base of the brain. The pituitary release of ACTH is under the influence of corticotropic hormone (CRH) from the hypothalamus. So well accepted is the role of cortisol in the stress response that it is often referred to simply as the stress hormone. Once in the blood stream, cortisol promotes the release of stored glucose and works in conjunction with the sympathetic nervous system to drive the stress response often referred to as the "fight or flight" response. As it turns out, high levels of cortisol is associated with less dopaminergic response to substance use. That is, the addict gets less effect of the drug not only because of tolerance but because they are using. Thus, HPAA activation may accelerate the progression to addiction by amplifying the pleasure sensation associated with initial use and may maintain addiction by heightening the negative sensations of withdrawal associated with later use.

Much less is known about the extra-hypothalamic stress circuits. Still, research points to the amygdala with it's own CRH system as a key region involved in extra-hypothalamic stress circuitry. What George Koob and others propose is that initially the chemical milieu that results from repeated drug use promotes sensitization in the pleasure circuit. Thus, the pleasurable sensation is great as is the motivation to repeat use. As the HPAA continues to produce cortisol, the circulating levels of this stress hormone sensitize the extra-hypothalamic stress circuits, in particular the CRH system within the amygdala. Since increased CRH activity in the amygdala is associated with anxiety, this increase subsequent to substance use is proposed to underlie the anxiety-like feelings or negative affect that emerges as the substance abuse continues. The emergence of this change in affect coincides with the onset of withdrawal symptoms. Thus, what may begin as a behavior motivated to receive pleasure becomes a behavior motivated to avoid negative affect and withdrawal (for more detailed information see Koob, 2008). As such, addiction can be viewed as a complex function of tolerance plus withdrawal exponentially affected by stress.

List of Abbreviations

ACTH	adrenocorticotropic hormone
ANS	autonomic nervous system
CRH	corticotropin releasing hormone
GABA	gamma-aminobutyric acid
GI	Gastrointestinal
HPAA	hypothalamic pituitary adrenal axis
PET	Positron emission tomography
PFC	prefrontal cortex
PIG	Problem of immediate gratification
SOBER	Stop, Observe, Breath, Expand, Respond exercise as part of mindfulness-based relapse prevention therapy
VTA	ventral tegmental area

Glossary

Anxiolytic antianxiety, anxiety reducing.

Conditioned compensatory reaction a classically conditioned response to a conditioned stimulus that has been associated with a drug due to repeated pairings between the conditioned stimulus and drug.

Behavioral economics describes behavior and patterns of behavior as being the result of the interplay between the cost of performing a behavior and the relative rate of gain from performing a behavior.

Drug tolerance a condition whereby a larger dose of a drug is needed to achieve a desired effect.

Drug withdrawal the appearance of symptoms opposite to those produced by a drug when drug administration ceases.

Homeostasis a state of balance or equilibrium in the body; the ability of a person or animal to maintain their internal body balance equilibrium.

Pavlovian psychopharmacology describes changes in drug efficacy that is due to behavioral or associative mechanism.

Pharmacodynamics is the study of drug effects and their mechanisms of action.

Pharmacologic synergy when two drug agents act synergistically to exert their effects on the body.

Positron emission tomography (PET) a functional brain imaging method utilizing the administration of a positron-emitting radionuclide that emits pairs of gamma rays which are detected by the scanner to construct a map of metabolic activity in the brain.

Sensitization an increase in drug effects with repeated drug administrations.

OUTLINE

DEFINITION OF OVERDOSE

Definitions of overdose encompass a number of facets. One commonly cited definition is built on the intuitively straightforward idea of "excessive use," as seen in "an accidental or deliberate dose of a medication or street drug that is in excess of what is normally used" in Medical Subjective Heading (Mesh) system. However, it is important to know that although overdose has been one of major issues concerning health professionals and scientists in addiction for decades, the term of "overdose" has not been introduced into the Mesh system under the disease category of substance use disorders until 1990; between 1966 and 1989, such condition was only indexed under the term "poisoning" to describe "a condition or physical state produced by the ingestion, injection, inhalation of or exposure to a deleterious agent." The present description in Mesh, underscoring a rather obvious, yet probably distant cause, may reflect gradual evolution in conceptual issues for overdose.

With the accumulation of scientific knowledge in the past 20 years, now there seems to be a general understanding that certain individual, pharmacological, and contextual factors may also facilitate or exacerbate the risk of overdose among drug users, even when the amount of drug consumed is normal as compared with that in other drug users. That is, the excessive consumption appears to be not a necessary cause, and some scientists even argued whether the term overdose is a misnomer. Available evidence may favor another definition which in turn draws attention to the manifestation of adverse physical and mental effect shortly due to drug intake, as exemplified in the Worth Health Organization's lexicon for substance use problems. The emphasis on clinical presentation may help establish a working conceptual model which explicitly suggests that, excess use is certainly an important contributory factor, but the occurrence of overdose should depend on individual physical and contextual conditions and drug nature.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00019-X

Overdose can occur accidentally or intentionally. To illustrate, unintentional overdose can take place when a person concomitantly uses opioid with other central nervous system (CNS) depressants (e.g. alcoholic beverages or sedatives-hypnotics), which together may lead to respiratory depression. Although relatively rare than accident cause, drug overdose can also take place as an intentional act. In the past decade, there has been an alarming increase in suicide cases due to psychotropic prescriptions, such as taking prescription more than medically recommended dose. Either accidental or intentional, some may have survived an overdose, and the ratio of nonfatal versus fatal, approximately ranging from 20 to 25, might differ by region and primary drug.

SYMPTOM AND DIAGNOSIS

A variety of psychotropic drugs have been linked with the occurrence of overdose, among which the most prevalently reported are opioids (primarily heroin), sedatives-hypnotics (e.g. barbiturate and benzodiazepines), prescribed opioid analgesics, ethanol, stimulants (e.g. cocaine, amphetamine, and Methylenedioxymethamphetamine (MDMA)), and club drugs (e.g. γ-Hydroxybutyrate (GHB)). On the basis of drug category, clinical symptoms of overdose were summarized in Table 19.1. Largely depending on type of drugs and overdose severity, the presentation of symptom constellation may lend certain indication for diagnosis. It should be noted that, even within the same medication category, overdose symptom presentation and risk of fatal cases can differ by compound, partly due to variation in onset time and duration of behavioral effects and elimination half-time; for example, Alprazolam and Flunitrazepam were more commonly mentioned in fatal overdose than other compounds of Benzodiazepines. Clinically, the diagnosis of opioid overdose commonly covers CNS and respiratory depression, myosis, together with the evidence of opioid use (e.g. needle tracks or soft tissue infection). For heroin overdose, a triad of abnormal mental status, depressed respiration, and miotic pupils may provide a sensitivity of 92% and a specificity of 76% for diagnosis. For sedative-hypnotic overdose, CNS and respiratory depression are key clinical features for diagnosis.

TABLE 19.1 List of Signs and Symptoms for Drugs Commonly Involved in Overdose

Drug	Symptoms
Heroin	Shallow breathing, pinpoint pupils, dry mouth, low blood pressure, weak pulse, bluish-colored nails and lips, bradycardia, constipation, drowsiness, delirium, disorientation, and coma.
Barbiturates	Shallow breathing, sluggishness, incoordination, slowness of speech, drowsiness, staggering, and coma.
Benzodiazepines	Mostly mild CNS symptoms (e.g. incoordination, ataxia, slurred speech, impaired attention and memory). Paradoxical reactions (e.g. delirium and hallucination) and GI symptoms were reported. Rarely fatal, unless in combinational use with CNS depressants.
Prescribed opioid analgesics (e.g. Oxycodone)	Shallow breathing, dizziness, slow heart rate, low blood pressure, confusion, and coma.
Methadone	Drowsiness, limpness, pinpoint pupils, hypotension, bradycardia, pulmonary edema or aspiration, depressed respiratory rate and depth, coma, and death. Risk of overdose increases while concomitant use with CNS depressants or medications interfering methadone metabolism (e.g. medications inhibiting Cytochrome P450 3A4(CYP3A4)).
Buprenorphine	Shallow breathing, cold or clammy skin, pinpoint pupils, fainting, slow heart rate, weak pulse, extreme drowsiness, and coma.
Ethanol	Confusion, vomiting, slowed breath, slurred speech, stupor, incoordination, and coma.
Cocaine/crack	Chest pain, palpitation, seizure, high blood pressure, increased heart rate, cardiac arrhythmias, paranoia, and delirium.
Amphetamine, Methamphetamine	Chest pain, palpitation, tremor, sweating, high blood pressure, agitation, hallucinations, seizures, tachycardia, arrhythmias, hyperthermia, delirium, and convulsions
Methylenedioxymethamphetamine (MDMA)	Nausea, cardiac arrhythmia, hyperthermia, cerebral hemorrhage, rhabdomyolysis, acute renal failure, and hepatotoxicity.
γ-Hydroxybutyrate (GHB)	Decreased consciousness, mild hypothermia, asymptomatic bradycardia, mild acute respiratory acidosis, and emesis.

Although each of the just-mentioned drugs alone can cause overdose, it is very common to find more than one drugs were involved in the event of overdose, which may increase difficulties in accurate diagnosis and treatment management.

TREATMENT

Contrary to popular conception, less than one-quarter of overdose took place within 3 h of drug administration. This critical period leaves an opportunity for early interventions such as calling an ambulance, seeking assistance, and timely transportation to emergency department. For accident and emergent management, severe clinical features (e.g. respiratory depression and coma) associated with opioids, heroin, and methadone overdose are usually treated by opioid antagonists (e.g. naloxone), with regular monitoring and incubation. Naloxone (Narcan) can effectively block the mu-opiate receptors and reverse the effects from an array of natural, semisynthetic, and synthetic opioids; for buprenorphine overdose management a higher dose of methadone is recommended given its higher affinity for mu-opiate receptors. Naloxone can be administered via intravenous and intramuscular injection, as well as intranasal insufflations. In addition to medical staff, there are also reports on the measures to expand the accessibility and reach of naloxone to high-risk opioid users and their peers.

Similarly, in order to attenuate clinical features of stimulants overdose, treatments involve medications with effects in (1) blockade of presynaptic catecholamine reuptake sites or postsynaptic receptors (e.g. bupropion, aripiprazole, risperidone, topiramate, and modafinil) and (2) reduction in drug availability in the CNS by antidrug antibodies or catabolism enhancers. In addition, careful monitoring is needed for seizures, cardiac arrhythmias, stroke, and pulmonary complication. As to managing sedative-hypnotic overdose, maintenance of the airway and ventilator support should be the first priority. Flumazenil, a competitive benzodiazepine receptor antagonist may be used to reverse the sedative effects of benzodiazepines, in particular short-acting ones.

EPIDEMIOLOGY

In general, epidemiological evidence of overdose has primarily been produced from some high-income countries in the North America (i.e. the United States and Canada), Europe (e.g. the United Kingdom, Italy, and Spain), and Australia, particularly that from longitudinal studies. In most cases, participants are recruited from clinical treatment, maintenance programs, or criminal justice system; in some situations, statistics were obtained from medical records, judiciary archives, and coronial reports. Although the impact of illegal drug use in Asia and Africa has gradually become problematic, to date, few countries have published studies assessing the problem nature of overdose and associated factors. The few studies that have been published are mostly descriptive and cross-sectional, and longitudinal evidence still awaits to be gathered.

According to the published literature, the profile of drugs involved in overdose events has slowly evolved over the past decades. From 1960 through 1980, the available evidence in many parts of the world was mainly focused on opioids or heroin, and starting in 1980s more attention has been paid to cocaine until recently. Later on, the evidence on amphetamine/methamphetamine, club drugs, and intravenous drug use-involved overdose has gradually emerged, and in the recent years prescriptions have appeared as one of the leading drugs reported in overdose, which is especially true in the United States.

PREVALENCE AND MORTALITY

Drug users are at risk of overdose, with nonfatal and fatal consequences. The risk estimates of overdose may vary quite widely, depending on drugs, sources of data, and region. In general, the lifetime prevalence of nonfatal overdose appears highest for opioids, with the estimates falling between 38 and 83%; roughly 10–30% opioids users have experienced nonfatal overdose in the past 12 months. The lifetime prevalence estimates of nonfatal overdose were 12–40% for cocaine. In terms of fatal overdose, the majority of the existing literature is about the case of heroin, which was estimated to be 2–4%. For other illegal drugs, although cases reports on MDMA, amphetamine/methamphetamine, or GHB-involved overdose have accumulated over the years, the evidence on prevalence estimates, both nonfatal and fatal, were generally lacking as compared with those for heroin and cocaine. A study in Australia indicated that roughly one in two GHB users have experience nonfatal overdose in their lifetimes. Recently, the hospitalizations for prescription opioids, sedatives, and tranquilizers-involved poisoning increased substantially in the United States and a further exploration has indicated the rise in the prevalence of nonfatal overdose may be due to the problematic use of benzodiazepine, methadone, and analgesics.

Overdose has been a major cause of premature death among drug users, especially opioids users. In 2000, it has been estimated that over 69 000 individuals died of opioid overdose globally. A recent review on cohort studies for heroin and other opioids users found the

proportion of deaths due to overdose ranged from 2.5% in Sweden and 7.3% in Portugal to 73.7% in Austria and 77.2% in the United Kingdom. The pooled estimate for overdose Crude mortality rate (CMR) was estimated to be 0.65 per 100 person-years (95% confidence intervals: 0.55, 0.75). For illegal drugs other than heroin and cocaine, available longitudinal studies on mortality were generally few. A study in Sweden on primarily cannabis, inhalants, Lysergic acid diethylamide (LSD), and stimulants users showed that the CMR of drug poisoning was roughly 0.0 5 per 1000 person-years. For methadone, the CMR of overdose was about 0.9 per 1000 person-years, according to studies conducted in Italy. As to prescription, a population-based observational study in West Virginia, US, reported the overall unintentional pharmaceutical overdose death rate was about 16 per 100 000 population in 2006, and the evidence of insurance enrollees in Washington, US showed that the mortality rate of prescribed opioid-related overdoses was approximately 6 deaths per 100 000 between 2004 and 2007. As to polydrug overdose, a series of studies provided evidence that alcohol and cocaine were the drugs most commonly found in heroin overdose death and the number of ploydrug-involved fatal seems to have a gradual rise over the past two decades.

RISK FACTORS

Over the past two decades, there have been many reviews and reports to summarize risk factors for nonfatal and fatal overdose, particularly for opioids. There is a broad spectrum of these suspected determinants, which can be generally grouped into individual-, drug-, circumstance-, and time-domains, on the basis of factor attributes.

Individual-level Characteristics

Male gender-related excess was generally found in all drug categories involved in overdose, including illegal drugs (e.g. heroin, cocaine, and amphetamine), prescription drugs (e.g. prescribed analgesics), and polydrugs. It should be noted that although drug users were predominately male, there is still male excess in likelihood of experiencing overdose among drug-experienced populations. As to age, the average age for fatal overdose typically fell between late twenties and early thirties for heroin, and the victims usually had used heroin for 5–10 years; the ages for nonfatal heroin overdose tended to be younger. Similar age-associated excess risks of fatal overdose also appear for cocaine and unintentional pharmaceutical overdose. In addition, longer health condition was another well-known risk factor affecting the risk of fatal and nonfatal overdose. Systematic diseases, such as liver cirrhosis, ventricular hypertrophy, bronchopneumonia, have frequently been indicated in fatal overdose. Furthermore, individual history of other substance use disorders and differential tolerance toward drug effects have been identified as predictors for overdose. In the case of heroin fatal overdose, many cases had the experience of lowered drug consumption prior to death, indicating the possibility that these individuals might be in a state of loss of tolerance to heroin. Finally, individual prior experience of nonfatal overdose has been linked with subsequent death due to overdose. Evidence from follow-up studies indicated that the risk was approximately 3–4-fold for those with two nonfatal overdose events, and was elevated to 7 for those who experienced three or more nonfatal overdose.

Drug-level Characteristics

Drug-level attributes may strongly influence the episode of overdose, including concomitant use of other drugs, route of administration, and purity, among many others. With respect to polydrug use, for heroin users, alcohol and benzodiazepines were two drugs commonly found in overdose cases, and it is hypothesized that the combined depressant effects may precipitate the occurrence of respiratory depression than a usual dose of heroin. Similar polydrug-excess risk in fatal overdose cases appears in cocaine (e.g. cocaine with heroin or alcohol), MDMA (e.g. MDMA with cocaine or amphetamine), and prescription drugs (e.g. prescribed analgesics with alcohol or antidepressants or methadone with benzodiazepines or prescribed analgesics). Route of administration has long been known as one of the most salient predictors for overdose, and route-related differences in overdose risk may depend on drug. To illustrate, for heroin the risk for overdose associated with smoking use was estimated to be 4–6%, significantly lower than that of intravenous injection (~60%). Only three to five per thousand nonfatal heroin overdose were intramuscular and subcutaneous routes-involved. Likewise, for cocaine, amphetamine, and methadone users, overdose tend to found in users by means of intravenous injection rather than inhalation or oral intake.

Circumstance-level Characteristics

Some studies have highlighted the role of circumstance in relation to overdose and fatality, although there still is rather meager evidence as compared with other three domains. Recent data collected from overdose witness suggested that overdose episodes occurring in public or abandoned building seem more likely to lead to deaths than those at homes. Witnesses calling an ambulance or taking to hospital was linked with lower odds of death,

yet the companies sometimes were reluctant or delayed to seek medical help. In addition, a series of studies in New York indicated ambient temperature was strongly correlated with the events of accidental cocaine fatal overdose or cocaine overdose mortality.

Time-level Characteristics

The risk of overdose may depend not only on one's chronological age and history of drug use (e.g. age of initiation and years of drug use), but also on recent period of abstinence. For example, evidence from the follow-up of recently released prisoners has shown a higher proportion of deaths were caused by overdose (20–60%). Their mortality rate was usually elevated within the first 2–3 weeks and 40-fold higher than those with same age and gender in the general population. Observed differences in the risk of overdose were also consistently in those (1) who were discharged from hospital after drug treatment or (2) who entered or re-entered the methadone maintenance programs; similarly, the mortality due to overdose often was elevated within the first month of change in treatment status.

All of the factors in each domain described above may be correlated with one another, and work together to shape one's risk of overdose. For example, for individual-level characteristics, a longer history of heroin or cocaine use may affect individual's liver or pulmonary function as a result of cumulative toxicological effects and infection, which may subsequently influence one's metabolic process or safety threshold toward drug effects. These individual factors, together with factors in other domains (such as concomitant drug use or reduced tolerance due to recent release from prison), may collectively increase ones' subsequent overdose risk or overdose mortality.

CONSEQUENCES AND COMPLICATIONS

In addition to mortality, nonfatal overdose may result in a wide range of health problems. In the general clinical literature and in population-based research, it is known that victims of nonfatal overdose often suffered from multiple systematic dysfunction manifested in pulmonary (e.g. pulmonary edema: 1–90%), cardiac (e.g. endocarditis), muscular (e.g. rhabdomyolysis), and neurological (e.g. cognitive impairment) systems. These above mentioned health problems may together influence drug users' vulnerability toward subsequent overdose mortality. For instance nonfatal overdose-related damage in neurological system may impair drug users' decision making concerning the ability to judge dose and tolerance, which may partly account for the observation that fatal overdose was more likely to be found in the older or experienced rather than the young or inexperienced.

PREVENTION

Much research effort has focused on the prevention of illegal drug overdose (particularly heroin and intravenous injected drugs) and several promising approaches to reduce illegal drug overdose and associated mortality and morbidity have been devised in clinical and community settings. For example, the enrollment in opioids substitution therapies such as Methadone and Buprenorphine programs may have effects in reducing deaths associated with overdose among heroin users. Other forms of harm-reduction activities were also found to have beneficial effects on overdose problems in drug-using populations, including need exchange program, supervised safe injection facility, and heroin maintenance. Improving responses on overdose are aimed at heroin users, families, and peers and usually involve basic training on cardiopulmonary resuscitation skills and general information of reaching medical assistance. Also, the provision of prescribed Naloxone, an opioids antagonist to reverse the effects of acute narcosis, for home use has been shown to provide significant protection from fatal overdose. Expanded access to Naloxone, including peer-administered Naloxone and providing Naloxone in prison and on release, are now being considered to offer as future preventive strategies.

Although the details about possible risk factors and mechanisms responsible for recent rise in prescription overdose mortality still need further investigation, there are some preventive efforts directed to medical professionals and patients. Examples of such preventive programs on medical professionals include continued education on physicians regarding evidence-based guidelines for opioid prescribing and provider detailing. In addition, researchers and practitioners are pursuing other pathways for preventing prescription overdose, such as the prescription drug monitoring programs and community-based health education. To date, limited research has shown that the above-mentioned approaches may produce significant changes in prescription overdose and associated mortality and morbidity.

SUMMARY

Drug overdose has long been one of the major causes for premature death in many parts of the world, especially in developed countries. Over the past two decades, the expansion of overdose has broken the social boundaries and gradually touched many facets of societies; meanwhile, clinical manifestations of overdose

sequelae have become more complicated than ever. Factors contributing to fatal and nonfatal overdose can be generally classified into four domains: individual, drug, circumstance, and time, and all of the factors in each domain described above may be correlated with one other, and work together to shape one's risk of overdose and subsequent health consequences. Clinical and community-based preventive strategies have emerged to reduce overdose mortality and morbidities, including increasing availability toward emergency health care services, providing emergency services and take-home Naloxone, and establishing prescription drug monitoring programs. Although a great number of studies have characterized the pattern and identified many factors that contribute to fatal and nonfatal overdose, literatures on overdose in drug addiction has mostly focused on opioids or heroin; much work remains to be done, especially for middle economies. For devising preventive strategies, detailed studies are needed in identifying high-risk groups, factors increasing risk of overdose, and barriers accessing overdose management and prevention, with urgent attention to polydrug and prescription; evidence-based effectiveness evaluation for preventive programs should be a priority.

CHAPTER

20

Prenatal Exposure to Alcohol and Illicit Substances

Rebecca L. Schacht

Johns Hopkins University School of Medicine, Baltimore, MD, USA

OUTLINE

INTRODUCTION

Recent estimates of illicit drug use among pregnant women in the United States range from 5 to 12%. National US surveys indicate that 8% of pregnant women report illicit drug use in their first trimester of pregnancy, 4% in the second trimester, and 2% in the third trimester. A similar pattern is evident for alcohol use: 22% report first-trimester use, 7% second-trimester use, and 5% third-trimester use. Rates vary depending on substance (Table 20.1). Rates of prenatal substance use are likely to be higher in adolescent than adult women, as adolescents report higher rates of substance use in general.

Rates of prenatal substance use can be difficult to accurately assess based on patient self-disclosure, given the stigma associated with such use. Some researchers ask individual patients to report their drug use while collecting anonymous toxicology data on the patients as a group. Data from such research suggest that between 66 and 82% of prenatal use is identified via interview techniques, implying that up to one-third of prenatal substance use goes unreported. Some pregnancies may spontaneously abort before being detected or reported as a result of maternal substance use. Therefore, prenatal substance use may be underestimated. In addition, isolating the effects of specific substances can be challenging because substance use is associated with numerous other high-risk phenomena (e.g. poly-substance use, poor nutrition, violence exposure, lack of prenatal care).

Perhaps the most challenging methodological issue in regards to research on prenatal substance exposure is the problem of isolating the cause of differences found between exposed and nonexposed groups. Prenatal substance use rarely occurs in the absence of other potentially harmful environmental phenomena. Extensive research has identified numerous correlates of

Principles of Addiction, Volume 1

substance use in pregnancy. These include historical and current abuse, poverty, substance-using partners, a past history of substance use disorders, higher rates of sexually transmitted infections, elevated rates of serious physical illness such as HIV/AIDS and hepatitis C, and polysubstance use. Prenatal substance use is also associated with poor nutrition in pregnancy, prenatal complications such as bed rest or bleeding, preterm labor, placental insufficiency, intrauterine fetal death, low birth weight, lack of prenatal care, high blood pressure, and complication of pain management in labor. Substance-using pregnant women often meet criteria for psychiatric diagnoses in addition to their substance abuse diagnosis.

Early conceptualizations of problems associated with preterm exposure were based strictly on the physiological effects of substances. However, subsequent research has supported a model of bidirectional relationships among psychosocial processes that co-occur with substance exposure and the direct effects of the exposure. Thus, current conceptualizations consider the effects of prenatal exposure within the context in which the exposure occurs. In one study of relative risk contributions for low birth rate, the researchers assessed numerous variables, including low socioeconomic status, psychosocial stress and mental health functioning, lack of prenatal care and nutrition, and polysubstance use. Results indicated that no single substance was significantly associated with low birth weight when psychosocial and biological factors included in the statistical model. This finding suggests that prenatal drug use may function as an indicator of other problems associated with deleterious fetal outcomes, and may be one of many causes of postnatal problems, rather than the sole cause.

Another confounding factor is shared maternal–fetal genetics, which represent an additional contributor to any behavioral, structural, or neurological anomalies that may be identified in the offspring. All of these factors interact with each other, thereby further complicating the relations between prenatal substance exposure and postnatal outcomes.

In this chapter, we briefly review research on the effects of *in utero* exposure to alcohol and illicit substances, including marijuana, cocaine, methamphetamines, opioids, benzodiazepines, and inhalants. We limit our discussion to human findings, as a review of animal research is beyond the scope of this chapter.

BIOLOGICAL EFFECTS OF PRENATAL SUBSTANCE USE

Prenatal substance exposure is associated with a range of problematic outcomes in children. These include congenital malformations, low birth weight, intrauterine death, infant mortality and prematurity, fetal growth restriction, neonatal withdrawal symptoms, and lower Apgar scores. Prenatal substance exposure has also been linked with longer-term problems, such as intellectual delays, inability to focus, impulsivity, and higher rates of behavioral problems.

Effects of substance exposure can vary significantly based on the type of substance used, concurrent exposure to multiple substances, dose and frequency, and weeks of gestation. For example, an infant chronically exposed to an opioid (e.g. methadone) may be physiologically dependent at birth and experience withdrawal symptoms, but long-term prognoses can be good. In contrast, an infant exposed to moderate levels of alcohol while *in utero* might experience lifelong developmental issues as a result. Following birth, an infant's prognosis is further influenced by the nature of the care the child receives.

Fetuses are thought to be approximately 100 times more sensitive to environmental toxins than adult humans. As a result, substances that may cause little or no maternal harm may cause significant harm to the fetus. This sensitivity is due to several factors, including the fetus's small size, the speed and complexity of prenatal development, and the cascading nature of fetal development (i.e. each step of development depends on the preceding step).

Effects of substances on fetuses depend on the timing of use and the substance used. Cell development (cytogenesis) and tissue development (histogenesis) occur

mostly during the first half of pregnancy; therefore, exposure during early pregnancy is likely to affect these processes. The second half of pregnancy is dominated by cell specialization (differentiation) processes and growth. For example, a well-known problem that develops early in pregnancy is neural tube malformation, which is one of the most commonly observed congenital defects. The neural tube forms very early in pregnancy, during gestational days 23–26, often before women are aware of their pregnancy. Neural tube defects, which result in severe and often terminal developmental problems, occur when the neural tube, which evolves into the brain and spinal cord later in pregnancy, fails to close properly.

Most substances are believed to cross the placenta and exert effects on fetal well-being. However, some substances cross the placenta more readily than others, resulting in higher fetal exposure to these substances. In addition, qualities of the placenta are believed to affect the dose received by the fetus, as biological analyses of neonatal substance levels in identical twins – who share a placenta – are similar, whereas those of fraternal twins diverge. Another factor that determines the extent of a substance's effect is the sensitivity of fetal biological structures, which varies from substance to substance.

Evidence suggests that an individual's experience *in utero* affects not only that individual's health, but also the health of that individual's offspring. "Fetal programming" refers to how the uterine environment affects, or "programs," fetal development. The idea that the uterine environment could affect subsequent generations developed from observations of pregnant Dutch women exposed to severe malnutrition in 1944 as a result of World War II, and the discovery that these women's children and grandchildren are of smaller-than-average size. Subsequent research has supported the possibility that fetal programming could affect an individual throughout life and also affect that individual's offspring. Such findings suggest that addressing prenatal substance use can have cascading effects throughout subsequent generations.

"Neonatal abstinence syndrome" (NAS) refers to symptoms in newborns of withdrawal from substances as a result of prenatal exposure resulting in physical dependence. Neonates experiencing NAS symptoms can be difficult to soothe, have difficulty feeding, and exhibit neurobehavioral symptoms such as increased startle reflex. Marijuana and cocaine are believed not to cause NAS symptoms. Infants will often show signs of NAS following alcohol, opiate, and sedative exposure, but pharmacologic treatment is often either not available or not clinically warranted based on the severity of symptoms. NAS can affect the infant–caregiver relationship, as infants with NAS are challenging to care for (e.g. are difficult to soothe, do not sleep regularly, and may experience difficulties in feeding).

SPECIFIC SUBSTANCES

Alcohol

"Fetal alcohol spectrum disorders" (FASD) refers to the range of abnormalities that can result from maternal alcohol consumption. FASD does not constitute a diagnosis. "Fetal alcohol syndrome" (FAS) refers to a specific diagnosis, the criteria for which an individual on the FASD spectrum may meet. Prevalence estimates suggest that FAS occurs in 0.2–2.0 infants per 1000 born annually in the United States, although these data likely underestimate the scope of the problem because maternal alcohol use is underidentified and underreported. In addition, recent research suggests that neurobiological damage can occur without the presence of readily identifiable facial dysmorphisms typically seen in FAS.

FAS has been recognized perhaps as long as alcohol has been consumed, but did not become a named syndrome until a 1973 report in *The Lancet.* In 2004, the US Centers for Disease Control and Prevention published formal diagnostic criteria for FAS. FAS is not included in the DSM-IV-TR, but can be found in ICD-9 and ICD-10. Symptoms fall into three clusters. Facial abnormalities include a smooth philtrum (the flattened area between nose and mouth, which is ridged in typical development), thin vermillion border (upper lip), and small palpebral fissures (decreased distance between upper and lower eyelids). A second symptom cluster is inhibited growth, defined as prenatal or postnatal height and weight below the 10th percentile of typical development. The third and most diverse symptom area is central nervous system abnormalities, which includes structural, neurological, and functional damage. The effects of FAS may be most pronounced in the central nervous system, and FAS is a significant cause of intellectual disabilities. To receive a diagnosis of FAS, individual must have documented abnormalities in all of the three symptom clusters. FAS diagnostic criteria do not require confirmed prenatal alcohol exposure. The 4-Digit Diagnostic Code, developed at the University of Washington, is one commonly used diagnostic approach for suspected FAS.

Alcohol is a central nervous system depressant which crosses the placenta. It is believed to induce teratogenic effects via a variety of mechanisms, such as fetal hypoxia and oxidative stress, and interference with neuronal development. Fetal exposure to alcohol affects most brain systems, as evidenced by differences in brain structure, metabolism, and functioning. Neuroimaging studies indicate that these differences persist at least

through adolescence and, in some cases, are present even in children without facial dysmorphism.

Some research suggests that even modest quantities of alcohol – seven or fewer drinks per week, or three or more drinks in one drinking episode – can have teratogenic effects. Other research suggests a threshold of 15 drinks per weeks before fetal harm occurs. The reasons for these discrepant findings are not entirely clear. It is possible that the effects of alcohol exposure on a developing fetus vary widely among individuals for reasons that have not been identified. Without an established safe dose and little evidence to suggest that alcohol consumption confers significant health benefits in pregnancy, women have long been advised to maintain abstinence from alcohol throughout their pregnancies. However, approximately 13% of pregnant women consume some alcohol during their pregnancy. Rates of prenatal alcohol consumption are higher in at-risk populations, including individuals who have been treated for alcohol use or mental health disorders, tobacco smokers, economically marginalized populations, and women experiencing physical abuse or other forms of stress. Data from the Pregnancy Risk Assessment Monitoring System (PRAMS) indicate that higher income, older age (35+ years), and years of education are also linked with prenatal alcohol use.

Alcohol consumption can be a particularly problematic substance in pregnancy for several reasons. First, maternal alcohol consumption confers risks of severe teratogenic effects for the fetus. Second, the fetus is believed to be particularly vulnerable to alcohol's effects very early in pregnancy – often before a woman knows that she is pregnant. Third, alcohol is widely available, widely consumed, and legal, which may imply to the general population that it is safer than other substances. Fourth, social norms vary widely in regards to acceptable levels of consumption, particularly for younger drinkers (*see* Peer Influences on Addiction). Fifth, drinkers' estimates of their consumption are often based on number of glasses or number of drinks consumed, which are often not reflective of the actual number of ounces consumed. Drinkers' memories may also be impaired by alcohol's effects on cognitive function. Therefore, women may underestimate the amount of alcohol they consume and thus underestimate the risks to their fetuses. For these reasons, pregnant women are advised to maintain complete abstinence from alcohol, particularly in the first trimester of pregnancy.

FAS can have lifelong consequences for offspring, and fetal development is less severely affected the earlier in the pregnancy the alcohol exposure stops. Therefore, early identification of prenatal alcohol consumption is vital. Nevertheless, stopping even late in pregnancy protects fetuses from subsequent harm. Mothers should be encouraged throughout pregnancy to become abstinent from alcohol.

Marijuana

Marijuana is the most commonly used illicit substance by pregnant women. Approximately one-third of the psychoactive component of marijuana – Tetrahydrocannabinol (THC) – crosses the placental barrier, thereby exposing the fetus to significant doses of THC. In spite of marijuana's popularity, fetal exposure to the active ingredient in marijuana remains understudied and questions remain regarding its effects on developing fetuses.

Much of the data regarding longitudinal outcomes associated with prenatal marijuana exposure are from two epidemiological studies: the Ottawa Prenatal Prospective Study (OPPS) and the Maternal Health Practices and Child Development Study (MHPCDS). In these studies, marijuana exposure has not been associated with increased risk of miscarriage or other perinatal complications, but has been associated with low birth weight. Marijuana is typically consumed via smoking, which exposes the fetus to carbon monoxide. Low birth weight, which has been associated with prenatal cannabis use in these studies as well as in meta-analytic studies, is thought to be the result of carbon monoxide exposure.

Research suggests that prenatal cannabis exposure is associated with developmental delays observable at birth. Findings from the OPPS and MHPCDS are consistent in implicating marijuana exposure in higher rates of increased tremors and exaggerated startle reflex in neonates. Alterations in neonates' visual functioning have also been reported. These delays appear to be mild and to disappear by the age of 6 years. Based on the research to date, THC appears to be less likely than other substances to cause congenital malformations in fetuses, although findings are not entirely consistent.

Much of the research assessing differences following prenatal cannabis exposure focuses on cognitive ability. Evaluations of cognitive ability in older cannabis-exposed children have revealed mixed results. Some studies suggest that prenatal marijuana exposure is associated with lower intelligence quotient, whereas others reveal no effect. Similar contradictory patterns of findings have been discovered for other forms of frontal lobe functioning, such as planning and perception, with some studies showing significant associations and some not. Prenatal cannabis exposure also appears to be associated with higher levels of antisocial or delinquent behavior in late childhood and adolescence. In addition, cannabis exposure has been implicated in disruption of neuronal development in the fetal brain, particularly in areas relating to mood, executive function, and reward. One explanation for these apparently

contradictory findings is that prenatal cannabis exposure affects some types of executive function while leaving others intact. Although the extant research suggests that prenatal cannabis exposure is associated with developmental issues, behavioral differences following prenatal cannabis exposure could also be accounted for by other environmental factors (e.g. polydrug exposure, parenting approach, and socioeconomic status). Additional research is needed to more precisely identify areas of concern following prenatal cannabis exposure.

Cocaine

Approximately 15–17% of cocaine users are women of childbearing age. Cocaine is a central nervous system stimulant that increases catecholamine ("fight or flight" hormone) levels, thereby activating the sympathetic nervous system. As a vasoconstrictor, cocaine increases maternal blood pressure, thereby increasing risk of hemorrhage and decreasing uterine blood flow and fetal oxygen supply. Cocaine also appears to block reuptake of some neurotransmitters, including serotonin, dopamine, and norepinephrine. Cocaine is believed to readily cross the placenta, thereby directly exposing the fetus to its effects. However, analysis of neonates' hair suggests that fetuses do not receive the entire dose of cocaine ingested by the mother.

Initial reports on cocaine-exposed children ("crack babies") in the 1980s and 1990s indicated that prenatal cocaine exposure was associated with severe teratogenic effects. More recent research suggests that prenatal cocaine use often occurs in tandem with other problems, and many of the effects initially attributed to prenatal cocaine exposure are at least partially attributable to other comorbid phenomena (e.g. poor nutritional, maternal stress and psychiatric illness, polysubstance use, lack of prenatal care, chronic medical problems such as HIV/AIDS).

However, researchers have discovered that some problematic effects associated with prenatal cocaine exposure persist independently of those resulting from other teratogens. These effects, which intensify as doses increase, include higher rates of preterm labor and early birth, low birth weight, shorter gestational period, placental abruption (placental separation from uterine wall), and neonates who are small for their gestational age.

Evidence suggests that prenatal cocaine exposure is also associated with functional deficits in later childhood. Children who are prenatally exposed to cocaine tend to exhibit small but detectable deficits in academic, intellectual, and language functioning relative to nonexposed children. In addition, neurocognitive deficits in maintaining attention and regulating behavior have been observed in cocaine-exposed children. These deficits appear to result from inhibited neurological developmental processes; as a result, they may not be evident until children reach school age and attempt tasks that require increasingly complex brain function. Most researchers who evaluate postnatal effects of cocaine exposure use demographic and other environmental factors as statistical covariates, thus increasing their capacity to isolate effects of cocaine exposure from those of other environmental factors. However, covariates and other research methods differ from study to study. As a result, the task of identifying which observed effects are due to prenatal exposure and which effects are due to other factors is ongoing.

Opioids

Babies exposed to opioids, including heroin, methadone, and prescription drugs (e.g. OxyContin, Percocet, and Vicodin) while *in utero* often experience withdrawal symptoms after birth. Although rarely fatal, opioid withdrawal can cause significant infant distress. Withdrawal is evident in four systems: autonomic nervous (e.g. sleep disturbance, fever, tearing and sweating, disrupted sucking patterns), central nervous (e.g. tremors, seizures, twitching, irritability, hyper- or hypo-activity, high-pitched crying), respiratory (nasal congestion, sneezing, respiratory distress), and gastrointestinal (e.g. vomiting, diarrhea, losing or failing to gain weight, hiccups). Withdrawal symptoms appear in 55–94% of neonates with prenatal opioid exposure. Signs of withdrawal appear within several minutes to 72 h after birth, depending on the mother's last opioid ingestion and amount, fetal health and gestational age, and type of analgesia used during labor. No clear dose–response relationship between amount of exposure and severity of withdrawal symptoms has been established.

Infants typically recover from prenatal opioid exposure after initial withdrawal symptoms resolve, but some long-term developmental problems in opioid-exposed children have been observed, including higher rates of attention deficit hyperactivity disorder, impulsivity, and diminished motor and language performance compared to nonexposed children. However, the research in this area is scant and additional work is necessary to draw firm conclusions regarding prenatal opioid exposure and long-term prognoses in children.

Methamphetamines

After marijuana, methamphetamines are the most commonly used illicit substance in pregnancy. Comparisons of methamphetamine levels in neonatal and maternal hair indicate that the levels are comparable, implying that methamphetamine readily crosses the

placenta without any decrease in dose. Methamphetamine, like cocaine, is a central nervous system stimulant with vasoconstrictive properties, and thus confers similar risks as cocaine such as fetal hypoxia and decreased uterine blood flow. Like cocaine, methamphetamine alters neurotransmitter levels, such as increasing levels of serotonin, dopamine, norepinephrine, and amines, while increasing catecholamine levels. Methamphetamine may also decrease maternal appetite, leading to poor fetal nutrition and, as a result, intrauterine growth restriction. Prenatal methamphetamine use has been associated with other pregnancy complications such as preterm birth and placental abruption.

Methamphetamine-exposed neonates tend to be smaller than their nonexposed peers. In addition, they may exhibit signs of exposure that mimic those observed in cocaine-exposed neonates, such as increased startle response due to hyperarousal. Birth defects such as cleft palate and cardiac anomalies have been observed in methamphetamine-exposed neonates. Methamphetamine-exposed neonates have been found to exhibit more severe health problems, such as fetal distress and neurological and physiological anomalies, relative to opioid-exposed neonates. Smaller head circumference, higher rates of behavioral problems, and lower academic functioning have been observed in older children exposed to methamphetamine prenatally. Neurocognitive anomalies in childhood have also been observed, including decreased attention span and working memory capacity. These phenomena have been observed in some samples, but not all, possibly as a result of methodological variability between studies. In addition, as with other assessments of prenatal outcomes following substance exposure, the behavioral, structural, and neurological anomalies that are observed could also be the result of problems that occur concurrently with methamphetamine exposure.

MDMA (3,4-methylenedioxymethamphetamine; Ecstasy) is structurally similar to methamphetamine. The effects of prenatal MDMA exposure in humans have not been widely studied. Limited extant data suggest that prenatal MDMA exposure is associated with higher rates of cardiac malformations and clubfoot in infants.

Inhalants

Inhalant abuse includes inhalation of household products containing toluene, which is an organic solvent that readily crosses the placenta. Products containing toluene include paint, gasoline, ink, lighter fluid, and glue. Other abused inhalants include nitrous oxide (laughing gas), chloroform, and ether; however, toluene is currently the most widely abused inhalant in the United States. Symptoms of prenatal toluene exposure in neonates are referred to collectively as fetal solvent syndrome or toluene embryopathy. Symptoms include early parturition, fetal growth restriction, and facial dysmorphisms similar to those observed in FAS. NAS following toluene exposure has been observed and is characterized by excessive crying, tremor and increased Moro reflex, insomnia, and poor feeding. Developmental delays in later childhood have also been observed. Although additional research is necessary to isolate the effects of toluene exposure from other forms of prenatal substance exposure, toluene effects appear to occur reliably at high doses, suggesting that at least some fetal changes following toluene exposure can be attributed to the substance and not to other substances or environmental exposures.

Benzodiazepines

Benzodiazepines, including diazepam (Valium), alprazolam (Xanax), and clonazepam (Klonopin), are commonly misused prescription medications. Several reviews and meta-analyses have been conducted to evaluate potential teratogenic effects of benzodiazepine medications, including diazepam. Some data suggest that benzodiazepine exposure is associated with higher rates of cleft palate or other oral malformations in the fetus. However, this finding is not consistent across samples, and despite repeated attempts to establish a definitive answer, there is currently no consensus regarding the safety of benzodiazepines in pregnancy. Until such consensus is achieved, pregnant women should be advised to avoid licit and illicit use of benzodiazepines.

Phencyclidine

Research on the effects of prenatal phencyclidine (PCP; also known as angel dust) exposure in humans is limited. However, reports suggest that *in utero* PCP exposure is associated with signs of neonatal PCP intoxication (e.g. jitteriness, irritability, and digestive issues). In addition, PCP may result in birth complications including early parturition and low birth weight. Limited research suggests that, when other drug use is statistically controlled for, prenatal PCP exposure contributes independently to compromised neonatal functioning. However, it remains unknown whether PCP exerts effects on children after they are beyond the neonatal stage.

ADDRESSING PRENATAL SUBSTANCE USE

Detection

All women of childbearing age should be screened for substance use, particularly those who are sexually active

but do not consistently use a reliable form of birth control. Some research indicates that health care providers feel unprepared to address possible patient resistance should the provider broach the topic of substance abuse treatment. Lack of referral options can also be a limitation. However, as approximately one-half of pregnancies in the United States are unplanned, universal screening is vital.

The simplest means of detecting prenatal substance use is by asking the patient about her substance consumption. This approach is complicated by stigma and maternal concerns of possible legal involvement, and the health care provider should be aware that these concerns may result in reporting bias. Thus, health care providers are advised to ask open-ended questions and maintain a nonjudgmental demeanor with patients. This approach is likely to maximize the potential for honest responding and is consistent with The American College of Obstetricians and Gynecologists' (ACOG) statement, which suggests that addiction be treated not as a "moral failing" but as a chronically relapsing condition that should be treated medically. The T-ACE and the TWEAK are brief (4–5 items) alcohol screening questionnaires, similar to the CAGE, which are validated for use with pregnant women, but are limited in that their focus is on assessing alcohol consumption only. Additional assessment via interview or questionnaire should be conducted to identify use of substances other than alcohol. As prenatal substance use rarely occurs without additional concurrent psychosocial problems, additional assessment of the psychosocial context is advisable.

Biological assessment – typically using blood or urine samples – is complicated by the short half-lives of some substances (e.g. alcohol), which allows only a brief window during which a substance is biologically detectable in a woman's body. Cocaine and alcohol are rendered undetectable in fetal blood and urine after only one week, meaning that testing neonates would identify only use that occurred during the week before birth. Longer-lasting biological markers of prenatal substance use and exposure include hair cells (maternal and neonatal) and fetal meconium (first stool). Infants' hair grows during the last trimester of pregnancy; therefore, any exposure identified based on neonatal hair samples must have occurred during this period.

Education and Prevention

Public health campaigns in recent decades regarding the risks of prenatal substance use appear to have been successful, as substance use in pregnancy has dropped. However, serious and potentially widespread risks remain. Given the high rates of unplanned pregnancies, many women consume substances before discovering that they are pregnant. In addition, many women may underestimate the risks of prenatal substance use for their fetuses. Substance Abuse and Mental Health Services Administration (SAMHSA) survey findings indicate that over 80% of women who meet criteria for substance use disorders do not desire treatment or believe that treatment is necessary, implying that additional public education about substance use disorders may be necessary. Therefore, educating young women about the risks of prenatal substance use, particularly early in pregnancy, is vital. This information can be disseminated broadly, such as via public health campaigns, or person-to-person, such as by health care providers. Indeed, ACOG suggests that health care professionals provide women with psychoeducation and referrals to substance abuse treatments.

Incarceration and Other Forensic Involvement

Maternal substance use in pregnancy is defined as child abuse in 15 US states and is grounds for civil commitment in 3 states. In 14 states, health care providers are legally bound to report maternal prenatal substance use and, in 4 states, to test for prenatal substance exposure when it is suspected.

ACOG issued a statement in 2011 criticizing forensic involvement in prenatal substance use. ACOG based their stance on evidence of deleterious effects that such policies can have. Legally mandated reporting of suspected prenatal substance use can result in patient mistrust of medical providers and may deter substance-using women from seeking prenatal care. Indeed, extant data suggest that prenatal substance abuse is associated with significantly lower rates of prenatal care. Lack of prenatal care is a known risk factor for birth complications, such as preterm labor, low birth weight, and mortality. Prenatal care is also an opportunity to engage pregnant women in substance abuse treatment. Thus, statutes that discourage substance-abusing women from seeking prenatal care may result in unintended consequences that further compromise the health of the fetus without resulting in decreased substance use.

As noted in ACOG's report, such policies – in addition to carrying significant risk of harm – may also be of limited benefit. Irrespective of providers' professional opinion on statutes, those involved in caring for pregnant women should know the statutes in their jurisdiction regarding prenatal substance use. In addition, providers should be ready to answer patients' questions about what is likely to occur if a report is made (e.g. incarceration, referral to treatment, Child Protective Services involvement).

Treatment

Once substance use has been identified, women should be offered treatment. Also, as substance use is associated with high rates of complications for mother and child, additional assessments might also be indicated at diagnosis and throughout pregnancy. These include HIV testing, liver and heart function assessments, and monitoring for infection. Substance use disorders are typically comorbid with Axis I and II disorders; therefore, additional psychiatric evaluation may also be indicated. Finally, pregnant substance-using women are at elevated risk for violence exposure and should be assessed and monitored accordingly. The Antenatal Psychosocial Health Assessment (ALPHA), developed at the University of Toronto, is designed to assess pregnant women's risk exposure in multiple domains: family factors (e.g. stress and support), maternal factors (e.g. extent of prenatal care, attitude toward pregnancy, current or past psychiatric problems), substance use, and current or past family violence exposure.

Brief, motivational interventions (*see* Motivational Enhancement Approaches) to engage women in treatment have been empirically supported in primary care settings, and the American College of Obstetricians and Gynecologists recommends such approaches for pregnant women. Motivational techniques are especially appropriate for pregnant women, as their concern for their babies' well-being provides an additional source of motivation to change.

Unfortunately, effective substance abuse treatment programs may not be available for pregnant women who want treatment. In addition, some women may have logistical barriers to attending such programs, such as limited transportation, childcare, and finances. Such barriers, in addition to concerns of legal involvement for women seeking treatment, may prove insurmountable for many. A 1998 study indicated that 7% of substance abuse treatment centers in the United States offer prenatal care services and 9% offer childcare services. However, a 2003 survey indicated that 59% of methadone clinics offered specialized care for pregnant women and that most (83%) consider pregnant women to be priority admissions.

Ideally, treatment for substance-using pregnant women, in addition to treating substance abuse, should comprehensively address the medical needs of mother and fetus including the treatment of comorbid psychiatric disorders. Case management is also indicated to address potential contributors to substance use such as socioeconomic, lack of vocational training and housing, legal, transportation, and childcare issues. Maternal exposure to violence should be addressed if present. Risk assessment and safety planning should be conducted with any women for whom current violence exposure is suspected. In addition to the typical stress associated with caring for a newborn, substance-using mothers may face additional challenges in parenting a fragile, substance-exposed infant with complex needs.

The rationale for a comprehensive treatment approach is strengthened by the large body of research indicating that prenatal substance exposure is almost always associated with other environmental issues. Without treatment, factors that perpetuate substance abuse during pregnancy are likely to persist following pregnancy. The postpartum period represents additional opportunities for health care providers to intervene and improve the infant's prognosis by teaching the mother parenting approaches that can attenuate the effects of substance exposure by improving the parenting relationship. For example, instruction on effective techniques for soothing a chronically fussy infant can reduce maternal stress and improve maternal functioning, including potentially reducing substance use. Research indicates that such "wrap-around care" in high-risk populations is associated with better health for neonates and significant cost reductions compared to noncomprehensive care.

Opioid Treatment in Pregnancy

Methadone treatment for opioid-dependent pregnant women has been the standard of care in the United States since 1970s. Before then, the standard of care – per FDA requirements – was that pregnant women be weaned from opioids. This standard was developed after the US FDA's requirement that women be weaned from opioids was associated with fetal death due to opioid withdrawal. Currently, federally prescribed indications for methadone maintenance include opioid dependence, per DSM-IV-TR criteria, lasting over a year (*see* Heroin Addiction).

Methadone maintenance confers benefits over abstinence- or detoxification-based approaches for multiple reasons. It increases patients' contact with health care providers because patients typically must present at a clinic daily to receive their medication. In addition, research indicates that the likelihood of relapse to illicit drug use – and its associated risks – is significantly lower with methadone maintenance than with abstinence-based treatment. Also, attrition is lower in methadone programs than for abstinence programs. Despite evidence that methadone programs are beneficial for mothers and infants, the use of methadone in pregnancy can be controversial, in part because administering methadone to the mother results in fetal exposure and, often, NAS.

Recently, researchers have begun evaluating buprenorphine as an alternative to methadone treatment for heroin addiction in pregnancy. Like methadone, prenatal buprenorphine exposure results in NAS. However, the NAS effects of buprenorphine are less pronounced than those of methadone. Switching from methadone to

buprenorphine maintenance therapy may not be indicated in pregnancy, as the mother and fetus may experience withdrawal symptoms in the process. Therefore, buprenorphine maintenance in pregnant women may be most appropriate for women who are initiating heroin replacement therapy or who are already being maintained on buprenorphine prior to conception.

Postnatally, treatment for opioid withdrawal consists of administration of diluted opium tincture (laudanum), which consists of 10% opium in an alcohol-based solution. Methadone can be problematic for use with neonates because of challenges in establishing safe and effective dosing. Swaddling the neonate in a quiet, dimly lit environment may also support the infant's recovery from withdrawal symptoms. Research to date suggests that the short- and long-term prognoses for the opioid-exposed neonate appear to be good.

Because methadone treatment for pregnant women typically is one element of comprehensive treatment services, the improved outcomes seen with methadone treatment may be due to increased access to prenatal care. Nevertheless, the benefit associated with prenatal methadone treatment for opiate dependence is clear. Pregnant women in methadone programs experience fewer pregnancy complications and health issues compared to those who continue using heroin throughout their pregnancy.

Women typically return to substance use soon after their children are born, with the majority who reported using substances pre-pregnancy or prenatally resuming use by their child's first birthday. Future work could build on the current success of public health campaigns to reduce prenatal substance consumption by expanding the message to include early childhood. In addition to reducing prenatal health risks, decreasing women's substance use perinatally also presents an opportunity to support women in continuing to make healthy choices regarding substances as they develop as parents.

For information regarding behavioral treatment of perinatal substance use, see 00174.

CONCLUSION

Prenatal substance exposure is associated with significant harm to fetuses. Substance use in pregnancy is often a symptom of other environmental stressors that may be equally harmful to offspring. Effectively treating prenatal substance use requires comprehensive care that addresses the factors that drive women's substance use. Untangling these issues in a way that can affect meaningful changes in the lives of substance-using pregnant women and their children is a complex task which, if successful, can have significant payoff for both generations, and potentially future generations as well.

Glossary

Catecholamines hormones, including epinephrine (adrenaline), norepinephrine, and dopamine released by the adrenal glands in response to stress. Foster "fight or flight" reaction by increasing heart rate and respiration, dilating pupils, and increasing blood glucose.

Cytogenesis cell formation and development.

Fetal alcohol syndrome ICD-9 and ICD-10 diagnosis that describes changes in a fetus following alcohol exposure while *in utero*. Includes facial abnormalities, inhibited growth, and neurological changes associated with developmental delays.

Fetal hypoxia lack of sufficient oxygen supply to fetus that can damage central nervous system cells.

Fetal programming hypothesized association between fetal environment and health of offspring and subsequent generations. Also known as the "Barker hypothesis."

Histogenesis process by which cells differentiate into specific tissue types.

Intrauterine growth restriction slowed or restricted fetal growth while *in utero* such that fetal weight is in the 10th percentile for age. Assessed by measuring uterine fundal length (distance from mother's pubic bone to top of uterus).

Low birth weight weight of less than 2500 g (5 lb. 8 oz.) at birth.

Moro reflex an infant's involuntary response to feeling of falling characterized by reflexive spreading of arms, followed by drawing in of arms to body. Typically disappears by age 3–5 months. Absence of the Moro reflex indicates central nervous system dysfunction.

Neonate newborn baby up to 28 days old.

Neural tube defects occur when the neural tube (embryonic cells that become the brain and spinal cord) does not close properly (occurs in gestational days 23–26), resulting in a hole in the neural tube. Approximately 1 in 1000 babies in the United States are born with neural tube defects. Examples include spina bifida and anencepaly.

Parturition childbirth.

Placental abruption separation of placenta from uterine wall after 20 weeks' gestation and before birth. In severe cases, associated with maternal hemorrhage and fetal injury or death.

Placental insufficiency inability of placenta to deliver sufficient levels of nutrition and oxygen to fetus due to diminished blood flow.

Preterm birth and labor Uterine contractions that are strong and coordinated enough to cause progression of labor and possibly birth between weeks 20 and 37 of gestation. Also known as early parturition.

Teratogen substance capable of causing harm to fetus by altering development.

OUTLINE

INTRODUCTION

Addiction involves continued engagement in a particular behavior despite adverse consequences. There are a wide range of addictive behaviors including substance use, binge eating, and gambling. Although each has unique features, there are common themes including diminished control over the problematic behavior, an appetitive urge or craving state before engagement in the problematic behavior, and a hedonic quality during the performance of the problematic behavior. For these reasons, addictive behaviors have been conceptualized as disorders of misdirected motivation and impaired self-control. A substantial body of research utilizing a variety of techniques (e.g. behavioral, neurobiological, imaging, self-report) has demonstrated a strong association between addictive behaviors and the constructs of disinhibition, impulsivity, and risk taking propensity. In the current chapter, we review these constructs including key definitions and consideration of their interrelationships, followed by a review of their relationship to addictive behaviors.

DEFINING DISINHIBITION, IMPULSIVITY, AND RISK TAKING

Disinhibition

It is important to begin the definition of disinhibition by acknowledging that it appears in the literature in two distinct ways: (1) as an umbrella term referring to a broad category of inhibitory dysfunction or behavioral undercontrol and (2) as a specific subtype/dimension of

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00021-8

impulsivity that refers to a process in which an individual has reduced capacity to alter an immediate response to some situation.

In considering the first use, disinhibition as an umbrella construct, the term is used to refer to an overarching category to include broadly overlapping but nonredundant variables such as impulsivity, sensation seeking, and risk taking propensity. As such, a range of behaviors fall into this category including loss of restraint, lack of regard for conventions, and poor risk assessment (i.e. tendency to focus on and pursue reward, even in the face of punishment). A number of reasons why these behaviors occur have been proposed including a neurobehavioral vulnerability (frontal lobes implicated), difficulty thinking about the consequences of behavior, misinterpreting social cues, poor social adjustment, inability to communicate in an appropriate way, discomfort, and response to provocation.

Disinhibition also is conceptualized as a specific type of impulsivity and is defined as manifestations of core impairments in inhibitory control, a self-regulatory process that has been conceptualized as the ability to withhold a prepotent response, interrupt an ongoing response, and protect cognitive activity from interference. This conceptualization of disinhibition as a dimension of impulsivity is measured by tasks in which participants are expected to inhibit prepotent motor behaviors or, said more simply, stop a behavior once it has been initiated. For example, the Stop and Go Task begins with the presentation of either an *X* or an *O* in the center of the computer screen. Subjects are instructed to press the "*z*" key when the *X* appears and the "/" key when the *O* appears. The letters are presented at 2-s intervals, and reaction times (RTs) are recorded. On 25% of the trials (25% of the *X* trials and 25% of the *O* trials), a tone (stop-signal) sounds after the presentation of the *X* or *O*. Subjects are instructed to refrain from pressing any keys when they hear the sound. The delay from the onset of the letter presentation to the onset of the tone (stop-signal delay) is systematically adjusted in 50-ms increments. If the subject fails to refrain from pressing a key after hearing the tone, the stop-signal delay is decreased by 50 ms on the following stop-signal trial. If the individual successfully refrains, the stop-signal delay is increased by 50 ms on the next trial. Eventually, the stop-signal delay will reach a duration at which the subject will inhibit his or her key press responses on approximately 50% of the trials. Individuals characterized by greater disinhibition are unable to inhibit their responses at longer delays (i.e. can't stop a response when the signal to stop comes later into the response) and therefore require a shorter delay to reach the point at which they are able to inhibit their responses 50% of the time. For our purposes, we will focus on this latter definition, and therefore, discuss disinhibition as a dimension of impulsivity rather than an umbrella term referring to a broad category of inhibitory dysfunction or behavioral undercontrol.

Impulsivity

While the term "impulsivity" is commonly used, it is a construct that has poor universal meaning. Several definitions of impulsivity have emerged including poorly conceived and/or prematurely expressed actions that are either inappropriate or unduly risky for a particular situation, a tendency to act without forethought (i.e. respond quickly and without reflection), excessive discounting of rewards and punishments as a function of their delay, an inability to inhibit inappropriate behavior (see definition of disinhibition above), being impatient when asked to wait, having a short attention span, and difficulty persisting at a particular activity. This multitude of definitions has led to confusion and disagreement as to the exact nature of the construct and the appropriate means of measurement. One approach to resolving the discrepancy in the definitions has been to treat impulsivity as a multidimensional construct. Despite general agreement on this matter, there remains little consensus regarding how to best characterize the different components.

A number of proposals have been set forth to define the multiple dimensions of impulsivity. First, some researchers have proposed that there are two major components of impulsivity: (1) resisting urges versus giving in to urges and (2) responding immediately to a stimulus versus planning before making a move. Second, other researchers have defined impulsivity with three subfactors: acting on the spur of the moment (motor activation), not focusing on the task at hand (attention), and not planning or thinking carefully (lack of planning). More recently, based on a comprehensive review of the literature, researchers have suggested that impulsivity is best conceptualized as a two-dimensional trait. The first trait, labeled Reward Drive, is argued to reflect individual differences in sensitivity to incentive motivation and engagement in appetitive behavior on detection of reward cues. Individual differences in reward sensitivity are thought to be mediated by the strength of responding in the mesolimbic dopamine system. The second trait, rash impulsiveness, is proposed to reflect individual differences in the ability to modify or inhibit prepotent (reward drive-initiated) behaviors in light of potential negative consequences. Individuals characterized by rash impulsiveness tend to make unwise or irrational choices because they fail to anticipate consequences or plan ahead. They may be described as insensitive to consequences, particularly when the reward sensitivity is high, leading them to perseverate in well-established (i.e. dominant)

behaviors, even when the behavior is no longer rewarded or elicits punishment. Individual differences in rash impulsiveness are thought to be mediated by the orbitofrontal cortex and anterior cingulate cortex, with the involvement of the dopamine and serotonin systems. Across the different definitions and usages, the core features seem to be (1) the tendency to execute actions too hastily or in a thoughtless manner, (2) difficulties withholding or inhibiting actions, and (3) the tendency to seek out immediate gratification at the cost of longer-term gains. Although these categories fit well with theory and empirical evidence and correspond with several widely accepted operational definitions, the exact nature of the dimensions remains controversial, and there is evidence for both relatedness and independence. More globally, the careful reader can see that although dimensions help emphasize the different aspects of impulsivity, the resulting range of dimensions and particular definitions as they appear form one conceptualization of the dimensions to another complicate efforts to develop a degree of consensus when considering what exactly is meant by impulsivity across different sources. We will attempt as we proceed here to distill the dimensions down to a manageable and useable framework, focusing on common themes across conceptualizations as opposed to sticking closely to any particular one.

Various measures have been developed to assess impulsivity, including self-report measures that rely on self-perceptions of behavior at a trait level and behavioral tasks that measure overt behavior which is thought to tap trait level measurement while also providing the opportunity to measure state responding. Three commonly used self-report measures to assess trait level impulsivity are the Barratt impulsiveness scale (BIS), the Eysenck impulsiveness scale (EIS), and the UPPS impulsive behavior scale (UPPS). The BIS is one of the most widely used self-report measures of impulsive personality traits; it has been through several revisions, with version 11 being the most recent (BIS-11). The scale consists of 30 self-descriptive items, with responses in a four-point Likert-type scale ranging from "*Rarely/Never*" to "*Almost Always/Always*." The questionnaire contains three subscales: attentional impulsiveness (actions precipitated by lack of attention), motor impulsiveness (hyperactivity due to need of movement), and nonplanning impulsiveness (attitudes and conclusions precipitated by lack of reflection). The EIS is also a widely used, self-report measure. In conceptualizing the scale, the Eysenck's distinguished impulsiveness from venturesomeness and separate scales were constructed to assess these constructs. The EIS is a 23-item, yes–no scale that is face valid for impulsivity (e.g. "Do you generally do and say things without stopping to think?"). In response to the lack of consensus on the definition of impulsivity, the UPPS was developed. The scale includes four dimensions: (1) premeditation (i.e. tendency to think and reflect on the consequences of an act before engagement); (2) perseverance (i.e. an individual's ability to sustain attention on a task that may be boring or difficult); (3) sensation seeking (i.e. a tendency to enjoy and pursue activities that are exciting as well as an openness to trying new experiences); and (4) urgency (i.e. compromised ability to resist impulses that are driven by negative affect). The UPPS scale is one of the few self-report measures to attend to state as the urgency scale assesses impulsivity specific to negative affect. More recently, urgency has been expanded in a separate 5th dimension called positive urgency to acknowledge the role of positive affect in impulsive behavior.

The behavioral paradigms used to measure impulsivity and the various subconstructs resulting from these measures can be broadly divided into two categories: (1) those that measure impulsive choice or impulsive decision-making and (2) those that measure impulsive action or motoric impulsivity (as described above in the disinhibition section). The common principal among these first types of tasks (impulsive choice or decision-making) is that the subject has to choose between a safer strategy that will produce a greater final gain and a strategy of bigger immediate wins paired with possible penalties that could result in a smaller final reward. Multiple tasks exist to study impulsive decision-making, and one of the most common measures used is the delay discounting procedure. The concept of delay discounting offers a well-known behavioral operationalization of impulsivity based on the tenet that reward is discounted as a function of its delay, with those individuals evidencing the steepest discounting considered impulsive. Said more simply, impulsive individuals often prefer smaller immediate rewards over larger delayed rewards. Consequently, the highly impulsive person has the propensity to choose the course of action that maximizes immediate gains as they are either unlikely to take into account or give value to future gains, or to give up immediate satisfaction. In contrast, the self-controlled individual gives value to future gains and thus, more successfully delays gratification.

A common mean to assess delay discounting is by the delay discounting procedure, a paper/pencil-administered version of the original monetary-choice questionnaire. The questionnaire consists of a fixed set of 27 choices between smaller immediate rewards and larger delayed rewards. For example, participants are asked "Would you prefer $54 today or $55 in 117 days?" Participants are instructed to show preference by choosing an option, with the effect of delay resulting preference for smaller sooner amounts of money indicative of impulsivity. More recently, the experiential discounting

task (EDT) was created based on the adjusting amount procedure to assess delay discounting. In this task, participants make choices between real delayed and probabilistic amounts of money, delayed by 0, 7, 14, or 28 s. Choices are between a probabilistic (35% chance of receiving) delayed standard amount and an adjusting smaller amount that is immediate and certain. All choice consequences (delays, probabilities, and rewards) are experienced during the testing session, that is, while the participant is still making choices.

Both self-report and behavioral tasks have some limitations. Impulsivity self-report scales are subject to response bias. Specifically, with self-report measures, participants must recognize and report on their own behavioral tendencies in various contexts relative to other individuals, and these self-perceptions may not always accurately reflect their behavior. Self-reports require insight or cognitive ability to understand questions to provide an accurate report of behavior. In other words, an impulsive individual may not always be sufficiently reflective to perceive his or her own impulsivity. In contrast, performance on behavioral tasks is potentially more objective and thus less sensitive to biased self-perceptions. On the other hand, the behavioral tasks typically measure only one specific dimension of behavior (e.g. the value of delayed rewards or response inhibition), which may have limited generalization to broader behavioral contexts or to the multidimensional construct of impulsivity. Further, self-report generally is limited to a more global assessment and may miss current state effects, whereas the opposite is of concern with behavioral tasks in that they may be overly influenced by proximal factors (e.g. mood, setting).

Risk Taking

Risk taking can be described as engagement in socially defined problem behavior that may bring positive consequences to the individual, but may be considered undesirable by the norms of society and often includes the potential for harm or danger. Research on risk taking has encompassed a variety of behaviors including alcohol consumption, tobacco use, risky sexual activity, dangerous driving, interpersonal aggression, and delinquent behaviors. One line of research considers risk taking to result from poor decision-making processes. A well-validated strategy for assessing this perspective on risk taking is the Iowa gambling task (IGT). In the IGT, participants are instructed to pick cards from different decks. Some decks include cards signifying large wins, while other decks include cards with smaller wins. Over time the decks with the larger wins also begin to include an even larger loss (resulting in an overall loss and referred to as the disadvantageous decks) while the decks with the small wins start to also include a loss but one that is smaller than the win (resulting in an overall gain and referred to as the advantageous decks). Risky decision-making is measured by the number of selections from the disadvantageous decks.

As a compliment to this conceptualization of risk taking as poor decision-making, risk taking propensity is the consideration of risk behavior highlighting the balancing of positive and negative consequences associated with a particular risk. As such, risk taking propensity considers one's willingness to take risks along a continuum where some level of risk is beneficial and it is up to the individual to determine their own level of risk tolerance. The most common strategy for measuring risk taking propensity is the balloon analog risk task (BART), a computerized measure. In this task, the participant is presented with a display of a small balloon and asked to pump the balloon by clicking a button on the screen. With each click, the balloon inflates a small amount and actual money is added to the participant's temporary winnings. At any point, the participant has the option to press a button labeled "Collect $$$," which deposits the amount in temporary winnings to the bank (i.e. it can no longer be lost) and ends the trial, at which point a new trial begins. However, each balloon is programmed to pop somewhere between 1 and 128 pumps, with an average breakpoint of 64 pumps. If the participant fails to press "Collect $$$" before the balloon pops, all earnings for that balloon are lost and the next balloon is presented. Risk taking is defined as the average number of pumps on unpopped balloons, with higher scores indicating greater risk taking. The task was developed to provide a controlled setting in which to model risk taking in the natural environment, where risk taking up to a certain point leads to positive consequences, with further excessive risk taking leading to greater negative consequences that outweigh the positives. Risk taking propensity assessed in this way captures the appetitive processes underlying a behavioral tendency to take risks in response to cues for a potential reward with a probability for undesirable results, which has shown correlations with a variety of real world risk behaviors from adolescents through adults. There are several other frequently used tasks, but most capture similar dimensions to the IGT or BART and therefore are not discussed here.

It is important to consider the manner in which risk taking propensity overlaps with, and is distinct from, sensation seeking which is a construct also quite relevant for understanding the development of risk taking behavior. Sensation seeking refers to the tendency to seek out novel, varied, and highly stimulating experiences, and the willingness to take risks to attain them. Sensation seeking can be divided into four traits: thrill- and adventure-seeking, experience-seeking, disinhibition, and boredom susceptibility. Clearly, the drive to

seek out novel and exciting experiences fits well conceptually with a willingness to take risks more broadly. However, it is important to note clinical examples where a willingness to take certain risks such as not wearing a seatbelt have little to do with sensation seeking. Empirical data indicate only modest overlap between the constructs.

Link between Disinhibition, Impulsivity, and Risk Taking

The links between disinhibition, impulsivity, and risk taking are apparent from the overlap in their definitions. All involve diminished restraint or control and continued behavioral engagement despite adverse consequences. This link also relates to addiction which entails a compulsive pattern, characterized by impaired control over the use of the substance and or engagement in a behavior (e.g. gambling) and continued use/engagement in the face of negative consequences. Yet, performance on laboratory measures of impulsive choice (e.g. delay discounting) and disinhibition (e.g. stop and go task), and risk taking propensity (e.g. BART) are not necessarily related in humans. Although differences may result from measurement issues, they also may indicate different specific mechanisms underlying performance across these constructs. As mentioned briefly above, a recent study exploring the relationship between three widely used self-report measures and four laboratory-task measures found that the correlations among the various self-report measures were high, but self-reports were not correlated with behavioral task measures. Conducting a principal-components analysis on data from four behavioral tasks, two components emerged, labeled "impulsive decision-making" and "impulsive disinhibition." Impulsive decision-making included measures that involve participants making decisions about delayed versus immediate or probabilistic versus definite outcomes, namely delay discounting and the BART, while behavioral disinhibition included measures in which participants are expected to inhibit prepotent motor behavior that is the stop task and the go/no-go task (behavioral disinhibition task that measures withholding a response to avoid punishment). This study supports other recent findings indicating that self-report and behavioral tasks probably measure different constructs and suggest that even among the behavioral measures, different tasks measure different components of impulsive behavior.

RELATION TO ADDICTIVE BEHAVIORS

There is a large collection of research demonstrating a relationship between addictive behaviors and impulsivity and risk taking propensity. Drug users have consistently been found to have impaired inhibition compared with nonusers. Cocaine and methamphetamine users have displayed inhibitory deficits on the stop and go task compared with nonusers. Cocaine users and individuals with alcohol dependence have demonstrated decreased ability to inhibit prepotent responses on the go/no-go task compared with controls. Outside of illicit drug use, research has indicated that cigarette smokers show decreased inhibitory control compared with nonsmokers and that the number of packs smoked each day is positively related to inhibitory failures.

Delay discounting tasks have shown that alcohol, cocaine, opioid, methamphetamine, and cigarette users perform more impulsively relative to nonsubstance users. For example, in a study comparing opioid-dependent participants and nonuser participants, those who were opioid-dependent discounted delayed monetary rewards more frequently. Additionally, opioid-dependent individuals who share needles have been found to discount delayed rewards at a greater rate than their opioid-dependent counterparts who do not share needles.

In addition, substance users have performed more poorly on the IGT than control groups, as evidenced by lower overall scores in the task and their inability to shift game card selections to more advantageous decks. Research utilizing the BART suggests positive correlations with a range of addictive behaviors. For example, the BART has differentiated between nonsmokers and smokers, for which the latter displayed higher scores on the task, and has been related to a larger set of real world risk behaviors including several addictive behaviors among adolescents.

Characteristics of substance use, including frequency and quantity, have also been associated with impulsivity and risk taking propensity. For example, heavy drinkers have been shown to be more impulsive than light drinkers, and those who are more impulsive use greater quantities of cigarettes, alcohol, and marijuana. This finding has been replicated across diverse age groups. For example, among adolescents, those who discount delayed rewards at a greater rate have exhibited more illicit drug abuse. In a sample of college students, those that displayed stable, heavy-episodic drinking made fewer advantageous choices on the IGT compared with the low, binge drinking participants.

Animal models have also supported evidence linking impulsivity with addictive behaviors and greater substance use. Rats categorized as highly impulsive (assessed by a delay discounting procedure involving access to two response levers with varying delivery times and a food pellet dispenser) have been found to consume more of a 12% ethanol solution than rats with

lower impulsivity. In addition, rats that display higher impulsivity have self-administered cocaine more often and at a faster rate than those that were identified as lower impulsivity rats.

Impulsivity has also shown to have an effect on drug treatment outcomes, which are worse for those who have shown increased trait impulsivity. For example, impulsive adolescents (defined by discounting monetary rewards more on the EDT and committing more commission errors on a continuous performance task) have been found to be less likely to achieve smoking cessation in a 4-week treatment program compared with their less impulsive counterparts. Similarly, individuals that scored high on self-report measures of impulsivity were more likely to drop out of cocaine abuse treatment. They also remained in treatment for shorter lengths of time than those with lower impulsivity scores. Impulsive individuals also experience increased drug cravings during withdrawal, as well as a greater likelihood of relapse. For instance, smokers who scored high on impulsivity exhibited increased craving in response to cigarette cues and they relapsed more quickly than less impulsive smokers.

Prospective

Moving to understand causal relationships, there is a growing body of work suggesting that impulsivity and risk taking propensity predict addiction. For example, research with community samples has consistently shown that personality traits related to behavioral undercontrol including impulsivity, measured using various self-report inventories in early to late adolescence, predict the subsequent development of tobacco, alcohol, and illicit drug symptoms and disorders in early adulthood. However, it is not the case that these variables necessarily remain static over time, as more recent research suggests that risk taking propensity and sensation seeking change over time in adolescence and that change is related to change in real world substance use behaviors.

Animal studies have helped to clarify links between disinhibition and addictive behaviors. Researchers have investigated links between impulsivity and novelty seeking and the shift to compulsive cocaine use that characterizes human addiction. Researchers characterized rats as high or low responders based on their level of locomotor reactivity in a novel environment (thought to model sensation seeking) and as high or low in impulsivity based on their observed ability to delay performance in a five-choice serial reaction time task. They compared high and low responding rats and high and low impulsivity rats in their likelihood of initiating cocaine self-administration and in the transition to compulsive use (e.g. continued cocaine use despite negative consequences). They found that while high responders were more likely to initiate cocaine self-administration, high impulsivity predicted the propensity to transition from use to a compulsive pattern of use. These findings suggest that sensation seeking predicts cocaine consumption, while impulsivity predicts risk of developing an addiction.

Substance Use as a Causal Variable

Together, these data support the hypothesis that impulsivity and risk taking propensity predict addictive behaviors. However, the reverse relationship – impulsivity and risk taking are exacerbated by substance use – has also been supported within the literature. Theoretically, it has been posited that addiction results from an imbalance that occurs in the course of drug use in which the impulsive system comes to dominate the reflective system, leading to a decrement in the user's willpower to resist using drugs. Thus, addictive behaviors may drive maladaptive decision-making through pharmacologic interactions with neurophysiological mechanisms that evolved for the process of normal learning. Such decisions may at times be considered impulsive and risky. Substance use may initially be deliberate and involve significant planning, but with frequent repetition, these behaviors may transition to involving more rapid, unplanned, habitual actions. These habitual actions may be less sensitive to consequences. For addicted individuals, the decision to continue to use substances may reflect the habit system dominating the decision-making process. Thus, substance use may lead to decreased behavioral control. In addition, addictive behaviors may place an individual in situations in which impulsive, risk-prone actions are more likely, for example, being around other impulsive people or ending up in situations in which impulsive or risky decisions are more valuable given uncertainties in a chaotic environment.

In terms of empirical support, researchers have found that drug abstinence is associated with lower levels of impulsivity in substance users. In a study examining the effects of residential substance abuse treatment on behavioral control variables, risk taking propensity was found to significantly decrease from pre- to post-treatment. Furthermore, after a long-term period of abstinence from continued smoking, ex-smokers have been shown to discount delayed money rewards to the same extent as those who have never smoked and less than current smokers. These findings suggest that impulsivity and risk taking are heightened during periods of use, and return to nonsubstance using levels after cessation; however, other research suggests long-term impairment in impulsivity as a result of substance use. For example, researchers have compared the

performance of detoxified, alcohol-dependent patients with the performance of control participants in behavioral tasks measuring impulsivity. In comparison with the control participants, individuals with a history of substance abuse performed worse on the impulsivity measures. These results were interpreted by the researchers as suggesting that exposure to drugs is sufficient to cause long-lasting increases in impulsivity. Further research is needed to clarify these potentially conflicting findings.

To address the acute effects of drugs on impulsivity and risk taking behavior, researchers have begun to study the effects of these drugs administered in a lab setting, much of which has focused on alcohol. For example, there is a body of work examining the effects of acute alcohol administration on specific state-dependent measures of impulsivity showing that low, moderate, and high doses of alcohol increase impulsive performance among moderate alcohol drinkers recruited from the community. Similarly, a moderate dose of alcohol has been found to increase response inhibition failures measured among college students. Further, among college students defined as binge drinkers, alcohol has increased response inhibition failures relative to nonbinge drinkers. On the other hand, studies examining the relationship and effects of alcohol on delay discounting measures have shown mixed results. After consumption of either moderate or large alcohol doses, increased impulsive responding on delay discounting measures (i.e. increased numbers of shorter-sooner reward choices) was found in a sample of alcohol abusers, but among healthy adults, there was no effect on impulsive responding. Data are less clear with risk taking measures. Although more research is needed to draw firm conclusions, studies conducted largely have not shown a clear and reliable effect of alcohol on risk taking. Interestingly, although a smaller body of research, studies examining stimulant drugs actually seem to indicate a decrease in impulsivity and risk taking. Although counterintuitive in some ways, this effect mirrors the effect of stimulant drugs on impulsive behavior in clinical conditions such as ADHD and more research is needed to fully understand the nature of these relationships.

Common Underlying Cause

To summarize, research has demonstrated a relationship between impulsivity and risk taking propensity and addiction; however, the exact nature of the association warrants clarification. There is available evidence that these variables may act as a precursor to the onset of addiction; yet, addictive behaviors may also lead to increased risk taking and impulsivity. A third possibility is that the association between disinhibition and addiction may be explained by common etiologies, an explanation we now turn to in more detail.

Behavioral Genetics

Such common etiologies may present at the genetic level. It is commonly thought that addiction has a genetic component. Family and twin epidemiologic studies have estimated that genetic contributions can account for up to 60% of the variance in the risk for addictions. Relatives of probands with substance use disorders have been found to be at an eightfold increased rate for these disorders. Yet, it has been difficult to replicate reports of specific genes for substance use disorders as genetic association studies have been characterized by inconsistent results which have raised interest in more complex approaches including larger scale genome-wide association studies (GWAS) and efforts to consider gene by environment interactions. Additionally, researchers have become increasingly interested in the variables that serve as the intermediary step between genes and substance use disorders; referred to as endophenotypes, risk taking propensity and impulsivity serve as two especially promising examples.

Research has shown addiction to be highly correlated with other psychological disorders in which impulse control is implicated. Compelling evidence suggests that problems such as substance use disorders, attention deficit hyperactivity disorder, conduct disorder, and antisocial personality disorder, among others, should be classified together under the rubric of externalizing disorders. This argument is based on evidence indicating that specific externalizing syndromes are often comorbid. For example, a national survey consisting of participants between 15 and 54 years old showed that alcohol dependence, drug dependence, and antisocial personality disorder formed a single externalizing factor, which could be distinguished from a separate factor that represented internalizing disorders (e.g. major depression, generalized anxiety disorders). Among externalizing disorders, impulsivity serves as a common link.

Additional support for classifying these disorders under one rubric comes from genetic correlations that have been observed among externalizing disorders, including alcohol abuse/dependence, drug abuse/dependence, and the child and adult aspects of antisocial personality disorder. Research has demonstrated that the genetic influences on the personality trait of behavioral undercontrol accounted for the majority (90%) of the genetic risk factors common to conduct disorder and alcohol dependence. Other research has presented significant genetic correlations among the personality traits of social deviance and excitement seeking, and alcohol consumption and problems, in young adult Finnish twins. Similarly, significant genetic correlations linking alcohol misuse and a variety of

personality scales indexing antisocial tendencies has been found. Finally, in the Virginia Twin Cohort, a common factor encompassing externalizing disorders such as antisocial personality disorder and conduct disorder accounted for 71% of the genetic liability to alcoholism and 67% of the inheritance of vulnerability to illicit drug abuse and dependence. While these findings point to main effects of genes in relation to externalizing psychopathology, research also indicates the likelihood of environmental experience moderating the effects of specific genes.

Neurotransmitter Systems

A number of systems are implicated in the connection between impulse control and addictions, including dopamine, GABA and glutamate, serotonin, and MAO. For example, genetic studies have linked several dopamine-related genes to impulsivity and addiction, including genes encoding the DA D4 receptor (*DRD4*) and dopamine transporter (*SLC6A3*). Additionally, the *D2A1* allele of the D2 receptor has been implicated in drug abuse smoking and is significantly more common in subjects with problem gambling compared with controls. Additionally, alterations in dopaminergic pathways have been proposed as underlying the seeking of rewards that trigger activation of the dopaminergic system, producing feelings of pleasure.

γ-aminobutyric acid (GABA), which is the main inhibitory neurotransmitter in the brain, has also been implicated in impulse control disorders and addiction. There is evidence of anatomic and functional connectivity between GABA and dopaminergic systems as well as increasing support for effects of modulation of GABAergic systems on substance use disorders. For example, tiagabine, a GABA reuptake inhibitor used primarily to treat seizures, has shown preliminary efficacy in cocaine addiction, and in a case report, was shown to help with control of impulsive aggression. Further, glutamate, an excitatory neurotransmitter and precursor of GABA, has also been associated with addictions. In preclinical studies, levels of glutamate within the nucleus accumbens mediate reward-seeking behavior. Taken together, these data suggest possible roles for glutamatergic and GABAergic systems in addictions.

In addition, a role for serotonin (5-HT) has also been supported in both impulsivity and addictions. In animal models, forebrain 5-HT depletion has been shown to lead to impulsive choice, while the indirect 5-HT agonist fenfluramine decreases such behavior. Nonselective 5-HT antagonists have been shown to promote self-controlled choice. Low levels of the 5-HT metabolite 5-hydroxyindolacetic acid (5-HIAA) have been found in individuals with impulsive characteristics and early-onset alcoholism. Low levels of cerebrospinal fluid 5-HIAA have also been associated with risk taking behaviors in primates (e.g. monkeys taking longer leaps in the jungle, violent criminals, and impulsive suicide committers). In general, low levels of brain 5-HT activity have been associated with impulsive behaviors, such as outward and self-directed violence and aggression, suicide, fire starting, and pathological gambling. Taken together, multiple lines of evidence support a role for 5-HT in mediating impulsivity.

Several studies have also demonstrated a strong link between low platelet monoamine oxidase (MAO) activity and drug use, alcohol dependence, antisocial behaviors, suicide, and gambling. In addition, low levels of MAO have also correlated with self-reported impulsivity and novelty seeking. In a sample of 557 young adult males aged 21–26, low MAO activity was associated with low impulsive control as indicated by high scores on measures of antisocial tendencies, higher rates of cigarette smoking, and increased rates of drug use. However, low MAO activity was not related to either alcohol use or abuse.

Developmental and Neurodevelopmental Factors

Developmental research suggests that, in general, impulse control continues to mature over the course of adolescence and early adulthood. For example, in a sample of individuals ranging in age from 7 to 29, a significant negative correlation between chronological age and impulsivity (using the Connors impulsivity scale) was found. Similarly, a significant decline in impulsivity from ages 14–16 to 20–22 on the EIS and the BIS has been observed. This was recently replicated in a large, socioeconomically and ethnically diverse sample of individuals between the ages of 10 and 30. Specifically, using both self-report and behavioral measures, impulsivity followed a linear pattern, declining steadily from age 10 on (as a note of caution these are cross-sectional findings). Delay discounting was also examined within this sample; results demonstrated that younger adolescents had a greater willingness to accept a smaller reward delivered sooner than a larger one that is delayed than did individuals aged 16 and older. Similar delay discounting findings have been found with other between-group cross-sectional comparisons of young adolescents (age 12), young adults (average age 20 years old), and older adults (average age 70 years old). These studies demonstrate that young adolescents discount monetary rewards more steeply than young adults, who discount at a faster rate than older adults. Together these findings suggest a decline in impulsivity from childhood through adolescence and into adulthood.

These findings parallel evidence showing structural and functional maturation over the course of adolescence in brain regions that subserve impulse control and other aspects of self-regulation. The development

of the prefrontal cortex (PFC) is believed to play an important role in the maturation of higher cognitive abilities such as decision-making and cognitive control, processes inherently related to impulse control. A number of paradigms, including response inhibition tasks, have been used, in conjunction with functional magnetic resonance imaging (fMRI), to assess the neurobiological basis of these abilities. Together, these studies show that children recruit distinct but often larger, more diffuse prefrontal regions when performing these tasks than do adults. The pattern of activity becomes more fine-tuned with age, with regions not correlated with task performance diminishing in activity with age.

In considering these findings in relation to observed increased risk taking behavior, including addictive behaviors, in adolescence, there has been a recent focus within neuroimaging studies to examine reward-related processing, focusing primarily on the region of the accumbens (a portion of the basal ganglia involved in predicting reward) in conjunction with top-down control regions (i.e. PFC). For example, a recent study examined behavioral and neural responses to reward manipulations across development. Results suggested enhanced accumbens activity in anticipation of rewards during adolescence relative to children and adults. Further, both children and adolescents showed a less mature response in prefrontal control regions than adults. The authors concluded that these findings suggest different developmental trajectories for these regions which may underlie the enhancement in accumbens activity and in turn relate to the increased risky behaviors observed during this period of development.

Thus, two core neurobiological networks seem to underlie human decision-making and are important in the emergence of risky behavior, including addictive behavior, observed in adolescence. The first, a cognitive control system, which consists of prefrontal and parietal regions, as well as the anterior cingulate, facilitates executive functioning. The second, affective system includes regions which are important to processing reward and social and emotional salience, including but not limited to the amygdala, ventral striatum, orbitofrontal cortex, medial PFC, and the superior temporal sulcus. Empirical evidence supports the notion that it is the affective network which dominates during adolescence, with heightened reward sensitivity throughout this developmental period.

The emergence of this affective network coincides with the onset of puberty, while the cognitive control network develops across a longer developmental trajectory, further supporting the dominance of the affective system in adolescent decision-making and increasing risky behavior. This dissociation between an affective and cognitive system has also been conceptualized as dissociation between an activational system and an inhibitory system, with delayed development of the inhibitory system and the dominance of the activational system being responsible for the onset of risky behaviors. In sum, the staggered development of these two brain regions is thought to result in heightened reward drive and cognitive disinhibition leading to increased engagement in addictive behavior.

In adolescents with conduct problems and adults with alcohol use disorders, reports from electrophysiological studies have found an association between inhibitory control impairment and PFC dysfunction. In an extensive review of imaging studies, it was reported that neuroimaging techniques have consistently documented differential activation in PFC in individuals with substance use disorders compared with controls when performing tasks of cognitive inhibition. Findings have also documented smaller PFC volumes across different studies in individuals with substance use disorders relative to controls. The PFC has also been associated with tolerance of delayed rewards.

CONCLUSION

Impulsivity (including disinhibition) and risk taking propensity represent complex, multifaceted constructs with relevance to addictions. Researchers are refining the definitions and assessment of different subtypes of impulsive behavior and relating these to the causes and consequences of addiction-related behaviors and disorders. The relationships may be best described as reciprocal and bidirectional, where these constructs are viewed as determinants and consequences of addictive behaviors, as well as concurrent factors emanating from similar causal mechanisms with particular relevance of biological, individual difference, and developmental factors. As research leads to a better understanding of these complex relationships, there will be much needed advancements in how we assess and treat addictive behaviors, which have the potential to contribute to advancements in public health.

RTs	reaction times
SLC6A3	dopamine transporter
UPPS	UPPS impulsive behavior scale

Glossary

Accumbens a collection of neurons within the striatum. It is thought to play an important role in reward, the experience of pleasure, laughter, addiction, aggression, fear, and the placebo effect.

Anterior cingulate cortex a part of the brain located in the frontal part of the cingulate cortex. It plays an important role on automatic and cognitive functions, including reward anticipation and decision-making.

Appetitive processes pleasant or wanted stimulus that a person will naturally try to approach.

Dopamine neurotransmitter that has been associated with cognition, motivation, learning, punishment, and rewards.

Functional magnetic resonance imaging Neuroimaging technique that focuses on blood flow in the brain to detect areas of activity.

γ-Aminobutyric acid main inhibitory neurotransmitter in the brain, which has been implicated in impulse control disorders and addiction.

Glutamate an excitatory neurotransmitter and precursor of GABA, which has also been associated with addictions.

Monoamine oxidase an enzyme that catalyzes the oxidation of monoamines. Low platelet MAO activity has been associated with drug use, alcohol dependence, antisocial behaviors, suicide, and gambling.

Orbitofrontal cortex prefrontal cortex brain region in the frontal lobes. It is involved in the cognitive processing of decision-making.

Prefrontal cortex anterior part of the frontal lobes of the brain responsible for executive functioning.

Reward drive argued to reflect individual differences in sensitivity to incentive motivation and engagement in appetitive behavior on detection of reward cues.

Serotonin a neurotransmitter involved in transmitting nerve signals between nerve cells and that causes blood vessels to narrow. It is thought to play an important part in impulsivity and addictions.

Urgency impulsivity accompanying negative affect.

Emotions and Addictive Processes

Jon D. Kassel, Jennifer C. Veilleux, Adrienne J. Heinz, Ashley R. Braun, Megan Conrad

University of Illinois at Chicago, Chicago, IL, USA

OUTLINE

INTRODUCTION: THE COMPLEX RELATIONSHIP BETWEEN EMOTIONS AND ADDICTIVE PROCESSES

Individuals take drugs for a variety of reasons, including peer pressure, genetic transmission of vulnerability to drug effects, parental modeling, and celebratory (positive reinforcing) rituals, to name but a few. The vast majority of people who use drugs (be they legal or illicit) do not ultimately transition to a state of drug addiction or dependence. Drug use more typically serves as an experimental rite of passage, or an occasional behavior marked by social engagement.

However, and as we discuss in more detail below, those unfortunate individuals who progress to the deleterious stage of drug addiction are the focus of this chapter. But why examine the relationship between drug addiction and emotion? What is to be gained by such an inquiry? In response to these questions, we argue that of all of the reasons (or attributions) provided by people who abuse drugs, the relationship between addiction and emotion may ultimately prove the most important and salient. Hence, if one were to simply ask abusers and addicts why they use drugs, the modal response would typically reflect aspects of the extent to which drugs make them feel something, be it the

removal of unpleasant affect (negative reinforcement), or the heightening of positive affect (positive reinforcement). Such associations between feeling states and addictive behaviors have been well studied in the empirical literature and have important implications for prevention and intervention efforts.

This chapter begins with an overview of several important terms: emotion and addiction. We then examine the comorbidity of drug abuse problems and disorders of affect (e.g. depression, anxiety) and consider several influential theoretical models positing critical associations between drug use and emotional states. Next, we provide a brief review of the evidence on whether drugs genuinely do render influence on emotional states. The chapter concludes with a summary discussion and future research directions.

CLARIFICATION OF TERMS: ADDICTION AND EMOTION

Emotion

Defining the constructs of emotion and addiction is essential to understanding the multidirectional relationship between emotion and addictive processes. Although most frequently conceptualized as subjective feeling states, emotions are multifaceted experiences that also include facial expressions, changes in autonomic arousal, cognitive appraisal processes, and behavioral sequelae. Generally, emotional processes are differentiated by the terms affect, mood, and emotion. Affect is the most general term, often used as a superordinate category to describe any emotional process, including basic evaluation of environmental stimuli as positive or negative. Moods are longer-lasting states of limited intensity that do not typically have a discernible causal object. Emotions are intense but short-lived acute states that are directly prompted by specific environmental experiences and/or objects. The basic emotional states (anger, fear, sadness, disgust, surprise, and happiness) are thought to be associated with particular patterns of neural responding that cut across cultures and can be observed in numerous species.

The terms emotion, mood, and affect describe relatively acute states, to be differentiated from affective traits and disorders of affect. Affective personality traits are longstanding, typically unconscious predispositions that influence the likelihood of experiencing an emotional response. For example, individuals high in neuroticism are more likely to experience negative emotional responses to stress and have more difficulty regulating their emotions. They are also more likely to experience disorders of affect such as mood disorders (depression, bipolar disorder) and anxiety disorders. Disorders of affect reflect pervasive alterations of mood that confer deleterious effects on thoughts, emotions, and behaviors, and frequently require psychotropic medication or psychotherapeutic intervention.

Addiction

Drug and alcohol use are not synonymous with addiction, although use is a necessary pre-requisite for development of addictive processes. Addiction reflects a maladaptive pattern of repeated use that results in significant harmful consequences. The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (Fourth Edition, Text Revision)* (DSM-IV-TR) has identified 11 classes of substances and a series of diagnoses associated with adverse effects of substance use including abuse, dependence, intoxication, withdrawal, and delirium. The term addiction is most closely tied to substance dependence disorders, characterized by at least three of the following symptoms: physical tolerance, withdrawal, greater use than intended, inability to reduce or control use, devotion of time and resources to obtaining the drug, and reduced social or occupational functioning due to drug use and continued use despite knowledge of the harmful consequences.

The terms addiction and dependence, particularly as differentiated from the use and abuse of substances, reflect underlying changes in brain functioning due to repeated substance use. Physiologically, drugs and alcohol influence brain systems and neurotransmitters associated with emotion (serotonin, dopamine, norepinephrine, etc.), with prolonged use appearing to exert long-term effects on the brain's emotional circuitry. Individuals addicted to drugs or alcohol may, therefore, have a biological need for the drug to maintain a consistent level of functioning, including in the realm of emotional processing.

Comorbidity

The relationship between addiction and emotion is likely bidirectional, reflected in the acute influences of heightened emotion on self-administration of substances, and the complimentary effect of substance use on immediate emotional responding. At a broader level of analysis, epidemiological studies have established a clear link between addictive disorders and disorders of affect. For example, rates of anxiety and depression are considerably higher in samples of substance-abusing individuals compared with the general population. Moreover, affective distress appears to increase in conjunction with the severity of substance issues. The

prevalence of anxiety and mood disorders is higher among those with substance dependence than substance abuse; individuals with multiple affective disorders also manifest more drug problems than people with a single mood or anxiety diagnosis. However, evidence is mixed as to the directional nature of these processes, such that affective disorders may confer vulnerability to substance use, and/or addictive processes may result in disorders of affect.

Part of the difficulty in elucidating causal patterns may be due to differences in symptomatic presentations across the specific disorders of affect, and/or differences among classes of drugs. For example, comorbidity rates of substance use disorders with mood disorders are typically higher than for anxiety disorders. Moreover, comorbidity rates differ by specific disorder; drug dependence rates are generally higher for depression than bipolar disorder, and higher for social phobia, simple phobia, and generalized anxiety disorder compared with panic disorder. Similar differences in comorbidity occur by drug classes, such that rates of affective disorders are higher for individuals addicted to drugs such as inhalants, tranquilizers, and sedatives compared with more commonly used drugs such as alcohol and marijuana. These nuances are important because they speak to different mechanisms that may drive the association between drug use and affective distress, and suggest that future research will need to solidify patterns of comorbidity as well as underlying processes that may account for the high rates of co-occurrence.

The relationship between disorders of affect and addictive behavior is also influenced by other moderating factors. For example, female addicts experience a higher degree of affective distress than male addicts, whereas men who abuse substances manifest higher rates of externalizing problems (i.e. antisocial personality disorder) than women. Comorbidity rates also vary by country and among sociodemographic factors within a given country (e.g. ethnicity, socioeconomic status). Moreover, factors such as childhood adversities, temperament, and peer and family processes all alter vulnerabilities to both substance use initiation and affective distress.

Delineating the casual direction of addiction and affective disorders suggests that the two are theoretically independent. However, several of the symptoms overlap, making clear distinctions between the disorders difficult to discern. For example, irritability and difficulty concentrating are frequent symptoms of depression, and are hallmark features of many drug withdrawal syndromes. To accurately assess factors associated with comorbidity, researchers must differentiate substance-induced psychiatric conditions that are direct sequelae of substance use or withdrawal from independent disorders that occur or persist more than 4 months after amelioration of withdrawal. Other methodological decisions have a bearing on the interpretation of epidemiological findings, including the choice of clinical or general population level samples, statistical control of sociodemographic factors such as race or income, and consideration of the high degree of comorbidity between anxiety and depression.

The literature on comorbidity between disorders of affect and substance use is definitive in one regard: there is clearly a link between emotion and addiction. It appears that affective distress begets problems with substance use, and substance use disorders lead to problems of affect. When viewed through a biopsychosocial lens, these findings are not surprising. At a neurochemical level, affective disorders and recurrent substance use cause altered brain chemistry, typically in brain regions associated with emotional processing. At a psychological and sociological level, addicts regularly encounter relationship conflicts, financial woes, and engage in other risky behaviors that may lead to prolonged emotional pain. Correspondingly, individuals suffering from affective disorders may choose to use drugs or alcohol as a way of self-medicating emotional distress. The high comorbidity rates between these classes of psychiatric conditions suggest the need for further research across multiple levels of analysis and methodologies (e.g. epidemiological, developmental, within-person, laboratory based, etc.) to further elucidate the bidirectional relationship between affective distress and addiction.

THEORETICAL FRAMEWORKS FOR THE ROLE OF EMOTION IN ADDICTIVE PROCESSES

Negative Reinforcement Models

Steeped in the traditions of Skinner's operant conditioning, negative reinforcement models of substance use and dependence posit that on learning that drug administration is followed by a reduction in distress, an individual will be more likely to use substances when distressed in the future. Hence, a vicious cycle is initiated and a seemingly intractable addiction emerges. This conceptualization is also represented within a web of related hypotheses (i.e. self-medication, stress coping, tension reduction) that collectively espouse that motivation to use substances is driven by promise of a key emotional pay-off: alleviation of negative affect (NA).

Withdrawal-Relief Model

The experience of drug withdrawal is typically characterized by NA symptoms that include depression,

anxiety, and irritability among other unpleasant mood states. The withdrawal-relief model, one of the oldest and most enduring proposed explanations for drug addiction, suggests that following repeated substance use, individuals begin to use substances for the purpose of avoiding withdrawal symptoms, and not to ameliorate organic NA. Although a compelling framework for understanding the later stages of drug dependence, the withdrawal-relief model does not explain why relapse can occur well after withdrawal symptoms have subsided. Moreover, it fails to adequately explain how patterns of use are established well before the onset of physical dependence and withdrawal (e.g. experimental and initiation phases). Most individuals in the early developmental stages report using substances to enhance positive mood (i.e. positive reinforcement).

Classic Conditioning and Cue Pairing

Principles of associative learning can be applied to account for some of the limitations associated with models that view negative reinforcement as the sole motivational core of substance use. For instance, exposure to drug cues previously associated with withdrawal symptoms can elicit a conditioned withdrawal response and subsequently evoke craving. More importantly, affective distress can signal an individual to use drugs even in the absence of withdrawal symptoms. This is because with repeated use, NA can eventually function as a warning flag that signals to the user that substances are typically consumed in this context.

During active use, the acute effects of a substance serve as an unconditioned stimulus (UCS). Initially, when a substance (UCS) is introduced to the system, regulatory processes attempt to restore homeostasis (i.e. unconditioned response (UCR)). After repeated pairings, the strength between the UCS and the UCR increases and the link between them becomes cognitively, emotionally, and physiologically entrenched. Eventually, the substance itself becomes a conditioned stimulus and the defensive regulatory response becomes the conditioned response. Once these associations become fully conditioned, exposure to the substance – or even substance-related cues – can elicit a compensatory response even in the absence of the individual actually having to use the substance. This response may be experienced as withdrawal, craving, and increased NA, all of which promote and heighten the likelihood of future substance use.

Reformulated Model of Negative Reinforcement (RMNR)

As mentioned earlier, it is generally accepted that as substance levels in the system drop and a withdrawal state emerges, the user begins to experience NA. Accordingly, these NA cues are believed to signal urges and promote substance use. The RMNR offers several important nuances to this conceptualization and asserts that avoidance of the affective components of withdrawal is the primary motivating force behind substance use. More specifically, the model proposes that as experience with substance use mounts, the user becomes more attuned and sensitive to the intereoceptive cues (i.e. internal sensations) associated with withdrawal symptoms. This withdrawal-associated internal state eventually becomes a potent conditioned stimulus that elicits NA. In the early stages of withdrawal, NA cues are subtle and fail to be perceived on a conscious level. Instead, the user's preconscious detection of the cues start to bias responding in a way that increases the probability that substance use, a previously reinforced response, will occur. In other words, once signs of withdrawal are preconsciously detected, the autopilot switch is flipped on in anticipation of affective distress. Subsequently, the individual's motivational processes are swayed toward substance use ostensibly to relieve or avoid the NA caused by declining levels of drug in the system.

These processes transpire outside of the user's awareness in an automatized fashion, that is, until a notable environmental stressor is experienced (e.g. interpersonal conflict) or access to a substance becomes challenged (e.g. smoking and air travel). At this point, the user crosses an affective threshold and enters into conscious awareness of the NA. Once the presence of NA is noted, urgency intensifies and the user's ability to process information is compromised. Attention and response selection are biased toward hot information – information regarding responses that have decreased NA in the past (i.e. substance use). Consequently, information about alternatives to procuring affective relief without substances (i.e. cold information) is deemphasized (e.g. going to a 12-step meeting). In addition, the influence of cognitive control (e.g. attention to goal-relevant information, action monitoring) on decision making is significantly diminished, resulting in increased likelihood of substance use.

The RMNR clearly takes a more ecological approach to describing the role of emotion in substance use in that it considers both endogenous (e.g. withdrawal symptoms) and exogenous factors (e.g. environmental stressors). It is thought that their inclusion can rectify some of the limitations noted in other negative reinforcement models, namely, that substance use can be induced by nonpharmacological affective distress – a stance that can explain why relapse may occur well after withdrawal-related aversive states have abated.

Positive Reinforcement Models

Traditional positive reinforcement models of drug motivation assert that individuals use drugs primarily

because they confer emotional benefit (rather than decreasing affective distress or relieving withdrawal symptoms). A wealth of neurobiological evidence shows that substance use induces a hedonic effect by increasing the levels of dopamine in the brain's reward center. Hence, drug users frequently describe their subjective experience as highly pleasurable, and this supports the idea that substance use is related to the neural basis of positive affect. The reward learning hypothesis suggests that dopamine plays a key role in teaching or stamping in that certain responses are followed by reward. That is, individuals become conditioned or programmed to repeat behaviors that result in reward. Once a substance has been associated with reward, the drug itself, along with associated cues, functions to activate the reward system. Such a framework may be particularly helpful in describing the processes governing early drug use (typically in adolescence), where positive reinforcement typically drives consumption.

Problems with Purely Positive or Negative Reinforcement Models of Addiction

Several inconsistencies have been highlighted in the literature regarding the models of drug motivation described above. First, withdrawal and craving do not reliably predict drug use. Furthermore, relapse is also known to occur in the context of positive affect (i.e. celebration). Second, many individuals express that they continue to use substances even when they no longer derive any affective benefit. Some substance users go so far as to express a genuine hatred of their drug use despite engaging in such use every day. Such observations suggest that negative reinforcement or positive reinforcement alone may not be the only mechanisms governing substance use. Other reinforcement models of substance use hint toward an interplay of positive and negative reinforcement processes in combination with key neurological and physiological processes. Such blended perspectives actually function to address many of the problems noted with models that cite only negative or positive reinforcement as the primary motives for substance use.

Blended Models

Opponent Process Model

The opponent process model of addiction is based on the premise that substance use disturbs individuals' natural balance (i.e. homeostasis). Initially this disturbance is in a positive and hedonic direction (the *a* process) although eventually the *b* process, the opponent process, is enacted to restore homeostasis. The difference in magnitude between the *a* and *b* processes determines the user's affective response to the substance. For instance, if the *a* process is larger in magnitude than the *b* process, the user is believed to experience a pleasurable state. Conversely, if the *b* process is larger, it is thought the user will experience a dysphoric affective state. In the initial phases of substance use, the appetitive a process appears more robust and ostensibly reinforces the individual to continue using. However, over time with repeated use and growing tolerance, the *b* process begins to dominate the *a* process. This shift results in a negative net effect where disrupted homeostasis manifests as withdrawal symptoms. Accordingly, abstinence is the only means by which the *a* and *b* processes can be restored to baseline levels.

Allostatic Reward Model

Derived from animal research, this model claims that addictive processes cannot be fully explained by homeostatic functions because addiction is inherently an allostatic state. That is, chronic drug use moves the homeostatic reward set point away from its naturally calibrated position. More specifically, in the development of addiction, functional changes are induced in the brain's reward system and other neuroadaptive mechanisms. Although compensatory processes are at work (e.g. the opponent process), they eventually fail to bring the user back to a normal homeostatic range. The individual then begins to derive a disproportionate amount of reward from substance use relative to other rewards such as food, sex, etc. An allostatic state is achieved when the brain circuitry becomes so dysregulated that it can no longer maintain stable reward functioning and the reward set point remains chronically off. When in this state, hormonal stress responses are triggered and activation of the cortico-striatal-thalamic loop among other brain areas promotes compulsive drug seeking and eventual loss of control. Overall, the model offers a viable explanation for the frequently observed downward spiral of distress experienced by addicts. The allostatic reward model also goes some way toward explaining why individuals are neurologically vulnerable to relapse even after extended periods of abstinence.

Incentive Sensitization/Salience Model

A common observation in clinical settings is that substance users continue engaging in use even though they report not liking it. For instance, some cigarette smokers express a deep hatred of smoking or report trivial affective benefits, yet continue to smoke regularly and without serious intention of quitting. In addition, users can recall catching themselves starting to use after a long period of abstinence without even consciously wanting to do so. Such marked discrepancies between

expressed motivational intent and observed objective behavior are puzzling and challenge the tenets of traditional motivational models. Ultimately however, this anecdotal evidence has served as a foundation for researchers to examine whether differences between liking a substance and wanting a substance could illuminate the pathways to abuse, dependence, and even relapse.

In keeping with the notion that persistent and complex changes occur in the brain over the course of addiction, the incentive sensitization theory posits that compulsive substance use is caused by a progressive hypersensitization of neural mechanisms (involved in reward) to the pleasurable effects of a substance (e.g. liking). In the initial phases of drug use, this means that motivational significance, or reward salience, of the desirable effects of the substance begins to shift such that increased reward is derived from each subsequent use (i.e. sensitization). As hypersensitivity to the incentives associated with the substance develops, attentional processes become strongly biased toward the substance as well as substance-related stimuli. This shift, coupled with other known substance-related impairments in executive functioning, induces a compulsive wanting of the drug that is thought to constitute the pathological core of addiction. In effect, the system becomes conditioned to want the substance in a way so powerful that it can occur outside the realm of conscious awareness and even after long periods of abstinence. The critical piece here is that neural mechanisms involved in the pleasurable (liking) effects of substance use do not become sensitized nearly to the same extent as wanting. Burgeoning evidence supports the presence of neural mechanisms underlying the subjective, pleasurable (liking) effects of a substance that are distinct from mechanisms associated with reinforcing (wanting) effects.

Cognitive Models

Although cognitive theories of substance use are well developed, their intersection with emotional processes is understood to a somewhat lesser extent. More commonly, specific cognitive mechanisms are identified as mediators in the relationship between emotion and substance use. Such an approach honors the inherent complexities that characterize the role of emotion in substance use, and may help to explain why emotional response to the same substance-related stimuli or internal states can vary so greatly within the same individual over time and across contexts. Moreover, cognitive models appear to address some of the unexplained variance in situations where the effects of emotion fail to demonstrate predictable influences on substance use.

Expectancy Theory

Data from decades of research with placebo designs undoubtedly attest to the notion that what one expects to happen tends to strongly influence what actually happens. Accordingly, several cognitive mechanisms have been proffered to explain why expectations so strongly dictate experience. In the case of drug outcome expectancies, individuals formulate beliefs about the affective consequences of using a substance (e.g. feeling relaxed after a cocktail). These expectancies are acquired through social learning and media messages, and are shaped by repeated experiences of positive and negative reinforcement with a substance. As the user becomes more experienced, connections between schematic representations (i.e. cognitive framework for organizing information) for substances and affective expectations strengthen in the brain. These affectively laden expectancies lie at implicit as well as explicit levels of awareness. When activated in memory, they are thought to govern substance-seeking behavior in a seemingly automatic fashion.

Attention Allocation Model

Based on the observation that, both within and across individuals, the effects of alcohol on a host of cognitive, behavioral, and emotional outcomes seem inconsistent, Claude Steele and colleagues formulated the influential attention allocation model. Simply put, the model posits that whereas alcohol's effects on emotional response are indirect, alcohol does yield several consistent effects on certain aspects of cognitive processing: Alcohol both reduces overall attentional processing capacity (working memory) and induces a state of attentional narrowing, such that after drinking, individuals cannot attend to as many stimuli as they could prior to drinking. The ramifications of the theory suggest that if, for example, an individual who is anxious about an upcoming examination drinks in the presence of benign distraction (e.g. seated at a local bar with friends and music playing), his narrowed and shrunken attention would necessarily be reallocated to the more salient distraction and away from the cognitions that were otherwise promoting the anxiety. Under these circumstances, drinking in combination with such pleasant distracters would result in anxiety reduction. If, however, that same individual chooses to drink at home, alone in his kitchen (ostensibly in the absence of pleasant distraction), his attention would remain focused on the anxious cognitions and, hence, not only would consumption of alcohol not serve to reduce anxiety, it would exacerbate it.

Kassel and colleagues applied the basic tenets of this model to better understanding cigarette smoking's seemingly inconsistent effects on stress and anxiety reduction. Their findings were remarkably similar to those observed with alcohol: Whereas anxious smokers

who smoked in the presence of benign distraction experienced dramatic decreases in self-reported anxiety, those smokers who smoked in the absence of distraction experienced either no change or an increase in anxiety. Thus, the model appears to offer an interesting framework for understanding, and even predicting, emotional response as influenced by two very different drugs: alcohol and nicotine. Nonetheless, more research is needed to determine whether this proposed mechanism – reallocation of attentional resources – is volitional or governed by forces operating outside of conscious awareness.

Appraisal Disruption Model

The appraisal disruption model rests on the assumption that before experiencing an emotional response, cognitive processing must occur within the individual in order to evaluate and appraise the subjective meaning (i.e. personal relevance) of the antecedent causal event (e.g. argument with spouse). Thus, it is the appraisal of the situation that produces one's emotional response. If this cognitive appraisal is disrupted, an emotional response would be lessened or blunted as the information normally primed and triggered to formulate emotion would not be accessible in memory. Many substances, including alcohol and tobacco, have been found to disrupt the cognitive faculties critical to this appraisal process (e.g. alcohol reduces response to an anxiety-provoking situation; going on a first date). Substance use, particularly alcohol, is thus believed to influence emotion through this particular cognitive pathway.

ADDICTION AND EMOTION: DEVELOPMENTAL PHASES

Thus far, we have discussed the burgeoning evidence pointing to robust associations between drug addiction and various indices of emotion. Moreover, these links are steeped in sound theoretical frameworks. We now consider the notion that the relationship between substance abuse, addiction, and emotion may vary across developmental stages of addiction. Hence, we briefly review such associations across the phases of drug initiation, maintenance, and relapse.

Initiation

In recent years, research has increasingly focused on the role played by affective states, and their interaction with the environment, in the initiation of substance use and the development of subsequent disorders (i.e. addiction). When considering emotion regulation, a compelling area of interest is the transition from adolescence to adulthood, sometimes referred to as emerging or young adulthood. These developmental stages are when most addicts begin using drugs. This period is marked by a general increase in NA and emotional lability, as well as a widening array of social stressors. To deal with these stressors, adolescents and young adults typically use emotion-focused and/or problem-focused coping strategies. Emotion-focused coping strategies manage the emotions linked to, or resulting from, stressors over which individuals believe they have little or no control. Problem-focused strategies, however, focus on effectively altering or removing the stressor and attendant feelings.

Affective dysregulation, or poor emotional control, and routine use of emotion-focused strategies have been linked to increased alcohol and substance use. When the drug itself is used to manage emotion, the use itself becomes an emotion-focused coping strategy. Thus, just as NA increases during young adulthood, so do rates of alcohol use and abuse. This is especially true in the years immediately following high school, before these rates peak when adults reach their early 20s.

During this time, alcohol expectancies play a large role in motivating drinking behavior. Drinking for positive reinforcement (i.e. to get high) is associated with positive alcohol expectancies and overall reward seeking. As discussed earlier in this chapter, these motivations are most likely based on alcohol's activation of reward centers in the brain. Conversely, others report drinking to relieve NA (i.e. to forget about problems) and have a very strong belief that alcohol reduces stress and anxiety. Longitudinal research strongly suggests that those adolescents and young adults whose drinking is primarily motivated by negative reinforcement are at much greater risk of subsequently developing abuse and addiction problems. Regarding the extent to which alcohol (and other drugs of abuse) actually serve to reliably reduce NA and other indices of affective distress among adolescents and young adults, the jury is still out. It appears that the effects of alcohol and other drugs on NA are highly conditional, relying on both individual (e.g. expectancies) and environmental factors.

Alcohol use during adolescence and emerging adulthood predicts both concurrent and later tobacco and illicit substance use. Accordingly, most experimental smoking occurs during adolescence; the prevalence of all substance use disorders increases steadily throughout this time period. The extant literature indicates that, like many adult smokers, a significant proportion of adolescents smoke initially to relieve stress and NA. Critically, longitudinal studies of adolescents have shown that those who become regular smokers perceive more stress in their lives and do not use coping strategies effectively, relative to those whose smoking does

not progress. Hence, for these at-risk adolescents, smoking is more typically viewed as a viable coping resource.

Maintenance

Emotional distress plays a crucial role in the transition from controlled to excessive substance use. Persistent substance use often represents a way to cope with negative emotions and obtain rewards, as acute substance use can result in both positive arousal and alleviation of NA. It follows that addicted persons often experience heightened negative emotional states, prompting persistent, compulsive substance use without thought of negative consequences.

The self-medication hypothesis, as originally informed by psychoanalytic theory, but later modified by social–cognitive perspectives, suggests that continued substance use functions as a means to modulate affect and soothe psychological distress. Accordingly, it asserts that substance users find negative emotions intolerable and overwhelming and are unable to manage these emotional states on their own. Thus, they seek the physiological and psychological effects of their chosen substance to regulate their distress and achieve emotional stability. Whereas this model has garnered empirical support, the specific emotional effects of individual substances remain unclear. Hence, as discussed earlier in the section on Theoretical Frameworks, it appears that contextual factors likely play an important role in modifying drug effects on emotional response.

An alternate tripartite model helps explain how substance use is maintained, describing the central components of the addiction cycle in clinical terms: preoccupation–anticipation, binge–intoxication, and withdrawal–NA. First, there is an initial preoccupation with obtaining the substance despite persistent physical or psychological consequences. Subsequent intoxication results in the failure to fulfill social, occupational, and recreational obligations. These failures often result in increased NA that is exacerbated by emerging withdrawal symptoms. A cycle of repeated failures to self-regulate follows, and each violation brings greater NA and results in greater tolerance than the last. A similar model of addiction asserts that the relief of NA is the primary motivation for substance use. Through repeated cycles of substance use and withdrawal, users become more sensitive to the interoceptive cues of NA and the soothing effects of the substance.

It follows that negative emotionality, anxiety, and depression have all been linked to alcohol use and other substance use disorders. For example, compared with social drinkers, excessive users often report drinking to relieve personal distress and cope with negative emotions. Those with alcohol use disorders manifest higher rates of anxiety and depression and score higher on measures of neuroticism and negative emotionality than nondisordered individuals. The relationship between emotional distress, emotion regulation, and drinking is complex, however, as prior research identifies NA as both a predictor and consequence of alcohol use, creating a cycle of negative emotionality. Self-regulation, the process by which one formulates a plan and adjusts one's behavior accordingly, is an important component in managing this kind of emotional response. Deficits in self-regulation have been reliably linked to the development and maintenance of substance use disorders. The most effective interventions often focus on increasing self-regulation to break this affective cycle.

Correspondingly, although there is ample anecdotal evidence of smoking's ability to relieve NA among regular smokers, research findings have been mixed. Generally, the psychological gains experienced while smoking are thought to result from the reversal of withdrawal symptoms. Indeed, withdrawal effects have been demonstrated with increasing accuracy. Researchers have begun to measure mood before and after participants smoke a series of cigarettes. Mood ratings generally improve after they smoke the first cigarette compared with baseline, decline during the abstinence period, and improve again after they smoke the second cigarette. Similar results have been shown with self-reported stress and arousal.

Relapse

As discussed throughout this chapter, most models of drug use identify negative mood states, such as stress and depression, as important precipitants and motivators of drug use. Moreover, drug abuse and dependence have been conceptualized as chronically relapsing conditions. Decreased NA as well as an increase in positive affect may both play a role in continued drug use, including vulnerability to relapse. The relationship between NA and relapse, perhaps even more so than NA's relationship with use during the initiation and maintenance phases of use, appears particularly robust.

One way to view the relationship between emotion and drug relapse is through a conditioning paradigm. Over time, chronic drug users may experience negative mood states, such as stress and depression, as conditioned stimuli that illicit craving for the drug. Several laboratory studies have shown increased craving among drug users after exposure to NA cues, such as visual images or music. Animal studies have also indicated that stress often leads to reinstated drug-seeking behavior among abstinent animals. Moreover, reinstatement of drug-seeking behavior in animals, in response to drug cues as well as

stress cues, has been shown to increase dopamine release in the nucleus accumbens. Therefore, the conditioning properties of both positive and negative cues have been attributed to dopamine release in this brain region.

Another model in which emotion and relapse have been conceptualized is through proposed brain changes in reward and stress systems. Most drugs of abuse stimulate the mesocorticolimbic dopaminergic systems, the brain reward pathways, accounting for the rewarding properties of drugs of abuse. Furthermore, neural stress and reward pathways are closely related. Therefore, stress pathways in the brain, including norepinephrine systems and corticotrophin-releasing factor, are also affected by drug use. Several theorists postulate that neural changes to these brain reward and stress systems caused by repeated drug use may increase vulnerability to stress and in turn, increase the risk of relapse.

Robust evidence exists for the relationship between stress and relapse to several drugs including nicotine, alcohol, heroin, and cocaine. However, not all abstinent drug users who experience stressful life events relapse. Furthermore, it appears that some individuals are better able to cope with stressful life events compared with others. Several studies have shown that the use of adaptive coping mechanisms is associated with decreased risk of relapse. Both the type of coping mechanism and the number of coping mechanisms used have been shown to be important factors in predicting relapse. However, as noted previously, chronic drug use may lead to neuroadaptations in the stress system. Thus, not only may drug users possess an increased sensitivity to stress, they may also be less well equipped to cope with stress. Some have proposed that teaching coping mechanisms to recovering drug users should represent a critical component of any drug and alcohol intervention.

CONCLUSIONS AND FUTURE DIRECTIONS

Based on a review of the empirical literature, we have argued that the relationship between drug addiction and emotional processes is a critical one. The idea that people self-administer drugs and alcohol because of their respective affective payoffs is hardly new. It has endured for centuries, is steeped in common folk psychology, and certainly holds intuitive appeal. None of these realities reify the notion that drug use and abuse is integrally tied to emotional processes. In order to truly understand and assess the links between emotion and drug addiction, science must turn to rigorous studies rooted in sound theoretical bases. Fortunately, in recent years, we believe that the field has been moving in such directions.

At the level of large-scale epidemiological inquiry, the relationship between drug use and emotional distress, as expressed both in subclinical symptoms and full-blown disorders, is borne out again and again. The question of directionality remains at least partially unanswered, although burgeoning evidence seems to support bidirectionality: drug use predisposes to affective distress, and affective distress renders individuals vulnerable to drug abuse and addiction. A thorough understanding of such relationships does have bearing in very real ways on both prevention and intervention approaches to substance abuse and addiction. It would be difficult to find any state-of-the-art addiction programs that do not incorporate some aspect of emotion regulation, affect tolerance, and/or adaptive coping into their treatment regimens.

We conclude this chapter with five recommendations, or considerations, for those interested in further examining drug/emotion associations.

(1) Whereas cross-sectional epidemiological surveys are quite useful in establishing associations, at the population level, among various indices of affective distress and drug-related problems, one must be careful not to infer causal processes from such data. So, for example, whereas it is compelling to observe that depression in adolescence significantly heightens vulnerability to drug abuse and addiction in young adulthood and adulthood, such data do not indicate causal mechanisms (e.g. that depression causes addiction or that depressed people self-administer drugs in order to cope with their depression). Whereas such inferences may turn out to be valid, they must be scientifically addressed in their own right.

(2) The study of drug/emotion associations must be steeped in sound theoretical frameworks. In this chapter, we provided brief overviews of several influential theories that have bearing on this issue. This overview is not complete, however, and many other sound theoretical perspectives are available to guide research. Our concern is that research in this area frequently uses non-theoretical approaches, and that this state of affairs ultimately renders the field's database and understanding of these important issues weaker by decree.

(3) In this chapter, we alluded to the likelihood that drug/emotion relationships change over the developmental course of drug use. Hence, the association between, say, NA and cigarette smoking may be different in the initiation phase than it is in the maintenance phase (when smokers have escalated to daily dependent use). An important implication of this suggestion is that the stage of drug use must be taken into account when exploring the association between use and emotion.

(4) The links between drug addiction and emotion are likely moderated by a host of variables. Thus, future

research in this area should consider and assess the potential role played by such moderating factors. Likely candidate variables include gender, cultural factors, personality variables (e.g. neuroticism, sensation seeking, impulsivity), and a host of contextual variables.

(5) We believe it is important to note that drug researchers frequently reside in independent camps, resulting in a lack of communication between those who study, for example, cigarette smoking, or heroin use, or cocaine use, or alcohol use, and so on. Although it may turn out that the associations between the use of these respective drugs to emotional processes are unique to that particular drug, it would seem that the field would benefit tremendously from more cross talk among researchers ensconced in their particular drug camps.

In summary, the field of addiction science has made tremendous progress in recent years, both in describing and understanding the causative processes governing the development of drug addiction, as well as applying such knowledge to treatment programs. But much work lies ahead. We believe that further study of the crucial links between drug addiction and emotional processes will yield tremendous benefits in terms of lives saved.

OUTLINE

INTRODUCTION

Stress is known to increase the risk of addictive behaviors. The last two decades have led to a dramatic rise in research on understanding the underlying mechanisms for this association. Behavioral and neurobiological correlates are being identified and there is growing evidence of molecular and cellular changes associated with chronic stress and addiction. Human studies have benefited from the emergence of sophisticated brain imaging tools and the cross-examination of laboratory-induced methods of stress and craving and their association with specific brain regions associated with reward and addiction risk. This chapter focuses on these links between stress and addiction in humans, but also draws on supporting evidence from the broader animal literature. A definition of stress and its neural underpinnings are presented with specific emphasis on its effects on motivation and behavior. Epidemiological evidence linking early childhood and adult adversity with risk of addiction, and current research on the putative mechanisms underlying this association is presented. The prefrontal brain circuits are seen as playing a critical role in adaptive learning and executive function, including controlling distress and desires/impulses, and in the association between stress and addiction risk. The effects of chronic drug use on brain reward and motivation pathways combined with the premorbid

Principles of Addiction, Volume 1

and ongoing effects of repeated and chronic stress are presented as the pathophysiology that promotes addiction relapse risk. Finally, novel prevention and treatment approaches to addressing the deleterious effects of stress, and the combined effects of stress and addictive behaviors on relapse are discussed.

STRESS, EMOTIONS, AND ADAPTIVE BEHAVIOR

Definition and Conceptualization of Stress

The term "stress" refers to processes involving perception, appraisal, and response to harmful, threatening, challenging events or stimuli. Stressors are stimuli that are overwhelming and challenging to an individual. Stress experiences can be emotionally or physiologically challenging, and they activate stress responses and adaptive processes to regain homeostasis. Examples of emotional stressors include interpersonal conflict, loss of relationship, death of a close family member, and loss of a child. Highly threatening or stressful events also include emotional and physical, traumas such as violent victimization and emotional, physical, and sexual abuse. Common physiological stressors are hunger or food deprivation, sleep deprivation or insomnia, psychoactive drug use, extreme hyper or hypothermia, and drug withdrawal states. This kind of conceptualization allows for consideration of (1) internal and external events or stimuli that exert demands or load on the individual; (2) the neural processes that evaluate the demands and assess availability of adaptive resources to cope with the demands (appraisal); (3) the subjective, behavioral, and physiological activity that signal stress to the organism; (4) neural and physiological adaptations in emotional and motivational systems associated with repeated and/or chronic stress; and (5) behavioral, cognitive, and physiological adaptation in response to stressors.

While stress is often associated with negative emotions, external and internal stimuli that are mild/moderately challenging but limited in duration, and result in flexible cognitive, physiological, and behavioral responses with a sense of mastery and accomplishment can be perceived as pleasant and/or, exciting. Such experiences are often thought of as opportunities for learning and growth, particularly in the context of resilience factors that promote mastery (e.g. social support, adequate motivational and executive functioning), to achieve goal-directed outcomes and homeostasis. On the other hand, the more prolonged, repeated or chronic the stress (e.g. states associated with increased intensity or persistence of distress), the greater the uncontrollability and unpredictability of the stressful situation, lower the sense of mastery, greater the risk of inflexible behavioral and physiological responses, and greater the magnitude and persistence of the stress response, with higher risk of the negative effects on brain and body systems involved in adaptive function. Thus, the dimensions of intensity, controllability, predictability, mastery, or adaptability are important in understanding the role of stress in increasing risk of maladaptive behaviors such as addiction.

Neural and Physiological Pathways Involved in the Stress Response

The perception and appraisal of stress rely on specific aspects of the presenting external or internal stimuli, personality traits, availability of internal resources, physiological condition of the individual, emotional state, including beliefs and expectancies and specific neural state of brain regions mediating the appraisal of stimuli as distressing and the resulting physiological, behavioral, and emotional experiences and adaptive responses. The brain cortical regions such as the insular and prefrontal cortices along with the middle temporal regions play a key role in perceiving and appraising emotion and stress states. Also, the brain's limbic and striatal regions contribute to identifying emotional signals, learning about emotional stimuli and their aversive and rewarding properties and contribute to the emotional experience of stress and emotional stimuli. The brainstem (locus ceruleus and related arousal regions), hypothalamus, thalamus, striatal and limbic regions are also involved in the physiological, emotional, and behavioral responses and together these regions contribute to the experience of distress.

The physiological responses are manifested through two major stress systems, namely, the hypothalamic-pituitary-adrenal (HPA) axis and the autonomic nervous system, which in turn also influence the immune system. These stress pathways are intricately connected with each other and also with the brain pathways described above so that a coordinated stress response may be mobilized in the face of challenge. The HPA axis is stimulated by the corticotropin releasing factor (CRF) released from the paraventricular nucleus (PVN) of the hypothalamus, to stimulate the adrenocorticotropin hormone from the anterior pituitary, which initiates the secretion of cortisol/corticosterone from the adrenal glands. The autonomic nervous system includes the sympathetic nervous system that mobilizes the cardiovascular and immune arousal responses and the parasympathetic nervous system that is involved in regulating the sympathetic arousal by providing the "brakes" to the sympathetic arousal and in regaining homeostasis via the sympathoadrenal medulary systems. Recent evidence

also indicates that the sympathetic pathways provide further modulation of the adrenal glands for release of cortisol as well as release of norepinephrine (NE) and epinephrine (EPI). These are the core stress pathways involved in stress arousal and mobilization of the body and brain to respond to stress and in regulation of stress so as to regain homeostasis.

In addition, CRF has extensive influence in extrahypothalamic regions across the corticostriatal-limbic pathways and plays a critical role in modulating the subjective and behavioral stress responses. Furthermore, central catecholamines, particularly noradrenaline and dopamine, are involved in modulating brain motivational pathways (including the ventral tegmental area (VTA), nucleus accumbens (NAc), and the medial prefrontal cortex (mPFC) regions) that are important in regulating distress, exerting cognitive and behavioral control, and influencing choice or response selection and decision making critical for adaptation and homeostasis. The hypothalamic and extrahypothalamic CRF pathways and central catecholamines target brain motivational pathways to critically affect adaptive and homeostatic processes. For example, different parts of the mPFC are involved in higher cognitive or executive control functions, such as controlling and inhibiting impulses, regulating distress, focusing and shifting attention, working memory, monitoring conflict and behavior, linking behaviors and consequences over time, and considering alternatives before acting and decision making responses. Psychosocial and behavioral scientists have elegantly shown that with increasing levels of emotional and physiological stress or negative affect, there is a decrease in working memory function, poor attention and flexibility, lower behavioral control and increases in impulsive responding.

Neurobiological Responses to High Uncontrollable Stress

Recent evidence from human brain imaging research shows that recent life stressors and chronic stress decreases gray matter volume in medial prefrontal and hippocampus and insula regions of the brain. These are key regions in perception and appraisal of stress and emotions and in regulating the physiological and behavioral response to stress. Similarly, exposure to recent life stress and acute stress decreases responses in the dorsolateral and mPFC associated with working memory and reward processing. Thus, with increasing levels of stress, there is a decrease in prefrontal functioning and increased limbic-striatal level responding, a brain pattern associated with low behavioral and cognitive control. Low behavioral and cognitive control linked to the prefrontal and insular cortex and high responding in limbic-emotional and striatal-motivation brain regions under stress provides the specific pattern for promoting addictive behavioral patterns where there is a decreased ability to control rewarding behaviors. Thus, motivational brain pathways are key targets of stress chemicals which point to an important potential mechanism by which stress affects addiction vulnerability.

STRESS AND THE DEVELOPMENT OF ADDICTIVE BEHAVIORS

A substantial amount of literature exists on the significant association between acute and chronic stress and the motivation to abuse addictive substances. Many of the major theories of addiction also identify an important role of stress in addiction. These range from psychological models that view drug use and abuse as a coping strategy to deal with stress, to reduce tension, to self medicate, and to decrease withdrawal-related distress, to neurobiological models that propose incentive sensitization and stress allostasis concepts to explain how neuroadaptations in reward, learning and stress pathways may enhance the key features of addiction, namely, craving, loss of control, and compulsion. This section reviews the converging lines of evidence that point to the critical role that stress plays in increasing addiction vulnerability.

Chronic Stress and Adversity and Increased Vulnerability to Drug Use

Considerable evidence from population-based and clinical studies indicate a positive association between psychosocial adversity, negative effect, and chronic distress and addiction vulnerability. It is important to note that there are some negative studies that do not support the notion that stress increases drug use, and such studies highlight the need to consider a variety of measurement issues, such as, measurement of stress (e.g. acute versus chronic; subjective or perceived stress versus repeated adverse life events, mood versus stress induction, subjective rating of stress) and measurement of addictive behaviors (self-report, objective tests; assessment of one substance such as alcohol or multiple substances including nicotine) and measurement over a period of days (single assessment versus repeated real life daily assessment, retrospective reporting versus prospective reports). Despite these caveats, the majority of studies show positive support for the association between stress and addictive behaviors. The evidence in this area can be categorized into four broad types. The first are prospective studies demonstrating that

adolescents facing high recent negative life events show increased levels of drug use and abuse. Negative life events such as loss of parent, parental divorce and conflict, low parental support, physical violence and abuse, emotional abuse and neglect, isolation and deviant affiliation, and single parent family structure have all been associated with increased risk of subsequent substance abuse.

The second are data showing the association between trauma and maltreatment and addiction, and negative affect, chronic distress, and risk of substance abuse. Overwhelming evidence exists for an increased association between childhood sexual and physical abuse, victimization and increased drug use and abuse. In addition to sexual and physical abuse, negative effect and chronic distress states are predictive of addiction vulnerability. Findings indicate that negative effect, including temperamental negative emotionality are associated with substance abuse risk. Several studies have also shown a significant association between prevalence of mood and anxiety disorders, including post-traumatic stress disorder, behavioral conduct problems, and increased risk of substance use disorders.

The third set comes from research on lifetime exposure to stressors and the impact of cumulative adversity on addiction vulnerability after accounting for a number of control factors such as race/ethnicity, gender, socioeconomic status, prior drug abuse, prevalence of psychiatric disorders, family history of substance use, and behavioral and conduct problems. Increasing levels of cumulative stressful life events are significantly predictive of alcohol and drug dependence in a dose-dependent manner, even after accounting for control factors. Furthermore, the dose-dependent effects of cumulative stressors on risk for addiction exists for both genders and for Caucasian, African-American, and Hispanic race/ethnic groups. The types of adverse events significantly associated with addiction vulnerability are parental divorce or conflict, abandonment, forced to live apart from parents, loss of child by death or removal, unfaithfulness of significant other, loss of home to natural disaster, death of a close one, emotional abuse or neglect, sexual abuse, rape, physical abuse by parent, caretaker, family member, spouse or significant other, victim of gun shooting or other violent acts, and observing violent victimization. These represent highly stressful and emotionally distressing events, which are typically uncontrollable and unpredictable in nature (see Table 23.1).

Finally, the fourth line of evidence comes from human laboratory experiments and studies using ecological momentary assessment techniques to assess ongoing drug use in daily life. Laboratory studies provoke emotional, cognitive, or social stress in the context of an experiment followed by opportunities for drug self-administration. Such studies examining effects of stress exposure on drug use are limited to legal drugs such as alcohol and nicotine, due to ethical reasons of providing opportunities for illicit drug use to nonaddicted or nonexposed samples. Findings from these studies generally support the notion that acute exposure to stress or negative mood or high ratings of negative mood and stress are associated with alcohol and nicotine use, but the effects of drinking history, history of adversity, social stress and expectancies are known to play a role in these studies.

Putative Mechanisms Underlying Stress Effects on Addiction Vulnerability

This section presents the neurobiological links between stress and reward pathways activated by abusive drugs. It is well-known that the reinforcing properties of drugs of abuse involve activation of the mesolimbic dopaminergic (DA) pathways, which include dopamine neurons originating in the VTA and extending to the ventral striatum (VS/NAc) and the PFC. This pathway is also involved in assigning salience to stimuli, in reward processing, and in learning and adaptation. Human brain imaging studies support the role of these systems in drug reward, as psychostimulants, alcohol, opioids, and nicotine all activate the mesolimbic DA systems, in particular, the ventral and dorsal striatum, and such activity has been associated with the drug ratings of high/euphoria and/or craving.

Interestingly, biological stress responses with increases in the stress hormone, cortisol (corticosterone in animals) can significantly affect dopamine signaling in the reward and motivation pathways. For example, stress exposure and increased corticosterone enhance dopamine release in the NAc. Suppression of corticosterone by surgical removal of the adrenal glands (adrenalectomy) reduces extracellular levels of dopamine under basal conditions and in response to stress and psychostimulants. However, chronic corticosterone inhibits DA synthesis and turnover in the NAc. There is also evidence that like drugs of abuse, stress and concomitant increases in CRF and corticosterone enhance the activity of the excitatory neurotransmitter glutamate, in the VTA, which in turn, enhances activity of DA neurons. Human brain imaging studies have further shown that stress-related increases in cortisol are associated with increased dopamine transmission in the VS, and some evidence also reveals that amphetamine-induced increases in cortisol are associated with both dopamine binding in the VS and with ratings of amphetamine-induced euphoria. Furthermore, both stress and drugs of abuse activate the mesolimbic pathways, and

TABLE 23.1 Types of Adverse Life Events, Trauma, Chronic Stressors, and Individual-level Variables Predictive of Addiction Risk

Adverse Life Events and Chronic Stressors	Life Trauma	Individual-level Variables
- Loss of parent - Parental divorce and conflict - Isolation and abandonment - Single parent family structure - Forced to live apart from parents - Loss of child by death or removal - Unfaithfulness of significant other - Loss of home to natural disaster - Death of significant other/close family member - Victim of gun shooting or other violent acts - Observing violent victimization	- Physical neglect - Physical abuse by parent/caretaker/family member/spouse/significant other - Emotional abuse and neglect - Sexual abuse - Rape	- Negative emotionality - Poor behavioral control - Poor emotional control

each result in synaptic adaptations in VTA dopamine neurons and in morphological changes in the mPFC.

In addition to a role in reward, a growing body of human imaging studies and preclinical data indicate that the VS NAc is also involved in aversive conditioning, experience of aversive, pain stimuli, and in anticipation of aversive stimuli. Such evidence points to a role for the mesolimbic dopamine pathways beyond reward processing, and one that more broadly involves habit formation, motivation, and attention to behavioral response during salient (aversive or appetitive) events. Furthermore, additional regions connected to the mesolimbic DA pathways and involved in reward, learning and adaptive, goal-directed behaviors are the amygdala, hippocampus, insula, and related corticolimbic regions. These regions along with the mesolimbic DA pathways play an important role in interoception, emotions and stress processing, impulse control and decision making, and in the addictive properties of drugs of abuse.

Stress Mechanisms Involved in Acquisition of Drug Self-administration

Animal studies have shown that stress exposure and corticosterone administration increase the rapidity with which animals learn to self-administer abusive drugs. Corticosterone administration facilitates psychomotor stimulant effects of cocaine and morphine. Furthermore, antagonists of the glucocorticoid (GC) receptors to which corticosterone (and cortisol) binds, injected into the VTA decreases morphine-induced locomotor activity, suggesting that activity of GC receptors in the VTA could mediate dopamine-dependent behavioral effects. Mice with deletion of the GC receptor gene shows a dose-dependent decrease in motivation to self-administer cocaine. These data suggest that HPA-related corticosterone release could partially mediate the dopamine increase soon after drug administration.

Although in nonhuman primates the link between cortisol, dopamine, and drug self-administration has not been reported, there is evidence that stress related to social subordination is associated with lower levels of D2 receptors and higher cocaine self-administration. In humans, Positive Emission Tomography (PET) studies using [^{11}C]raclopride indicate that acute stress exposure increases dopamine release in the VS. For example, healthy individuals with low early life maternal care showed greater dopamine release in the VS during an acute psychological stress task as compared to those with a history of high early life maternal care. Furthermore, cortisol response during the stress task correlated significantly with VS dopamine release. Although these data support the link between stress/cortisol and dopamine transmission, human research linking stress-induced changes in VS activity or dopamine binding and risk of addictive behavior is needed to directly establish the association between stress, mesolimbic dopamine, and addiction risk.

Early Life Chronic Stress, Dopamine Systems, and Drug Self-administration

There is growing evidence from basic science studies that early life stress and chronic stress significantly affect the mesolimbic dopamine pathways and play a role in drug self-administration. Repeated and prolonged exposure to maternal separation in neonatal rats significantly alters the development of central CRF pathways. These animals as adults show exaggerated HPA and

behavioral responses to stress. Such physiological and behavioral changes are associated with altered CRF mRNA expression in the PVN, increased CRF-like immunoreactivity in the locus coeruleus (LC), and increased CRF receptor levels in the LC and raphe nuclei. The adult animals also show decreased negative feedback sensitivity to GC and these changes are accompanied by decreased GC receptor expression in the hippocampus and frontal cortex. Decreased gamma-aminobutyric acid (GABA) receptor levels in noradrenergic cell body regions in the LC and decreased central benzodiazepine receptor levels in the LC and the amygdala have also been reported. More importantly, rats exposed to maternal separation in childhood show significantly elevated DA responses to acute stress along with increased stress-induced behavioral sensitization and robust behavioral sensitization to psychostimulant administration, suggesting heightened behavioral responses to psychostimulants. Such cross-sensitization of stress and drugs of abuse is associated with enhanced release of DA in the NAc, lower NAc-core, and striatal DA transporter sites, and reduced D3 receptor binding sites and mRNA levels in the NAc shell. In addition, changes in brain NE are also known to alter DA signaling and increase behavioral and psychostimulant sensitization.

A number of studies have shown that early life stress and prolonged and repeated stress adversely affects development of the PFC, a region that is highly dependent on environmental experiences for maturation. Repeated and chronic stress-related changes in prefrontal cortical neuron spines, density, and synapses have been documented in animal studies. The PFC, and particularly the right PFC, plays an important role both in activating the HPA axis and autonomic responses to stress and in regulating these responses. For example, lesions of the ventromedial PFC result in enhanced HPA and autonomic responses to stress. High levels of GC receptors are also found in the PFC and chronic GC treatment results in a dramatic dendritic reorganization of PFC and hippocampal neurons. Human studies on the neurobiological effects of child maltreatment document neuroendocrine changes as well as alterations in size and volume of prefrontal, thalamic, and cerebellar regions associated with maltreatment and with initiation of addiction. Similarly, adult human structural neuroimaging studies show stress-related decrease in gray matter volume in the medial PFC and reduced gray matter volume in prefrontal and anterior cingulate regions in samples of addicted populations. Together, the data presented in this section highlight the significance of stress effects on mesolimbic and prefrontal regions that are important in stress regulation, behavioral control, and decision making.

Stress, Self-control, and Addiction Vulnerability

High uncontrollable stress is associated with loss of control over impulses, an inability to inhibit inappropriate behaviors and to delay gratification. Neurobiological data indicate that stress impairs catecholamine modulation of prefrontal circuits, which in turn impairs executive functions like working memory and self-control. There is also growing evidence that adolescents with high exposure to life stress (as those listed in Table 23.1) and at risk for substance abuse are more likely to show decreased emotional and behavioral control, and decreased self-control is associated with risk of substance abuse and other maladaptive behaviors. Adolescents at risk for substance abuse are known to have decreased executive functioning, low behavioral and emotional control, poor decision making, and greater levels of deviant behavior and impulsivity. The corticostriatal-limbic dopamine pathways have been associated with impulsivity and decision making and addiction risk, and as discussed in previous sections, specific regions of this pathway, such as the VTA, NAc, PFC, and amygdala, are highly susceptible to stress-related signaling and plasticity associated with early life stress, repeated and chronic stress experiences. Interactions between chronic stress and impulsivity and dopamine responses in the VS have also been observed. Individuals with low to moderate stress and low impulsivity had greater dopamine release, but in individuals with high stress, both low and high impulsive individuals showed low DA release in response to amphetamine. These findings demonstrate the important effects of stress and impulsivity on mesolimbic dopamine transmission, and highlight that both factors need to be carefully considered to fully understand the role of stress and impulsivity on addiction risk.

The above sections are summarized in a schematic diagram in Fig. 23.1 to illustrate how stress may affect addiction vulnerability. It highlights cross-sensitization of stress and drug abuse on specific behavioral and neurochemical responses, and indicates the common neurobiological pathways upon which both stress and drugs of abuse act (Fig. 23.1 reprinted from Sinha, 2008).

DRUG USE AND ABUSE AND CHANGES IN STRESS AND REWARD PATHWAYS

There is growing evidence that abusive drugs when taken acutely and chronically potently influence brain stress pathways. These changes in turn alter cognitive, subjective, and behavioral responses to stress and also

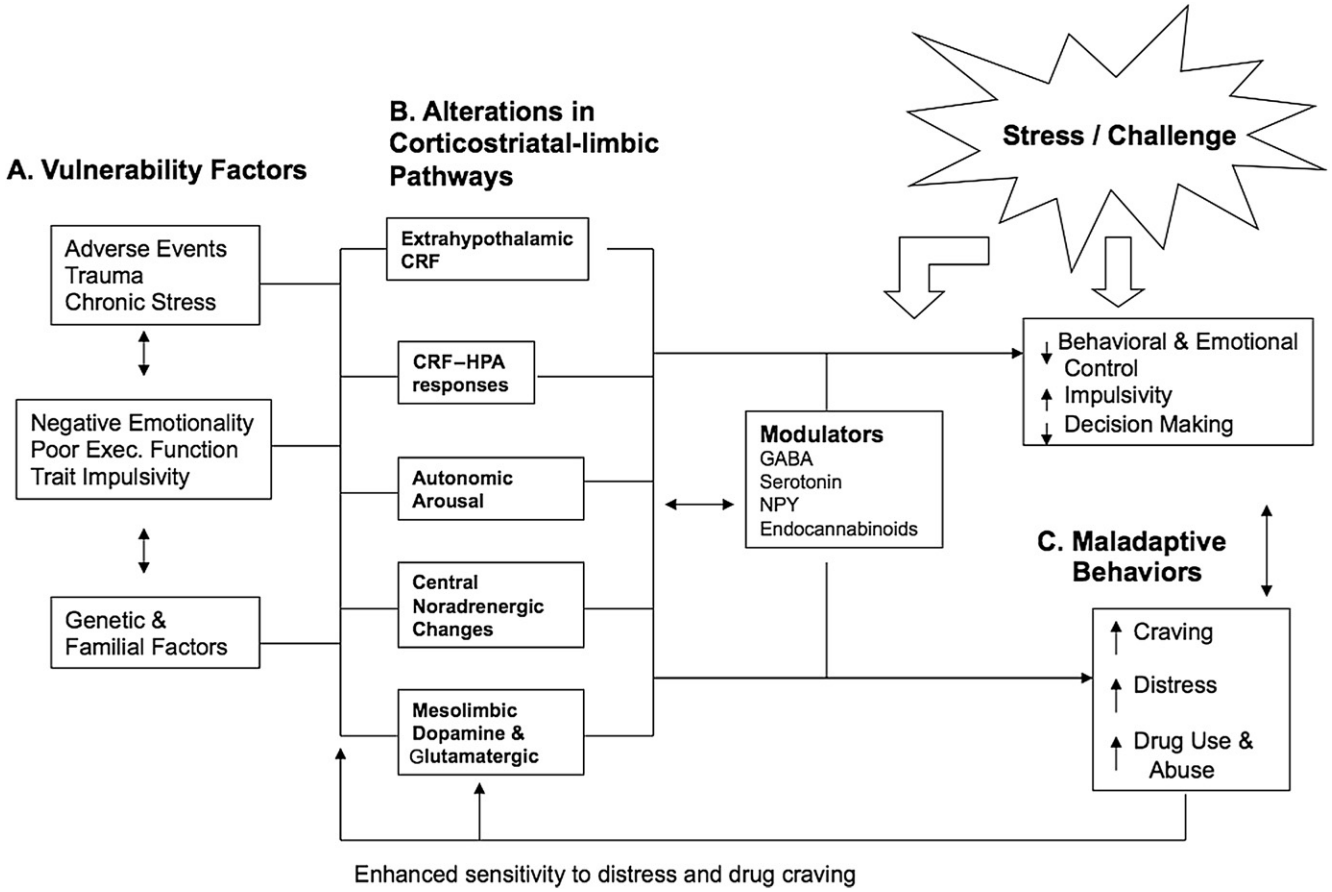

FIGURE 23.1 A schematic model of stress effects on addiction representing the cross-sensitization of stress and drugs on behavioral and neurochemical responses that are mediated by the stress and reward pathways. Column A lists three types of vulnerability factors: (1) developmental/individual-level factors such as frontal executive function development, negative emotionality, behavioral/self-control, impulsivity or risk taking, altered initial sensitivity to rewarding effects of drugs; (2) stress-related vulnerability factors such as early adverse life events, trauma and child maltreatment experiences, prolonged and chronic stress experiences; and (3) genetic influences and family history of psychopathology and addiction which have not been discussed here but have significant interactive effects on addiction risk and in emotion and stress markers. Each of these factors may influence each other to significantly affect alterations in neurobiological pathways involved in stress regulation and cognitive and behavioral control (column B). Specific synaptic changes in these pathways at molecular and cellular levels provide the basis for the mechanism by which stress and individual and genetic factors in column A interact to increase risk of maladaptive behaviors represented in column C. The model suggests that stress experiences in the presence of these vulnerability factors result in maladaptive stress and self-control responses that increase addiction risk. The specific mechanism by which the maladaptive stress responding increases this risk involve dysregulation in brain stress circuits, particularly the CRF and NE systems, and their interactions with the mesocorticolimbic-striatal dopamine pathways and its modulation by glutamate and GABA. Furthermore, recent evidence suggests that stress regulatory molecules, including neuropeptides such as neuropeptide Y, endocannabinoids, brain-derived neurotrophic factor (BDNF), and neuroactive steroids play a role in addiction vulnerability. *Reprinted with permission from Sinha (2008).*

impact desire/craving for drug and perpetuations of addictive behaviors.

Acute and Chronic Drug Use and Changes in Stress Responses

It is well-known that acute administration of the most commonly abused drugs, such as alcohol, nicotine, cocaine, amphetamines, and marijuana that activate brain reward pathways (mesocorticolimbic DA systems), also affect brain stress pathways (CRF-HPA axis and the autonomic nervous system pathways) with increases in plasma adrenocorticotropic hormone (ACTH) and corticosterone, changes in heart rate and blood pressure and skin conductance responses. Regular and chronic use of these drugs is each associated with adaptations in these stress systems that are specific to each drug. For example, changes in heart rate and heart rate variability (HRV) are reported with regular and chronic alcohol use. Sustained increases in HPA axis function in the case of psychostimulants and tolerance to the inactivating effects of the drug

in the case of morphine, nicotine, and alcohol has also been demonstrated. These direct effects of drugs of abuse on major components of the physiological stress responses support their classification as "pharmacological" stressors.

Acute withdrawal states are associated with increases in CRF levels in cerebrospinal fluid, plasma ACTH, cortisol, and NE and EPI levels. Early abstinence is associated with high basal ACTH and cortisol responses, and a blunted or suppressed ACTH and cortisol response to pharmacological and psychological challenges in alcohol-dependent individuals and chronic smokers, while hyperresponsivity of HPA hormones in response to metyrapone has been reported in opiate and cocaine addicts. Furthermore, withdrawal and abstinence from chronic alcohol is also associated with altered sympathetic and parasympathetic responses, and altered noradrenergic responses to yohimbine challenge in early abstinence from cocaine have also been observed. The above changes highlight the significant effects of drug use and abuse on physiological stress responses.

Although acute administration of drugs increase mesolimbic dopamine, regular and chronic use of abusive drugs and acute withdrawal states decrease activity of the mesolimbic dopamine pathways with decreases in basal and stimulated dopamine reported in several preclinical studies. Basic science research shows chronic use of cocaine has also been shown to dramatically alter central noradrenergic pathways in the ventral and dorsal striatum, other areas of the forebrain, and the ventromedial prefrontal cortex. Human brain imaging studies corroborate these preclinical data, with reduced D2 receptors and dopamine transmission in the frontal and VS regions reported in alcohol-dependent individuals and cocaine-dependent individuals during acute withdrawal and protracted withdrawal (up to 3–4 months). Furthermore, blunted dopamine release in the VS and anterior caudate was also associated with choice to self-administer cocaine over money in human cocaine abusers. These changes are similar to the effects of prolonged and repeated stressors on mesolimbic dopamine and NE deficiency noted in the previous section, and suggest that chronic drug effects on extrahypothalamic CRF, noradrenergic or GC systems may directly impact the corticostriatal-limbic dopamine pathways.

On the other hand, acute, regular, and chronic exposure to drugs results in "sensitization" or enhanced behavioral and neurochemical response to drugs and to stress. Synaptic alterations in the VTA, NAc, and medial PFC modulated by glutamate effects on dopamine neurons, and CRF and noradrenergic effects on DA and non-DA pathways contribute to behavioral sensitization of stress and drugs of abuse. In addition, increased levels of brain-derived neurotrophic factor (BDNF) in the mesolimbic dopamine regions has been associated with increases in drug seeking during abstinence from chronic drug use. Furthermore, behavioral sensitization observed with drugs of abuse and with stress are associated with synaptic changes in mesolimbic dopamine regions, particularly the VTA, NAc, and amygdala, and such changes contribute to compulsive drug seeking. Thus, there are significant physiological, neurochemical, and behavioral alterations in stress and DA pathways associated with chronic drug use, which in turn could affect craving and compulsive seeking, maintenance of drug use, and relapse risk. It is not entirely clear how long these changes persist, and the extent to which there is recovery or normalization of these pathways and responses.

Altered Stress Responses and Increased Drug Craving with Chronic Drug Abuse

Clinical symptoms of irritability, anxiety, emotional distress, sleep problems, dysphoria, aggressive behaviors, and drug craving are common during early abstinence from alcohol, cocaine, opiates, nicotine, and marijuana. A mild "negative affect" and craving state ensues postwithdrawal associated with the alterations in stress and dopamine pathways. Severity of these symptoms have been associated with treatment outcomes with greater dependence and abstinence severity predictive of worse treatment outcomes.

Drug craving or "wanting" for drug is conceptually different from other anxiety and negative effect symptoms as it comes from desire or a wish for a rewarding or hedonic stimulus. However, with chronic drug use the terms craving and wanting often become associated with a physiological need, hunger and strong intent to seek out desired object, thereby representative of the more compulsive aspects of craving and drug seeking identified by addicted patients. In particular, craving and compulsive seeking is strongly manifested in the context of stress exposure, drug-related cues and drug itself and can become a potent trigger for relapse. Heightened craving or wanting of drug is associated with more severe drug use and is thought to represent the behavioral aspects of molecular and cellular changes in stress and dopamine pathways discussed in the previous section. Indeed some support for this idea comes from laboratory and imaging studies summarized below.

A series of studies in human addicted samples examined drug craving and stress responses in the context of stress and drug cues as compared to exposure to relaxing control cues. Significant increases in drug craving and subjective anxiety were observed in abstinent

addicted individuals compared to controls, but altered autonomic and HPA axis responses were observed with exposure to stress and nonstress drug cues as compared to neutral-relaxing cues in recently abstinent addicted individuals. For example, cocaine patients showed an enhanced sensitivity to emotional distress and physiological arousal and higher levels of drug craving to both stress and drug cue exposure compared to controls. Similarly, recovering alcohol-dependent individuals at 4-weeks abstinence show greater levels of basal heart rate and salivary cortisol levels compared to control drinkers. Upon stress and alcohol cue exposure, they showed persistently greater subjective distress, alcohol craving, and blood pressure responses, but suppressed heart rate and cortisol responses compared to controls. Interestingly, both cocaine-dependent and alcohol-dependent individuals show increased anxiety and negative emotions during drug cue exposure while social drinkers report lower levels of negative affect and anxiety with alcohol cue exposure. These data provide direct evidence of high drug craving and altered hedonic responses to both stress and drug cues in addicted individuals compared to social drinkers (see Fig. 23.2, reprinted with permission from Sinha, 2009). They also indicate that alteration in physiological stress responses are associated with high levels of stress-induced and cue-induced craving and distress states. The nature of the alterations are marked by increased emotional distress, heightened craving, altered basal responses, and blunted or suppressed physiological responses in abstinent addicted individuals compared to social drinkers.

Neural Correlates of Drug Craving in Addicted Samples

Many studies have also examined brain regions associated with craving in addicted individuals using functional magnetic resonance imaging procedures. Exposure to drug cues, known to increase craving, results in greater activation of the amygdala and regions of the frontal cortex, with gender differences in amygdala activity and frontal cortex response in cocaine-dependent individuals. Cue-induced craving for nicotine, methamphetamine, and opiates also activate regions of the prefrontal cortex, amygdala, hippocampus, insula, and VTA. Furthermore, exposure to stress cues increases brain response in paralimbic regions such as the anterior cingulate cortex, hippocampus and parahippocampal regions in healthy controls during stress while cocaine patients showed a striking absence of such activation. In contrast, patients had increased activity in the caudate and dorsal striatum region during stress, activation that was significantly associated with stress-induced cocaine craving ratings. Recent data from abstinent alcohol-dependent and cocaine-dependent patients have also shown higher activation in corticostriatal-limbic regions during relaxed trials, and particular blunted prefrontal and anterior cingulate responses during stress and drug cue exposure, and the latter being positive associated with drug craving responses.

Recent PET studies have also shown significant positive correlations between the dorsal striatum and drug cue-induced cocaine craving. These findings are

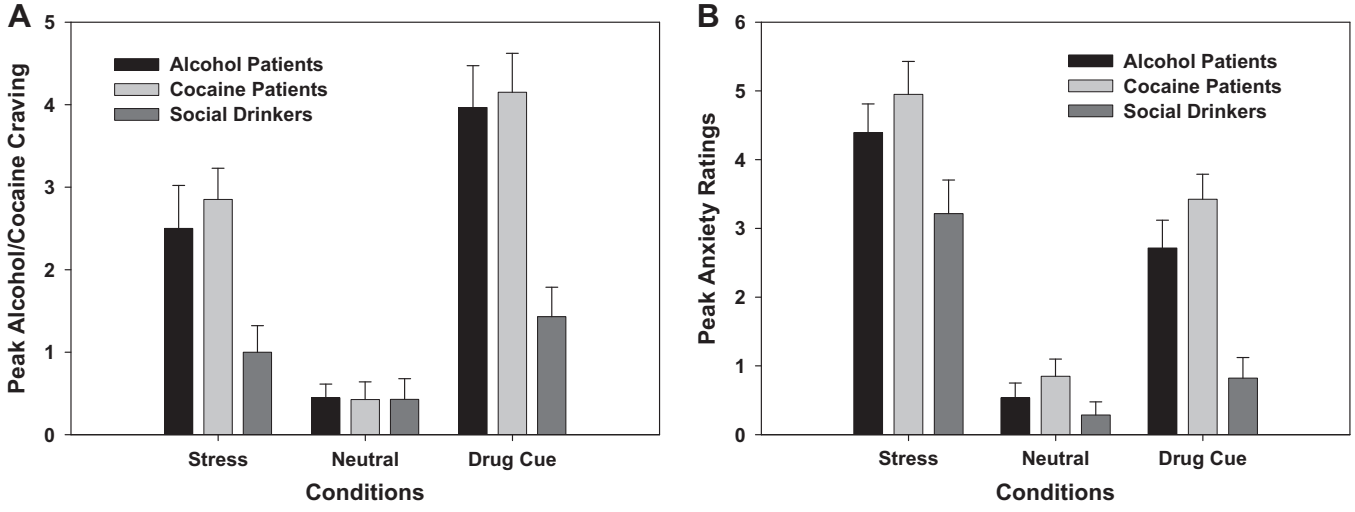

FIGURE 23.2 Mean and standard errors for peak craving and anxiety ratings during exposure to stress, drug cues, and neutral imagery conditions. **A:** Peak craving is significantly higher in abstinent alcohol-dependent and cocaine-dependent patients compared to social drinkers ($p < .0001$). **B:** Peak anxiety ratings is significantly higher in abstinent alcohol-dependent and cocaine-dependent patients compared to social drinkers ($p < .001$).

consistent with imaging studies with alcohol-dependent patients showing increased association between dorsal striatum regions and alcohol craving in response to presentation of alcohol-related stimuli. Using PET imaging with alcohol and cocaine patients, research has shown a significant association between dopamine D2 receptor binding in the VS and drug craving as well as motivation for self-administration. On the other hand, neuropsychological and imaging studies examining prefrontal executive functions, including impulse control, decision making, and set shifting, have shown executive function deficits and hypofrontal responses in addicted individuals compared to control volunteers. Together, these findings indicate that increased stress and cue-induced craving and compulsive drug seeking states in addicted individuals are associated with greater activity in the striatum, but decreased activity in specific regions of the cingulate and prefrontal cortex and related regions involved in controlling impulses and emotions.

Stress-induced Relapse

While several efficacious behavioral and pharmacological therapies in the treatment of addiction exist, it is well-known that relapse rates in addiction remain high. Exposure to stress, drug-related stimuli and drug itself each reinstate drug seeking behavior in animals and increase relapse susceptibility in addicted individuals. Such data underscore the need for specific attention to the chronic relapse susceptibility as a target in addiction treatment development.

In the last decade, a substantial number of preclinical studies have shown that brain CRF, noradrenergic and glutamatergic pathways contribute to reinstatement of drug seeking. Neuroadaptations associated with chronic drug use include overactive brain CRF and glutamatergic pathways, altered autonomic responses and underactive dopamine and GABA systems, and these changes may accompany the high craving states and relapse susceptibility associated with the chronic nature of addiction. Furthermore, using animal models of drug self-administration and relapse, preclinical studies have identified CRF antagonists, noradrenergic agents such as alpha-2-adrenergic agonists, alpha-1-adrenergic antagonists, and more recently glutamatergic agents, as playing a role in reducing stress-induced seeking in addicted laboratory animals.

Human research has also begun to identify markers of the stress and craving states that are predictive of relapse outcomes. Human laboratory models of drug craving and relapse risk have been developed to assess whether provoked drug craving and stress responses in the laboratory are predictive of relapse in the laboratory (e.g. smoking behavior) or relapse assessed prospectively following inpatient treatment. Thus, stress exposure increases drug craving in abstinent alcohol-, cocaine-, and nicotine-dependent individuals, and in each case stress-induced drug craving and dysregulated HPA axis responses are predictive of subsequent drug use and relapse. Thus, high levels of drug craving (stress or drug cue related) and dysfunctional HPA axis responses result in an enhanced susceptibility to addiction relapse.

NOVEL TREATMENT APPROACHES TO ADDRESS STRESS AND DRUG CRAVING

Findings from basic science and human laboratory and clinical outcome studies identify several pharmacological treatment targets to address stress-induced reinstatement of drug seeking and relapse susceptibility. Basic science data suggest CRF antagonists, noradrenergic agents, GABA and glumatergic agents could be promising in addressing stress-related relapse. Human laboratory studies using randomized, placebo controlled designs are now being conducted to screen these types of agents to assess their promise with regard to intermediate markers of stress-related relapse susceptibility. Such studies would target stress and cue-induced drug craving, craving-related anxiety, HPA measures and heart rate or HRV and also responses in specific brain regions. Early investigations have shown alpha-2-adrenergic agonists such as lofexidine and guanfacine to significantly decrease stress-induced and drug cue-induced drug craving and negative emotions in addicted samples. Recent evidence with Prazosin, an alpha-1-adrenergic antagonist has also shown prazosin-related reductions in stress-induced alcohol craving, anxiety, and negative emotions in alcohol-dependent individuals.

Behavioral interventions are also being developed and are in the process of validation to address the above outlined stress pathophysiology in addiction. Cognitive behavioral treatments that focus on drug craving and cognitive skill training in self-control are being considered. Stress interventions are being included in adapted cognitive behavioral interventions. A novel approach to redirect attention and address the cognitive bias that addicts show toward drugs and cravings has been developed and is currently being tested. Finally, mindfulness based relapse prevention adapted from mindfulness based stress reduction has been developed and is currently being tested to improve craving and stress dysfunction in addiction.

These new directions in pharmacological and behavioral interventions highlight the potential of developing

new therapies to address stress-related pathophysiology in addiction.

CONCLUSIONS AND FUTURE DIRECTIONS

This chapter focuses on the accumulating evidence from preclinical, clinical, and population studies that highly stressful situations and chronic stress increases addiction vulnerability, which increases both the risk of developing addiction and risk of relapse. The types of stressors that increase addiction risk are identified in Table 23.1. The stressors tend to be highly emotionally distressing events that would be uncontrollable and unpredictable for both children and adults. The themes range from loss, violence and aggression, poor support, interpersonal conflict, and isolation and trauma. There is also evidence for a dose-dependent relationship between accumulated adversity and addiction risk, with the greater the number of stressors an individual is exposed to, the higher the risk of developing substance use disorders. Work-related stressors have weaker support but individual-level variables such as trait negative emotionality and poor self-control (possibly similar to poor executive function) appear to also contribute uniquely to addiction risk. Exposure to such stressors early in life and accumulation of stress (chronicity) result in neuroendocrine, physiological, behavioral, and subjective changes that tend to be long lasting and adversely affect development of brain systems involved in learning and motivation and stress-related adaptive behaviors. Research that directly addresses stress-related neurobiological changes and its association with behavioral outcomes is sorely needed. Evidence to clarify the contribution of stress on alterations in mesolimbic dopamine activity and it's association to drug use is also needed.

A review of evidence indicating the effects of drug use and abuse on stress responses and dopamine transmission is presented. Altered emotional and motivational responses that are associated with craving and relapse to drug use are reviewed. While substance abuse results in changes in stress and DA pathways involved in motivation, self-control and adaptive processes necessary for survival, whether such changes enhance drug seeking or craving and drug use behaviors is lacking. For example, studies on whether prior exposure to licit and illicit drugs modifies the association between stress and drug self-administration are rare. While there are specific neuroadaptations in reward and associated regions, it is also important to examine which of these changes are involved in increasing drug intake and supportive of addictive processes such as progressive loss of control, persistence of craving and escalating drug self-administration. As stress also increases risk of mood and anxiety disorders which are highly comorbid with addiction, it is important to examine whether there are specific stress-related factors that contribute to risk for mood and anxiety disorders and addiction risk. Exploration of gene–environment interactions could be particularly helpful in answering such questions.

A review of recent studies on stress-induced reinstatement to drug seeking, drug craving, and relapse susceptibility is also provided. Clinical implications include the development of new assessment procedures and markers that will be useful in identifying those who are at particular risk for stress-related relapse and testing of novel pharmacological therapies that target the link between stress and relapse risk. As shown in Fig. 23.2, addicted individuals show enhanced sensitivity to craving and greater anxiety in stress and drug-related situations, but whether such altered responses represent transitions due to chronic drug use or chronic stress states needs to be further examined. Research on the mechanisms by which chronic stress and drug use alter executive functions that are involved in adaptive behavioral responses is needed. Efficacious behavioral treatments focus on improving coping response. However, stress exposure and chronic distress decrease stress adaptive and coping mechanisms, and hence treatments that focus on enhancing coping may not be suitable for those with stress-related addiction risk. Development of new interventions that target self-control, especially in the context of stress is needed. Systematic research on these questions will lead to a greater understanding of how stress is associated with relapse. Furthermore, such research may be significant in developing new treatments targets to reduce relapse, risk in addictive disorders.

List of Abbreviations

ACTH	adrenocorticotropic hormone
BDNF	brain-derived neurotrophic factor
CRF	corticotrophin releasing factor
DA	dopaminergic
EPI	epinephrine
HPA axis	hypothalamic-pituitary-adrenal
HRV	heart rate variability
mPFC	medial prefrontal cortex
NAc	nucleus accumbens
NE	norepinephrine
PET	positive emission tomography

PVN paraventricular nucleus
VS ventral striatum
VTA ventral tegmental area

Glossary

Catecholamines amines that act as a hormone or a neurotransmitter. Includes epinephrine (adrenaline), norepinephrine (noradrenaline), and dopamine.
Corticosterone a steroid hormone produced in the adrenal cortex that affects carbohydrate, potassium, and sodium metabolism and plays a key role in stress experiences and regulation.
Corticotrophin releasing factor (CRF) a hypothalamic neuropeptide thought to mediate autonomic and behavioral responses to stress.
GABA gamma-aminobutyric acid is the primary inhibitory neurotransmitter of the central nervous system.
Glucocorticoids (GC) a class of steroid hormones involved predominately in the metabolism of carbohydrates, that exert an anti-inflammatory effect and include cortisol (hydrocortisol).
Hypothalamic-pituitary-adrenal (HPA) axis the interaction between the hypothalamus, pituitary gland, and the adrenal glands, thought to regulate many processes, including our reaction to stress.
LC locus coeruleus
Noradrenergic areas of the body that are affected by or produce norepinephrine.
Nucleus accumbens (NAc) a group of neurons located beneath the frontal lobe, forming the main part of the ventrial striatum. It plays a role in the reward response and in experience of pleasure.
Prefrontal cortex (PFC) located in the anterior region of the frontal lobes, and thought to be responsible for higher order executive functions.
Sympathoadrenal medulary system activated when exposed to sudden stress. Results in the stimulation of adrenergic neurons of the hypothalamus, then the release of epinephrine from the adrenal medulla and norepinephrine from the sympathetic ganglia.
Ventral tegmental area (VTA) located in the midbrain and containing dopamine cell bodies. The mesolimbic dopamine pathway originates here.

CHAPTER

24

Self-Medication

Virginia Gil-Rivas, Linda McWhorter
University of North Carolina, Charlotte, Charlotte, NC, USA

OUTLINE

Substance use, both licit (e.g. alcohol, nicotine) and illicit (e.g. marijuana, cocaine, and heroin), can have serious health, social, legal, and financial consequences for individuals and society. The estimated combined annual cost of the medical, economic, criminal, and social consequences of substance use in the United States is approximately half a trillion dollars.

In 2008, approximately 8% of the US population aged 12 years or older reported using illicit substances during the past month. Further, 5% of adults reported heavy drinking (two or more drinks per day) and 15% reported binge drinking (five or more drinks in one occasion). Of those using drugs, it was estimated that 8.9% met diagnostic criteria for a substance use disorder (SUD) (i.e. substance use dependence or abuse) as defined by the *Diagnostic and statistical manual of mental disorders, 4th edition* (DSM-IV). SUDs are characterized by (1) a compulsion to seek and take a particular psychoactive substance; (2) lack of control over substance intake; (3) the presence of negative affective states (i.e. anxiety, dysphoria, and irritability) and somatic symptoms associated with discontinued use; and (4) a tendency to relapse after a period of abstinence.

Researchers and clinicians remain puzzled by the fact that individuals continue to use substances despite negative consequences. Multiple explanations have been offered for substance use and addiction, and perhaps one of the most influential explanations is the self-medication hypothesis (SMH) proposed by Khantzian. The SMH views substance use as an effort to cope with stress and distressing emotions (e.g. depression, anxiety, anger) among individuals with deficits in emotion regulation, self-care, interpersonal skills, and self-esteem that may or may not be related to a psychiatric disorder. In other words, SUDs are disorders characterized by self-regulation deficits. Further, the theory also suggests that individuals select specific substances based on their expected ability to reduce or increase specific emotions. For example, opiate use is thought to be related to efforts to manage hostile and violent emotions, while alcohol is frequently used as a way of facilitating social interaction and the expression of emotions among individuals with deficits in these areas.

In the short-term, the use of substances to manage distressing emotions can be adaptive as these substances provide individuals with a reprieve from intense emotional states. In the longer term, chronic use can contribute to the development of SUDs. Once individuals transition from occasional use to addiction, substance use withdrawal leads to distressing emotions

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00024-3

and somatic symptoms that contribute to relapse. Recent developments on the neurobiology of addiction provide some support for the idea that substance use has the potential of eliciting intensive positive affective states early in the process of addiction. Also, these findings suggest that in the longer term chronic substance use leads to neurobiological changes that are associated with psychiatric symptomatology.

NEUROBIOLOGICAL BASIS OF SUBSTANCE USE AND ADDICTION

The Brain Reward Circuit

The area of the brain known as the "reward circuit" or pleasure pathways that is located in the limbic regions including the ventral tegmental and nucleus accumbens has been shown to be activated at varying degrees by both licit and illicit substances. Although different drugs may affect these pathways somewhat differently, they all lead to the release of dopamine, a neurotransmitter that is associated with the experience of reward or pleasure. Importantly, the amount of dopamine released in the brain as a result of substance use is 2–10 times greater than the release associated with natural stimuli (e.g. food). The amount of dopamine released and the pattern of activation in the reward pathways explains the experience of euphoria or "high" associated with a particular substance. Thus congruent with the SMH, in the initial stages of addiction, substance use may be viewed by individuals as a way of achieving a reprieve from negative emotional states. After a period of experimentation, individuals may select a substance or family of substances (e.g. stimulants, opiates) that are the most effective in producing the desired affective state. It is important to consider that individuals' initial motivation for substance use may or may not reflect a desire for ameliorating negative affective states. It is also possible that individuals' motivation to use reflects a desire for the "high" associated with a substance, a need to regulate their overall emotional experiences, or an effort to obtain desired social rewards.

Research on the neurobiological basis of addiction has shown that dopamine not only acts as a "reward" but also plays a role in the encoding reward expectancies and of memories of events or stimuli that are associated with its release. As a result, simply the expectation of the reward leads to dopamine release in the reward pathways. In addition, stimuli associated with substance use (e.g. specific settings, emotional states, and images) may elicit dopamine release and increase drug craving and substance seeking behaviors. In other words, learning processes may play a role in the maintenance of substance use.

Over time, chronic substance use leads to dysregulation or a state of hedonic allostasis in the reward pathways. Further, these changes persist long after discontinuing substance use. In particular, chronic use is associated with reductions in basal dopamine levels, the amount of stimulated dopamine released, and in the number of dopamine receptors in these areas of the brain. Downregulation of positive reward systems and the negative affective states (i.e. anxiety and dysphoria) that accompany substance use withdrawal seem to underlie continued use despite negative health and social consequences. Thus, these neurological changes seem to explain the transition from use that is motivated primarily by the desire to obtain the "high" or the desired affective states associated with a particular substance (positive reward), to use as a way of reducing negative affective states (negative reward) when the substance is not present. In other words, addicted individuals use substances with the goal of gaining a sense of "normalcy" rather than to simply achieve a high.

Stress and Substance Use

In addition to the pleasure pathways, changes in the area of the brain associated with stress regulation play a role in substance use initiation, maintenance, and relapse. The stress response involves the activation of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic adrenomedullary (SAM) system in response to stressful stimuli. The HPA activation begins with the release of corticotropin-releasing factor (CRF) from the paraventricular neurons of the hypothalamus. In turn, CRF stimulates the synthesis and release of adrenocorticotropin hormone (ACTH) by the anterior pituitary. ACTH stimulates the adrenal cortex to synthesize and release glucocorticoids (cortisol in humans). Activation of the SAM results in the release of catecholamines (adrenaline and noradrenaline). The activation of both the SAM and HPA results in the physiological changes (i.e. increase heart rate, blood pressure, respiration, and circulating glucose) associated with the physiological stress response. Importantly, the stress response also involves an increase of CRF in the amygdala, an area of the brain that plays an important role in anxiety-related affective states.

Available research suggests that early in the addiction process the activation of the HPA by both stress and substance use contributes to the sensitization of the reward pathways by glucocorticoids. In fact, animal studies have shown that glucocorticoids will trigger the release of dopamine in these pathways. Further, glucocorticoids augment the positive reinforcing effects of substances by altering the dopamine signaling in these areas. As individuals continue to use substances,

stress and glucocorticoids contribute to dysregulation of the brain reward pathways leading to increased substance use. Once individuals become addicted, high levels of glucocorticoids and other substances associated with the stress response lead to internally generated negative affective states. Additionally, substance use withdrawal is associated with increases in anxiety-like affective states. These negative affective states seem to contribute to craving and substance-seeking behaviors and in turn to continued substance use. In sum, the combined effects of chronic stress and substance use can result in neuroendocrine changes that can lead to dysfunction in the brain reward pathways and contribute to the development of addiction.

Substance use, however, does not always lead to the development of SUDs; rather it seems that genetic, individual, social, and environmental factors make some individuals more vulnerable to transition from occasional use to addiction. At the individual level, neurobiological studies suggest that differences in HPA axis activity may help explain why some individuals are more vulnerable to the development of SUDs compared to others. For example, adults who secrete high levels of cortisol are also high dopamine releasers and report greater effects from psychostimulants (e.g. cocaine, methamphetamines) compared to individuals with low cortisol and low dopamine levels. In addition, exposure to traumatic events (e.g. combat, physical assault, major disasters) and chronic stress have been shown to be associated with increases in substance use. The clinical and developmental literatures also suggest that exposure to unresponsive and insensitive caregiving environments and trauma (e.g. physical and sexual abuse) early in life affects the developing brain and the physiological systems associated with the stress response. Further, individuals with histories of exposure to adverse childhood environments seem to have diminished capacity to regulate their negative emotions and behavior, and to cope effectively with stress. As suggested by the SMH, these deficits in regulatory capacity could explain the increased risk for the development of SUDs later on in life among these individuals. Chronic stress and traumatic experiences in both childhood and adulthood seem to contribute not only to the development of SUDs, but also to the emergence of some psychiatric disorders. In fact, some researchers have characterized psychiatric disorders as chronic stress states.

SUBSTANCE USE AND PSYCHIATRIC DISORDERS

Current estimates among community samples indicate that 45–72% of adults with SUDs also have at least one co-occurring psychiatric disorder. Among individuals diagnosed with a psychiatric disorder (e.g. schizophrenia, major depression, posttraumatic stress disorder (PTSD), attention deficit disorder) approximately 30% also meet criteria for a concurrent SUD. Importantly, the presence of co-occurring disorders has been found to compromise both mental health and substance abuse treatment outcomes. Neurobiological studies have identified some abnormalities in the stress pathways that are involved in both psychiatric disorders and SUDs. In particular, researchers have focused on a potential common neurobiological basis for SUDs, depression/mood disorders, anxiety disorders, and schizophrenia.

Mood Disorders

Substantial symptom overlap between mood disorders (e.g. major depression, dysthamia, bipolar disorder) and SUDs exists. For example, irritability, sleep difficulties, anxiety, and concentration difficulties are frequently reported among individuals with major depression and those undergoing substance use withdrawal. Large population studies have found that about 32% of individuals with any mood disorder also met DSM-IV criteria for an SUD. At the neuroendocrine level, individuals diagnosed with major depression present abnormalities in the reward and stress pathways that are also seen among individuals with SUDs. For example, in response to CRF stimulation, depressed individuals have been found to have lower levels of ACTH and cortisol responses compared to healthy individuals, suggesting increased HPA axis activity. Longitudinal studies examining the temporal association between SUDs and mood disorders generally indicate that mood disorders emerge after the onset of SUDs. These findings suggest that neurobiological changes associated with addiction may contribute to the emergence of mood disorders, and thus contrary to the SMH, depressed mood seems to be a consequence of substance use.

Anxiety Disorders

Epidemiological studies have found that individuals with an anxiety disorder are more likely to also have SUD compared to those without such histories. Mixed empirical findings have emerged regarding the temporal association between SUDs and anxiety disorders. Some studies have found that the presence of a lifetime anxiety disorder (e.g. general anxiety, social phobia) is associated with an increased risk for the development of SUDs later on in life. In contrast, a recent study found that alcohol dependence preceded the onset

of several anxiety disorders (i.e. general anxiety, panic) but followed the onset of other disorders (i.e. specific phobia and social phobia). Congruent with the SMH, these findings suggest that some individuals may have started using substances as a way of managing anxiety-related symptoms. In support of this idea, some studies have found that individuals with lower tolerance for internally generated negative affective states and who rely on emotional avoidance are more likely to have co-occurring anxiety and SUDs. Contrary to the SMH, however, it seems that in some cases substance use may have contributed to the development of some anxiety disorders.

PTSD is an anxiety disorder that seems to be strongly related to SUDs. Specifically, current estimates indicate that among individuals seeking substance abuse treatment, 19–62% also meet diagnostic criteria for PTSD. Rates of co-occurring PTSD in community samples of adults range from 52 to 35% for men and 28 to 27% for women. Investigators have identified potential pathways that may link these disorders. Specifically, the following pathways have been suggested: (1) SUDs can increase the likelihood of exposure to trauma and thus contribute to the development of PTSD; (2) chronic substance use and the anxiety-like symptoms associated with withdrawal from use may make individuals with SUDs more vulnerable to the development of PTSD after trauma exposure; (3) consistent with the SMH, individuals may use substances in an attempt to alleviate memories and painful symptoms associated with PTSD; and (4) contrary to the SMH, substance use may interfere with the processing of traumatic memories and thus contribute to the exacerbation of PTSD symptoms.

Epidemiological studies have shown that typically PTSD precedes the development of SUDs providing support for the component of the SMH suggesting that individuals use substances with the goal of alleviating negative affective states. Neurobiological and neuroimaging studies suggest some common pathways that may help explain their co-occurrence. Specifically, the HPA axis and SAM are involved in stress, PTSD, and SUDs. Recent studies have identified high levels of CRF in the amygdala and chronically increased levels of catecholamines among individuals with PTSD which are suggestive of chronically increased stress responses and are believed to contribute to an increased risk of developing SUDs.

Schizophrenia-Spectrum Disorders

Schizophrenia-spectrum (i.e. schizophrenia, schizophreniform, or schizoaffective) disorders show high levels of co-occurrence with SUDs. Epidemiological estimates indicate that approximately 50% of individuals with these disorders have a lifetime history of substance use and 27% meet criteria for an SUD. These rates are significantly higher than those among the general population. In particular, alcohol and marijuana use are common among individuals diagnosed with schizophrenia. Researchers have suggested that SUD and schizophrenia may share some common biological, individual, and social risk factors that may explain their high rates of co-occurrence. Of particular relevance, are changes in the reward pathways involving dopamine and glutamate that are associated with schizophrenia. These changes may render individuals more vulnerable to SUDs. In addition, the SMH has been a dominant framework for understanding their co-occurrence as individuals report using substances as a way of reducing symptoms such as social withdrawal, apathy, cognitive impairment, and as a way of managing the side effects of antipsychotic medications.

SUPPORT FOR THE SMH

Substance Use to Manage Negative Affective States

The SMH has garnered a great deal of interest among clinicians and researchers attempting to find potential explanations for SUDs. Despite the intuitive appeal of this hypothesis, the empirical literature provides mixed support for each of its components. The first component of the SMH, that is, the assumption that substance use represents a way of managing negative affective states or symptoms among individuals with self-regulation deficits, has received the most attention in the literature. Studies with nonclinical samples of adolescents and young adults suggest that self-medication may not be the only or the most important factor predicting the initiation of substance use in this group. In particular, it seems that individual differences in sensation seeking and the social meaning given to substance use play an important role in the initiation of substance use. Compelling evidence for the limited role of management of negative mood in explaining substance use among adolescents and young adults has been provided by studies using momentary assessment methodology. This methodology allows for the examination of the temporal association between negative mood states and substance use. For example, adolescents high in novelty seeking have been found to be more likely to use alcohol and marijuana when they are experiencing high levels of positive mood, rather than when experiencing distressing emotions. In contrast, a study of adults that also made use of momentary assessment methodology showed that both anxious mood and pleasant mood states were associated with increases in later alcohol consumption.

Further, among those reporting anxious mood, alcohol consumption contributed to reductions in anxiety. Studies using more traditional methodologies suggest that compared to emotional states, personality characteristics are stronger predictors of substance use among youths. Specifically, trait anxiety, trait aggression, and attention and behavioral difficulties in school have been found to be associated with an increased risk for developing SUDs later in life accounting for risk factors such as parental education and mental health. Overall, these findings suggest that individuals may have a variety of reasons for using substances and that the management of negative affective states may be the primary reason for only a subset of individuals.

The evidence supporting the SMH among individuals with SUDs and those with co-occurring psychiatric conditions is also mixed. Substance use motivated by the need to alleviate negative affective states seems to be common among individuals with SUDs and those with psychiatric disorders; however, this is not the only reported reason for use. A review of the literature of self-reported reasons for substance use among individuals with schizophrenia-spectrum disorders indicated that while 2–86% of respondents endorsed substance use as a way of relieving negative affective states, 62–95% of these individuals reported using to increase pleasure and 35–98% reported using to achieve the "high" or intoxicating effects.

It is important to consider that although individuals may use substances in an attempt to relieve negative or distressing emotions, substance use may also elicit feelings of shame, guilt, and powerlessness leading to an exacerbation of these negative states. In light of these findings, some addiction models suggest that negative affective states and substance use form a feedback loop in which changes in one of these factors influence changes in the other. Support for this feedback loop was reported in a recent longitudinal study that found that changes in negative affect (i.e. anger and depression) were associated with alcohol use and that changes in drinking were associated with changes in negative affect after alcohol treatment.

The SMH has also been used to understand substance use relapse after a period of abstinence. The literature suggests that both intrapersonal and interpersonal factors are common precursors to substance use relapse. Intrapersonal factors are those generated by the individual and include negative emotions (i.e. depressed and anxious mood), negative physiological states (e.g. pain), positive emotional states, testing personal control, and urges and temptations. In contrast, interpersonal factors involve external or environmental influences such as social pressure, and interpersonal conflict. Consistent with the SMH, anger, frustration, interpersonal conflict, and depressed mood have been shown to be the most commonly reported antecedents of substance use relapse. Similarly, among individuals with co-occurring SUDs and psychiatric disorders, depression, boredom, insecurity, anxiety, loneliness, and sleep difficulties frequently precede relapse to substance use after treatment.

Among individuals with psychiatric disorders, substance use early in the addiction process may serve to reduce psychiatric symptoms; however, over time substance use may lead to an exacerbation of symptoms. In fact, some investigators have proposed that substance use among addicted individuals may have a rebound effect, leading to the exacerbation of psychiatric symptoms rather than symptom improvement. From this perspective, the neurobiological changes associated with chronic substance use and the ability of these substances to occasionally elicit symptoms improvement may help explain the maintenance of this behavior. Further, some substances may help alleviate some symptoms and contribute to an increase of other symptoms on termination of their psychoactive effects. Congruent with the proposed rebound effects, recent empirical findings suggest that although increases in mental health symptoms (i.e. anxiety, depression, and sleep disturbances) may be reported before substance use relapse, substance use does not seem to ameliorate these symptoms. For example, a recent study tested the SMH and the "rebound hypothesis" among adults with SUDs and those with co-occurring disorders. Congruent with the SMH, individuals reported increases in symptoms before substance use relapse. In contrast, a majority (about 60%) of participants demonstrated an exacerbation of symptoms immediately after use and 2 weeks later, and only 25% of the sample reported any symptom improvement after use. Further, substance use resulted in an exacerbation of symptoms that were related to individuals' lifetime mental health diagnosis. Specifically, individuals with bipolar disorders experienced an exacerbation of depressive symptoms and those diagnosed with schizophrenia reported increases in psychotic symptoms. Similarly, a study with adolescents with SUDs found that psychiatric and depressive symptoms preceded substance use relapse; however, substance use contributed to increased symptom severity for over half of these individuals, while only 20% reported symptom improvement. Overall, these findings provide support for the rebound effects of substance use among individuals with SUDs and co-occurring disorders and mixed support for the SMH.

Substance Specificity

By and large, support for the "specificity" component of the SMH suggesting that individuals select specific substances based on their expected pharmacological effects is based on case studies and anecdotes from

substance-abusing patients receiving psychotherapy. The empirical literature, however, provides mixed support for this assertion. Importantly, the available literature testing this component of the SHM has focused on individuals who were receiving substance abuse treatment, and thus it is unclear to what extent early in the addiction process specific substances were selected by individuals based on their ability to induce the desired effects.

Studies among individuals with psychiatric disorders have not found strong evidence for a match between the symptoms that characterize the disorder and the type of substance used by individuals. Partial support for the "specificity" component of the SMH emerged in a study of individuals receiving inpatient mental health treatment. Specifically, participants with depressive disorders were more likely to meet criteria for opiate abuse compared to those diagnosed with a bipolar disorder or schizophrenia. Further, individuals with schizophrenia were more likely to abuse alcohol compared to the other two groups, while individuals with bipolar disorder were more likely to meet criteria for marijuana abuse. However, it is important to note that in this study a majority of participants reported using more than one substance. Other studies have not found support for the specificity component of the SMH among individuals with SUDs and those with co-occurring disorders.

SUMMARY

The SMH suggests that (1) individuals with self-regulation deficits use substances in an attempt to manage negative or distressing affective states and (2) individuals select specific substances based on their ability to elicit desired affective states.

Congruent with the SMH, substance use early in the addiction process can successfully lead to reductions in negative affect among individuals who lack more adaptive emotion and self-regulation skills. In the longer term, chronic substance use contributes to neurobiological changes in the reward and stress pathways, which play an important role in motivation, learning, and behavior. These changes may underlie the transition from substance use motivated by achieving the "high" or relief associated with substance use to use that is motivated by the need to regain a sense of normalcy.

The empirical literature supporting the SMH is mixed. Among nonclinical samples of adolescents and young adults, the primary motivation for substance use does not seem to be the management of negative affective states. Rather, sensation seeking and the social meaning given to the use of these substances seem to be the primary motivating force for substance use. Importantly, positive rather than negative affective states seem to increase the likelihood of substance use among adolescents.

Among adults, a majority of studies aiming to test the SMH have been conducted with clinical samples of individuals diagnosed with SUDs and/or psychiatric disorders. Available research indicates that these individuals report using to relieve negative affective states as well as to obtain the "high" or pleasurable effects associated with a particular substance. Further, the evidence suggests that substance use increases rather than alleviates negative affective states. It is possible that during the intoxication period substance use provides relief but leads to increases in symptomatology once the effects have worn off. In fact, these findings provide support for the "rebound" hypothesis and addiction models that propose a feedback loop between substance use and negative affective states.

Support for the second component of the SMH, that is, the idea that individuals select "specific" substances based on their effects on relieving distress or negative affective states, is rather limited. Specifically, the available studies have not examined whether individuals experiment with different substances early in the addiction process until they identify the substance that most effectively elicits the desired effects. Studies among individuals diagnosed with SUDs and a psychiatric disorder also provide mixed support for the "specificity" assumption. These individuals typically report using multiple substances. Further, a pattern of substance selectivity based on symptoms or psychiatric diagnosis has not been consistently identified.

In conclusion, empirical support for the SMH is mixed. Reliance on cross-sectional studies and methodologies that do not allow for an adequate assessment of the temporal relationship between negative affective states and substance use has not allowed for an adequate test of the SMH at all stages of the addiction process. Future research is needed to clarify the role of negative affective states in the initiation, progression, and maintenance of substance use.

Glossary

ACTH adrenocorticotropin hormone – A hormone produced by the pituitary in response to stimulation by CRF. This hormone stimulates the cortex of the adrenal glands to release glucocorticoids as part of the physiological response to stress.

CRF corticotropin-releasing factor – a hormone released by the hypothalamus as part of the stress response. This hormone stimulates the pituitary to produce ACTH.

DSM-IV *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* – a manual published by the American Psychiatric Association that provides standard criteria for the classification of mental disorders.

HPA hypothalamic-pituitary-adrenal axis – a component of the neuroendocrine system that plays an important role in the body's physiological response to stress. Activation of this system leads to the release of glucocorticoids by the adrenal glands.

PTSD posttraumatic stress disorder – an anxiety disorder that can develop after exposure to traumatic events. This disorder is characterized by persistent thoughts or memories about the traumatic event, sleep difficulties, emotional numbness, and high levels of emotional arousal.

SAM sympathetic adrenomedullary system – a neuroendocrine system involved in the body's physiological response to stress. Activation of this system during stress leads to the release of catecholamines (epinephrine and norepinephrine).

SMH self-medication hypothesis – a hypothesis that suggests that addiction is the result of self-regulation deficits. Specifically it proposes that (1) individuals use substances as a way of coping or managing with negative emotional states and (2) individuals select specific substances for their expected ability to reduce or increase specific emotions.

SUD substance use disorder – a disorder that involves the repeated use or abuse of psychoactive substances despite negative consequences.

CHAPTER

25

Contextual Factors in Addiction

John M. Roll

Washington State University, Spokane, WA, USA

OUTLINE

INTRODUCTION

Like all organisms, humans exist in a complex environment. In this chapter, it is argued that our behavior is largely controlled by our perceptions of this environment. It is useful to consider how this environment can be parsed. Perhaps the simplest conceptualization postulates that the environment consists of both external and internal components with respect to an individual – a perceiver. The external components are those things we typically consider to be environmental. The external environment includes things that the perceiver senses as being outside their anatomy such as air purity, ambient temperature, and elevation. The internal environment consists of factors that are inside the perceiver. This includes such observable states as hunger, thirst, fatigue, illness, and various affective states. The constant interplay between the external and the internal environments provide a molar framework in which to explain behavior. For instance, a person standing outside may don a coat as a blizzard approaches because the ambient temperature has dropped and made increased demands on their metabolic system to keep them warm. However, a person who has a high fever may welcome the approach of cold weather and not don a coat because they anticipate the relief from their feverish state.

However, the richness of human behavior cannot be fully accounted for in terms of a dichotomization of the internal and external environments. Minimally, two additional features need to be considered. The first is the social environment, which is a refinement of the external environment. The second is the genetic environment, which is a partial determinant of the internal environment.

The social environment is incredibly complex, as it encompasses all social interaction (or isolation) that an individual experiences throughout their life time, from birth to the instant before death. In addition, it encompasses the history of all previous social interactions that an individual has experienced. A full account of the social environment is far beyond the scope of this brief chapter. Such an account would include works from psychology, sociology, anthropology, communication sciences, and economics.

To better understand how the social environment can exert an influence on behavior, consider the following example. Suppose an individual is hiking in a remote wilderness area by himself and feels a need to urinate. It is quite likely that he will simply step off the trail and void his bladder. Now consider the same individual walking down Fifth Avenue in New York City. When he feels the exact same bodily sensation, he will act in a very different fashion. Instead of seeking immediate relief, he will seek out a public restroom. The main difference in the situation is the social environment. In the first case he is isolated from all others and in the second he is surrounded by a sea of humanity.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00025-5

Consider the myriad genetic influences on our internal environments. Imagine twins. One of the twins has a genetic makeup that has rendered him or her unable to experience the taste we commonly refer to as bitter. The other twin does not have this genetic anomaly and can fully appreciate the taste of bitter. Now suppose both are equally thirsty (internal environment), but the only water available is laced with quinine, which makes it very bitter. It would likely be unpalatable to the twin with the ability to normally experience bitter but the twin with altered genetic makeup will have no trouble slaking his or her thirst with the quinine-laced water.

All four of these arenas – genetic, internal, social, and external environments – constantly interact to determine an individual's behavior on a moment-by-moment basis over the course of their life. These influences are depicted in Fig. 25.1. This results in an incredibly complex system of behavioral determinants in which an individual's genetic predispositions, current physiological and affective states, the current external environment, and the social context – both current and historical – interact to determine an individual's current behavior. Consider also that many of these factors can change over time, some very rapidly, and you begin to appreciate how daunting a task it is to try and account for even the simplest of behaviors. Now imagine trying to understand a behavior like drug use, as opposed to a simple behavior like putting on a coat when it is cold outside, and the complexities seem almost insurmountable.

The challenges notwithstanding, providing such an account is critical if we are to understand, prevent, and treat addiction. Efforts to understand this complex problem are largely the realm of the experimental and clinical behavioral pharmacologist. This multidisciplinary field draws on the expertise of many disciplines including genetics, epigenetics, molecular biology, biology, psychology, sociology, anthropology, and economics, among others. In addition, bidirectional approaches to understanding the determinants of drug abuse, in which those afflicted with addiction and their friends and families participate, are key to developing the fullest understanding of the determinants of this behavior as possible.

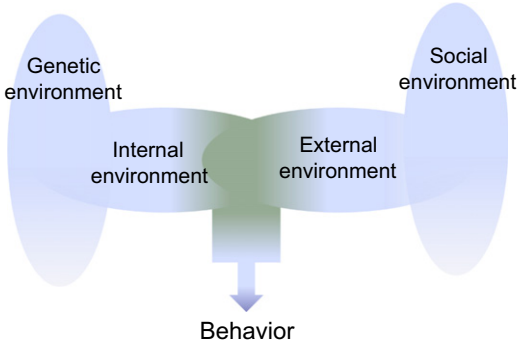

FIGURE 25.1 This schematic represents the continuous interplay between genetic makeup, social context, internal and external environments, and the production of behavior. As indicated in the figure, all four environments can influence each other.

A useful conception for gathering all of the various influences depicted in Fig. 25.1 into one rubric is a reinforcement and punishment categorization. This idea is not new. The roots of the idea can be traced at least as far back as Bain and the Scottish (and British) philosophers who noted how behavior tended to congregate around those things that satisfied a biological need (e.g. a presumably hungry lamb tended to organize its behavior around nursing). The relationship between behavior and its consequences was further described by Thorndike who enshrined it in his Law of Effect, which roughly states that those behaviors that produce satisfaction tend to increase in frequency while those behaviors that result in frustration tend to decrease in frequency. For example, Bain's hungry lamb learns how to nurse from his mother's udder because it results in the delivery of food, whereas nursing on her tail does not. Skinner, in one of the most elegant and productive careers in the field of psychology, refined this work into what is the modern field of the experimental analysis of behavior. Central to this work is the definition of reinforcement and punishment.

A reinforcer is a stimulus that, when presented after the occurrence of a behavior, increases the likelihood of the behavior being repeated in a similar context. A punisher is the opposite: a stimulus that, when it follows a behavior, results in a decreased likelihood that the behavior will be emitted in a similar context in the future. For example, if you have a garden gate and its latch does not work well so that you have to shake the gate to release the latch and permit you to open the gate (the reinforcer), you are likely to try the same shaking behavior next time you want to gain access to your garden. However, if shaking the gate results in you getting a splinter (punisher), you are less likely to try the same behavior in the future. For much more detailed descriptions of reinforcement and punishment, please consult the Further Reading list. The remainder of this chapter focuses on reinforcement for simplicity's sake; however, many of the same principles apply to punishers.

Reinforcement (and punishment) can be parsed further into both negative and positive varieties. In the garden gate example above, the opening of the gate is an example of a negative reinforcer because it results in the removal of a barrier (the gate) between you and something you want (access to the garden). If once you are in the garden you pick a strawberry and eat it because you are hungry, the strawberry is a positive reinforcer.

Reinforcement (and punishment) can be augmented (or degraded) depending on the contextual associations that surround it. For example, imagine you are fishing and having no luck. You are hot and thirsty. You decide to open a cold soda of a variety you have never tasted before and drink it. As soon as you begin to drink the soda, you have a strike and catch a fish. Now suppose this pairing of events (drinking and catching a fish) happens several times. An association will form such that the reinforcing efficacy of the soda is greater than could be accounted for by its thirst-quenching properties alone. Instead, it has acquired additional reinforcing efficacy through its repeated association with the catching of fish. In the parlance of behavior analysis, the soda is said to now possess primary reinforcing qualities (thirst quenching) and conditioned reinforcing efficacy (fish catching associations). My group has studied this process in human laboratory settings and further reading on the topic is included in the Further Reading list.

While it is not difficult to understand the environmental factors that pressure us to open a garden gate and eat a strawberry or that compel us to put on a coat when it is cold, it is difficult to understand why humans do something as complex as abuse drugs.

The observation that drugs of abuse could function as positive primary reinforcers opened the door to applying a behavioral account of behavior to addiction. Most drugs of abuse activate the same neural circuitry as nondrug primary reinforcers. In our earlier example, eating a strawberry when hungry served as a primary reinforcer. This behavior activated certain brain pathways, often referred to as the reward pathway. This pathway is associated with the receipt of a primary reinforcer (e.g. sexual activity, food, and water).

When a cocaine- or methamphetamine-dependent individual ingests a dose of either drug, the same neural circuitry is activated. The neural circuitry may become hyperactivated. This led Dr Leshner, former director of the National Institute of Drug Addiction, to term the process as a hijacking of a user's motivational system. The end result of such a process is that the individual begins to engage in compulsive drug use. This leads to a pattern of behavior in which drug seeking pushes everything else into the background. Many if not most people who experiment with a drug like cocaine or methamphetamine never develop a full blown addiction to the drug. This suggests that the process is somewhat malleable.

Drugs can also act as negative reinforcers by removing a noxious state. For example, consider a harried stockbroker. She often works 12-h days; many individuals rely on her to manage their retirement accounts on which their future depends. In addition, she has a family that is dependent on her for all the interactions associated with being a spouse and a mother. Now imagine that she makes a mistake one day and her clients lose the majority of their savings. Her family still expects her to be there for them, but her clients want her locked up because of her negligence. Her career is certainly over, at least as a stockbroker. Our unfortunate stockbroker could hardly be blamed for drinking excessively. But consider what the drinking does. It removes, at least temporarily, the stress of her life. In an intoxicated state, she may be able find respite from the anxiety and despondency she feels. In this sense, the alcohol can be considered to function as a negative reinforcer.

The same thing applies to the homeless man living on the streets of a large urban area. He has no place to sleep, no food, no clean clothes, and is probably sick. Moreover, there is a very high likelihood that he is physically assaulted on a routine basis. However, when he shoots up with heroin, it undoubtedly feels good. Like the stockbroker, he gains a respite from the despair he faces in his day-to-day existence. The heroin acts as a negative reinforcer.

Drugs may also function as conditioned reinforcers. Imagine a family with a 15-year-old daughter who has just moved into a new neighborhood. The young woman has left all of her friends behind and knows nobody in her new neighborhood. However, she desperately wants new friends. She meets a group of folks her own age; however, they all smoke marijuana when they are together. They are very uncomfortable with strangers around when they are doing this. They will not tolerate the new girl's presence unless she too smokes marijuana. So, in order to gain access to the reinforcer – the social group – she begins to smoke marijuana. In this case, the marijuana not only has the primary reinforcing efficacy attributable to its interaction with the young woman's reward pathway, it has also acquired properties of a conditioned reinforcer. It can be argued that this is one way in which addictive behavior is likely initiated.

The obvious complexity of obtaining a full understanding of the intricate environmental determinants of drug use cries out for an experimental line of work in which laboratory-based animal and human work influences human clinical trials. In the following sections each of these sources of data is considered. Entire books can and have been written on each of these topics, so only a flavor of the work is provided here. Selected additional readings are included in the Further Reading list.

LABORATORY STUDIES

A robust finding that has been observed by numerous investigators is that the density and magnitude of reinforcement in an environment is an important determinant of behavior. Work by Dr Nader and colleagues

(and many others) has demonstrated that when an animal (e.g. a primate) is given the opportunity to choose between self-administering cocaine and food, the number of choices made for cocaine varies as a function of the magnitude of the concurrently available food reinforcer. In this paradigm, the food is considered to be an alternative source of reinforcement to the cocaine. In a prototypic experiment, a monkey would be allowed to make repeated choices between a constant dose of cocaine and one pellet of food during an experimental session. In this case, the monkey might elect to take 80% of the available cocaine doses. In the next session, the monkey makes 10 choices between the same dose of cocaine and four pellets of food. In this situation, the monkey chooses cocaine on only 50% of the trials. Finally, a session occurs in which the monkey chooses between the same dose of cocaine and eight pellets of food. In this arrangement, the monkey elects to administer cocaine on only 20% of the trials. This preparation and series of experimental conditions demonstrates, in an elegant fashion, how the availability of an alternative source of reinforcement – when available in a sufficient magnitude – can moderate the reinforcing efficacy of a drug. This is shown by the reduced proclivity to self-administer the drug in the presence of increasingly large magnitudes of alternative reinforcement. This pattern of results has been obtained by many investigators and for many different drugs of abuse and animal species. Examples of this line of work are included in the Further Reading list.

Dr Stephen T. Higgins and colleagues were among the first to demonstrate the above principle in a human laboratory preparation. In a human laboratory procedure closely based on prior animal work, Dr Higgins and colleagues demonstrated that the same principle – high-magnitude alternative reinforcement competes with drug self-administration – pertained to humans. They recruited recreational cocaine users to take part in an outpatient study. Participants were allowed to make 10 repeated choices between 10 mg unit doses of intranasal cocaine and money. In this preparation, money was the alternative reinforcer. When the monetary magnitude was low (i.e. $0.05), participants selected cocaine almost exclusively, when the amount of available money per choice increased to $1.00 about 50% of the choices were for cocaine. When the amount of available money was further increased to $2.00 the choices were almost exclusively for money. As in the animal study, drug self-administration decreased as the magnitude of the available alternative source of reinforcement increased. In other words, cocaine users were able to readily forego cocaine self-administration when they had to choose between cocaine and a sufficiently high magnitude of alternative reinforcement. Many investigators have essentially replicated this work. In one project, we used methamphetamine users who met the diagnostic criteria for methamphetamine use disorder (not recreational users) and the same relationship held. High-magnitude alternative sources of reinforcement decreased the reinforcing efficacy of the methamphetamine.

The above examples demonstrate one way in which behavior can be altered by engineering specific environments. Essentially, the reinforcer-directed behavior of drug self-administration was altered by utilizing external environmental manipulations that decreased the reinforcing efficacy of the drug. There are other ways to influence a drug's reinforcing efficacy and the self-administration of the drug. As Fig. 25.1 illustrates, any of the four environments (genetic, internal, external, and social) could potentially alter the drug-taking behavior of an individual. In the above examples, the behavior was altered by manipulating the external environment directly (i.e. arranging forced choices between the drug and different magnitudes of salient alternative sources of reinforcement). Other commonly investigated methods include the use of pharmacotherapeutic approaches that alter the internal environment. For example, nicotine replacement therapy occupies the internal nicotinic receptors and decreases the compulsion for the individual to self-administer nicotine. Another promising line of work is to utilize an immunotherapeutic approach to interfere with drug's ability to exert its effect. Many psychosocial procedures, such as relapse prevention, seek, in part, to alter the drug user's social environment so that they remove themselves from situations that have historically been associated with drug use.

All of these procedures have a goal of reducing a drug's reinforcing efficacy in common. This in turn reduces the likelihood that the drug will be consumed. This reduction of reinforcing efficacy is the hallmark of successful drug abuse treatment paradigms. Arguably, the most successful treatment paradigm is contingency management, a procedure that provides salient reinforcement to treatment-seeking individuals contingent on drug abstinence. This is a procedure that, when successful, alters the drug user's external and social environments in such a fashion as to decrease the drug's reinforcing efficacy.

CONTINGENCY MANAGEMENT

One could make a strong case that contingency management has the strongest basic science foundation of any behaviorally based substance abuse treatment. In brief, contingency management for the treatment of substance use disorders is a procedure that decreases the reinforcing efficacy of a drug via the delivery of

reinforcement contingent on abstinence and/or the delivery of punishment contingent on drug use. Given that it is widely accepted, and has been recognized for decades, that drugs of abuse function as potent positive reinforcers, a procedure designed specifically to decrease the drug's reinforcing efficacy, and hence the control the drug will exert over an individual's behavior, has much to recommend it from a theoretical framework.

Contingency management interventions have been developed to decrease substance use and improve treatment attendance through the judicious application of behavioral principles. Contingency management is based on a robust basic science literature supporting a position that drug use is, in part, a form of operant behavior. The availability of alternative nondrug reinforcers (i.e. vouchers, prizes) should decrease drug use if they are available in sufficient magnitude and according to a schedule that is incompatible with substance use. Contingency management is a powerful technique that has been used effectively to promote abstinence from alcohol, benzodiazepines, cocaine, nicotine, opiates, marijuana, and methamphetamine. Three meta-analyses support contingency management efficacy. A meta-analysis of controlled studies of psychosocial treatments for addiction (published in the *American Journal of Psychiatry*) observed that contingency management interventions demonstrate the largest reductions in drug use when compared with other treatment modalities. In a separate meta-analysis, contingency management treatment resulted in successful treatment episodes 61% of the time, while comparison treatments resulted in successful treatment episodes 39% of the time. Contingency management has demonstrated reductions in drug use that persist for 12–18 months after completion of the contingency management intervention in some randomized clinical trials. The long-term effects of contingency management on drug use have been found to be comparable with the long-term effects of cognitive behavioral therapies in the treatment of cocaine dependence. Research is currently underway that is focused on determining schedules and/or durations of reinforcement that maximize the long-term effect of contingency management interventions on drug abstinence.

The efficacy of contingency management has been demonstrated in community clinic settings in large randomized clinical trials. Contingency management was included as a recommended treatment in guidelines published by the National Institute for Health and Clinical Excellence in the United Kingdom. Investigations of contingency management dissemination are currently underway, including studies designed to better understand systemic and clinical variables that impede and facilitate contingency management implementation. Novel approaches have been developed to assist in funding contingency management interventions, such as providing greater control of disability benefits and providing opportunities for employment contingent on drug abstinence.

In a prototypic contingency management intervention, drug abusers come to a clinical setting and provide a urine test, which is analyzed for drug metabolites three times per week. Every time the urine test is negative (e.g. no recent drug use has occurred), participants receive a voucher worth a certain monetary value. The value of these vouchers escalates for consecutive instances of abstinence and resets to an initial value for failure to abstain. Treatment typically lasts 3 months but recent work from our group has shown that longer duration treatments are associated with greater rates of posttreatment abstinence. Vouchers can be exchanged for goods or services that are in line with the development of a drug-free lifestyle. For example, a mother in treatment might use her vouchers to buy a toy for her young son. Another person may use vouchers to buy clothes for a job interview.

These procedures produce high rates of in-treatment abstinence and statistically and clinically significant rates of posttreatment abstinence. Positive outcomes are associated with higher magnitudes of reinforcement, minimal delays between providing urine tests and receipt of reinforcement, baseline severity of drug use (less severity at baseline predicts better treatment outcome), and longer duration of the intervention. Contingency management interventions are among the best studied means to clinically alter a person's environment in an attempt to reduce a drug's reinforcing efficacy.

CONCLUSION

Behavior is determined by multiple influences. This brief chapter presents a framework that expands conventional accounts of environment to include those factors internal to an individual. It is my belief that such an expansion is necessary if we are to fully appreciate the complexities of human drug-taking behavior. I have also argued that multiple environmental interactions influence a person's moment-by-moment behavior through a reinforcement (and punishment) process. With this as a starting point, it follows that those procedures designed to alter a drug's reinforcing efficacy will have the greatest treatment impact. Contingency management is arguably one of the most successful interventions for treating substance use disorders (especially psychostimulant addiction) and it clearly operates by rearranging the drug user's environment to alter the reinforcing efficacy of continued drug use. Many

additional facets such as epigenetic modulation of the internal environment, research into individual differences, and prevention studies are not considered in this chapter. A full account of human drug taking will also need to consider these topics.

OUTLINE

Most modern theories of addiction view drug self-administration as an operant behavior that is maintained by the reinforcing properties of drugs. Widely abused drugs such as nicotine, heroin, and ethanol reliably reinforce the behavior that leads to their administration. A key task of any theory of drug use, however, is to predict the conditions in which drugs will be highly preferred or valued reinforcers. Behavioral economic theory uses the term reinforcing efficacy (RE), which in laboratory settings is quantified by the amount of behavior (e.g. lever presses, time) allocated to gain access to the reinforcer, to describe the relative level of preference for a reinforcer such as alcohol or drugs. According to behavioral economics, the reinforcing value of a given drug is a dynamic and contextually determined product of the direct reinforcing effects of the drug, individual difference factors related to decision-making (e.g. impulsivity), and the availability of alternative reinforcers, rather than a fixed property of the drug or an immutable characteristic of the individual. The following sections describe several key features of behavioral economic theories of addiction. After this general overview of behavioral economic models of addiction, the article ends with a review of studies that have specifically examined the role of several key behavioral economic variables in the development, progression, and cessation of substance use: drug price, the RE of drugs relative to alternatives, and manipulations of substance-free reinforcement.

EFFECT OF AVAILABILITY AND PRICE OF DRUGS AND ALTERNATIVE REINFORCERS

Behavioral economic theory predicts that the primary environmental influences on drug use are both constraints on access to drugs and the availability and value of alternative substance-free sources of reinforcement. Drug use is most likely when there are minimal constraints on drugs and substantial constraints on

Principles of Addiction, Volume 1

access to valued nondrug reinforcers. Indeed, both naturalistic and laboratory research indicate that rates of substance use are highly sensitive to changes in the response cost or price associated with drug use; high rates of substance use are most likely in contexts devoid of substance-free sources of reinforcement, and substance use will generally decrease if access to alternative reinforcers is increased. It is important to note, however, that although several studies have identified alternative reinforcers that substitute for drug use (an inverse relation between levels of drug use and levels of the drug-free activity), drugs and alternative reinforcers can also be independents (no relation between levels of drug use and levels of the drug-free activity) or complements (positive relation between levels of drug use and levels of the drug-free activity) and this relation may be moderated by other variables. For example, whereas social activity has been shown to be a substitute for substance use in many adult samples, among young adults levels of socializing are often positively correlated with drinking, indicating a complementary relation.

It is important to point out that behavioral economics is a molar theory, which means that its goal is to account for patterns of behavioral allocation toward drugs and alternatives over time, rather than discrete instances of drug use. Drug use is assumed to vary predictably in relation to the relative availability of drugs and alternatives, but no predictions are made about whether an individual will use drugs in a given instance. In contrast, biological, social learning, and cognitive theories of addiction focus on proximal explanations for specific instances of drug use (e.g. craving, expectancies, peer pressure).

Changes in Relative Value as a Function of Engagement in These Activities

A key assumption of behavioral economic theories of addiction is that the cost–benefit ratio of drug consumption versus engagement in other activities changes as a function of the amount of engagement in these respective activities. The nature of the change in the cost–benefit ratio as a function of consumption (or participation), however, is markedly different for drugs versus many potential substitute activities. Drugs are viewed as price-habituated activities, which means that there is a negative relation between the amount of consumption over time and the benefit derived from a given consumption episode. This is consistent with the observation that tolerance reduces the rewarding effects of a given drug dose in experienced drug users. In contrast, many substance-free activities are price-sensitized, which means that there is a positive relation between participation and the benefits derived from the activity. Interpersonal relationships, exercise/sports, and hobbies such as knitting and playing bridge are examples of activities that will generally result in increased benefits over time, as intimacy (in the case of relationships) and skill generally increases with repeated engagement in these activities. If these activities are neglected, conversely, their cost–benefit ratio will increase (e.g. running after a period of immobility, attempting to access social support after a period of social isolation, attending statistics class after missing the previous 3 classes).

Behavioral economic theories suggest that the central dynamic of addiction is the relative distribution of behavior over time to constructive price-sensitized activities versus drug use. Because drug use is price-habituated, it is in theory a self-limiting activity. Whereas moderate substance use (e.g. a glass of wine with dinner, or several drinks during a weekly happy hour) results in reliable benefits (euphoria, relaxation, social facilitation), regular heavy drug use generally will diminish the value of any single unit of use, perhaps due to physiological or behavioral tolerance and perhaps mounting negative consequences that begin to tip the cost–benefit ratio. Indeed, the fact that the number of moderate drinkers and drug users far exceeds the number of heavy users and that even many substance abusers have periods of moderate use is consistent with this self-limiting prediction.

Behavioral economic theory predicts that there are several conditions that could result in increased drug use. First, an event that results in a reduction in substance-free substitutes, such as the loss of friend, family member, or job, moving to a new environment, or an injury or illness. Second, an event or situation that results in a reduction in the monetary or behavioral price of drug use. For example, for many young adults the college environment drastically reduces the total price of both alcohol and drug use, which includes more than just monetary cost. Alcohol and drugs are readily available at bars and parties, reducing the cost of time and effort to procure them, and the parental sanctions that served to increase the price of drinking or drug use during high school are generally absent. Moreover, many students have ample free time and are able to avoid taking morning classes, factors that minimize the extent to which heavy drinking results in functional impairment. All of these environmental factors may partially explain the fact that although as many as 40–50% of the US college students report frequent heavy drinking, most of these students substantially reduce their drinking in the years after graduation. Similarly, soldiers in Vietnam, an environment in which drugs such as heroin and marijuana were readily available without the threat of legal sanctions, reported high rates

of drug use and dependence but most stopped or reduced their consumption after returning to the United States, despite the fact that few participated in formal drug treatment. Other examples of situations that result in a reduction in the price of drinking and or drug use include turning 21 and being able to purchase alcohol legally, beginning a relationship with a heavy drinker or drug user, and moving into a neighborhood with a high density of drug dealers and liquor stores.

Because drug use and many substance-free activities are mutually substitutable, an increase in drug use related to these price reductions will often result in decreased engagement in substance-free activities. This decrease will in turn reduce the value of these price-sensitized, substance-free activities, resulting in greater behavioral allocation toward substance use. Thus, although the value of any individual occasion of substance use will continue to decrease as use escalates, the concurrent reduction in the value of price-sensitized, substance-free substitutes will often make drug use the option with the greatest immediate benefit. This is especially true for drugs of abuse that produce strong withdrawal effects (e.g. sedatives and opiates), which result in negatively reinforced patterns of use. This progression toward greater drug use is exacerbated by the fact that drug use often has a direct negative impact on other activities (e.g. hangover or withdrawal-related impairment, substance-related arguments, social stigma, legal fines/sanctions) in addition to the price-sensitized effect associated with diminished engagement in substance-free activities. Moreover, recent neurobiological research indicates that many drugs of abuse have direct neurochemical effects that exacerbate this narrowing of the behavioral repertoire toward drug use. Acute drug use has been shown to reduce the dopamine reward threshold such that dopamine firing occurs in response to milder rewarding stimuli. This might lead to greater pleasure or RE associated with activities that occur during a drug or alcohol use episode (e.g. creative activities, socializing, sexual activity). Chronic drug use, conversely, raises the dopamine reward threshold, making substance-free activities less reinforcing and less likely to effectively substitute for drug use.

It is also possible, however, for contextual events – such as an increase in the price of drugs or a decrease in the price of substance-free activities – to decrease the cost–benefit ratio of substance-free activities, leading to reduced drug use. In the examples cited above, graduating college and assuming adult responsibilities such as full-time employment and or beginning a family, or returning to the United States after military deployment, might be events that generate such a change in the cost–benefit ratio. The efficacy of contingency management interventions – a substance abuse treatment that provides positive reinforcement for verified periods of drug abstinence – suggests that even highly dependent substance abusers are sensitive to changes in the cost–benefit ratio of drug and alternative reinforcers. Furthermore, research has demonstrated that individuals who successfully recover from substance abuse without participating in treatment often note increases in rewards from key life domains (work, family, hobbies), which suggests that substance abuse patterns are sensitive to contextual events that change the relative availability of drug-free rewards.

Important Temporal Influences on Choice between Drugs and Alternatives

The choice dynamic described above is critically influenced by the temporal context of the decisions. Drug choices will often maximize utility (i.e. happiness, satisfaction) if the time frame for reward maximization is short. Drinking heavily at a bar on one particular night might maximize utility for that evening compared with staying home and studying. If the temporal context is extended (e.g. 1 month, or year), however, behavioral allocation toward constructive, price-sensitized activities such as studying would maximize utility. Behavioral economics is a molar theory of choice and as such assumes that addiction entails a series of "distributed choices" (e.g. drinking vs abstaining on a given night) rather than a discrete choice (to be a heavy drinker vs an abstainer) and that the frame of reference used to estimate the relative value of a series of choices concerning drug use will determine the amount of drug use over time.

Available data suggest that there are interspecies, developmental, and individual differences in the extent to which decisions are made on the basis of relatively short-term versus long-term outcomes. For example, although the value of all rewards decreases as their receipt is delayed (i.e. delay discounting), there are substantial individual differences in the degree of discounting of delayed rewards, and behavioral economic theory suggests that this discounting phenomenon may be a core feature of addiction. That is, consistently using drugs instead of engaging in activities with greater long-term benefit (e.g. work, relationships, school) may be due to sharp devaluing of these delayed rewards relative to the immediate benefits of drug use. Research with humans and animals suggests that relative preference for smaller, sooner rewards increases sharply as the receipt of the smaller reward is imminent. This choice pattern is well described by a hyperbolic discount function and is quite consistent with the choice dynamics associated with substance abuse, including switching preference from larger delayed rewards (e.g. academic or vocational pursuits, physical health) to substance use when drugs are immediately available.

Studies have found that a variety of substance-abusing groups (alcohol, cocaine, heroin, nicotine abusers, pathological gamblers) discount delayed monetary rewards more steeply than matched controls. Research examining delay discounting in both human and nonhuman animals suggests that delay discounting can be exacerbated by the effects of chronic drug use and drug withdrawal, and might even improve after extended abstinence. Delay discounting also seems to be an etiological risk factor that contributes to the development of substance abuse and has implications for the likelihood of change after treatment. One compelling animal study found that rats that showed a strong preference for smaller, immediate amounts of food compared with larger, delayed food rewards subsequently showed greater levels of cocaine use. Among humans, discounting may predict the acquisition of tobacco use, and nonsubstance-abusing teens with a family history of substance abuse report higher discounting than similar teens without a family history of substance abuse. Studies with smokers and alcohol-dependent individuals indicate that steep discounting at baseline predicts relapse or poor treatment response. Finally, although delay discounting rates are fairly stable over time, the state versus trait nature of discounting remains unresolved, and researchers have begun to identify techniques to extend an individual's time horizon.

The Influence of Price on Drug Use

As predicted by the Law of Demand, consumption of most commodities, including alcohol and other psychoactive drugs, is inversely related to price or response requirement. However, there are cross-commodity and individual differences in the relative price sensitivity or elasticity of consumption. Demand for a reinforcer is unit-elastic when increases in price lead to proportional decreases in consumption (resulting in no change in overall expenditures on that reinforcer) and elastic when increases in price lead to greater than proportional decreases in consumption (resulting in a reduction in overall expenditures on that reinforcer). Demand for nonessential and/or luxury items, such as restaurant meals, is generally elastic. Alternatively, demand for a reinforcer is inelastic when increases in price lead to less than proportional decreases in consumption, resulting in an increase in overall expenditures on that reinforcer (e.g. demand for gasoline during the summer travel season). It is worth noting that the elasticity of a good may be partially moderated by the income of the consumer. In behavioral terms, income is defined as the total amount of money, time, energy, or other resources that can be allocated to various reinforcers. The behavior of consumers with a relatively high income may be less sensitive to price increases than those with relatively low income. Thus, individuals with large amounts of free time (e.g. college students, unemployed adults) are more likely to "spend" large amounts of time procuring and using drugs.

In considering the effects of price on consumption, it is important to note that the behavioral economic definition of price goes beyond the simple monetary cost. Chaloupka and Pacula provided a comprehensive review of a variety of factors that can influence decisions about smoking, including the monetary costs of purchasing cigarettes, restrictions on where and when people can smoke, the fines and other legal consequences of smoking at unauthorized locations, and awareness of the short- and long-term health risks associated with smoking. More generally, the full price of any good, service, or reinforcer consists of four basic components: (1) monetary cost, (2) time and effort costs, (3) potential legal cost, and (4) potential health cost. Increases in any of these costs can lead to decreases in substance use, and, conversely, lowering the cost can lead to increases.

Several laboratory studies have modeled the relationship between price and substance consumption. One study used a simulated alcohol purchase task to assess levels of alcohol consumption across a range of prices in a sample of social drinkers. The average number of standard drinks consumed was approximately seven when the price was $0.25 or less per drink, remained at or above five drinks at prices up to $1.50 per drink, and then became more elastic and showed a steady linear decrease as prices increased. Not surprisingly, participants with a history of engaging in heavy episodic drinking were willing to spend more to consume alcohol, demonstrating that individual difference factors such as history of use and dependence can play a role in the demand elasticity of alcohol. A similar purchase task was used to assess cigarette consumption in adolescents. The authors found that while hypothetical cigarette purchases were elastic, the majority of adolescents would purchase at least one cigarette at prices up to $2.50 and 20% will still purchase a cigarette at $7.00. Another study that used a sample of 200 heavy drinking college students revealed that students' hypothetical drinking decreased across the entire range of drink prices if they were instructed to imagine that they had a college class the next morning, and decreased further if they were instructed to imagine that the morning class included a test. The next morning class can be viewed as an alternative reward or as an indirect method of increasing the "cost" of drinking; the results provide support for the behavioral economic view that decisions to drink or use drugs are sensitive to price and alternative reinforcement contingencies.

An abundance of population-based research also supports the notion that an increase in the monetary price of alcohol leads to decreases in consumption,

making demand for alcohol fairly elastic. However, recent studies suggest that the relationship between price and consumption is quite complex. An analysis of Swedish alcohol price and sales data collected between 1984 and 1994 confirmed that increases in price led to decreases in consumption for spirits, wine, and beer, but also revealed that increases in price led some consumers to switch to lower-quality (and lower priced) products so that they could maintain their level of consumption.

The RE of Drugs Relative to Alternative Reinforcers

Behavioral economic theory views addiction as a state in which the RE of drugs is high compared with the RE of available drug-free alternative activities. In laboratory settings, the RE of drugs is generally measured by the levels of operant responding for a drug, the quantity of the drug reinforcer earned or consumed during the session, the extent to which drug-reinforced responding is sensitive to increasing price or schedule requirement, or the proportional response rate toward drugs. Herrnstein's matching law ($\log B_1/B_2 = a \log r_1/r_2 + \log c$), for example, states that the proportional resource allocation directed toward available activities (B_1/B_2) equals the proportion of reinforcement obtained from the activities (r_1/r_2). The a and c parameters reflect sensitivity to reinforcement frequency and bias for one or the other alternative, respectively. The matching law has accurately predicted choice in numerous laboratory studies involving a variety of species and reinforcers, including studies examining drug administration. RE measures that plot the sensitivity of drug consumption and drug-reinforced responding to increases in price (demand curves) have also been used to predict the abuse liability of drugs.

There are several measures of RE that can be administered to human participants in clinical settings, and several recent studies provide initial support for the validity of these novel measures of substance abuse problem severity. Tucker and colleagues developed a measure of RE based on proportional discretionary monetary expenditures to alcohol. Their discretionary expenditure measure, which is modeled after laboratory paradigms that consider response output and consumption as distinct facets of RE, is based on the premise that alcohol is a more valued reinforcer for an individual who allocates 45% of her expenditures to alcohol consumption than it would be for an individual who allocates only 10% of her expenditures to alcohol consumption, even if these individuals had similar alcohol consumption levels. In two studies of natural recovery from alcohol dependence, Tucker and colleagues assessed the proportion of discretionary income allocated to alcohol in alcohol-dependent individuals before a quit attempt. The results indicated that relative resource allocation to alcohol predicted drinking outcomes, whereas traditional measures of consumption and dependence did not. Participants who relapsed within the 2-year follow-up period allocated a greater proportion of their money to alcohol in the year before the attempted resolution, even though their levels of alcohol consumption and problems during this period were similar to resolved participants. Thus, consistent with behavioral economic predictions, RE measures based on resource allocation seem to have utility in predicting clinically relevant changes in drinking.

Another way to measure reinforcement is to assess the frequency of specific, rewarding activities. Reinforcement surveys such as the Pleasant Events Schedule and the Adolescent Reinforcement Survey Schedule measure the frequency of participation in and subjective enjoyment derived from various activities (e.g. eating good meals, meeting someone new, gardening). The cross product of the frequency and enjoyment ratings provides an approximation of obtained reinforcement (e.g. the sum of recent time spent in enjoyable activities). Participants make two sets of frequency and enjoyment ratings for each item – one for drug-free activities and one for activities that take place while using drugs or alcohol. The substance-related reinforcement score is a measure of drug-related enhancement of other activities (e.g. socializing while high) rather than a direct index of the reinforcing effects of drug use (e.g. sedation, euphoria). The substance-free cross product score provides an index of substance-free reinforcement. The primary score derived from the modified reinforcement surveys is the ratio of substance-related reinforcement to total reinforcement, an index of the RE of substance use. Correia and colleagues derived this index from Herrnstein's matching law: substance-related reinforcement/(substance-free reinforcement + substance-related reinforcement). Cross-sectional studies with college drinkers and psychiatric patients demonstrated that the ratio measure predicted unique variance in drinking quantity beyond the effect of substance-related reinforcement alone.

Another study examined whether this reinforcement survey measure of RE was related (prospectively) to drinking outcomes among heavy drinking college students who completed a brief alcohol intervention. Only women showed a significant reduction in drinking at the 6-month follow-up, and RE accounted for unique variance in their drinking outcomes. Women who derived a smaller proportion of their total reinforcement from substance use at baseline reported lower levels of follow-up drinking, even after controlling for their baseline drinking level. Thus, individuals

who have a number of enjoyable alternatives to drinking may have an easier time reducing their consumption after an intervention. Men and women who reduced their drinking by at least five drinks per week showed increased proportional reinforcement from substance-free activities at follow-up, which suggests that successful drinking reductions are associated with more global changes in lifestyle and activity participation.

Another analysis from this treatment trial examined a reinforcement measure derived from a hypothetical alcohol purchase task wherein participants report the number of drinks they would purchase across 14 different prices ($0–$13.00). Reported consumption and expenditures are plotted as a function of price (demand curves), which are in turn used to generate several indices of RE, such as maximum level of alcohol consumption at low cost (intensity of demand), maximum level of alcohol expenditure (O_{max}), and several measures that reflect the degree to which consumption decreases with increasing price (breakpoint, P_{max}, and elasticity of demand). Murphy and colleagues examined the psychometric properties of the indices derived from the alcohol purchase task and found them to correlate with alcohol consumption, alcohol-related problems, and other RE variables, demonstrating good construct validity, and to have good test–retest reliability at a 2-week interval. As hypothesized, a number of the facets of reinforcement predicted weekly alcohol consumption and heavy drinking at the 6-month postintervention follow-up assessment. Participants who at baseline reported greater maximum expenditure (i.e. O_{max}) for alcohol and lower price sensitivity (i.e. breakpoint, P_{max}, and elasticity) reported greater follow-up weekly drinking. Other studies have shown that greater intensity of demand is associated with more problematic use (i.e. alcohol use disorder symptoms, alcohol problems), which suggests that this index may be useful in identifying more severe patterns of use.

Little and Correia provided further evidence for the construct validity and potential utility of self-report reinforcement measures that utilize hypothetical alcohol purchases. Hypothetical alcohol purchases on the multiple choice procedure (MCP) were significantly correlated with measures of alcohol consumption and problems and with a laboratory paradigm that included real choices between alcohol and monetary amounts. Another recent study of adolescent smokers found that RE measures derived from hypothetical cigarette demand curves demonstrated significant associations with smoking and nicotine dependence. Thus, RE measures that are based on simulated drug purchases seem to be valid and to show meaningful relations to real-world patterns of substance use and problems. RE indices may provide unique information about the value or strength of preference for substance use that is not typically included in clinical or applied research contexts. Existing substance abuse measures provide important information on consumption levels and the immediate risks and harmful effects of drinking/drug use, but they do not describe the relative prominence of substance use in an individual's overall lifestyle or the amount of resources allocated to substance use, which may be more predictive of the course of substance use over time. Proportional reinforcement from substance use relative to substance-free activities operationalizes an important feature of substance misuse: devoting considerable time/resources to substance use and neglecting other important activities. This concept is included in the DSM-IV–dependence criteria but is not explicitly measured in traditional substance use assessment batteries. RE may be an especially useful means of discriminating between individuals with similar substance use patterns, but different levels of risk (and need for treatment) based on their overall pattern of behavioral allocation/reinforcement.

Drug Use Can Be Decreased by Increasing Drug-Free Reinforcement

The relationship between drug use and drug-free reinforcement has been studied through a combination of laboratory, naturalistic, and clinical studies. When studied in the laboratory, the dependent variable is typically a measure of drug use preference. Examples include the amount of the drug consumed, the amount of effort devoted to obtaining a drug, or the number of times the drug use is chosen over an alternative reinforcer. Independent variables involve manipulations of the availability, magnitude, and delay associated with an alternative reinforcer. For example, a series of studies conducted by Higgins and colleagues have shown that the reinforcing value of cocaine is malleable and highly influenced by the presence and magnitude of an alternative monetary reinforcer. Higgins, Bickel, and Hughes examined the influence of an alternative reinforcer on cocaine use among four adult humans. During 11 laboratory sessions, participants made repeated choices between cocaine versus placebo or between cocaine versus varying amounts of money ($0–$2.00). Participants always chose cocaine, rather than placebo, indicating that the drug served as a reinforcer. When subjects were asked to chose between cocaine and money, the amount of cocaine consumed decreased as the amount of concurrently available money increased. More recent studies by Correia and colleagues have used an MCP to investigate preference

for alcohol among college students. The results indicate that preferences are influenced by the immediacy of alternative monetary reinforcers. Thus, for both cocaine and alcohol, the preference for the drug decreases as the alternative monetary reinforcer is larger and more immediately available. The relationship has now been studied across a wide range of drugs (e.g. cigarettes, alcohol, cocaine, heroin), species (e.g. rats and mice, human and other primates), and human populations (e.g. drug-dependent users, nondependent users, college students). Across these laboratory studies using a variety of methodologies, participants generally show a greater preference for drug use when the value of the alternative reinforcer is small, the alternative reinforcer is delayed, or when the price of the alternative reinforcer is increased. These findings led Vuchinich and Tucker to conclude that drug use emerges as a highly preferred activity when constraints on the drug are minimal and alternative reinforcers are sparse or difficult to acquire.

The relationship between drug use and alternative reinforcers has also been studied and well documented in the natural environment. Several of these studies have used measures of behavioral allocation, such as the Pleasant Events Schedule and the Adolescent Reinforcement Schedule Survey, to measure engagement in a range of potentially reinforcing activities. A series of studies on college student drinking reported that the frequency, quantity, and negative consequences of alcohol use are predicted by the ratio of reinforcement derived from drug-related reinforcement to reinforcement derived from drug-related activities (e.g. school work, relationships, employment). These studies have also revealed that drug-free reinforcement is associated with increased motivation to change alcohol use; that increases in substance-free activities like exercise can lead to decreases in substance use; and that reduced drinking after a brief motivational intervention is associated with an increase in substance-free reinforcement. Studies using similar measures of behavioral allocation to study substance use among psychiatric outpatients and individuals enrolled in treatment for cocaine use disorders have produced consistent results. Interestingly, a recent study that examined substance-free reinforcement in heavy drinking college students found that frequent heavy drinkers reported greater substance-free reinforcement from peer and sexual activities. So, although overall substance-free reinforcement may increase after making a drinking reduction, several seemingly important reinforcement domains might suffer, at least among young adults, an outcome that might contribute to the overall low levels of treatment seeking and high rates of relapse. In general, the aforementioned studies suggest that alternative drug-free reinforcement is critically related to the development, progression, and cessation of substance abuse patterns.

BEHAVIORAL ECONOMIC INTERVENTION APPROACHES

The research reviewed above has influenced the development of several treatment approaches that explicitly attempt to increase the price of drug use and to increase access to alternative reinforcers. Contingency management (CM) is perhaps the most explicit example of a treatment designed to decrease substance use by increasing the density of drug-free reinforcement and the cost of substance use. As summarized by Higgins, all forms of contingency management, regardless of the substance(s) being targeted, the population, or the exact nature of the procedures, share a common conceptual framework, which calls for changes in the substance user's environment such that (1) drug use and abstinence are readily detected, (2) drug abstinence is readily reinforced, (3) drug use results in a loss of reinforcement, and (4) the density of reinforcement derived from nondrug sources is increased. As previously noted, contingency management procedures have been used effectively to reduce the use of a number of substances, including cigarettes, alcohol, cocaine, marijuana, and opiates.

The community reinforcement approach (CRA) is one example of a CM intervention. In the original Hunt and Azrin study, CRA participants were provided with counseling and material resources (e.g. telephones, televisions) to improve employment prospects, marital and family relationships, and nondrinking social and recreational interactions. These goods and services were provided to help clients access alternative sources of reinforcement by providing entertainment, or facilitating communication with employers and social partners.

Several other treatments highlight the various ways in which the reinforcing value of drug use can be decreased by increasing drug-free reinforcers. Several treatment approaches focus on the development of substance-free coping and social skills. These approaches are designed to address basic skill deficits that prevent clients from adequately coping with emotions and deriving satisfaction from a social-interpersonal situations at work, with friends, and with significant others. The coping skills training (CST) program, developed by Peter Monti and colleagues, focuses on delivering positive and negative feedback, listening skills, conversation skills, developing a sober support network, and assertiveness training. Behavioral activation therapy also promotes the development of skills to promote engagement in substance-free reinforcers. Consistent with the behavioral economic perspective the CST and behavioral activation serve to

decrease the reinforcing value of drug use by increasing the reinforcing value of drug-free social interactions and activities. Recent clinical outcome studies and meta-analysis continue to support the clinical efficacy of CM and other behavioral approaches. In addition to supporting the clinical utility of specific treatments, these treatment studies also provide additional evidence on the relationship between drug use and drug-free reinforcement.

CONCLUSIONS

Behavioral economic researchers have made considerable progress in describing the individual difference and contextual variables that influence the development, progression, and cessation of a variety of addictive behavior patterns. Key strengths of behavioral economic research include (1) a strong theoretical foundation in economic and learning theory, (2) a clear translation of concepts and measures from basic laboratory research on drug self-administration, including research with nonhuman animals to clinical settings, (3) a tradition of applying quantitative models to the description and prediction of substance abuse and associated decision-making processes, (4) decision-making tasks and paradigms that are amenable to both clinical translation (e.g. predicting treatment outcome) as well as to basic science translation (e.g. identifying genetic and fMRI correlates of discounting, studying interventions for discounting, or RE in animal models), and (5) concepts and experimental paradigms that have lead to the development of efficacious treatments such as CM. Key future directions include (1) the continued development of practical and valid measures of RE and delay discounting that could be used in clinical settings to predict need for and response to intervention, (2) the continued development of intervention approaches that are informed by behavioral economics, including brief and efficacious approaches for reducing delay discounting and increasing engagement in substance-free activities, and (3) efforts to understand the neural correlates of the destructive decision-making processes that underlie addiction. Regarding the final suggestion, the emerging field of "neuroeconomics" has the potential to contribute to the development of improved pharmacological and behavioral intervention that directly target and improve individuals' executive functioning and self-regulatory systems.

Glossary

Behavioral economics a theory that integrates the principles and empirical methods from psychology and economics to understand how humans and animals allocate scare resources (behavior, time, money) under systems of constraint. Behavioral economics views the decision to use drugs as a cost–benefit analysis that is based on the relative availability, delay, and value of drugs versus alternative reinforcers.

Community reinforcement approach a behavioral approach to treating substance abuse problems that aims to reduce positive reinforcement for substance use and to increase positive reinforcement in social, recreational, familial, and vocational domains.

Complement a reinforcer acts as a complement when consumption of that reinforcer varies inversely with the price of another reinforcer. Coffee and sugar may function as complements such that an increase in the price of coffee may lead to a decrease in the consumption of sugar.

Contingency management a behavioral treatment approach that provides contingent positive reinforcement (vouchers, money) based on chemically verified abstinence for a given period of time (typically 1–3 days). Escalating schedules of reinforcement are often used to achieve prolonged stretches of abstinence.

Delay reward discounting refers to the level of decrease in the subjective value of a reinforcer as a function of the time until it is delivered; provides a behavioral economic index of impulsivity.

Demand curve a quantitative representation of consumption and response output (expenditures) for a given commodity (e.g. drug, food product) across a range of prices. Consumption and expenditures/response output are plotted on the *Y*-axis; price is plotted on the *X*-axis.

Intensity of demand maximum consumption level observed in a demand curve paradigm; consumption level at the lowest price increment.

O_{max} maximum expenditure or response output observed in a demand curve paradigm.

P_{max} the price associated with the maximum expenditure or response output (O_{max}) observed in a demand curve paradigm. P_{max} corresponds to the price at which demand becomes elastic.

Breakpoint the price at which consumption is completely suppressed in a demand curve paradigm.

Elasticity the rate of decrease in consumption as a function of price in a demand curve paradigm; demand is considered to be relatively elastic if a 1% change in price results in a greater than 1% change in consumption.

Price the total cost to acquire a good, service, or reinforcer which is the combination of (1) monetary costs, (2) time and effort costs, (3) potential legal cost, and (4) potential health and social costs.

Price-habituated activities when there is a negative relation between the amount of participation in the activity over time and the benefit derived from a given occasion of participation.

Price-sensitized activities when there is a positive relation between time spent engaging in the activity and the benefits derived from the activity.

Reinforcing efficacy the ability of a reinforcer to maintain high levels of operant responding. RE is generally measured by the levels of operant responding for a drug, the quantity of the drug consumed during a laboratory session, or the proportional response rate toward the reinforcer relative to alternative reinforcers.

Substitute a reinforcer that shares some essential property with another reinforcer, such that an increase in price in one reinforcer will lead to increased consumption of the substitute reinforcer (e.g. coffee and tea often function as economic substitutes).

OUTLINE

INTRODUCTION

Attempting to define cognitive factors in addictive processes is a daunting task. One might argue that cognition is at the root of virtually every aspect of addiction, beginning with the decision to smoke a cigarette for the first time or to take a first sip of beer, to the successful navigation of occasional temptations encountered by a former substance abuser who has maintained abstinence for many years, and all of the points in between. There are many domains that might be considered in this context, including learning and memory, motives, intentions, attitudes, social perception, coping, self-awareness, self-control, self-regulation, attention, craving and urges, expectancies, attributions, cue-reactivity, neural networks, and implicit processes. We have elected to focus on a subset of these domains and are painfully aware that there are many other relevant topics which should and would be included in a more comprehensive treatment of the topic.

There are a number of contextual issues that warrant brief mention at the outset. First, it seems important to define what we mean by addictive processes. Second, it seems important to point out that processes may differ considerably depending on where an individual may be in the developmental course of addiction. Third, it is difficult to disentangle cognition entirely from emotion. Fourth, and finally, many of the cognitive processes underlying addiction (and behavior, more generally!) are not entirely conscious.

For the purposes of this chapter, we define addictive processes as the psychological and behavioral operations which relate to continued engagement in activities which an individual or society perceives as maladaptive, undesirable, and beyond the individual's control. Problematic substance use is a prototypical domain for discussing cognitive factors in addictions but similar processes may characterize a wide range of behaviors when taken to the extreme, including gambling, eating, shopping, internet use, sex, and so on.

Principles of Addiction, Volume 1
DOI: http://dx.doi.org/10.1016/B978-0-12-398336-7.00027-9

The developmental course of addiction may vary considerably across behaviors and individuals, but there are some common landmarks that seem universal. Ideally, all journeys have a beginning, a middle, and an end, and so it is with addiction. In the beginning, engagement in an addictive behavior is characterized by many positives and few negatives. For example, drinking is associated primarily with fun and social facilitation and gambling is often seen as a source of enjoyment and recreation. The middle of the journey may be divided into many subsections – characterized by increasingly disproportionate negative consequences and repeated attempts to disengage from the behavior. The end, in an ideal case, is a look in the rearview mirror, and a sigh of relief that one has survived a long and difficult journey. While it is the middle of the journey that typically receives the bulk of the attention in the research on cognitive factors and addictions, cognitive factors operate across the developmental course and will differ depending on an individual's place or stage in the journey. For example, cognitive processes related to self-control, cravings, and urges seem less relevant early and more evident later. In contrast, the opposite seems true for processes regarding perceptions of peer influence and positive expectancies. Furthermore, all along the way, cognition and emotion go hand in hand. A focus on cognitive processes may seem to suggest a focus on logical (or illogical) operations that are independent of affect. Human nature belies this possibility as many people's thoughts are about feelings and vice versa. Moreover, it is impossible to divorce how people think from how they feel. Thus, while our focus is on cognitive processes, it is important to keep in mind that affect is always intertwined with cognition. Finally, more and more work has begun to consider cognitive influences on addictive processes which operate outside of explicit awareness, often referred to as automatic or implicit processes. These are considered in some detail in the latter half of the chapter.

OUTCOME EXPECTANCIES

Among the broadest cognitive processes that have been shown to play an important role in addictive behaviors are those referred to as "outcome expectancies" or "expectancies." Most commonly studied with respect to alcohol, but more recently receiving increasing attention in studies of other drugs (e.g. cocaine, marijuana, tobacco) and addictive behaviors (e.g. gambling), expectancies refer to an individual's expectations of the outcomes associated with drug use. Theories of outcome expectancies reflect influences both from basic learning (e.g. positive and negative reinforcement) and cognitive theories. Expectancies are thought to reflect both an individual's past experiences of engaging in a behavior – that is, the extent to which one has experienced positive or negative reinforcement or punishment when using a drug – and that individual's expectations of the future consequences of engaging in that behavior. Thus, expectancies are argued to reflect both direct and indirect (vicarious) forms of learning that are, ultimately, stored as cognitive representations in memory. Whether expectancies stem largely from conscious or nonconscious cognitive processes is under debate, but, as discussed in more detail below, there appears to be general agreement that there is at least a significant nonconscious component to expectancies.

Expectancies are believed to develop from experience; thus, expectancies will vary as a function of the outcomes that an individual has experienced in conjunction with specific behaviors. Thus, a person who has smoked crack cocaine will likely have different expectancies about crack cocaine than an individual who has never tried it. Expectancies can also be derived from vicarious learning and observation of the results of behaviors performed by models (e.g. parents, peers, the media). For example, a child with limited observation of people consuming alcohol will have different expectancies than one growing up in a home where both parents drink heavily. Not only are there variations in expectancies across individuals but there are also variations within individuals. Thus, a child with limited exposure will have different expectancies as she ages and encounters more models and/or begins to have her own direct experiences with alcohol. Expectancies, both in terms of type (positive and negative) and intensity (weak vs. strong), have been shown to predict behaviors with stronger positive expectancies predicting greater use.

Expectancies have often been measured using self-report questionnaires with Likert-scale response options. Most scales include measures of both positive (e.g. social facilitation, tension reduction) and negative expectancies (e.g. increased aggression, cognitive impairment). Consistent with expectancy-value models, some scales also include an additional set of questions that ask respondents to rate the extent to which they view each outcome as positive or negative, which is designed to account for variance in how positively or negatively a given outcome is viewed by an individual. For example, some respondents may view an increase in aggression associated with drinking as a positive effect of drinking and/or a decrease in the ability to remember things as a positive outcome of marijuana use. Individual items within and across questionnaires also vary in the extent to which they: (a) focus on outcomes that affect one's self versus others; (b) assess outcomes that reflect cultural attitudes, mood changes, beliefs, physiological changes, and/or social effects; and (c) measure distinct versus

overlapping constructs. This variation has led some researchers to raise substantial concerns about measurement, in general, and construct validity, in particular. In addition, the nearly exclusive reliance on self-report questionnaires to measure expectancies is problematic to the extent that expectancies reflect cognitive processes that are nonconscious or automatic. Specifically, to the degree that one's beliefs about outcomes have at least a component that is reflexive, nonvolitional, and/or possibly not requiring attention or awareness, those beliefs cannot necessarily be captured by self-report questionnaires, which require deliberate introspection and awareness.

Despite measurement concerns, expectancies have been shown to be consistent predictors of behavior, especially alcohol consumption. For example, both positive and negative alcohol expectancies have been linked to alcohol consumption over time, including hazardous drinking, with some research suggesting that positive alcohol expectancies are better predictors. Responding to critiques in the field, researchers have continued to refine expectancy measures and analyses, and thus have been able to examine respondents' appraisals of specific outcomes (i.e. whether respondents view what researchers describe as "negative" outcomes as positive and vice versa). Similarly, the field has increasingly begun to identify and test moderators of expectancies and evaluate whether expectancies function as mediators of addictive behaviors. While much of the literature on expectancies in addictions has focused on alcohol and has relied heavily on college and adolescent samples, research has established that there are strong, positive relationships among expectancies and drinking behaviors. Less work has established the generalizability of these findings to other populations and/or other addictive behaviors. A growing literature has begun to show expectancy effects for marijuana, cocaine use, and gambling behavior. Additional studies – particularly those that establish causality, use prospective designs, and include diverse (clinical and nonclinical) populations – will be critically important.

MOTIVES

Whereas expectancies are presumed to precipitate behavior based on beliefs about probabilities of outcomes and subjective values associated with those outcomes, motives for engaging in addictive behaviors have been described as being more direct than expectancies. For example, an expectancy that alcohol will lead to tension reduction does not necessarily imply that a person will drink for this reason, even if the individual views tension reduction as a desirable outcome. Individuals typically have multiple motives for drinking or engaging in an addictive behavior. Therefore, on any given occasion, an individual may be drinking for social reasons even if he or she has positive tension reduction expectancies. Thus, motives are typically assessed by asking individuals about their reasons for engaging in addictive behaviors directly. The association between expectancies and behavior is likely to be mediated by motives, although some have argued that distinctions between expectancies and motives are primarily semantic.

Varying motives have been attributed to using different substances and behaviors that are typically classified as addictive. Although specific substances and behaviors are associated with unique motives, at least two categories of motives are common across substances and behaviors. These categories include social motives and affect regulation motives, which may be positive (e.g. affect enhancement) or negative (coping or tension reduction). These motives have been identified for drinking and marijuana use, but marijuana use is also motivated by unique factors, including "cognitive expansion" (e.g. perceptual and cognitive enhancement) and desires for experimentation. Similarly, gambling motives include not only social and affect regulation but also the desire to win money and the enjoyment of competition. Tobacco use also includes social and affect regulation motives. Notably, although common motives exist across substances and behaviors, their relative endorsement varies considerably. For example, stress reduction is a more commonly endorsed motive for cigarette smoking than for alcohol or marijuana use. Motives also vary in their relations to different outcomes. For example, social motives and enhancement motives are more strongly related to alcohol consumption, whereas coping motives are more strongly related to alcohol-related problems. Similarly, as alluded to above, motives are also likely to vary along the developmental course of an addiction, with curiosity, social facilitation, and positive affect enhancement likely to be more common in the initiation and early stages of the behavior. Engaging in addictive behaviors as a means of forgetting problems, regulating negative affect, and avoiding withdrawal symptoms are likely to be more prevalent later in the course of addiction.

Motives or reasons for changing behavior have also been extensively evaluated in the context of considering how, when, and why people successfully disengage from or quit addictive behaviors. In studies of natural recovery, former cigarette smokers and substance abusers who have successfully quit or learned to use moderately have been asked what prompted them to change. In these studies, health concerns are the most frequently endorsed motive for reducing or eliminating substance use. Financial reasons and negative personal reasons such as shame and guilt are also frequently endorsed reasons for change. A general assumption is that, over the course of addiction, individuals become

more motivated to quit or cut down as the perceived costs and negative consequences of the behavior begin to outweigh the perceived benefits and desired outcomes of the behavior.

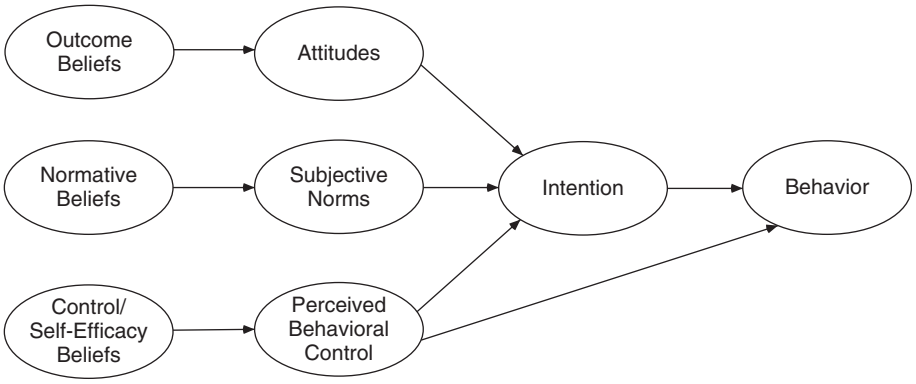
Identification of motives for initiation of use, continuing use, reduction, and abstention are critically important for the development of prevention and treatment strategies. Behavior change strategies should necessarily differ for an individual whose use is primarily motivated by perceived expectations from friends in comparison to an individual whose use is largely motivated around numbing negative emotions.

SOCIAL NORMS

Brief attention is provided here because the influence of social norms is inherently a cognitive process, and social norms are a consistent factor associated with initiation of substance use and other addictive behaviors. Many behaviors, including addictive behaviors, are influenced by other people. Specifically, our behaviors are influenced directly and indirectly by our parents, friends, peers, spouses, coworkers, children, and authorities, among others. Social norms refer to what is considered appropriate or normal behavior in a group of people. The influence that specific others have on us depends on how much we care about those others and our perceptions of their thoughts and actions regarding a specific behavior. One of the foundations of social psychology is the assumption that we are often not directly influenced by reality but rather by our subjective perception of reality. More importantly, in social contexts there are often discrepancies between subjective perception and reality. For example, substance use among adolescents and young adults is heavily influenced by perceptions of peer use and peer approval of use and it has been well documented that these perceptions are exaggerated. More generally, perceived social norms can increase or decrease the likelihood of engaging in addictive behaviors. We may correctly or incorrectly believe that our coworkers expect us to drink at the office Christmas party. One adolescent may smoke a cigarette if offered for fear of rejection, whereas another may resist when thinking about potential disappointment from parents.

BEHAVIORAL INTENTIONS

In contrast to our perceptions of others' expectations (i.e. social norms), cognitive influences on addictive processes also include our expectations of ourselves. Behavioral intentions refer to an individual's own expectations to engage in specific behaviors. Behavioral intentions are presumed to be proximal antecedents of behavior. Therefore, integrated models of addictive behaviors have sought to include proximal and distal predictors. Among the most widely studied of these models are the theory of reasoned action (TRA) and its extension, the theory of planned behavior (TPB). In these approaches to decision making, attitudes predict behavior through a single proximal antecedent, behavioral intentions. Intentions are typically defined as goals that are formulated through introspection or reasoning. Thus, from this perspective, the best predictor of substance use is the intention to use substances. Alternatively, the best predictor of changing use or entering treatment would be the intention to change or to seek treatment, respectively. Subjective norms and attitudes regarding the behavior influence one's intentions for engaging in the behavior. Subjective norms are one operationalization of social norms and refer to perceptions of the degree to which important others support the specific behavior (e.g. the extent to which friends and family approve of smoking cigarettes). Attitudes reflect the individual's global evaluations of performing a particular behavior (i.e. positive vs. negative evaluations of smoking). In general, the more favorable the attitude, the stronger the individual's intention is to perform it. The TPB is an extension of TRA that also includes measures of perceptions of factors that may facilitate or prevent engaging in a behavior (control beliefs), which impact perceived ease or difficulty of performing the behavior (perceived behavioral control).



The addition of control beliefs and perceived behavioral control provide additional information about potential constraints on action and were included to explain why intentions do not always predict behavior. For example, an individual may have favorable attitudes about substance abuse treatment and believe her family and friends are very supportive of her getting treatment. However, if she perceives that there are significant obstacles to getting treatment (e.g. that she has little control over being able to get treatment), she may be less likely to intend to and actually enter treatment. Each of the three major constructs (attitudes, subjective norms, and perceived behavioral control) is presumed to stem from cognitions that are behavior specific. For example, the TRA and TPB assume that decision making is a reasoned and deliberative process which involves consideration of behavioral options and anticipated outcomes. Two meta-analyses of TPB indicate that behavioral intentions explain 30–40% of the variance in health behaviors. The meta-analyses also found that TPB accounted for 27% and 39% of the variance in behavior and intention, respectively. The relative importance of attitudes, subjective norms, and perceived behavioral control in predicting intention is expected to vary across situations and behaviors.

Some researchers have argued that these rational models of decision making are less effective in predicting some kinds of behavior than others. Both TRA and TPB have proven effective at predicting health-promoting behaviors (e.g. family planning, cancer screening, exercise, treatment seeking) but have been less successful when applied to risky behaviors (e.g. heavy drinking and unprotected sex). This is especially true among adolescents as they are first exposed to risky health behaviors. The prototype willingness model (PWM) was created as an extension of TPB and, with the added component of behavioral willingness, explains how a common explanation for adolescent risky health behavior is simply that "it just happened." Willingness measures are designed to tap into an openness to engage in a behavior, or curiosity about a behavior that is internal rather than a reaction to social pressure. Behavioral willingness is reactive rather than deliberative, and that difference is the predominant distinction between behavioral intention and willingness. The PWM identifies intentions and willingness as independent predictors of behavior and posits that in the beginning stages of experience with the behavior, willingness is a better predictor than intentions.

SOCIAL COGNITIVE THEORY

Social cognition and social cognitive theories generally refer to our cognitions about others and about ourselves in relation to others. Within these domains, attributions are a central construct and relate to how we make sense of our own and others' behaviors, including addiction and substance/drug use. Attributions are explanations individuals give for the causes of events, others' behavior, or their own behavior. Attributions are made regarding why one's self or others misuse addictive substances, use moderately, or abstain altogether. People use different kinds of information when assigning causes to behaviors. For example, people consider consensus information or presumptions of how most people typically act in similar situations. Behavior that seems atypical is attributed to the individual versus to the specific circumstances of the situation. Thus, having a shot of vodka first thing in the morning is atypical, whereas a cup of coffee is not. A person who has a cup of coffee every morning will probably not be considered a caffeine addict but a person who has a shot of vodka every morning will probably be considered an alcoholic. Consistency information also plays a large role in attributions. Chronic use – meaning frequent, regular use – of any substance is almost a prerequisite for attributions of abuse or dependence. An individual who uses a substance once or only occasionally is unlikely to be considered addicted.

Individuals can make a variety of attributions for their own behaviors in the realm of substance use and abuse, and the nature of these attributions can have effects on subsequent behavior. For example, if a previously heavily drinking woman, who is a new mother, gets drunk after an extended period of abstinence, she could make a variety of attributions about her behavior, and these attributions can affect her subsequent use. Internal, stable, and global attributions, (e.g. "I just don't have much willpower," "I am a bad mother," or "I have a disease and therefore I simply can't control my actions"), in the absence of perceived alternative sources of available help, are likely to be associated with giving up or abandoning sobriety or attempts to moderate substance abuse. On the other hand, if she makes external, unstable, and local attributions, she may conclude such things as, "Everyone there was doing it, so it was a really difficult situation to be in and resist successfully," "I had the worst day of my life yesterday, so I was weak and turned to the alcohol/drugs to cope," or "I made a mistake, but this doesn't define who I am. I will forgive myself and get back on the path to abstinence." An event with attributions emphasizing situational (i.e. external) causes or exceptional factors will more likely be viewed as a mistake which can be learned from and allow one to go forth with new knowledge and be better prepared for similar future situations versus a certain verdict that one is "doomed" or "destined" to return to addiction.

In general, individuals tend to make trait or internal attributions when considering other people's behaviors and tend to make situational or external attributions when considering their own behavior. This is referred to as the fundamental attribution error or correspondence bias. For example, if you know that another person is getting drunk at a party instead of looking for a desperately needed job, you are more likely to attribute the cause of their behavior to something about their personality, and not the situation. However, when judging your own behavior, you bring self-knowledge and insight to the judgment, as well as greater knowledge of the environmental factors influencing you at the time. This results in a tendency to be more lenient in judgment. In the realm of addictive behaviors, this can lead to a tendency to generate more rationalizations for the self than an outside observer would, which can be either harmful or helpful in certain circumstances. If people make a mistake and have a small relapse, the tendency to be lenient in judging themselves can be helpful if they take from the experience knowledge of what led them to fail in that specific instance, as well as how they can better resist in the future. On the other hand, if people make mistakes and are lenient in self-judgment (i.e. continuously make excuses), but also never learn from their mistakes, then their leniency in judgment does not serve any constructive purpose in terms of improvement.

Another important cognitive factor related to regulating addictive behaviors is self-efficacy. Self-efficacy can be defined as individuals' beliefs in their personal capability to exercise control over a variety of tasks related to a specific domain. With respect to addiction, self-efficacy can be more narrowly defined as an individual's perceptions of his or her ability to control, moderate, or abstain from use of alcohol or other drugs. Self-efficacy largely determines an individual's performance in situations where there are opportunities to act upon personal goals. A person with high self-efficacy is more likely to press forward to accomplish their goals despite frustrations, physical or mental discomforts, or other challenges, whereas a person with low self-efficacy is more likely to abandon their goals when these challenges arise.

Self-efficacy plays a large role in determining performance; but it can also be very closely related to self-fulfilling prophecies. Self-fulfilling prophecies refer to instances where one holds a particular belief about oneself, acts in a way that validates the belief, and receives feedback from others that reinforces the belief. For example, if Susan thinks that she is too shy to make friends, Susan will act in ways that confirm her belief (e.g. by keeping quiet or by responding to friendly conversation with one-word answers). In turn, other people will likely respond to Susan's behavior by not initiating friendships with her. Susan, in turn, receives feedback from others that validates and strengthens her original belief about herself ("I am too shy to make friends"). The key to breaking the cycle of a self-fulfilling prophecy is to understand how one's own behavior (e.g. providing minimal responses to others who are trying to engage in friendly conversations) in response to a belief (e.g. "I am too shy to make friends") contributes to maintaining and confirming the belief (e.g. people may not have interest in pursuing friendships with someone who will not engage in conversation). Our understanding of attributions and self-efficacy are relevant in considering programs that emphasize complete abstinence. Specific consideration has been given to attributions people make when they violate abstinence goals. The same processes have also been discussed when people violate predefined limits.

ABSTINENCE VIOLATION EFFECT/LIMIT VIOLATION EFFECT

A specific process has been described regarding attributions that follow relapse after an extended period of abstinence or moderation. The abstinence violation effect can be defined as a tendency to continue to engage in a prohibited behavior following the violation of a personal goal to abstain. For example, an individual who has successfully abstained from alcohol, after having one beer, may drink an entire case of beer, thinking that since he or she has "fallen off the wagon," he or she might as well go the whole way. When an abstinence violation occurs, the attributions an individual makes play an important part in determining the trajectory of subsequent use. When abstinence violation occurs, individuals typically enter a state of cognitive dissonance, defined as an aversive experience resulting from the discrepancy created by having two or more simultaneous and inconsistent cognitions. Abstinence violators realize that their actions (e.g. "I drank") do not line up with their personal goal (e.g. "I want to abstain") and feel compelled to resolve the discrepancy. Attributions are made to try to resolve or justify the discrepancy. In this case, individuals try to explain to themselves why they violated their goal of abstinence. If the reason for the violation is attributed to internal, stable, and/or global factors, such as lack of willpower or possession of an underlying disease, then the individual is more likely to have a full-blown relapse after the initial violation occurs. On the other hand, if the reason for the violation is attributed to external, unstable, and/or local factors, such as an extremely tempting situation, then the individual is more likely to recover from the violation and get back onto the path of abstinence.

When abstinence is violated, individuals typically also have an emotional response consisting of guilt, shame, hopelessness, loss of control, and/or a sense of failure; they may use drugs or alcohol in an attempt to cope with the negative feelings that resulted from their abstinence violation. An abstinence violation can occur for a number of reasons. A person may experience a particularly stressful emotional event in their lives and may turn to alcohol and/or drugs to cope with these negative emotions. An abstinence violation can also occur in individuals with low self-efficacy, since they do not feel very confident in their ability to carry out their goal of abstinence.

These properties of the abstinence violation effect also apply to individuals who do not have a goal to abstain, but instead have a goal to restrict their use within certain self-determined limits. The limit violation effect describes what happens when these individuals fail to restrict their use within their predetermined limits and the subsequent effects of this failure. These individuals also experience negative emotions similar to those experienced by the abstinence violators and may also drink more to cope with these negative emotions. Cognitive dissonance also arises, and attributions are then made for the violation. In a similar fashion, the nature of these attributions determines whether the violation will lead to full-blown relapse.

IMPLICIT COGNITIVE FACTORS

Implicit cognitions are another important type of cognitive factor in addictions. They have received increasing attention in both the addictions and basic cognitive science literatures in the last 20 years as new techniques – often, but not exclusively, computer-based – developed to assess automatic cognitive processes. Implicit factors, also referred to as indirect and/or automatic factors, refer a class of factors that ostensibly occur without introspection, volition, attention and, possibly, awareness. They are thought to reflect cognitive processes that are more reflexive – that is, processes that are faster and simpler – as compared to those that are more reflective – that is, processes that are slower and more complex. Implicit factors are often categorized into one of three types: memory, attention, or interpretation factors. When individuals demonstrate a tendency or preference to associate one stimulus with another (e.g. associate alcohol pictures with good things vs. bad things); attend to a particular type of stimulus (e.g. an alcohol cue vs. a nonneutral cue); or interpret an ambiguous stimulus in a particular way (e.g. as an alcohol word vs. a neutral word), they are often described as demonstrating a bias (also called an information processing bias).

Implicit factors are often considered in tandem with explicit or controlled cognitive processes – that is, cognitive processes that appear to require introspection, volition, attention, and awareness. A variety of dual process models (i.e. models that focus on the influence of both implicit and explicit cognitive factors) have been proposed, including models specific to the development and maintenance of addictive behaviors. Common among dual models of addictive behaviors is the notion that addictive behaviors typically commence with explicit cognitive processes taking precedence. For example, a woman might decide to take drink because she is experiencing strong feelings of distress, or a man might decide to smoke a cigarette with friends because he needs a break from work-related duties. It is argued that, in both situations, the individuals are likely making conscious choices, selecting the substances from several deliberately considered options. Over time, it is argued that the "choice" of taking a substance becomes more automatic and less subject to introspection and that implicit factors may dominate or, at least, play a more influential role than explicit factors. For example, over time, the woman might attend more to cues related to alcohol when she experiences stress, and the man might tend to associate work breaks with cigarettes. Thus, repeated experiences are thought to lead to the development of biases related to implicit factors, which then, in turn, increase the likelihood of engaging in the addictive behavior. In addition, it has also been argued that specific circumstances or contexts increase the likelihood of implicit factors predominating over explicit factors, among them are experiencing strong emotions, being subject to a strong cognitive load, and being under the influence of substances. In such situations, effortful, deliberate processes are argued to be impaired whereas implicit factors are thought to be less affected.

As mentioned above, implicit factors are commonly, but not always, measured using computer-based tasks. Common computer-based tasks include adaptations of the implicit association test (IAT), single-target implicit association test (ST-IAT), extrinsic affective Simon task (EAST), dot-probe paradigm, the Stroop test, and lexical decision tests. Because implicit factors are thought to reflect more reflexive types of processes, these tasks usually include instructions to complete task trials as rapidly and accurately as possible. Thus, the primary analytical focus is on respondents' reaction time, with an occasional emphasis on respondents' error rates. Additional measures of implicit factors can be completed via pencil and paper and typically ask participants to respond to a word, phrase, and/or other stimulus as rapidly as possible. For those tasks, the content of the response is of primary concern. Within both the addictions and cognitive science field, there are ongoing

controversies regarding (a) exactly what implicit tasks are measuring; (b) the extent to which implicit tasks can capture "purely" automatic processes versus both automatic and controlled responses; and (c) the robustness (or lack thereof) of the psychometric properties of specific tasks. Such concerns are part of an even larger debate about what exactly is meant by the term "implicit" or "automatic" (i.e. those terms can be used to describe cognitive factors that do not require awareness, attention, volition, and/or consciousness) and the extent to which specific tasks can be said to measure all or some of those aspects is unclear.

Despite the substantial methodological concerns above, there is considerable promise with respect to implicit cognitive factors and addictions. The field is fairly young, yet despite its relative youth, it has already begun to address important questions and accumulate evidence that implicit factors are influential in addictions. In particular, research has shown that implicit cognitions related to alcohol, tobacco, and other drugs are associated with actual use and problems. Moreover, research has also shown that those cognitive factors predict variance in use and problems above and beyond explicit cognitive factors. Thus, there is evidence that implicit cognitive factors are uniquely associated with addictive behaviors. In addition, recent experimental studies have provided support that context – for example, exposure to alcohol cues, exposure to negative events, consumption of addictive substances, or depletion of self-regulatory resources – can affect implicit cognitive factors, and that in such circumstances, implicit cognitive factors may function as better, or at least unique, predictors of subsequent substance use than explicit factors. Similar to other types of cognitive factors, research on implicit factors is in need of more diverse samples (including clinical and nonclinical samples), prospective studies, and experimental research. Ongoing studies are also beginning to examine the extent to which implicit factors might also serve as additional targets for addictions treatment, which would further increase the potential importance of considering implicit cognitive factors in relation to addictions.

SELF-REGULATION

Daily, people successfully resist temptations such as overeating, excessive drinking, or ingesting harmful drugs through self-regulation. In sharp contrast, addictions and addictive disorders, including eating issues, substance abuse, and gambling, can be construed as examples of self-regulation failure. At the most basic level, self-regulation is the "exercise of control over oneself by oneself." Furthermore, self-regulation also includes the self's capacity to alter behaviors in order to achieve a desired goal state.

Self-regulation includes several theories, among them, and featured here, is Baumeister and Muraven's ego depletion theory, also known as "the strength model." This theory proposes that self-regulation depends on a finite resource of inner strength (ego) that becomes temporarily depleted after use. This depletion results in lowered ability to exercise self-control in subsequent tasks, even those under different self-control categories. Muraven and colleagues have likened ego depletion to a muscle – that is, a muscle has limited energy, and after doing a task, requires recovery time before it can perform another task at optimum levels. Similar to an athlete training muscles through repetitive practice, one can train the self-control "muscle," thereby improving self-regulation strength. Research has also shown that training can increase self-regulation in domains unrelated to the specific domain being trained. For example, participants who engaged in everyday self-control (e.g. improving posture) for two weeks performed significantly better in a dual-task paradigm (completing two unrelated self-control tasks consecutively) compared to a control group.

With regard to addictions, maintaining a balance between the desire to drink and the necessity of limiting intake requires self-regulation, and the strength model has been applied to addictions. For example, Muraven and colleagues found that compared to controls, participants who were instructed to resist thoughts about a white bear had lower self-control in a second task, namely resisting the temptation to drink in expectation of having to drive. Specifically, participants who focused on resisting thoughts consumed more beer and had higher blood alcohol content (BAC) levels than a control group. Research by Carey and colleagues has revealed that college students with better self-regulation skills reported fewer heavy drinking episodes and fewer alcohol-related issues. In that study, self-regulation was predictive of lowering both number of drinks consumed per day and peak BAC levels over 1 month following an intervention, thus, suggesting the potential utility of self-regulation training for preventing or treating addiction.

In addition to probable relationships between self-regulation and drinking, there also appear to be individual differences in self-regulation deficits, which are related to drinking behaviors. When moving toward addiction, the addictive behavior often becomes a habit (i.e. a behavior no longer under conscious control due to persistent repetition). As the habit continues to strengthen, the behavior becomes automatic and increasingly inaccessible to self-regulation. For example, some research has shown that self-regulation deficiency is positively related to habit, such that people with lower

amounts of self-regulation are more likely to develop habits, leaving them at an increased risk for developing an addiction. Thus, people with lowered self-regulatory resource levels can develop addictions because they are more likely to initiate alcohol consumption and fail to break their habit.

People may be unable to resist drugs or alcohol because of varying individual amounts of self-regulation and/or overuse of their self-regulation "muscle" in their lives. As the continued substance use progresses, behavioral habits can form, which may evolve into addiction. Repeated efforts that enhance the strength and endurance of self-regulation capacity may be effective in the long run. This may explain why repeated failures usually precede successful abstinence from smoking. Additional research is needed to further evaluate the efficacy of efforts designed to enhance self-regulatory capacity. As an alternative course, a number of studies have begun to explore strategies which functionally reduce cognitive effort expended in response to urges and cravings. A number of studies have evaluated mindfulness-based meditation, stress reduction, relapse prevention, and urge surfing as methods of reducing the cognitive effort expended in response to urges and cravings. The general idea here is to acknowledge desires or cravings without attempting to push them away, but simply observing them and watching them ebb and flow, without identifying with them or acting on them. Repeated practice of these approaches has shown some success with smoking and drinking. In summary, self-regulation is central to the construct of addiction and promising approaches for treatment from the perspectives of self-regulation theories are being investigated.

SPECIFIC SUBSTANCE EFFECTS

As described earlier, there are numerous cognitive factors that are influential in addiction. The aforementioned factors have applications to a range of addictive behaviors. There are also, however, some influential factors that are primarily associated with specific substances. Alcohol's effects on human social behaviors and emotions vary widely. For example, alcohol has been shown to elicit both aggression and altruism and both to reduce and increase anxiety. An obvious question is how can alcohol predict these contradictory behaviors? The notion that alcohol acts as a general disinhibitor and causes individuals to engage in risky and foolish behaviors is commonly accepted in the general public. Alcohol myopia theory was designed to provide a different perspective about how alcohol affects behavior and is one of the most accepted theories in this domain. It postulates that alcohol does not act as a general disinhibitor, but rather, that alcohol causes a restriction in controlled attentional capacity, such that intoxicated individuals no longer possess the executive cognitive processing skills to attend to all of the information in their environment. Disinhibition occurs, then, only when attention is focused toward salient instigatory (impelling) cues rather than inhibitory ones.

Sober individuals are able to attend to both impelling and inhibiting cues, evaluating the benefits and costs of engaging in various behaviors. For intoxicated individuals, complex deliberations about conflicts between competing impelling and inhibiting cues are precluded, and attention is granted only to the most salient and easily processed aspects of the situation. This disproportionate focus on the proximal environment represents a state of shortsightedness; the intoxicated person is only vaguely, if at all, concerned with considerations distal in time or place. In many situations, the impelling cues associated with risky behaviors (e.g. being sexually aroused) are more immediate than the inhibiting cues (e.g. the possibility of contracting an STD). In these cases, intoxication causes increases in reported intentions and performance of risky behaviors even when these behaviors contradict individuals' sober attitudes. Alcohol myopia theory is more comprehensive than disinhibition theory and explains a wide range of disinhibitory behaviors such as aggression, unprotected sex, driving under the influence, smoking, and suicide.

Alcohol is not the only drug that elicits specific cognitive effects. Caffeine, alcohol, and nicotine comprise the three most widely used psychoactive drugs in American society. Caffeine is an effective psychostimulant, ingested to obtain increased mental awareness, wakefulness, and a faster and clearer thought pattern. A consequence of this augmented mental alertness is continuous intellectual effort for prolonged periods of time without disruption of coordinated intellectual or motor activity. Caffeine and nicotine cause the least cognitive and behavioral impairment of all the addictive drugs. Nicotine is also a psychostimulant which results in increased cognitive functioning, attention, and memory consolidation. It can improve performance in a variety of cognitive tasks, the most consistent being on vigilance and rapid information processing. At higher doses, however, nicotine can induce nervous thought patterns which may develop into panic attacks.

Barbiturates are referred to as cognitive inhibitors because they are sedatives and depress memory functioning. The motor and cognitive inhibition and behavioral depression caused by barbiturates are similar to those caused by alcohol intoxication. In low doses, a person may respond either with a relief from anxiety or with withdrawal, emotional depression, or aggressive behavior. Higher doses elicit more general behavioral depression and sleep. One's mental state and social

setting interact to determine whether relief from anxiety, depression, aggression, or another unexpected response is experienced. Cognitive processing, judgment, memory, and motor skills become severely impaired during the period of intoxication, and may continue to be experienced for hours or days until the barbiturate is completely metabolized and eliminated.

Marijuana is the most commonly used illegal drug in the United States and is used for its relaxed, dream-like sense of euphoria. Two primary cognitive consequences of cannabis intoxication are impaired short-term memory and a perception that time passes more slowly. Marijuana also produces negative cognitive effects, such as distorted perceptions, disconnected or incoherent thoughts, and difficulty focusing, attending to, and solving problems.

Opiates (morphine, heroin, and numerous potent synthetic morphine-like compounds) rapidly produce an initial period of intense, euphoric, sublime pleasure. As the initial spike declines, a second phase begins – a pleasant, emotionally disconnected, dream-like perception, including strong feelings of contentment, well-being, and lack of concern. During this lightly sedated state, cognitive impairment occurs in the form of "mental clouding," accompanied by a lack of concentration, apathy, complacency, lethargy, and a sense of tranquility.

Psychedelic drugs (lysergic acid diethylamide (LSD), Phencyclidine (PCP), mescaline, and other hallucinogens) alter cortical functions, including cognition, perception, and mood. The psychological effects of LSD are alterations in perception, cognition, emotion, arousal, and self-image. Cognitive distortions include enhanced power to visualize previously seen or imagined objects and decreased vigilance and logical thought. PCP has been referred to as a "dissociative" drug, distorting perceptions and producing feelings of detachment. Users can experience several unpleasant psychological effects, with symptoms mimicking schizophrenia (e.g. delusions, hallucinations, disordered thinking, paranoia). Judgment and intellectual capacity are strongly impaired.

Cocaine and other amphetamines are powerful psychostimulants that markedly affect cognitive functioning and behavior. Temporary effects of cocaine in low doses include an immediate euphoria, giddiness, and enhanced self-consciousness and sense of grandeur. This period is followed by one of milder euphoria coupled with anxiety, followed by a lingering anxious state that spans hours. Thoughts typically race, and speech becomes extremely rapid, sometimes tangential or incoherent. Conscious awareness and mental acuity are increased but followed with a depression. As the dose or duration of cocaine use increases, all of these effects are intensified, followed by a rebound depression. Higher doses produce intense anxiety, hypervigilance, paranoia, and persecutory fears. These alterations in thinking patterns may lead individuals to become aggressive in response to imagined persecution. Other high-dose, long-term cognitive effects of cocaine include interpersonal conflicts, depression, dysphoria, anxiety, and vivid visual, auditory, and tactile hallucinations.

CONCLUSIONS

The purpose of this chapter is to provide a general overview of cognitive factors in addictive processes. As noted in the beginning of this chapter, cognitive factors comprise a wide range of more specific interrelated topics. In many cases, different terminology is used to describe fundamentally similar issues and ideas. For example, self-regulation is often referred to as willpower, and it seems clear that self-efficacy and attributions often lie at the heart of successes and failures of self-regulation. Moreover, for some researchers, the distinctions between motives and expectancies are only superficial. Regardless, both concepts seem to overlap considerably with descriptions provided in the TRA and the TPB. Social norms are also an inherent part of these theories as well as social cognitive theory and yet they are often considered independently from these theoretical confines. Across most constructs and perspectives is at least a background realization that much of what occurs is not entirely at the level of focused consciousness.

In considering cognitive factors involved in addictive behaviors, there are many perspectives which have evolved from traditions that vary in degree of interdependence. The variety of perspectives and overlap is directly related to training. Those trained in social cognitive theory are most likely to consider related topics from the perspective of social cognitive theory. Similarly, attribution theorists are likely to consider expectancies as specific types of attributions. One of the hopes for this chapter and the larger encyclopedia is to provide enough background so that readers can begin to consider connections and overlap across constructs in a way that will facilitate a deep and broad understanding of addictions. The specific content associated with this chapter is far from being a comprehensive survey of cognitive factors in addictive processes, but it is our hope that it provides a brief survey of the literature and a good introduction for the interested reader.

List of Abbreviations

TRA theory of reasoned action
TPB theory of planned behavior
PWM prototype willingness model

Glossary

Abstinence violation effect A tendency to continue to engage in a prohibited behavior following the violation of a personal goal to abstain.

Attributions Explanations individuals give for the causes of events, others' behavior, or their own behavior.

Behavioral willingness An openness to engage in a behavior, or curiosity about a behavior that is internal rather than a reaction to social pressure.

Controlled cognitive processes Cognitive processes that appear to require introspection, volition, attention, and awareness.

Limit violation effect A tendency to continue to engage in excessive behavior following the violation of a personal goal to moderate behavior.

Outcome expectancies An individual's expectations of the outcomes associated with drug use.

Perceived behavioral control Perceptions that one has control over his or her ability to perform a specific behavior.

Self-fulfilling prophecy A situation in which expectations create reality. For example, failure expectations may create reduced effort which, in turn, results in failure.

Subjective norms Perceptions of the degree to which important others support the specific behavior.

CHAPTER

28

Personality and Addiction Processes

Natalie Castellanos-Ryan, Patricia J. Conrod

Université de Montréal, Montreal, QC, Canada

OUTLINE

The emphasis placed on the role and significance of personality in the development and course of addiction has varied substantially through the past few centuries. While early models of addiction placed considerable emphasis on the role of personality, later more biological or pharmacological based models of addictions overlooked or disregarded personality as an etiological factor for addiction. During the 1960s and 1970s, new interest in the possibility of personality as a key factor in addictions arose, but was short-lived as, by the late 1970s, most of the studies carried out during this period failed to identify one single personality trait that conferred risk for addiction. In more recent years, however, models of addiction have placed a greater emphasis on the reciprocal interplay between biological, psychological, and environmental factors, and the heterogeneity of the addictive processes and profiles, identifying distinct pathways to addiction. One of the first and most influential of these models of addiction was proposed by Cloninger, who described two types of alcoholics. Type 1 was characterized by a relatively late onset, loss of control over drinking, experiencing guilt because of one's drinking, and high scores on the personality trait of harm avoidance (a trait associated with anxiety and pessimism). Type 2, on the other hand, was characterized by an early age of onset, displaying antisocial tendencies and behaviors, and high scores on novelty seeking (a trait related to impulsivity). Other influential studies carried out by researchers including Sher, Pihl, McGue, Stewart, Cooper, Conrod, and their colleagues, to name a few, have also highlighted the important role different personality and/or temperamental traits have in the development and maintenance of addiction. Among the personality factors most commonly cited in the literature as being associated with alcohol and drug misuse, as well as other addictions, are traits that fall within two main overarching personality domains of inhibited and disinhibited traits. Respectively and generally speaking, these two domains of personality correspond to a proneness toward negative and positive affective states, and the two main action tendencies of behavior, avoidance and approach, which are manifestations of the aversive and appetitive motivational tendencies in all humans. Within the inhibited domain, the personality dimensions that have been most consistently associated with addictive behaviors are (1) negative emotionality, introversion, or hopelessness; and (2) neuroticism, trait

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00028-0

anxiety, and anxiety sensitivity. Within the disinhibited personality domain, the two dimensions that have been most consistently implicated are (1) impulsivity, sometimes generally referred to as disinhibition; and (2) extraversion, including sociability and sensation seeking.

However, it is important to note that the association between personality and addiction is not simple or straightforward. Although these personality traits have consistently been linked with addiction, even across different forms of addictive behaviors, findings differ according to the methodology used and sample studied. For example, the personality traits that have often been found to characterize children of alcoholics or adolescent substance users are different from those that have been associated with clinical samples of substance misusers. Similarly, findings from cross-sectional studies highlighting concurrent associations between personality and addictions sometimes differ from the associations found in longitudinal studies. Differences could be attributed to the fact that the strength of associations between personality and addiction varies by developmental stage and, especially when it comes to substance misuse, at different stages in the course of the disorder, with severe or chronic substance misuse possibly resulting in changes in personality, negative affectivity, and impulsivity.

This chapter will provide a selective review of the literature establishing personality factors as correlates of, as well as risk factors for, addiction. Although addictive processes are similar across modalities or "objects of addiction," and similar personality traits have been implicated in a different range of addictive behaviors, it is important to mention that this chapter will mainly focus on findings related to addiction to substances such as alcohol and drugs. First, evidence linking specific personality traits to substance use and other addictive processes will be reviewed. The chapter will then review several causal pathways to addictive behaviors, in which personality traits play an important role. Finally, implications for prevention and clinical practice will be discussed.

PERSONALITY TRAITS IMPLICATED IN ADDICTION

Inhibited Domain

Research on the structure of neurotic symptoms and/or inhibited personality generally finds that negative affect is common to all neurotic traits but that they can be subdivided into two lower-order factors, characterized by low positive affect and fear, respectively. This hierarchical model of anxiety and depression also has relevance for understanding how neurotic/inhibited traits represent risk factors for addiction, but particularly for substance misuse. For example, while the higher-order factor of negative affect or neuroticism seems to be inconsistently related to risk for substance misuse, lower-order facets of neuroticism associated with low positive affect (e.g. hopelessness) and fear (e.g. anxiety sensitivity) have been consistently shown to have specific relationships to particular aspects of substance use and misuse.

Negative Affect and Hopelessness

Hopelessness has been defined, generally, as a set of negative expectations concerning self and future life, and, more specifically, as a tendency to expect negative things to occur, that nothing will improve negative circumstances, or, conversely, that highly desired outcomes will not occur.

In a number of cross-sectional studies, hopelessness or low positive affect has been associated with substance use and misuse. For example, hopelessness has been found to be associated with higher rates of alcohol abuse and dependence, sedative (including analgesics) drug use, and self-report reasons for substance use linked to depression coping and the numbing of painful memories in samples of college and secondary school students. Similarly, compared with adolescents with low levels of hopelessness, those with high levels of hopelessness have been shown to be at least twice as likely to report smoking tobacco in the last month, drinking in the last week, and using marijuana in the last month, as well as six times as likely to report cocaine use in the last month. Longitudinal studies confirm that hopelessness is a risk factor for substance misuse, showing that adolescents with high levels of hopelessness report greater acceleration in their trajectories of tobacco use, alcohol use, and marijuana use compared with those with low levels of hopelessness. These findings have now been replicated in American, Canadian, and British samples of adolescents. The association between this personality trait and addictive behaviors has also been found in clinical samples and community-recruited samples of adults. For example, Conrod and colleagues found in a community-recruited sample of alcohol-dependent women that a personality factor reflecting introversion and hopelessness was associated with a substance misuse profile that involved higher rates of dependence on analgesics and greater comorbidity with recurrent depression and social phobia. A study with college students also showed a greater likelihood of using sedatives/analgesics in college in those with increased hopelessness. The frequently reported finding linking hopelessness with a series of a number of internalizing problems, led researchers and clinicians in the

1980s and 1990s to hypothesize that hopelessness or low positive affect was associated with a particular susceptibility to substance misuse patterns through a self-medication process involving analgesia-induced numbing of painful experiences and memories. Through varied research, this hypothesis has been validated and has gained support as a specific pathway to addiction (*see* section "Casual Pathways to Addiction").

Anxiety Sensitivity

Another inhibited trait is anxiety sensitivity (AS), described as a fear of anxiety-related physical sensations due to an unrealistic expectation that they could lead to "catastrophic" consequences such as loss of physical or mental control, among others. Like hopelessness, AS has also been shown to be associated with high drinking levels and drinking problems, as well as with misuse of a variety of substances in adults, such as heroin, alcohol, nicotine, and anxiolytics. However, some of the findings linking AS and heavy alcohol use in community samples have been mixed and a number of studies have shown that AS is not associated with the use of marijuana, hashish, or stimulants. Other studies have shown increased levels of AS in individuals receiving treatment for substance use disorders, and Zvolenski and colleagues have shown that AS is associated with heightened reactivity to nicotine withdrawal and the tendency to rapidly return to smoking during quit attempts.

Although there is some prospective evidence that anxiety symptoms in childhood or adolescence often precede substance use and misuse, very few prospective studies on the association between AS and addiction have been undertaken. Of those that have, findings are mixed or suggest some developmental and gender specificity. For example, one study carried out in Finland found that anxiety/shyness assessed at the age of 8 predicted increased alcohol and other drug use 20 years later in women, but predicted reduced substance use in men. In contrast, another study carried out in New Zealand by Caspi, Moffitt, and colleagues showed that inhibited boys, described as fearful, anxious, and shy, were more likely to present alcohol-related problems. However, studies assessing AS in early adolescence and its association with the onset of or increased substance use across adolescence have not been able to confirm a prospective relationship between AS and early onset or higher severity of substance use across this period. However, the prospective link between AS and development of alcohol use disorders, becomes clearer in young adulthood, with studies carried out by Schmidt and colleagues, as well as Stewart and colleagues, showing that AS assessed at ages 18–20 predict alcohol use disorders a couple of years later. A possible reason for the inconsistencies in this literature is offered by O'Connor and colleagues who have shown that alcohol and drug expectancies, especially those related to tension reduction and cognitive and behavioral impairment, are important moderators in the association between AS and substance use but are not often taken into account.

What has been consistently reported in the literature, in both adolescent and adult samples, is the significant association between AS and self-report motivations for substance use that reflect self-medication of anxiety symptoms or drinking to cope with emotional distress. Many have also demonstrated that AS is associated with a pharmacological sensitivity to the arousal dampening properties of alcohol and benzodiazepines. Indeed, as AS has often been conceptualized as an "arousal-accelerator," it is not surprising that the evidence does not support AS as a risk factor for adolescent onset substance use, but rather indicates that AS represents a specific risk profile predicting who will use substances to cope with stressors that produce physiologic arousal, such as drug withdrawal, trauma, severe negative life circumstances, and, particularly in younger samples, those normative experiences such as social pressure to conform to peers' substance use patterns. It is important to note here, that there is some literature suggesting that high AS men are at greater risk for self-medication drinking than high AS women, especially when tension reduction expectancies are increased, and that, in more general terms, drinking for coping with negative affect (also related to hopelessness) is a stronger motivation for men than for women.

Disinhibited Domain

Disinhibition is often referred to a general failure to plan, control, or regulate behavior, especially behavior that can be unduly risky or can sometimes result in negative consequences. Recent research on the structure of disinhibited behavior and personality also supports a hierarchical structure of disinhibited or externalizing disorder symptoms and traits, indicating that while they are all correlated with each other and share common variance, subfactors exist that capture the unique variance of some disinhibited behaviors and traits. Certainly, disinhibited tendencies have been referred to in a number of ways in the personality, behavioral and psychopathology literatures, from "acting without premeditation," "lack of planning," "excitement seeking," "low tolerance to boredom," "behavioral undercontrol," and impulsivity, among others. Consequently, measures labeled "disinhibition" or "impulsivity" may measure different constructs from each other. Indeed, although general factor models of personality typically identify only one factor for

disinhibition/impulsivity, extensive research has been carried out on the differentiation between different dimensions of disinhibited personality, which usually results in between two and four subfactors of disinhibition. Using methodologies like factor analysis, recent research in the field of personality has identified, as many as four personality facets associated with impulsive-like behavior: lack of planning, lack of persistence, urgency (acting rashly when upset or anxious), and sensation seeking, but most studies in the field of personality as well as cognitive sciences, agree that at least two clear subdimensions of disinhibition exist: one which is referred to as impulsivity in this chapter, and another which is referred to as sensation seeking.

Impulsivity

Impulsivity is generally associated with a deficit in reflectiveness and planning, rapid decision-making and action, and a failure to inhibit a behavior that is likely to result in negative consequences. It is clear from the literature on substance misuse in adolescent and adult samples that impulsive traits play a prominent role in addictive behavior. Impulsivity has often been associated with substance misuse, specifically, quantity and frequency of drug use, and early experimentation with drugs. Impulsivity has also been associated with the consumption of a range of different drugs, such as cannabis, ecstasy, and heroin use, and is the personality trait that has most consistently been associated with alcohol disorders in the literature.

Longitudinal studies have also identified impulsivity/disinhibited traits as risk factors for future substance misuse. For example, impulsivity in childhood, as measured by either Eysenck's psychoticism or Cloninger's novelty seeking, has been found to predict substance misuse and alcohol-related problems in adolescence and adulthood, with a study by Cloninger and colleagues showing those reporting high scores in impulsivity to be 20 times more likely to report alcoholism in adulthood compared with those who do not report high scores on this trait. Impulsivity measured by higher-order factors or super-factors like constraint (i.e. Multidimensional Personality Questionnaire or the Minnesota Multiphasic Personality Questionnaire) or by lower-order, more specific measures of impulsivity (e.g. Substance Use Risk Profile Scale) assessed in childhood or early adolescence, have also been prospectively associated with alcohol and drug use in late adolescence and young adulthood. However, it is important to highlight that some laboratory studies have shown that severe and persistent substance use can result in deficits in behavioral and/or cognitive measures of impulsivity, such as response inhibition and decision-making, and even in increased levels of self-report trait impulsivity, suggesting the possibility that the pathway from impulsivity to substance misuse is bidirectional. This highlights the importance of assessing both measures of impulsivity and substance use simultaneously across time, so that cross-lag or bidirectional effects can be evaluated. With this in mind, a recent study by Littlefield, Sher, and Wood evaluated, using latent growth models, the extent to which changes in personality and changes in drinking behavior covary across early adulthood and showed that changes in drinking behavior from 18 to 35 years of age tend to co-occur with changes in impulsivity (as well as neuroticism). While this analysis does not provide direct evidence for causal effects between these two factors, the findings suggest that the relationship between impulsivity and drinking behavior may be more complex than a simple causal relation and may be reflecting a mutually exacerbating relationship.

There is now enough evidence – provided particularly by studies on children of alcoholics as well as by studies on nonsubstance use–related addictions such as problem gambling, where the vulnerability mechanisms underlying addiction can be studied without the confounding effects of substance use – showing that impulsivity is indeed a risk factor for addiction. For example, studies on children of alcoholics, considered to be at a higher risk for future alcohol problems due to genetic vulnerability, have found that many of these children exhibit high levels of impulsive personality traits and behaviors, with some even showing that disinhibited traits mediate the relationship between family history of alcoholism and drinking behavior.

Studies on problem gambling have shown similar results than those in the substance use field, indicating that compared with nongambling controls, problem gamblers demonstrate increased scores on a range of impulsivity-related measures. Similar to findings in the alcohol, and drug use literature, impulsivity scores have also been shown to predict gambling symptom severity in clinical samples of problem gamblers, as well as community-recruited adolescents. Finally, several studies provide evidence for the hypothesis that impulsivity is a common risk factor for (or associated with shared vulnerability to) gambling and substance use problems, as well as other addictive behaviors and externalizing problems, such as antisocial behavior.

Although there is some research showing that impulsivity (or undercontrol) assessed early in childhood is associated with alcohol problems in early adulthood in men but not women, varied research has shown that men and women tend to report similar levels of impulsivity – this is not the case though if the impulsivity measure includes "aggressive tendencies" (such as the measure of constraint) on which men score higher – and similar associations between

impulsivity and later substance use or other addictive behaviors.

Sensation Seeking

Sensation seeking is generally defined as a strong need for stimulation, a low tolerance to boredom, and a willingness to take risks for the sake of having novel and varied experiences. Findings on the association between traits related to extraversion and substance misuse in clinical samples as well as community samples of adults have been somewhat inconsistent, with a number of studies indicating only modest associations between extraversion and drinking onset as well as increased levels of alcohol use. However, sensation seeking, a trait related but not equivalent to extraversion, has been shown to be more robustly and consistently related to substance misuse behaviors, especially binge drinking or heavy episodic drinking, particularly in adolescents and young adults. Indeed, a recent study has shown that in a sample of drinking college students, sensation seeking explained a significant amount of variance in alcohol-dependence symptoms, above and beyond that explained by the trait of extraversion as measured by the Neuroticism Extroversion Openness Five Factor Inventory (NEO-FFI). Research carried out by Cooper and colleagues and Stewart and colleagues have consistently shown that sensation seeking is associated with using substances for enhancement motives rather than for social or negatively reinforcing motives.

Longitudinal studies in North American as well as European samples have shown that sensation seeking is not only associated cross-sectionally with binge drinking but can also predict drinking rates and growth in drinking quantity by frequency during adolescence. Although findings are not as consistent as with alcohol use, some studies have shown prospective association between this trait and marijuana, tobacco, and hallucinogen use in adolescence. Most of the positive findings linking sensation seeking and future substance use have been found in adolescent or young adult samples, suggesting that sensation seeking might be an important factor in earlier stages of substance use initiation or experimentation, rather than in the continuation or compulsive use.

Although men tend to score higher on sensation seeking measures than women (especially during adolescence), most research shows that the association between high Sensation Seeking and substance use is significant for both men and women, with only a few studies suggesting that the association between sensation seeking and alcohol use outcomes may be stronger for adolescent boys than girls.

A "need for intensity" and sensation seeking have also been associated with problem gambling. Some studies have characterized pathological gamblers as having a low tolerance to boredom, being attracted to stimulating situations, and finding it difficult to complete tasks they find boring – all characteristics used to describe sensation seekers. However, although often hypothesized that by their very nature sensation seekers should be more prone to gamble, findings have been mixed. While several studies have reported high levels of sensation seeking in adult pathological gamblers, particularly those who bet at race-tracks or casinos, this has not been the case in younger problem gamblers or across all gambling activities. In fact, one study by Coventry and Brown has found that those who bet exclusively in an off-course betting office scored lower on sensation seeking than non-gamblers and the general population. Findings like these highlight the fact that gambling, and addiction generally, can't be viewed as a homogeneous activity or process and that different pathways to addiction as well as different profiles of addiction can be identified.

CAUSAL PATHWAYS TO ADDICTION

The evidence reviewed above implicating personality as an important factor in addiction is but a few of the several longitudinal studies, familial aggregation studies, as well as genetic and animal studies, which provide strong evidence for causal relationships between personality and addictive behaviors. In line with the four personality traits described above, the available evidence suggests at least four different developmental or causal pathways to addiction, in which the different personality factors play an important etiological role. It is proposed that these causal pathways are described as (1) the negative affect regulation pathway, (2) the stress-dampening pathway, (3) the poor behavioral inhibition and/or deviance proneness pathway, and (4) the reward sensitivity pathway.

The Negative Affect Regulation Pathway

Several studies have shown that many individuals engage in heavy drinking or substance use, as well as excessive gambling or eating, to regulate affect or emotional states. Also referred to as the "self-medication" hypothesis, many individuals report that they use substances to regulate or cope with negative affect, such as depressed mood or anxiety, and to forget about difficult situations. Although the negative affect regulation model is one of the most enduring etiological perspectives on addiction, it has been shown that it is highly dependent on intraindividual factors such as personality, as well as other factors such as expectancies, genetics, and environmental factors.

Inhibited traits have typically been implicated in models of negative affect regulation of addictive

behaviors. For example, hopelessness has been argued to reflect sensitivity to punishment and has been linked, by researchers including Sher, Cooper, and colleagues, to the development of alcohol use by using its analgesic properties to suppress feelings of negative affect. Fitting with this profile of addiction are numerous findings indicating that depression and negative affect and/or hopelessness generally precede addictive behaviors (although it is important to note that extended substance use and gambling can also result in increased depression or feelings of hopelessness), and recent evidence that the link between hopelessness and future substance use is mediated through the occurrence of depressive symptoms, and motivations for drinking that include coping with depression.

Anxiety sensitivity has also been associated with substance misuse for negative affect regulation, but specifically to relieve feelings of anxiety. Consistent with this are studies by Kushner and colleagues and Stewart and colleagues showing that AS is associated generally with coping motives for alcohol use, and studies showing that those high in AS use substances specifically to avoid or escape anxiety symptoms.

Accordingly, this pathway to addiction has been associated with late onset, a greater tendency to engage in addictive behaviors (i.e. use substances or gamble) in solitary contexts, and, specific to substance use, a predilection for alcohol, sedatives, and/or analgesics, as well as reporting lower enhancement motives for use.

The Stress-Dampening Pathway

Over the last 20 years, a large body of research has assessed individual differences in their response to the effects of alcohol and other drugs, which may put certain individuals at higher risk for addiction. First proposed by Sher and colleagues, the pharmacological vulnerability model of addiction proposes that individuals are at risk for substance misuse because they are especially sensitive to the reinforcing effects of substances and are therefore more likely to use substances as they experience greater effects from the substance.

Inhibited traits such as AS and low positive affect have been implicated in differential psychopharmacological effects of substances. AS has been associated with experiencing increased withdrawal symptoms, particularly those related to tobacco, and thus poorer cessation outcomes. Similarly, low positive affect has been associated, even after controlling for depression symptoms, with higher withdrawal symptoms in a sample of adults attending a smoking cessation clinic. However, studies specifically assessing the stress response–dampening effects of alcohol, have implicated AS as a determining factor. Often described as an arousal-accelerating factor, AS seems to not only render individuals susceptible to high levels of arousal in normal stressful situations, but also in response to acute and chronic drug withdrawal, physiologic states that are easily dampened by the pharmacologic properties of alcohol and benzodiazepines.

Several studies have found that individuals with a family history of alcoholism often have an increased sensitivity to the dampening effects of alcohol on stress response, with findings showing that personality factors related to anxiety and AS seem to play an important role. For example, individuals who are high on inhibited traits like AS have been shown to display reduced electrodermal activity to threat cues when moderate to high levels of alcohol have been consumed. Similarly, Conrod and colleagues found that men with higher self-reported levels of anxiety sensitivity experienced electrodermal response and heart rate dampening effects to aversive stimulation after alcohol administration, compared with low anxiety sensitive men. These findings were interpreted as showing a pharmacologic sensitivity that is produced by an interaction between anxious personality and sedative drug effects to produce a highly negatively reinforcing fear reduction. This is further confirmed by findings from O'Connor and colleagues showing that risk for alcohol misuse in men results from increased scores on AS in combination with the belief that drinking alcohol can reduce tension (i.e. tension reduction alcohol expectancies). This combination of factors – high AS, the belief that alcohol or drugs can reduce tension, and the heightened sensitivity to their pharmacological effects – together with the fact that chronic substance use will, with time, dampen or reduce the "tension-reduction" properties of the substance being used, leading to further substance use, might explain why this pathway is associated with substance use dependence or problems, rather than with substance use onset.

The Poor Response Inhibition Pathway

This pathway to addiction posits that individuals with high levels of impulsivity (or low levels of constraint) are more inclined to engage in deviant behaviors in general, including substance misuse and other addictive behaviors. This pathway to addiction has been frequently investigated and thus is well documented. There have been a few models that have attempted to explain the link between impulsivity and/or poor response inhibition and deviant behaviors as well as substance misuse. As early as the 1970s, Jessor and Jessor, and other colleagues, believed that it was the interplay and interdependence of three systems of variables – the behavior system, the personality system, and the perceived environmental system – which resulted in the engagement in problem behaviors or level of

behavioral deviance, of which substance use was considered only an indicator. Although emphasis is placed on deficient socialization as a major "instigator" or risk factor, their model highlighted the role temperament and personality traits, particularly those related to impulsivity, had in socialization and developmental processes. Two more recent models explicitly implicate impulsivity or deficits in self-regulation as key in the development of behavioral problems and substance misuse, as well as their comorbidity: the social deviance model, proposed by Sher and colleagues, and the psychological dysregulation theory, proposed by Tarter, Clark, and colleagues. Both highlight the interplay between individual and environmental factors, and refer to substance use as part of a more general deviant pattern of behavior, which usually begins in childhood, and can be exacerbated by poor socialization. However, while the deviance proneness model is firmly based on sociopsychological theory, and places greater emphasis on the role of poor socialization, the psychological dysregulation theory is based on psychobiological theory of human behavior, and places greater emphasis on genetic liability. Consistent with both these models, longitudinal studies assessing early onset alcohol problems show consistent associations between alcohol problems and a history of childhood antisocial behavior, poor school achievement, poor interpersonal relationships, heightened activity or attentional problems during childhood, and inadequate parenting. Furthermore, studies have shown that early "difficult temperament" characterized by high levels of disinhibition or impulsivity, in combination with poor parenting, leads to unsocialized behavior. Impulsivity has also been shown to be associated with substance misuse that is comorbid with antisocial behavior, while other disinhibited traits like sensation seeking have not. Recent findings, using structural equation modeling which make it easier to assess the comorbidity between disorders, as well as their longitudinal associations, have also provided support for this pathway to substance misuse. For example, one study demonstrated that adolescents high in impulsivity showed their susceptibility to increased alcohol use through conduct disorder symptoms, whereas adolescents high in sensation seeking showed a direct susceptibility to increased alcohol use and were only susceptible to conduct disorder symptoms as a consequence of their increased alcohol use. Furthermore, another study by Castellanos-Ryan and Conrod showed that while impulsivity was associated with an externalizing behavior factor, which accounted for the shared variance between measures of conduct disorder and substance misuse, as well as a specific conduct disorder factor, it was not associated with substance misuse that did not co-occur with other externalizing behavior problems in adolescence. Finally, a study by Khan and colleagues investigating the structure of psychiatric disorders in adults also showed that impulsivity (i.e. novelty seeking), but no other personality traits, accounted for a proportion of the comorbidity between dependence to substances (alcohol and drug) and conduct disorder. These results, and the high rate of co-occurrence between substance misuse and antisocial behaviors, lend support to the deviance proneness and the behavioral dysregulation models of substance misuse and also suggest that impulsivity, but not other personality traits, may play a key role in these liability models.

Recent studies which use behavioral or cognitive measures of inhibition, also provide support for this pathway to addiction, with findings consistently showing that deficits in self-regulation, assessed by increased commission errors on go/no-go or stop tasks, are associated with a range of behavioral problems, including conduct disorder, hyperactivity, and substance misuse. Moreover, Castellanos-Ryan and Conrod showed that poor response inhibition, as measured by increased commission errors in a STOP task, partially mediates the association between self-reported impulsivity and externalizing behaviors, including substance misuse and conduct disorder symptoms. These results indicate that the link between impulsivity and substance misuse is, at least in part, explained by a deficit in response inhibition that makes impulsive individuals more prone to engage in externalizing behavior in general.

Finally, further support for this pathway and a common genetic liability for deviant or externalizing behaviors comes from several studies showing common genetic liability for conduct disorder, substance use, behavioral undercontrol, as well as studies by Iacono, McGue, and colleagues, as well as Slutske and colleagues showing common genetic liability between early measures of social deviance and later externalizing disorders and substance misuse. Although it seems likely that a large number of genetic variants are implicated in externalizing and substance use behaviors, several common variants have been implicated in these behaviors and their comorbidity, with some studies suggesting that a significant portion of the genetic contribution to early onset problem drinking and other drug use is mediated by personality. For example, studies have shown that the serotonin transporter (5-HTT) and the low variant of the monoamine oxidase A (MAOA) are implicated in substance use disorders and other problem behaviors, as well as being associated with the personality trait of impulsivity and, in the case of MAOA, with neurocognitive measures of disinhibition. Other genes, such as the serotonin transporter polymorphism (5-HTTLPR), the DRD2 polymorphism, and the D4 dopamine receptor (DRD4) have been shown to be

associated with impulsivity or disinhibited personality and substance misuse.

Besides the high rates of co-occurrence or comorbidity with other problem behaviors, such as antisocial traits and behavioral problems as mentioned above, this pathway to addiction has been characterized by early onset, more severe levels of substance used (as well as of gambling), as well as undefined motives of substance use and a lack of specificity to substance or addictive behavior of choice (i.e. impulsivity has been implicated in a wide range of addictive behaviors and substances).

The Reward (and Positive Reinforcing Properties of Substances) Pathway

This pathway to addiction posits that those individuals scoring high on sensation seeking or related traits, such as novelty seeking, extraversion, or reward seeking, will engage in addictive behaviors motivated by their positive reinforcing properties or to enhance positive feelings or emotions. Supporting this pathway to addiction are several studies, including those by Pihl, Peterson, and colleagues, that show that heightened physiological sensitivity to substances, such as accelerated heart rate after alcohol consumption, is associated with increased risk for alcoholism and substance misuse. Similarly, compared with controls, men with a family history of alcoholism have been shown to experience a heightened subjective stimulant response to amphetamine. In another study, college students with poor inhibitory control reported heavier drinking and exhibited enhanced subjective stimulation during the ascending limb of the blood alcohol curve. However, although disinhibited traits like impulsivity and sensation seeking have both been associated with increased and problematic substance use, only sensation seeking has consistently been associated with enhancement or reward-related motives for substance misuse. The motivation for positive reinforcement from substances has been shown to be founded on the neuropharmacological effect substances have on the brain centers involved in basic reward mechanisms, that is, substances stimulate mesolimbic dopamine activity and increase activity in brain opioid systems. Consistent with this, are studies showing that individuals who are high on disinhibited personality traits such as sensation seeking tend to be more sensitive to drug-induced reward and to display heightened heart rate response to alcohol, as well as experience more positive feelings in general after alcohol intoxication. Thus, the link between sensation seeking and substance use could be partly explained by the association between sensation seeking and this heightened response to the reinforcing properties of substances. Another possible explanation of the association between sensation seeking and substance misuse is offered by Leyton and colleagues, who found, in an exploratory study using positron emission tomography (PET), that sensation seeking (as measured by "exploratory-excitability," a subdimension of Cloninger's novelty seeking) was associated with greater amphetamine-induced dopamine release in the ventral striatum and drug wanting. The authors suggested that amphetamine consumption elicits a dopamine-mediated appetitive state which is stronger for those high in sensation seeking.

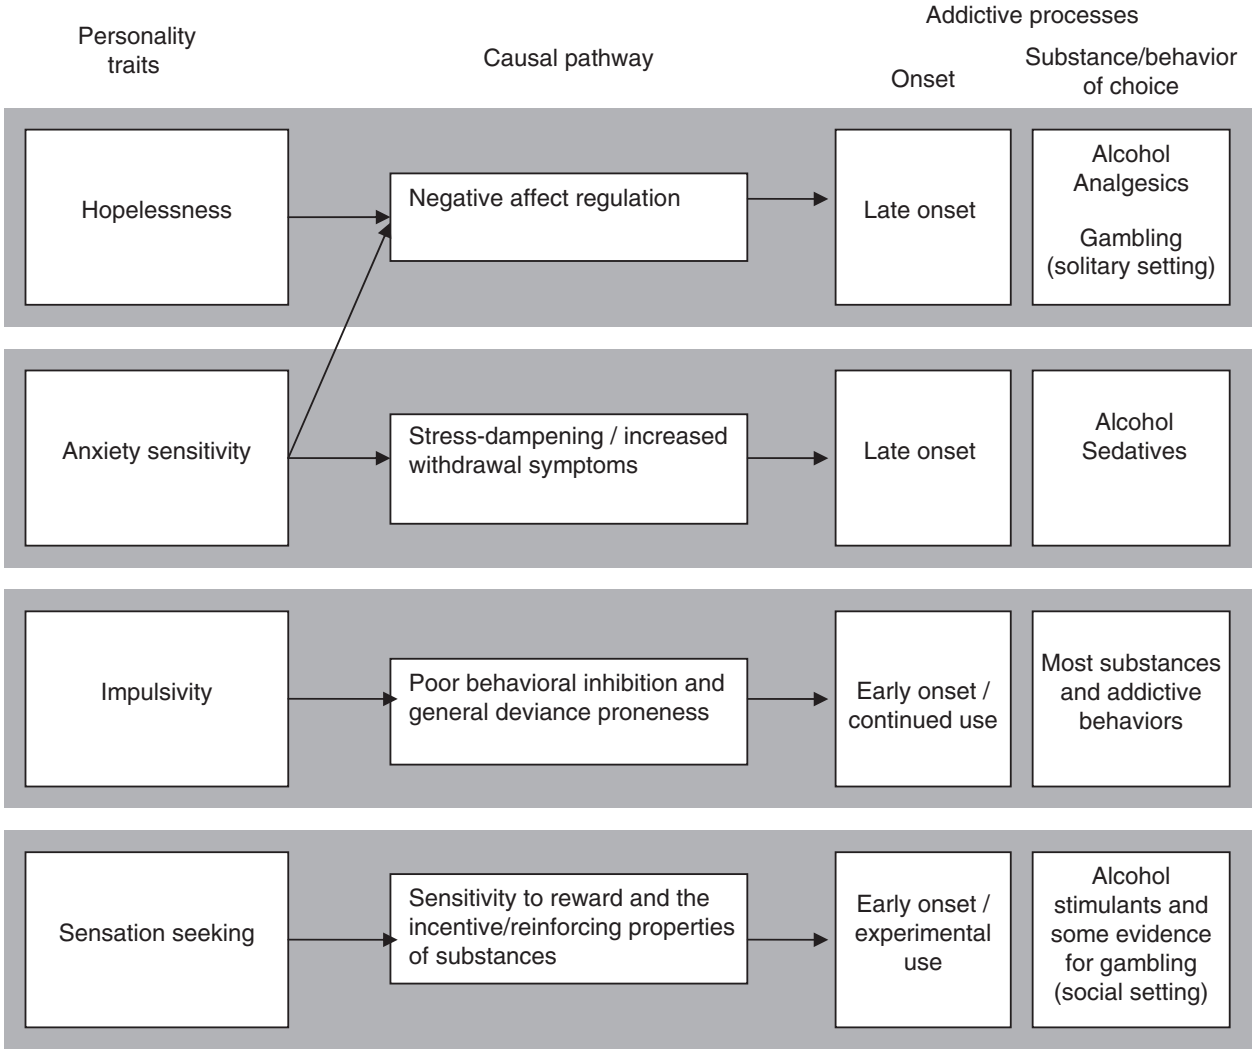
However, it is important to note that sensation seeking has also been linked to risk-taking in general. Accordingly, sensation seeking has been associated with general or nonsubstance-related measures of reward sensitivity/dependence, particularly in studies looking at gambling behavior. Moreover, a recent study by Castellanos-Ryan and Conrod has shown that the association between sensation seeking and binge drinking in adolescence was partially mediated by reward sensitivity, as measured by a (monetary) rewarded go-no-go task, while other measures of disinhibition, such as impulsivity, were not.

SUMMARY AND IMPLICATIONS

The development of addictive behaviors seems to be multidetermined and multiple risk factors for addiction have been identified, such as genes, individual differences in sensitivity to the reinforcing effects of substances, age of onset, and the presence of deviant peers, as well as conduct and emotional problems. However, it is also clear that some individuals, sometimes subjected to the same general risk factors, go on to develop an addiction and some do not. As reviewed, a number of research findings suggest that different pathways to addictions exist, where psychological factors such as personality traits, play an important role. These different casual pathways to addiction suggest that personality traits are related to substance misuse, and possibly other addictive behaviors, through different motivational processes, and are associated with different profiles and/or patterns of addiction. For example, while findings support that anxiety sensitivity is associated with substance misuse through its association with the anxiolytic or stress-dampening effects of specific substances, sensation seeking is associated with the initiation of substance use behaviors as well as substance misuse through the mediation of reward sensitivity and the positive reinforcing effects of certain substances. On the other hand, impulsivity seems to be associated with a large number of addictive behaviors and processes through a general inability to inhibit responses or behavior, while findings seem to

suggest that hopelessness is associated with substance misuse through a motivation to cope with high levels of negative affect.

Displayed graphically in Fig. 28.1 are the four hypothesized causal pathways to addiction reviewed in this chapter. Described in this figure are the distinct personality traits associated with each pathway, as well as the underlying mechanisms that help explain the way in which these personality traits are related to addictive behaviors. Included in Fig. 28.1 are also what one could refer to as addiction profiles – e.g. early or late onset, and specific substances or addictive behaviors – most commonly associated with each of the four pathways. The figure shows how individuals high in hopelessness are likely to engage in addictive behaviors through their need to manage or reduce their negative affect, while individuals high in anxiety sensitivity engage in addictive behaviors, primarily substance use, because of their sensitivity to the arousal dampening effects that are very negatively reinforcing to those who fear them. Both these pathways to addiction are associated with later onset, are more likely to lead to gambling or using



Note: This figure shows that individuals high in hopelessness engage in addictive behaviors that usually have a late onset through their need to regulate their negative affect. Their drugs of choice are usually alcohol or any other with analgesic properties. Individuals high in anxiety sensitivity also engage in late onset addictive behaviors, such as misuse of alcohol or substances with sedating properties, because of their sensitivity to their arousal dampening effects. Those high on the trait of impulsivity tend to engage in a range of addictive behaviors and have a more severe addiction profile, through deficits in response inhibition. Individuals high in sensation seeking, due to their specific sensitivity to reward, including alcohol- or drug-induced reward, are likely to engage in early onset or experimental substance use, especially with those with psycho-stimulant properties, or gambling in social settings.

FIGURE 28.1 Personality-related causal pathways to addiction.

substances in solitary contexts, and opting for substances with analgesic effects, in the case of hopelessness, or anxiolytic effects, in the case of anxiety sensitivity.

With regard to the more disinhibited pathways to addiction, Fig. 28.1 shows a third pathway indicating that those high on the trait of impulsivity are likely to engage in a range of addictive behaviors, as well as to engage in continued or severe addiction, through deficits in response inhibition. The fourth pathway illustrates how individuals high in sensation seeking through their specific sensitivity to reward, including alcohol- or drug-induced reward, are likely to engage in early onset or experimental substance use, develop drug-taking patterns to enhance psychostimulation (e.g. binge drinking), and/or engage in gambling, particularly in casinos or race-tracks or other social contexts, where emotions related to gains and losses are heightened. Although these two pathways are similar in that they are both related to early onset of addictive behaviors, they differ in a number of ways, one of the most important being that individuals high in impulsivity, as opposed to high sensation-seekers, in the context of substances that produce potent psychostimulant reward, are not protected by an intact response inhibition system and more easily develop compulsive (or uncontrolled) self-administration.

It is important to highlight that these pathways to addiction, like personality dimensions, which should not be considered as discrete but continuous measures, are not mutually exclusive and can overlap in some individuals. Thus, for example, individuals might experiment with alcohol or other substances in adolescence to satisfy their need for rewarding, novel or intense experiences, but might then be unable to control their substance use due to their impulsivity, and thus, their inability to self-regulated behavior.

Although addiction is a complex phenomenon, involving a range of biological, environmental, and psychological factors, the evidence reviewed identifies personality traits as important etiologic and moderating factors. This evidence makes it clear that addiction is not homogeneous and thus highlights the need to either tailor intervention approaches to specific profiles of addictions or to target personality profiles directly along with treatment as usual. The evidence also identifies personality traits or the different pathways to addiction as key targets for prevention efforts. Although most current prevention approaches target behaviors, such as substance use or gambling, directly, it seems more logical that interventions would want to target liability factors rather than behavior. Prevention models that target liability, like the ones described in this chapter, rather than specific behaviors are relevant to those engaging not only in the specific behavior targeted (i.e. drug use) but also in other addictive behaviors or maladaptive behaviors related to the personality profiles (i.e. such as gambling or antisocial behaviors in the case of impulsivity). Indeed a personality-targeted approach, targeting specific pathways to addiction, has already been shown to be effective in the prevention/early intervention of substance misuse, as well as other behavioral problems, in adolescence and adulthood. Although the effectiveness of this approach in the prevention or treatment of nonsubstance-related addictions has yet to be assessed, the consistent results obtained in the prevention of alcohol and drug misuse so far identifies this approach as promising and cost-effective, which can only improve current efforts in tackling substance use problems and other addictions so prevalent in society.

SS	sensation seeking

Glossary

Affect Emotion or subjectively experienced feeling and its influence on behavior.

Anxiety sensitivity a personality trait characterized by fear of anxiety-related physical sensations due to an unrealistic expectation that they could lead to "catastrophic" consequences such as loss of physical or mental control.

Arousal a state of alertness and of high responsiveness to stimuli.

Comorbidity the simultaneous presence of two conditions or disorders in a patient or participant, e.g. substance use dependence and depression.

Cross-sectional a study design which provides information on the characteristics of, and statistical relationships between, variables at a specified moment in time.

Disinhibition the inability to restrain or prevent a behavior or impulse (opposed to inhibition).

Extraversion a personality factor characterized by interest in the outside world rather than the self, associated with traits such as sociability and assertiveness.

Factor analysis a statistical technique which examines the internal structure of a set of variables by analyzing the correlations between them, to identify underlying dimensions or factors.

Go/No-go task a task in which stimuli are presented in a continuous stream and participants are asked to either perform a motor response (go) or withhold a response (no-go) to specific stimuli.

Hopelessness a personality trait characterized by a tendency to have negative expectations concerning self and future life.

Impulsivity a personality trait often characterized by a deficit in reflectiveness and planning, rapid decision-making and action, and a failure to inhibit a behavior that is likely to result in negative consequences.

Inhibition the act or process of restraining or preventing a behavior or impulse, or the state of being "restrained."

Longitudinal a study design in which the same sample of research participants is examined repeatedly over time (over several time points).

Positron emission tomography medical imaging technique that produces three-dimensional images of the brain. This technique monitors regional cerebral blood flow in the brain by recording the emission of gamma rays when radioactively labeled glucose or some other substance introduced into the bloodstream is metabolized by neurons as they are activated.

Sensation seeking a personality trait characterized by a strong need for stimulation, a low tolerance to boredom, and a willingness to take risks for the sake of having novel and varied experiences.

Stop task similar to a go/no-go task, but one in which most stimuli require a motor response ("go" response), and a less frequent "stop" or "no-go" stimuli is presented immediately after the "go" signal, to which participants are asked to interrupt or inhibit the already-initiated motor response.

Spirituality and Addiction

Thomas J. Johnson, Jean L. Kristeller

Indiana State University, Terre Haute, IN, USA

OUTLINE

BACKGROUND

Definitions of Religiousness and Spirituality

Defining religion or religiousness and spirituality (RS) has historically been a contentious issue, and it remains so today. Traditionally, functional definitions of religion focused on the why of religion; what does religion do for an individual or a group? Suggested functions have included supporting the social order, offering individuals a sense of meaning and purpose, prescribing codes of right living, or defending against the anxiety associated with our own mortality. Structural definitions focused more on what religion looks like; what are the necessary components or elements that make up religion? Such definitions often include some concept of ultimate goals, values, or truths and/or belief in the supernatural or in beings, powers, or principles that are more powerful, permanent, and/or transcendent than what humans typically encounter in the material realm.

Spirituality is being increasingly understood as a universal human capacity that involves experiencing a sense of meaning and purpose, a feeling of inner peace, feelings of awe, compassion toward others, and a connection with the sacred. Spiritual intelligence, although somewhat controversial as a construct, has been proposed as a way to conceptualize the pervasiveness of this capacity, the apparent range in regard to the degree individuals experience it, and the potential for cultivating such a capacity. One way that religion can be viewed is as culture-specific means to structure the needs engendered for understanding, codifying, and sharing the experiences labeled as spiritual.

Consistent with this, another contemporary approach is to equate spirituality with a search for the sacred (i.e. the ultimate, transcendent, or holy) and religion with

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00029-2

a search that occurs within some organized faith tradition. A related tendency is to equate spirituality with individual experience and religion with group traditions and rules. However, many religious traditions have been based on the spiritual experiences of their founders, and the stated goal of many faith traditions is to foster the spiritual development of adherents of that faith. Thus, RS are often seen as overlapping constructs rather than as opposites. Consistent with such a model, in national surveys in the United States, the majority of individuals report being both religious and spiritual, some see themselves as being religious but not spiritual, and a growing percentage report being spiritual but not religious. A few studies in the United States suggest that individuals in addiction treatment may be more likely than the general population to identify themselves as spiritual, but not religious, but broader samples are needed to determine how generalizable this finding is. Rates of church attendance and self-identification as being religious are generally lower in Europe than in the United States, but differences by country exist. In addition, in some European countries, spirituality is often conceptualized as related to Existential philosophy and questions of meaning in life.

Regardless of the relationship between religious belief and spiritual experience, it is important to recognize the variability that exists across individuals in the degree to which they identify with or experience these domains. Within the religious context, some people may identify themselves as religious but neither attend religious services nor espouse particular beliefs, other than general ones, such as in the existence of God; whereas for others, their religious beliefs and practices are core to their sense of self. Similarly, spiritual experience may vary from relatively common experiences such as the sense of well-being from walking through a natural setting or the feelings engendered while praying, to the intensity of a transformational or enlightenment experience that may occur only once in a lifetime.

In contemporary social science research, both spirituality and religion are commonly treated as multidimensional constructs. While global measures of one or the other can sometimes be useful, such research tends to focus on multiple aspects of RS. Key dimensions that have been identified and/or investigated in multiple studies include public religious behavior, private religious behaviors, importance of religious beliefs/faith to other aspects of self, spiritual or religious struggle, a sense of inner meaning and peace, the importance of values in shaping one's decisions, and the occurrence of mystical or transcendent experiences. Both spirituality and religion can each have both positive and negative relationships with substance use and abuse; furthermore, these relationships may differ depending on the type of substance involved (alcohol, smoking, other drugs of potential abuse, and compulsive overeating).

Psychoactive Substances and Religion

Psychoactive substances have been used in religious ceremonies for thousands of years. Sometimes substances were used to facilitate intense spiritual or transcendent experiences, such as use of hallucinogenic drugs in shamanistic ceremonies. Hallucinogens and other drugs were used to facilitate altered states of consciousness that the cultures engaging in these practices interpreted as entering or contacting the spirit world. Sometimes drugs were used along with other practices that were thought to facilitate such contact, including drumming, dancing, exposure to the elements, or abstaining from food, drink, or sleep for extended periods of time. Upon entering the spirit world, the Shaman could attempt to battle, banish, or appease spirits responsible for disease or other problems.

The use of substances to alter states of consciousness continues today. The Native American Church, incorporated in 1918 as a combination of native and Christian beliefs and practices, continues to use Peyote in highly structured rituals, but members generally do not appear to use the drug outside of the ceremonial context. Some Rastafarians use marijuana both as a part of religious ceremonies and outside such ceremonies. However, in both contexts marijuana is thought to facilitate spiritual wisdom and understanding of God. Several social movements in the second half of the twentieth century viewed drugs as part of a path to enlightenment and both inner and interpersonal peace. The psychedelic movement of the late 1960s advocated use of marijuana and lysergic acid diethylamide (LSD), while the Rave scene of the late 1980s and early 1990s combined use of 3,4-methylenedioxymethamphetamine (Ecstasy) with extended periods of dancing to loud, fast paced music. Sociologists do not agree on how to best classify or label such movements, but some have argued that they have quasi-spiritual elements.

Other religious uses of psychoactive substances have included giving substances as offerings to gods or spirits or assigning symbolic value to substances, such as association of wine with the blood of Christ in the Christian Eucharist. In contemporary settings, wine is used in religious rituals by Jews and some Christians. The amount of alcohol consumed in such rituals is usually not enough to have a noticeable effect on an individual. An exception is the Jewish holiday of Purim, where tradition dictates that one consumes alcohol to the point of confusion. Some faiths, especially Islam, some Buddhist traditions, and a number

of conservative Christian denominations (Latter Day Saints, some Baptists and Methodists, some Pentecostals) prohibit the use of alcohol as well as many other substances. Such prohibitions have been suggested as a way to mark religious boundaries or distinguish new religious movements from previously existing faiths. Faiths that prohibit alcohol use tend to have higher rates of abstinence than in the general population. However, in some, but not all, faiths that prohibit alcohol use, members who do drink may be at increased risk of alcohol abuse or dependence. Research in this area is complicated by the fact that not all members of such faiths are aware of or agree with their denomination's position on use of alcohol or other substances.

Religious and Spiritual Views on Addiction

In many Christian denominations, substance abuse problems have been labeled as sin. The nineteenth century approach to sinners of all types was often to try and persuade them to repent via threats of hellfire and damnation. While such approaches have not entirely disappeared, even in the nineteenth and early twentieth century, there were groups who took a more educational approach. The Emmanuel Movement started in 1905 in Boston, Massachusetts and attempted to use a combination of religious education and contemporary psychology in treating addiction and other problems. Today, Christian denominations vary widely in how they conceptualize sin. While some still attempt to inspire guilt to promote change, many others view sin as anything that comes between a person and God, and therefore focus their efforts on reconnecting a person to God. A related notion, common in various monotheistic faiths, is that addiction is a form of idolatry, placing something before God. Thus, the range of religiously based moral and theological positions on addiction is broad and complex.

Jewish writers note that alcoholism was once considered to be a problem that simply did not happen among Jews. While rates of alcohol dependence are typically lower among Jewish Americans than in the population at large, Jews can and do have problems with alcohol. Thus, a number of Jewish writers have worked to increase awareness of and provide supports for Jewish alcoholics. Authors from several other faith traditions have also expressed that when a religious group believes that drug or alcohol abuse is not likely to happen among their members, this can contribute to either a tendency to ignore such problems or to shun members who violate implicit or explicit norms, either of which could make it more difficult for such individuals to receive appropriate help for substance problems.

During the twentieth century, a common spiritual view of addiction has been that it is a spiritual quest gone wrong, stemming from individuals trying to find God in a bottle or seeking spiritual experiences via drugs. The prescribed solution then, is often giving the addict the correct religion or spirituality, which is, of course, defined differently by different groups. Much of the literature on RS and addiction has been in the form of personal narratives or case studies. However, even these reports suggest that there is no one single model or sequence for how RS is related to addiction or recovery. Some people may indeed begin using drugs as part of a spiritual search, but for others substance use might begin in a variety of ways, but become related to spirituality only when the substance problem becomes severe enough to interfere with a persons' spiritual or religious functioning.

In the United States, relatively few clergy from any denomination have had any training regarding addiction. In response to this the National Association for Children of Alcoholics (NACOA) and the National Institute on Alcohol Abuse and Alcoholism worked together to begin to create a training curriculum for clergy. NACOA has continued this work with some support from the Substance Abuse and Mental Health Services Administration, resulting in a variety of monographs and programs.

RESEARCH ON THE RELATIONSHIP BETWEEN RS AND SUBSTANCE USE

Numerous studies have identified inverse relationships between RS and substance use or substance use disorders (SUDs). Higher levels of religiousness, as measured by frequency of attending religious services or self-rated importance of religion, are generally associated with lower levels of substance use. However, prior to the 1990s, most such studies had used rather simplistic single item measures (e.g. frequency of religious service attendance, personal importance of religion, etc.). In contrast, contemporary research in the psychology of religion recognizes the importance of more sophisticated measurement of multiple aspects of RS.

The strength and even the direction of the relationship between RS and substance use can vary by culture, race, religious denomination, gender, and type of substance being used. For example, in the US personal religious commitment is generally inversely related to the amount of alcohol consumed or likelihood of being a cigarette smoker, but one national study found that in Lutherans, strength of personal religious commitment was actually positively related to heavy drinking. It is

not clear if findings such as this are related to aspects of religious belief systems, or if they could be due to other cultural traditions that might be correlated with religion (e.g. German family origin in American Lutherans, etc.). One specific aspect of religious beliefs that has been statistically linked to increased risk is the belief that God is harsh and punitive, as opposed to loving and forgiving. Individuals who hold a punishing view of God seem to show an increased risk for SUDs, but the nature of the causal relationship, if any, between these two variables is not yet clear.

Since the 1990s, more studies have attempted to identify mediators of the relationship between RS and substance use to clarify how RS might actually causally impact substance use. Beliefs about or attitudes toward substances, such as the belief that drinking alcohol is a sin, have some support as mediators, but the impact of beliefs may not be as strong as other factors, such as social influences or effects of RS on well-being. Some reviewers have suggested that RS beliefs may be more important in determining whether or not a person uses a particular substance than in affecting how much or how often a substance is taken among users. Furthermore, the impact of beliefs also appears to differ by religious denomination. In addition to the general finding that beliefs do not always predict behavior, there are a variety of reasons why beliefs about substances might not always show up as a strong predictor of the relationship between RS and substance use. In studies that collapse across denominations, the effect of beliefs for those in denominations that proscribe alcohol use might be diluted by the effects in denominations where such proscriptions do not exist. Further, averaged across all denominations, clergy in the US tend to believe that SUDs are a problem in their congregations, but seldom preach or offer information about substance use. This may contribute to the lack of knowledge of denominational policies regarding substance use evident in members of some denominations.

There is considerable evidence supporting the role of social influences as a mediator of the relationship between RS and substance use and SUDs. Social influences examined across studies have included modeling of use and nonuse behaviors, perceived norms for peer use, and access to substances. Both beliefs and social influences may affect substance use in part by reducing motivations to use substances as a way to have fun or socialize. Social influences also seem to have a direct effect on use, perhaps via reducing access to substances. It is also possible that some individuals self-select into particular peer groups based on their religious beliefs or patterns of substance use.

Another potential mediator of the relationship between RS and substance problems is well-being. Religious involvement tends to be associated with higher levels of well-being and positive affect, greater sense of purpose and meaning in life, and lower levels of negative affect. Thus, by enhancing well-being, RS may reduce the likelihood that individuals will use substances as a coping mechanism. There is in fact evidence from several studies that religious involvement reduces (moderates or buffers) the effects of stress on substance use. However, many of the studies that have focused on purpose or meaning in life used measures that are heavily confounded with depression, making it difficult to determine whether meaning in life is the key mediating variable, or some more general aspect of well-being. A number of other possible mediators have more limited support, including viewing the body as sacred and therefore not to be desecrated by unhealthy behaviors; helping others; and a sense of self-efficacy in resisting temptation.

Religious or spiritual struggles represent individuals' attempts to maintain or transform their connection to the sacred in the face of doubts, external stresses, negative life events, interpersonal conflicts within their faith community, or other problems. While doubts and struggles may be a common part of RS development, struggles seem to be particularly problematic when they persist and are not resolved over time. Substantial evidence connects struggles to negative affect and depression and a growing body of research indicates that struggles can also be related to SUDs. However, the direction of causality involved in the relationship between SUDs and struggles is not yet clear, and in fact may differ based on denomination or other factors. While some evidence supports religious and spiritual struggles as leading to the development of SUDs, in people coming from a denomination that proscribes alcohol use, using alcohol could itself be the cause of internal (e.g. feelings of guilt; self-condemnation) or interpersonal (e.g. criticism from co-believers, etc.) struggles.

RS AND MUTUAL HELP

Historically, religious organizations were among the first groups to attempt to provide treatment or support for individuals with SUDs. The Prohibition movement in the United States in the late nineteenth and early twentieth century was led by a vigorous coalition of primarily Protestant churches, growing out of concern related to the increasing social problems associated with virtually unregulated availability of alcohol. The development of mutual help groups, where addicts

help other addicts, has also been traced to religious movements as far back as the late eighteenth century.

Alcoholics Anonymous

The most well-known and widely available mutual help group is Alcoholics Anonymous (AA), founded by individuals who had been affiliated with the Oxford Group, an early twentieth century Evangelical Protest Christian movement. The founders of AA attempted to remove some of the more overtly religious elements of the Oxford Group, but aspects of that movement remain in AA practices such as the personal moral inventory, having a spiritual awakening, and spreading the movement to others. Twelve-step programs have also been developed for other substances (e.g. Narcotics Anonymous, etc.) and for behavioral addictions such as sex, gambling, and overeating. Most published research on mutual help has focused on AA. The dropout rate in AA is high, but exact rates are difficult to determine due in part to the organizations' emphasis on anonymity of members. Among individuals in treatment, degree of involvement in AA is a good predictor of positive outcome, but court mandated AA does not appear to be effective. Meta-analyses suggest a moderate effect size for the relationship between AA involvement and abstinence.

The role of spirituality in AA is widely cited, but empirical studies attempting to identify mediators of the effects of AA have not been able to document that having a spiritual awakening or other RS constructs explain the positive effects of AA. Rather, evidence supports a variety of constructs such as enhanced self-efficacy, increased motivation for abstinence, and finding a nondrinking peer group, as being the active ingredients by which AA helps some members. It is possible that the lack of evidence for RS mediators is due to existing studies doing a poor job of operationalizing and measuring RS in AA, so future work with more sophisticated measures would be helpful. Qualitative work identified an increased sense of spirituality and/or 'turning power over to a higher being' as an active component in the value of Overeater's Anonymous for individuals struggling with a pattern of compulsive or binge eating, but quantitative studies testing for statistical mediation are needed. Atheists and agnostics are less likely to affiliate with AA than individuals who have theistic beliefs. However, if atheists and agnostics do attend, they appear to derive as much benefit from the program as theists do. Some individuals have a negative response to AA because they view AA as being in conflict with their pre-existing religious beliefs. Some such individuals appear to affiliate with secular mutual help groups when those are available, while others may find help through mutual help groups specific to their faith.

RS and Other Mutual Help Groups

Following the spread of AA around the world, other mutual help groups were developed, often in reaction to the spiritual elements of AA. Secular groups such as Life Ring and SMART Recovery have attempted to remove spiritual elements from their programs. Perhaps paradoxically, some religiously committed individuals have been attracted to secular programs because they view AA spirituality as inconsistent with their personal religious faith. Other religious individuals have developed mutual help groups specific to their faith, including Catholic, Jewish, and Evangelical Protestant variations on the 12 steps. One of the most recent and widespread of these groups is Celebrate Recovery, a Christian recovery program founded in California in 1991. This program has spread worldwide, and is most popular in Evangelical and some Pentecostal churches. At present there is relatively little empirical research on either secular or faith specific mutual help programs. The Faces and Voices of recovery website maintains a list of secular and spiritual or religiously based recovery resources and mutual help groups, including the Buddhist Recovery Network; Jewish Alcoholics, Chemically Dependent Persons and Significant Others; and Celebrate Recovery.

RS IN THE TREATMENT OF SUDS

Meditation

In contrast to requiring abstinence or exerting self-control in the face of temptations, meditative or contemplative practices are intended to engage a higher level of awareness of the chain of addictive behaviors, thoughts, and feelings, as well as a gradual disengagement of the mind from desire for the addictive substance and related effects. Meditation practice can be grouped into three general types: concentrative, mindfulness, or guided. In concentrative practice, such as transcendental meditation (TM) or some Christian contemplative prayer practices, a word, sound, or mantra (often spiritually associated) or brief prayer is repeated to oneself. In mindfulness or Vipassana practices, a quality of quiet, detached awareness is cultivated through awareness of the breath or open, but nonreactive, awareness of whatever arises into consciousness. In guided practice, this quality of nonreactive awareness is directed toward a particular target, such as cravings, the quality of experience, or associated thoughts or feelings. Awareness of the breath, an aspect of many practices, is spiritually poignant; the word spiritual is derived from the Latin *spiritus,* which shares the root with *inspiration,* to breathe in. In Chinese (and Japanese) the word for spirit is *chi/qi* or *ki*, also the word for breath. In Jewish meditation,

incorporating the breath both metaphorically and as part of repetitive prayer is viewed as a way of taking in the spirit of God.

Even though contemporary meditation practices used for therapeutic purposes have largely been secularized, the traditional foundation for such practices was a spiritual/religious context in which it was understood that transformative processes were available to the serious practitioner. Furthermore, evidence suggests that even the secularized programs, such as Kabat-Zinn's mindfulness-based stress reduction program (MBSR), may increase a sense of spiritual well-being. Research over the last few decades has supported the value of a range of meditative practices for addressing and managing addictive behavior, and within the context of even relatively brief practice. A number of studies have investigated the effects of TM on both alcohol and drug dependency, including smoking. Use of alcohol and drugs appears to decrease, generally in relation to the amount of practice that is sustained.

Marlatt and his colleagues investigated two different formats to address drug and alcohol intake, within several different populations, including prison populations prior to release. Best known, and most easily translatable into general application, is his mindfulness-based relapse prevention (MBRP) program. The MBRP program melds his work on relapse prevention with principles of Buddhist psychology, including practices intended to cultivate a heightened sense of compassion and well-being. Although not explicitly engaging religious or spiritual themes, MBRP is intended to evoke spiritual engagement and cultivate these capacities. The other meditative context that Marlatt studied immerses individuals for a week within a silent traditional Vipassana retreat, developed by S.N. Goenka, a Vipassana teacher from Burma who has taught widely in the US and in India. This program has shown positive effects when used in a prison context, both in India and in the US. Notable in both programs is a flexibility in goals, such that abstinence is not considered the only optimal goal in regard to continued substance use. Rather, cultivating a great sense of control and wise choice is considered possible. This flexibility is also a hallmark of the mindfulness-based eating awareness training (MB-EAT) program developed originally for individuals with binge eating disorder. In contrast to Overeaters Anonymous, which maintains an abstinence model relative to certain types of foods, MB-EAT emphasizes cultivating awareness of "inner wisdom" to guide better food choices in regard to quality and quantity of food and the eating experience. Spirituality is engaged in this context, in regard to both the meditative experience and accessing a "higher" self to create better eating patterns. Evidence to date supports the value of MB-EAT in reducing binge eating and improving a sense of self-regulation.

Spiritual self-schema (3-S) therapy, while drawing on Buddhist principles and incorporating mindfulness meditation practice, is also tailored to each participant's own spiritual and religious beliefs. A variant of 3-S therapy, 3-S+, has been developed specifically for drug users who are HIV positive. When used in treating a group of HIV+ cocaine addicts, participants reported a greater sense of inner peace, increased spiritual faith, and a feeling of God's presence. In a randomized trial, impulsivity and addictive behaviors markedly decreased, and individuals tended to ascribe their improvement to both their mindfulness practice and to a deepening of their spirituality. Importantly, treatment manuals are available for both MBRP and the 3-S family of treatments, which should increase their dissemination and support further research on their efficacy with different populations.

Twelve-Step Facilitation Therapy

Twelve-step facilitation therapy (TSF) is a manualized therapy that focuses on helping the client become involved with a 12-step group and work the first three steps. In a large-scale national study of three manualized treatment approaches for alcoholism, TSF did at least as well as motivational enhancement therapy and cognitive behavioral therapy. TSF has also been explored in treatment of opiate and cocaine dependence, with at least preliminary evidence of benefit. While the first three steps addressed in TSF do include spiritual elements (believing in and surrendering to a higher power), there is as yet no strong evidence that religious or spiritual components of the intervention account for treatment effects.

Other RS Practices in Treatment

Prayer is often used in both twelve-step and faith-based (FB) (see below) programs, but relatively little research exists on how or if different types of prayer are related to treatment outcome or recovery. Complicating the picture is that there are a many different types of prayer. Petitionary prayer asks for God's help. Ritual prayer involves rote repetition of specific prayers. Intercessory prayer involves petitioning God to help some other person. One randomized trial of intercessory prayer found no difference between control participants and alcoholics who were being prayed for.

Some professionals working with individuals from a specific faith tradition have incorporated rituals or other elements specific to that tradition into the treatment process. For example, treatment programs for Native Americans may incorporate traditional symbols such as the medicine wheel, or traditional practices such as dancing and/or drumming. In some group

sessions an eagle feather is passed among the group members and whoever currently holds the feather is entitled to speak before the group. The published literature on spirituality in psychotherapy contains examples from other faith traditions, including Judaism and Christianity.

Given the interpersonal conflicts and complications that can occur in the lives of individuals struggling with addictive behaviors, several authors have suggested that forgiveness interventions may be helpful in addiction treatment. Early research in this area is promising, but more work is needed, because forgiveness, like prayer, is multifaceted. Forgiveness interventions can focus on forgiving someone else, forgiving one's-self, forgiving God, or asking for forgiveness by God.

Some studies have shown changes in various aspects of spirituality to occur over the course of addiction treatment, but more work is needed to establish that these changes mediate treatment effects. Studies have generally suggested that clients are open to discussion of spiritual issues in treatment, although this is liable to vary with the clients' specific faith tradition, specific type of addiction problem, or other client or cultural characteristics.

FAITH-BASED PROGRAMS

As noted above, religious groups have long offered treatment programs and various types of social services to individuals with substance abuse and other problems. For example, the Salvation Army worked with substance abusers from the very beginning of the organization. The House Personal Responsibility and Work Opportunity Reconciliation Act of 1996 (HR 3734) included a provision for Charitable Choice, which allowed states to contract with both secular and sectarian FB groups to provide various types of social services. Since that time, Faith-based Organizations (FBOs) have received considerable attention from politicians, researchers, and the media. Focus on addiction services was heightened with 2003 access to recovery (ATR) program, which was touted as expanding consumer choice and increasing availability of addiction treatment and recovery support services (e.g. child care, employment services, case management, etc.). States receiving ATR funding were expected to contract with both FB and secular providers.

Supporters of FBOs noted that FB groups often work with populations that are marginalized and have limited access to conventional programs, sometimes due to geographical, cultural, or financial barriers. Criticisms of FBOs have included the concern that ATR and Charitable Choice would violate separation of church and state, as well as the concern that government regulations and paperwork requirements would actually interfere with FB programs and lessen their availability or effectiveness. Early proposed versions of Charitable Choice attempted to prevent states from requiring specific training for individuals providing addiction services. Such proposals received stinging criticism from the National Association of State Drug and Alcohol Abuse Counselors and the National Association of Alcohol and Drug Abuse Counselors, so that by 2006 there was general agreement that individuals providing addiction treatment in both secular and FB settings should be held to the same level of professional accountability. Perhaps the most overlooked issue regarding FB programs has been the question of how effective FB treatment and social services programs are. Supporters claimed that FB programs would be more effective than secular programs, but what little evidence is available regarding efficacy of FB social services does not support this contention.

Several factors cloud the picture on the efficacy of FB treatments for addiction. First, there is no commonly accepted definition of what type of treatment program counts as FB. Published studies on FB programs typically allow organizations to self-identify as FB. Secondly, organizations that self-identify as faith-based differ widely in terms of the degree to which religious elements influence their organizational structure and the services they offer, as well the degree of explicit and implicit religiousness present in the organization. In studies conducted over the first decade of the twenty-first century, relatively few self-identified FB programs relied exclusively on religious methods in treatment.

FB programs aimed at addiction treatment range from small, local ministries or missions to international organizations with multiple locations and programs. Perhaps the most widely known of the latter is Teen Challenge. Teen Challenge was founded in 1958 by Pentecostal minister David Wilkerson, who wanted to help Puerto Rican gang members he was ministering to in New York city. He initially assumed that a conversion experience would eliminate the problems youth were having with addiction and involvement in crime, but soon became convinced that a more intensive program was needed, as well as a more supportive environment. The original Teen Challenge model involved two phases. The first was several months at an Induction Center, followed by 6–9 months or more at a Training Center. The program involved bible study, religious education, and working, often in a rural farm setting. Today, the program largely houses and works with adults. No outcome studies of Teen Challenge have been published in peer reviewed journals, but the program has been open to outcome research. A federally funded study from the 1970s has often been cited as evidence for the efficacy of

Teen Challenge, but in fact dropouts from the program were as likely to be drug free at follow-up as were treatment completers. Given that the Teen Challenge program has changed considerably since its founding, outcome studies that are more than 30 years old probably cannot be generalized to the program today. A similar situation exists for Salvation Army programs, in that published outcome studies are 30 or more years old and of questionable methodological quality. Given the current emphasis on FB programs, the field is in dire need of more rigorous and recent outcome studies of FB treatments and social services.

CONCLUSIONS AND RECOMMENDATIONS

While religious involvement is generally inversely related to substance use and problems, even individuals who come from traditions that prohibit use of particular substances can develop SUDs. Religious or spiritual involvement may lower risk by contributing to beliefs that condemn use or reinforce moderate use, by increasing exposure to individuals who do not use and decreasing access to substances, and by enhancing well-being. Religious or spiritual struggles have been connected with substance abuse problems, but the direction of causation is not yet clear, as addiction could cause impairment in spiritual or religious functioning. While the inverse relationship between RS and addiction is supported by hundreds of studies, fewer studies have examined the role of RS in treatment. Meditation practices currently have the strongest support as helpful, but research continues on other RS approaches and practices. Three manualized approaches, TSF, 3-S Therapy, and MBRP, have preliminary support from more than one study and are worthy of more extensive investigation with a variety of populations.

Clinicians may wish to include spiritual assessment when planning treatment. The suggestions for further reading at the end of this chapter provide several sources that can assist in planning and carrying out such assessment. Even if religious or spiritual methods are not part of a treatment package, it may help to assess spiritual and religious functioning as part of a comprehensive approach to progress in and after treatment. Religious or FB organizations may also be sources of social services that may help facilitate recovery. Clinicians should become familiar with local FB resources, congregations, and clergy to more appropriately refer clients to programs and services.

Involvement in mutual help programs appears to be beneficial for many clients. Clients' preference for, or resistance to, specific mutual help groups may be related to the clients' own religious or spiritual beliefs. While 12-step groups remain the most widely available option, a growing number of secular and sectarian alternatives are also available and may be preferred by some clients. Clinicians should discuss with clients about their past experiences with mutual help, as well as how clients' specific faith tradition might relate to mutual help group participation.

Glossary

Charitable choice a provision of the House Personal Responsibility and Work Opportunity Reconciliation Act of 1996 (HR 3734), allowing states to contract with both secular and sectarian (faith based) groups to provide various types of social services.

Faith-Based programs religiously affiliated programs offering social services, health care, social support, or other types of aid.

Religion organized faith traditions that articulate principles of ultimate values and truths, provide belief systems that transcend the material realm, and promote experience of the spiritual.

Sacred holy, ultimate, transcendent, pertaining to a realm beyond that of our everyday lives.

Sacrament a ritual or ceremony that is given sacred meaning.

Spirituality a universal human capacity that involves feelings of inner peace, deep meaning, compassion, connection with the sacred, and related experiences.

CHAPTER

30

Interpersonal Factors and Addictive Disorders

Dorian Hunter-Reel
University of Washington, Seattle, WA, USA

OUTLINE

Interpersonal and social factors play an integral role in substance use, abuse, and dependence. Members of the individual's social network can be quite influential in their decision to initiate use of alcohol and other substances, continue substance use and/or abuse, seek treatment for problems, as well as to discontinue use. This chapter summarizes and explains the role of interpersonal and social factors in the initiation, maintenance, and resolution of substance use disorders.

INITIATION OF ADDICTIVE BEHAVIORS

While it is not universal, the majority of individuals who develop addictive behaviors initiate use during adolescence and early adulthood. However, the majority of research on the role of interpersonal processes on the development of addictive disorders focuses on adolescence. Research supports several theories about how social factors influence substance initiation.

Theoretical Models

Social Learning Theory

Social learning theory proposes that individuals learn by observing the behaviors of others (models). They then evaluate the effect of those behaviors by observing the positive and negative consequences that follow. Social learning theorists assert that members of the adolescent's social network who use substances serve

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00030-9

as models for adolescents. If adolescents see role models, such as parents or friends, using substances with positive consequences, they are more likely to develop positive expectations of substance use, which increases the likelihood that the adolescent will use substances. Learning not to use substances occurs in a similar fashion when adolescents who observe negative consequences of use expect negative outcomes and are less likely to use substances. Self-efficacy, an individual's confidence in their own capabilities, is also thought to be learned socially. Self-efficacy to obtain and use or, alternately, to refuse substance use, may also be learned by observing a model. If an individual perceives that he/she can efficaciously obtain and use substances, he/she is more likely to use them.

Social Control Theory

Social control theory holds that adolescents will engage in deviant behavior unless bonded to conventional societal institutions, such as family, schools, and religion, and to conventional role models such as parents and teachers. Adolescents with weak bonds to conventional institutions and role models fail to internalize the values held by conventional society. Such failure to form strong bonds may result from strain caused by poor relationships with parents or a discrepancy between an adolescent's goals and perceived ability to reach those goals. Social disorganization (the breakdown of established institutions that provide social control) may similarly result in failing to bond with conventional institutions and values. Adolescents without goals or family strain and with intact societal institutions available may not have been adequately socialized to adopt societal values, and may therefore turn to deviant peers, facilitating the development of substance use.

Social Developmental Model

The social developmental model is related to social control theory but emphasizes individual relationships. Theorists posit that adolescents are likely to become involved with substance using peers and use substances if they are disconnected from rewarding interpersonal and academic experiences. These adolescents may have failed to develop the interpersonal and academic skills that result in rewarding interactions with parents and teachers.

Theory of Planned Behavior

The theory of planned behavior asserts that adolescents choose to use substances based on both a cost–benefit analysis of the expected social and affective consequences, as well as their self-efficacy in using or refusing substances. Adolescents who have a strong desire to please peers are more likely to use substances if they perceive their peers using substances and want them to initiate use as well. They are less likely to use drugs and alcohol if they perceive risk and social disapproval resulting from substance use.

Contagion Theory

Contagion theory focuses on the spread of alcohol use among members of social groups. Research has shown that several health risk behaviors, such as smoking and drinking, spread contagiously throughout social networks. Changes in alcohol consumption by the members in an individual's network have a significant effect on subsequent alcohol consumption of the individual. These changes are not related merely to selective formation of ties with other drinkers. Changes in the consumption of an individual's relatives and friends predict similar changes in the individual's consumption at subsequent time points.

Network Member Influence

Peers

Adolescents often use alcohol and other drugs to create, maintain, and enhance social relationships. While adolescents who perceive their friends to be supportive of them are less likely to develop substance use disorders, adolescents who do not believe they have supportive friends are more likely to use substances as a means of garnering support or positive regard. Research examining motives for drug and alcohol use finds adolescents frequently report using alcohol and drugs because they believe using substances makes themselves and their friends feel better, alleviates interpersonal conflict between friends, and helps individuals to better fit in with the peer network. These kinds of beliefs tend to be particularly strong in adolescents with higher social anxiety (the fear of being embarrassed or humiliated in social settings).

Relationships also exist between substance abuse and certain kinds of social problems, including poor interpersonal skills, having few friends, and being a target of bullying. Adolescents with social problems are likely to have more positive attitudes toward substance use, greater difficulty refusing use, and a higher likelihood of using substances to escape social problems. However, other studies have found poor social functioning to be related to the absence of experimentation with alcohol and other substances. It is thought that adolescents who turn toward substances typically lack other means of coping. Adolescents with fewer cognitive distortions and adequate coping skills are less likely to turn to drugs and alcohol to cope. Adolescents with poor social functioning who associate with deviant friends are more likely to use substances versus those that do not. Associating with deviant peers increases the acceptance of

delinquent behavior and increases the availability of alcohol and other substances.

Parents

Adolescents who perceive their parents to be supportive and caring toward them are less likely to initiate substance use or develop substance abuse or dependence. This relationship is primarily due to the stress-buffering effect of effective parenting, support for academic competence, and lower tolerance of behavior problems. Parental warmth and affection, parental involvement and contact, parents use of healthy structure and discipline techniques, a relationship low in conflict, and adolescent attachment to and identification with a parent are all factors that have been shown to be associated with less use of alcohol or other drugs. Adolescents who perceive their parents to be tolerant of substance use are more likely to use substances, while those who believe their parents will punish them for using substances are less likely to initiate or maintain use.

The drinking and substance use behavior of parents is also important. In line with social learning theory, it has been found that very young children imitate drinking behavior they observe in their parents. Children of parents with substance use disorders are more likely to have problems with alcohol and other substances themselves. Alcohol and drug use disorders are thought to be largely genetically transmitted. However, having a substance-abusing parent has been found to confer risk for substance problems over and above the genetic risk. Children of substance abusers are even more likely to use substances if family rituals (such as eating dinner together, holiday celebrations) and social relationships were disrupted due to alcohol or drug use. The maintenance of family rituals is an important protective factor for children of addicted parents, particularly when the abstinence of the addicted individual is required for these rituals to continue. The relationship between parental and child substance abuse does not end once the child leaves the home. Adults who have continued relationships with parents with alcohol use disorders are more likely to have problems with alcohol themselves.

Siblings

Children and young adolescents spend more time with their siblings than they do with parents, friends, or even alone. Substance use by older siblings predicts initiation of substance use in younger siblings. Older siblings have a greater influence on substance use than either parents or friends. Several theories have been proposed to explain the similarity of substance abuse between siblings. Researchers have suggested that having an older sibling who uses substances increases the availability of drugs and alcohol to younger siblings, increasing the likelihood of early initiation. Younger siblings are more likely to select friends from their older sibling's deviant peer group, thereby increasing the availability of drugs and alcohol.

In line with social learning theory, researchers have asserted that adolescent substance use is transmitted by older siblings through the modeling of deviant behavior for younger siblings. Other researchers have asserted that the transmission of substance use behavior occurs by way of transmitting positive substance-related attitudes. This hypothesis is supported by the findings that older siblings are often reluctant to use substances in front of younger siblings, and in children who have not yet initiated use, the perceptions of their older siblings use and attitudes toward use are strongly associated with their attitudes and intentions to use. Perceptions and attitudes develop as early as 10 years old and predict later substance use. Therefore, exposure to sibling's substance-related attitudes and perceptions of their behavior may cause adolescents to have similar use patterns to their siblings, even if they do not directly observe substance use.

The "partners in crime" model holds that the closer the siblings are to each other, the more likely they are to influence each other in regard to using drugs and alcohol. Research has found that the degree of emotional warmth and support felt between the siblings, the amount of time they spend together, and the extent to which they have mutual friends all predict similarity in substance use.

As with parent–child relationships, it is important to note that at least some of the relationship between sibling substance use similarity is accounted for by genetic similarity. Studies of twins have shown that monozygotic (identical) twins have more social contact and mutual friends than dizygotic (fraternal) twins. However, dizygotic twins share social environment similarity to a greater extent than standard full siblings, demonstrating that some of the similarity in social networks is accounted for by genetic and some by age similarity. Shared environment also accounts for a substantial portion of social network similarity. However, when environmental factors such as family structure and income are accounted for, the similarity between sibling substance use remains significant.

Individual Characteristics

Certain social traits of the adolescents are associated with greater substance use. Adolescents high in social anxiety are more likely to develop alcohol use disorders. Motivation to cope and to conform to social expectations explains the association between social anxiety and

drinking problems. Moreover, adolescents with high levels of social anxiety also have greater consequences of alcohol use than non socially-anxious peers who consume the same amounts of alcohol.

Aggressive behaviors are associated with a variety of deviant behaviors in adolescence, including substance use. In adolescent males, this typically takes the form of physical aggression, which is a common predictor of substance use. For adolescent females, aggression typically takes the form of relational aggression, or deliberately causing harm to another by damaging their interpersonal relationships or social status. As with boys, relational aggression in girls is associated with substance use. It has been theorized that adolescents who have difficulty regulating their emotions and who have limited coping skills are more likely to engage in both relational aggression and substance abuse.

MAINTENANCE OF ADDICTIVE BEHAVIORS

Early Theoretical Models

Theories regarding the role of interpersonal factors and maintenance of addictions have developed over the last century. Models of family dysfunction in the maintenance of addiction first became prominent in the 1930s. The earliest theories were primarily psychodynamically focused. These theories attempted to explain depression, anxiety, and somatic complaints observed in the wives of men with alcohol use disorders by asserting that these women married alcoholic men to resolve their own neurotic conflicts. Similar theories asserted that these women depended on their husbands drinking as a defense mechanism and that they would decompensate if their husbands drinking problems remitted.

Beginning in the 1950s, research on the wives of men with alcohol problems contradicted these theories and suggested that the distress observed in these women was largely the result of living with an alcoholic and that wives and families developed strategies to cope with the stress of living with an alcoholic that are similar to patterns seen in families with a chronically ill member. It was also suggested that families go through stages in dealing with alcoholic family members, including denial of problem, attempts to control the problem, feeling hopeless and chaotic, attempting to maintain functioning, attempting to escape, organizing and maintaining the family without the alcoholic, and, if the alcoholic stopped drinking, a final readjustment phase. Further research has supported this theory – women with spouses with alcohol use disorders who are currently drinking are quite distressed in comparison to controls, while women married to men who have resolved their drinking problems have similar levels of distress as women married to men without alcohol use disorders.

Current Theoretical Models

Family Disease Model

The family disease model is an extension of the standard disease model, postulating that the entire family has a disease. While the disease model was born of the Alcoholics Anonymous (AA) movement of the late 1930s and early 1940s, the family disease model evolved with the establishment of Al-Anon in 1949 to support the family members of individuals with alcohol problems and became formalized largely in the 1980s. Several books were published asserting that codependence develops in children raised in households with an addicted parent, as well as spouses living with an addicted individual. Codependence is marked by "enabling" any behavior that perpetuates substance use or mitigates the effect of alcohol and drugs on the addicted individual. Typical enabling behaviors include making it easier to obtain alcohol or other substances, shielding the drinker from the negative consequences of their use, and keeping the addiction a secret. The family disease model has been widely influential and many modern treatments and popular conception are based on this model. However, relatively little empirical support has been found for the family disease model.

Family Systems Model

The family systems model of addiction originated in the 1970s and is similar to the family disease model in that it views the entire family unit as being affected. While the family disease model views enabling behavior as serving the function of maintaining the disease, the family systems model views the substance use as serving to maintain homeostasis. Under this theory, substance use is thought to be initiated and/or maintained during times when the affected family member is having difficulty with a developmental issue (for adolescents), or when the family is facing internal difficulties. The substance use then serves to distract from the core problem, or to inhibit developmental changes, thereby helping to maintain homeostasis within the family unit. The use of alcohol is thought to have an interpersonally useful role in facilitating communication, expression of affect, and intimacy within the family.

Behavioral Family Model

Behavioral family model is similar to the family systems model in its focus on functionality of substance use. However, the behavioral family model is based on learning theory and holds that substance use is learned

and maintained through principles of positive and negative reinforcement, which can include the reactions and behaviors of the family. Specifically, spouses and children may pay more attention, interact more positively, take care of a family member while he/she is under the influence, and alienate and punish the individual when they are sober, thereby reinforcing substance use.

Network Member Influence

A good deal is known about the social support networks of individuals with alcohol problems. Unfortunately, less research has focused on the social networks of individuals with other addictions. Therefore, relatively little is known about the networks of individuals with other substance use disorders. Within the alcohol-social support literature, a distinction is made between alcohol-specific and general social support. Alcohol-specific social support refers to support for abstinence and support for drinking whereas general social support refers to how generally supported an individual feels by their social network members. While both general and alcohol-specific social support are related to problem drinking, alcohol-specific social support has been found to be more strongly associated with it.

With regard to general social support, contact with social network members provides much of the basis for individuals' perception of support. The more social contact one has, the more supported they tend to feel. Individuals suffering from alcoholism are not typically without friends and support. Most have fairly large social networks averaging seven or eight close people. However, almost half of the individuals with alcohol use disorders live alone and/or far away from their families. This isolation is associated with heavier drinking, particularly for men.

With regard to alcohol-specific social support, about half of the individuals with alcohol use disorder have no one in their network that discourages drinking. Also, having more drinkers in the social network is associated with more frequent and problematic drinking. This is a particular problem for women with alcohol use disorders as they are more likely to have a partner with an alcohol use disorder. About half women with alcohol use disorders have a significant other with an alcohol use disorder, while only about 15% of men with alcohol use disorders do. While women do tend to have a lower proportion of drinkers in their social network than do men, they also tend to have larger social networks and see their drinking friends as more important to them. Men generally receive less support for drinking from their network members. Typically, only about a quarter of the social network members of men with alcohol use disorder encourage him to drink. For women, network members are more likely to encourage them not to drink, although women with moderate to heavy drinking husbands are more likely to receive encouragement to drink.

In line with the family systems and behavioral family models, some research has focused on the behaviors of the social network that may perpetuate drinking. Often this work has focused on how alcohol may restore homeostasis to the family. When there is tension, an individual with an alcohol use disorder may leave the home to drink, therefore relieving tension and perpetuating drinking behavior. The spouse may complain or argue about drinking when the individual is sober but not when he/she is drinking, a pattern which serves to reinforce drinking. Alcohol often serves as a tool to increase positive affect and leads to more positive experiences among family members. Steady drinkers and their spouses often show lower rates of psychological problems and higher marital satisfaction. However, this relationship has not been found with binge drinkers.

When drinkers have rewarding social experiences, they are more likely to drink in a social context to further facilitate positive social experiences. When drinkers have negative interpersonal experiences, they are more likely to drink alone, a pattern associated with the development of alcohol use disorders. This is particularly true for individuals high in neuroticism (those who are more likely to experience negative emotions).

Some research has suggested a feedback loop between social support and problem drinking. Less social contact is associated with lower levels of perceived social support. Lower perceived levels of social support are associated with high levels of depression. Higher levels of depression are associated with more drinking, and more drinking is associated with less social contact. Once this cycle has begun, it may be difficult for an individual with an alcohol use disorder to break out of it.

Individual Characteristics

While most theory and research has focused on how the social network influences individual's substance use, little work has focused on the interpersonal characteristics of the individual in relation to the social network in predicting substance use. Several interpersonal characteristics are known to be more prevalent among individuals with alcohol problems. Individuals with alcohol use disorders have poorer overall interpersonal functioning and have a harder time understanding the emotional facial expressions of others. Individuals with alcohol use disorders typically have more extreme scores on measures of problematic interpersonal behaviors, social withdrawal, and mistrust of others. Binge drinkers and those with severe alcohol problems are

more likely to engage in aggressive and violent behaviors toward their families and other network members. These interpersonal deficits and maladaptive behaviors may serve to further distance an individual from social support, perhaps further perpetuating substance abuse.

RESOLUTION OF ADDICTIVE BEHAVIORS

Interpersonal Predictors of Treatment Outcomes

Help-Seeking

Social network members frequently comment on the problem drinking of individuals with alcohol problems. Mothers, followed by spouses, friends, fathers, siblings, and children, most frequently make such comments. These comments are often beneficial. Individuals whose network members have spoken to them about their problem drinking are more likely to enter treatment. However, this pattern is somewhat less true for women, as they often receive less support or pressure from network members to seek treatment and are more likely to have a network member oppose their seeking treatment. While men often receive encouragement to seek treatment from spouses, when women receive such encouragement it is most likely to come from parents or children. Women are particularly likely to seek treatment if they have had interpersonal problems or difficulties fulfilling obligations to others as a result of drinking. Involvement with AA can also lead to greater formal help seeking, as individuals who attend AA meetings tend to receive more feedback about their drinking and encouragement to seek help and change their drinking.

Treatment Outcomes

Having supportive relationships with other people is associated with more positive treatment outcomes. Both general and alcohol-specific social support are important in predicting drinking outcomes of those being treated for alcoholism. Support for abstinence is associated with reduced drinking, and this relationship is magnified when general social support is also high. Similarly, when support for abstinence is low, the relationship between general social support and drinking outcomes is stronger.

Having a partner, being socially involved, having a larger social network, and having supportive network members, are all associated with better drinking outcomes for individuals being treated for alcohol use disorders. Both the degree of support from the most supportive person in the network and the number of people providing support strongly predict better drinking outcomes. Having even one supportive person in the social network is associated with less drinking during treatment.

With regard to alcohol-specific social support, a number of studies have found that support for not drinking predicts less risk of relapse and some have shown that support for drinking predicts a higher likelihood of relapse and a lower likelihood of becoming involved with AA. Having nondrinking social network members is associated with better drinking outcomes, and more support for abstinence from family, friends, and even work colleagues predicts a lower likelihood of relapse. Alternatively, support for drinking has not been as reliably linked to drinking outcomes as has support for not drinking. It has been shown that support for drinking from the most important people in the network is unrelated to drinking outcomes, while the overall amount of support for drinking from the entire network does predict drinking, perhaps suggesting that the individuals closest to the drinker are the least likely to support drinking.

The substance use status of social network members predicts outcomes. Having more drinking friends and maintaining relationships with them predicts greater likelihood of relapse. Having only one person in the social network who drinks or one network member who uses the same drug of abuse predicts greater likelihood of relapse.

Social Network Functioning

Individuals with alcohol use disorders who have good marital and family relationships, and social networks that provide support and assurance of worth are less likely to relapse. Individuals who relapse or fail to change their drinking typically receive more encouragement for drinking from their social networks. They also have more stressful friendships, experience more criticism and hostility from their families, view their families as being less supportive and cohesive, and have less marital satisfaction.

The spousal relationship is particularly influential. Negative interpersonal events involving the spouse are a strong proximal predictor of relapse. Passive responses to drinking such as withdrawing from the drinker, avoiding dealing with the topic of drinking, and tolerating drinking, are associated with poorer drinking outcomes of those being treated for alcohol use disorders. However, providing direct, specific, alcohol-related feedback is associated with less binge drinking among those being treated for alcohol use disorders.

Individual Differences

Social investment, the subjective value an individual places on his/her social network, is also an important factor. Social support for abstinence predicts better

drinking outcomes only for individuals who are highly invested in their social networks. Strong social support for abstinence is not important and may perhaps have some adverse effects for those who are not invested in their social networks. Age is also an important variable. While older individuals tend to have fewer drinkers in their social networks, they are more likely to change their drinking for the sake of relationships. The research on gender differences in the effect that social support has on drinking outcomes is mixed. Some studies have shown that women are more likely to be influenced by their social networks. Women are more likely to drink after interpersonal stress and conflict with their partners, and more likely to return to drinking with their partners than are men. Other studies have shown that men are more likely to drink after a stressful interpersonal interaction with their partners than are women.

As with maintenance of substance use disorders, little research or theory has focused on the role of the addicted individuals interpersonal behavior on the resolution of substance use problems. However, it has been found that individuals with domineering and vindictive interpersonal styles, and more overall interpersonal problems, are more likely to drop out of treatment for alcohol and other substance use disorders.

Changes in the Network Resulting from Treatment

After successful treatment, social networks often change. The ratio of drinkers to nondrinkers typically decreases and contact with friends increases. Women are particularly likely to have greater contact with friends and to view their friends as being important to them. For individuals who are involved with twelve-step groups, the social network is typically larger and composed of more abstainers. Those involved in twelve-step groups also tend to have more social network members who know about their drinking and substance problems, receive less social support for substance use, and view their friendships as being of higher quality.

Treatments Involving Social Influence

Treatments that directly involve family members have been shown to predict better compliance, treatment retention, and drinking outcomes. Involvement of significant others in treatment has increasingly been viewed as an essential part of substance abuse treatment.

Treatments Involving Social Network Members

A variety of family therapies have been developed to treat adolescent substance abuse. These treatments often focus on creating a developmentally normative lifestyle and helping parents to develop effective parenting styles. In comparison to individual and group treatments, family-based therapy has been shown to be more effective in reducing adolescent substance abuse.

Family systems therapy is based on family systems theory. It is designed to modify the family structure so that alcohol or other substance abuse no longer serves to maintain homeostasis. Family members are involved in therapy and encouraged to provide corrective feedback to the substance abuser and to create a family environment whose equilibrium is not based on substance abuse.

Behavioral family therapy is based on the family behavioral model and is similar to family systems therapy. Typically, the two basic goals of this treatment are to immediately eliminate and stabilize change in substance use and support the individuals efforts to change and then to alter family behaviors to reinforce continued abstinence. Individuals best suited for this type of treatment are typically older, with more severe dependence, who reside with an intact family whose members do not have substance-related problems or other mental health issues, and who have come to treatment as the result of a crisis threatening family relationships. Behavioral couple therapy is based on this same model, although it focuses specifically on the spousal relationship. In comparison to individual treatment, couple treatments lead to greater reductions in intimate partner violence, lead to better outcomes for children living with the couple, and is more cost-effective.

Some clients are more likely to benefit from this kind of approach than others. Individuals who have unsupportive social networks but are highly invested in them are most likely to benefit. For those uninvested inunsupportive networks, individual treatment is recommended. Conversely, if an individual is uninvested insupportive social network, they are likely to benefit more from the couple approach. If the patient is already invested in a supportive network, they are likely to receive maximum benefit from individual treatment.

An important note about family interventions: Clinicians conducting this type of treatment are trained to carefully clarify that it is the responsibility of the individual to change his/her substance use. However, spouses and family members can be helpful to the individual in his/her attempt to modify substance use, and all members of the family can learn how to interact with each other in more positive ways.

Interventions That Modify the Social Network

Mutual help groups have commonly been referred to as "self-help" groups. However, the term "mutual help" is more accurate as these groups are in large part organized around being helpful to each other with the common goal of abstinence, and individuals within the

group are encouraged to rely on each other for support. Researchers have also referred to these groups as "folk" treatments and "informal help" to distinguish them from formalized addictions treatment.

Twelve-step groups function in part by modifying the composition of the social network. Within the twelve-step philosophy, "carrying the message" and being helpful to other individuals suffering from addictions constitute an important element of the program. Twelve-step groups are anonymous and informal, and therefore difficult to study. Most of the extant research has focused on AA and has suggested that one of the primary reasons that it is effective is that it increases social support for abstinence, which, in turn, results in less drinking.

Several secular groups have since developed a focus on the ability of addicted individuals to be mutually helpful to one another without a spiritual focus. The Secular Organization for Sobriety (SOS) was founded in 1985. Women for Sobriety (WFS), an organization whose goal is to help women recover by sharing their experiences and encouraging each other, followed it.

Several programs utilize the group process, but use trained facilitators to lead groups and teach information or skills. Self-Management and Recovery Training (SMART) utilizes a facilitator to teach skills to cope with stress, rather than using substances. Moderation Management is similar to SMART, but emphasizes moderate use alcohol.

In comparison to twelve-step groups, there are far fewer secular and guided-help groups. Little research has been conducted on the efficacy of involvement in these groups, or how the interpersonal nature of the groups helps individuals change.

Treatments That Enhance Participation in Mutual Help Groups

Given the prevalence and efficacy of twelve-step groups, some treatments have focused on increasing involvement with mutual help groups. Twelve-step facilitation (TSF) typically takes the form of individual or group therapy explicitly designed to work synergistically with twelve-step groups. Therapists present addiction as a disease with spiritual, emotional, and physical aspects, consistent with twelve-step philosophy, and encourage involvement with twelve-step groups and "working the steps." TSF has been found to be as effective as cognitive behavior therapy and other top formalized treatments in achieving and maintaining abstinence.

Network support therapy is based on TSF, although it has an explicit focus on using AA to change the individual's social network to be more supportive of abstinence. AA philosophy is downplayed in favor of increasing AA attendance as a way to avoid drinking, make new friends, and engage in enjoyable activities other than drinking (to reinforce abstinence). The development of supportive social networks outside of AA is also explored. This treatment has been demonstrated to be effective in reducing drinking, as well as in increasing support for abstinence and increasing AA involvement.

Therapeutic communities use a social psychological approach to addictions treatment. Therapeutic communities are typically substance-free residential environments and utilize the "community as method" approach for addictions treatment. These communities offer a variety of rehabilitative services and focus on training members to adhere to social norms. Therapeutic communities rely on group members to give feedback to one another and to help each other develop more effective social skills. All of the members of therapeutic communities assume responsibility for their own recovery as well as the recovery of their peers. Individuals typically join these communities for 1–2 years and move up a hierarchy of increasing responsibility within the community. Research has shown that individuals who successfully complete these programs have significantly lower rates of substance abuse, criminal behavior, depression, and unemployment.

Treatments Initiated by or for Social Network Members

The Johnson intervention is an approach in which people close to the addicted individual work closely with a trained counselor to confront them, inform them of the negative effects of their use, and to ask them to enter treatment. While the majority of social networks who consider an intervention do not ultimately follow-through, among those that do, 75–80% are successful in convincing the individual to enter treatment.

Community reinforcement approach and family training (CRAFT), also known as unilateral family therapy, is a treatment for the social network member of the individual with a substance use disorder that teaches the network member to allow the addicted individual to experience the negative consequences of substance use and to reinforce abstinence. This treatment has been found to be effective for both moderating the distress of the social network member and encouraging the substance user to seek treatment. Over half of the individuals whose family members undergo this type of treatment later enter treatment themselves.

Al-Anon, Nar-Anon, Alateen, and Alatot are companion fellowships to AA for the social network members of individuals with substance use disorders. These groups parallel AA and use a modified version of the twelve steps, focusing on lack of control over loved ones' addictions, and emphasizing caring detachment. While involvement in these groups has not been shown to have an effect on the behavior of the addicted

individual, it has been shown to decrease the distress of the family member.

SUMMARY

Interpersonal factors and relationships play an important role in addictions. A variety of theories have been developed to explain the role that interpersonal processes play in the development, maintenance, and resolution of substance use disorders. Research has shown that social network members have a profound effect on one another. Behavior of network members may serve to protect individuals from the development of substance use disorders, or to increase the likelihood of developing and maintaining addictions. Social network members can also play an important role in promoting help seeking and aiding treatment efficacy.

Glossary

Alcohol-specific social support the degree to which individuals perceive that social network members support either abstinence or drinking.

Behavioral family model based on learning theory, holds that substance use is learned and maintained through principles of positive and negative reinforcement, which can include the reactions and behaviors of the family.

Codependence a characteristic proposed to be present in family members of those with substance use disorders, marked by engaging in enabling behavior.

Contagion theory posits that health-related behaviors spread among members of social groups.

Enabling any behavior that perpetuates substance use or mitigates the effect of substance use on the addicted individual.

Family disease model an extension of the standard disease model, posits that the entire family unit has a disease.

Family systems model posits that substance use is serving to maintain relational homeostasis within families.

General social support the degree to which individuals perceive network members as being generally supportive.

Relational aggression the deliberate cause of harm to another by damaging interpersonal relationships or social status.

Social control theory holds that adolescents will engage in deviant behavior unless held in check by bonds to conventional societal institutions and role models.

Social developmental model posits that adolescents are likely to abuse substances if they lack rewarding interpersonal and academic experiences.

Social investment the subjective value an individual places on his or her social network.

Social learning theory posits that individuals learn by observing the behavior and apparent positive and negative consequences of social network members.

Theory of planned behavior posits that behavior is based on a cost–benefit analysis of the expected positive and negative consequences.

OUTLINE

INTRODUCTION

In order for clinicians and researchers to have a full understanding of the cause and treatment of addiction, it is important to consider the role of families in the development of and recovery from addictive behaviors. This article focuses on helping the reader to understand the association between major aspects of family functioning and their relationship with addiction. The article begins by describing the advantages and challenges in including family members into the process of assessing individuals with addictions, along with several major approaches to family-based assessment of addiction. We focus on family-based assessment and avoid discussion of specific family-based approaches to addiction treatment, since these are covered in other articles within this volume. The article then focuses on the association between addictive behaviors and relationship domains among romantic couples. We summarize major areas of research among romantic dyads, including couple's relationship satisfaction, behavioral communication patterns, and partner aggression and violence. Next, we turn to describing the empirical findings on the relationship between parental addictive behaviors and their children's adjustment. A summary of findings from the literature on adult children of alcoholic parents is also described. Finally, we provide suggestions for future research on the topic of families and addiction.

FAMILY-BASED ASSESSMENT

Incorporation of family members into the context of addiction-oriented assessment has several advantages. One advantage is that family members can serve as collateral sources of information as to the behaviors of the individual with the addiction. This can be helpful, as it is sometimes the case that the individual with the addiction will minimize his or her addiction behaviors and problems, due to stigma, shame, or other concerns.

Principles of Addiction, Volume 1
DOI: http://dx.doi.org/10.1016/B978-0-12-398336-7.00031-0

In addition, due to the difficulties that some classes of substances produce with regard to memory and cognitive functioning, asking a family member to provide collateral information as to the addicted individual's behaviors may help to increase accuracy of the information that is being collected. Another advantage of incorporating family members is that it can provide the opportunity to understand the role between family dynamics and addictive behaviors. As will be described throughout this article, there is compelling data to suggest that various domains of family functioning can influence addictive behaviors, and vice versa. Hence, assessment of family functioning and family member interactions may help to improve empirical and clinical models for understanding addiction. Lastly, incorporation of family members into assessment can provide the opportunity for their continuation in addiction-focused treatment. As is discussed in a companion article in this volume on Behavioral Couples Therapy for alcohol and drug use disorders as well as other articles in the volume, family-based interventions for addiction are shown to be effective, and there is some evidence that family-based interventions are more effective than individually based addiction treatment.

Although incorporating family members into addiction treatment and research has advantages, there are several challenges to obtaining information from family members. The first challenge is the willingness of the individual who is presenting with the addiction issue to consent to his or her family members being involved. Individuals with addiction issues may be fearful that inclusion of family members will lead to further embarrassment by family members revealing socially undesirable behaviors that occur within the context of the addiction. They may also be concerned that family members will bring up family-related problems that the person with the addiction would rather keep private. Another challenge is that the addictive behaviors may have contributed to family difficulties and resentment from the perspective of family members. Hence, family members may also be reluctant to want to involve themselves in providing information as it relates to talking about the addiction. Therefore, it is important for clinicians and researchers to provide clear expectations about what information will be communicated and how this information will be provided. To increase likelihood of family member involvement, it is also important to obtain consent for the researcher or clinician to speak with family members directly rather than relying on the individual with addiction to contact their family members. Further, we recommend explaining how involvement of family members will be helpful to them and their families and that the initial contact with family members be completed in the presence of the person with the addiction. A final challenge is that family members may be unable at times to serve as a reliable collateral source regarding the addiction behaviors. This may be due to individuals with addictions hiding these behaviors from loved ones. In this case, inclusion of the family member may not increase what is immediately known about the addictive behaviors.

There are three primary methods to consider when gathering information regarding family functioning. Some of these methods can be applied to gathering information on family functioning exclusively from the individual presenting with the addiction. However, as previously described, it is advantageous to collect data from multiple family members when using any of these methods. The first method to gather data on family functioning is to conduct a clinical interview. This method follows a practice that is widely used in general marital and family treatment. Clinical interview can be used to inquire about current family functioning, major family problems, and the role of the addiction in these, and the historical development of the addiction and family system over time. This approach has the advantage of allowing the assessor to explore in an unconfined manner nuances of the family system that may be relevant in understanding the addiction. This information can be useful, since relationship dynamics may play a role in the development of and recovery from addiction.

The second method for gathering information on family functioning involves the use of self-report questionnaires. There exist a multitude of widely used and well-validated questionnaires to assess various aspects of family functioning. A discussion of the advantages of specific questionnaires is beyond the scope of this article. However, use of questionnaires has a general advantage of allowing researchers and clinicians to obtain independent data from various family members in a standardized fashion. In addition, some family-based questionnaires provide normative-based comparison samples that allow for an interpretation of how individuals and families perceive themselves in relation to others on a given domain of functioning.

A third method that has both clinical and research application is to gather behavioral data from communication samples involving family members. Typically, this is done by asking family members to discuss a conflictual topic and recording observed behaviors and responses. There are methods for reliably coding these data (e.g. see work by Richard Heyman and colleagues). The usefulness of these data is that they provide microsamples of behavior with regard to how family members manage conflict among one another. As will be described later in this article and as described in the article on interpersonal factors in the addictive

process, methods for managing conflict are directly relevant to the development of and recovery from addiction.

ROMANTIC DYAD RELATIONSHIP SATISFACTION AND ADDICTION

One component of the family system that has been fairly well researched within the field of addictive behaviors is romantic dyad relationship adjustment. A common way of defining romantic dyad adjustment has been to measure overall levels of reported satisfaction within the couple relationship dyad. Relationship satisfaction has typically been construed as the degree to which partners feel supported by one another or are happy with the relationship. There are many measures of dyadic relationship adjustment, and some measures that have been commonly used in the addiction field include the Marital Adjustment Test and the Dyadic Adjustment Scale.

Numerous studies have examined relationship satisfaction among couples where one or both members exhibit an addiction. With regard to alcohol-related addiction, studies consistently show a negative association between having alcoholism and relationship satisfaction. For example, a study by Timothy O'Farrell and Gary Birchler compared 26 heterosexual couples in which the male partner had alcoholism to 26 nonalcoholic maritally distressed couples and 26 nondistressed couples from the community. They found that alcoholic couples reported less marital satisfaction versus nondistress couples and similar levels of marital satisfaction to nonalcoholic maritally distressed couples.

Consistent with the result that having a partner with alcoholism is related to lower relationship satisfaction, studies that have examined the frequency of heavy or problematic alcohol use have found a negative correlation between frequency of heavy or problematic drinking and couple relationship satisfaction. Further, according to a study by Mark Whisman, when compared to other mental health disorders, alcohol use disorder has one of the strongest negative associations with relationship satisfaction. Relative to the number of studies that examine the association between problematic alcohol use and relationship satisfaction, there has been less research on the relationship between illicit drug use and relationship satisfaction. Nonetheless, there is evidence that illicit drug use is also negatively associated with relationship satisfaction among couples. Finally, having a gambling addiction is also associated with less relationship satisfaction, although the number of empirical studies in this area is limited.

Although there seems to be an overall negative association between problematic substance use and relationship satisfaction, findings show that it is important to consider the pattern of substance use within the couple. Linda Roberts and Kenneth Leonard sought to identify how differing patterns of couple's drinking were associated with couple relationship satisfaction within a sample of newlywed heterosexual couples. Results showed that couples exhibiting heavy drinking on the part of the husband or heavy out-of-home drinking had lower relationship satisfaction versus those who reported lighter patterns of drinking, including those who drank together frequently but not heavily. Among a national sample of married and cohabitating couples, Katrin Leadly and colleagues found that couple discordance in partner drinking behaviors was associated with less relationship satisfaction versus when couples were concordant in drinking behavior.

In another large-scale longitudinal study of newlywed couples, Gregory Homish and others examined whether couples' drug use patterns were related to relationship satisfaction. They found the least female-reported marital satisfaction among couples where the partners had discrepant illicit drug use behaviors, followed by couples where both partners used drugs, and then couples where neither partner used drugs. These findings suggest that while drug use is associated with lower relationship satisfaction, discrepancy between partners with regard to drug use behaviors may have an especially detrimental effect on relationship satisfaction. Taken together, these findings suggest that specific patterns of substance misuse are likely to be associated with less relationship satisfaction.

ROMANTIC DYAD RELATIONSHIP COMMUNICATION BEHAVIORS AND ADDICTION

In addition to examining relationship satisfaction among couples with addictions, studies have also examined behaviorally coded measures of communication among couples. These studies generally show less constructive communication around conflictual topics for couples with addiction. Specifically, studies of couples in which one or both partners are alcoholic have generally shown higher levels of negative communication behaviors (e.g. hostility, criticism) and lower levels of positive communication behaviors (e.g. empathy, humor) among these couples versus nonalcoholic couples.

Theodore Jacob and Kenneth Leonard examined specific patterns of communication behaviors by comparing heterosexual couples with a male alcoholic partner to a demographically similar sample that was nonalcoholic. They found that in response to wives' problem-solving attempts during a communication sample, alcoholic husbands responded with less

positive and more negative behaviors in comparison to nonmaritally distressed, nonalcoholic husbands. In addition, when compared with nondistressed, nonalcoholic couples, wives in the alcoholic group were less likely to engage in problem solving and more likely to engage in negative behaviors in response to husbands' positive communication strategies. Findings among drug-abusing couples have also shown that when compared with nondrug-abusing couples, couples with a drug-abusing male partner tend to engage in negative communication styles that escalate over the course of conflictual discussions. Hence, when compared to those without addiction, couples with addiction exhibit a general pattern of higher dysfunctional and lower positive communication in response to conflict.

Similar to studies that examine overall relationship satisfaction as an outcome, there is evidence from alcoholic samples that contextual factors and partner characteristics may influence couples' communication styles. In an experimental study, Theodore Jacob and colleagues examined how drinking immediately before participating in a laboratory communication sample affected communication behaviors of heterosexual couples with a male alcoholic partner. This study also examined the degree to which husband antisociality affected couples' communication. They found that drinking before the communication sample increased negative couple communication behaviors among those with an antisocial husband. Wives of antisocial husbands were more likely to react with negative behaviors to their husbands' negative behaviors during the drinking versus no drinking condition. These findings suggest that having an antisocial male partner may increase the likelihood of couples engaging in negative conflictual communication during periods of drinking.

A more recent study by Frank Floyd and colleagues showed that partner discrepancy in alcoholism status may also be associated with couples' communication styles. The study compared couples on behaviorally coded communication tasks to see whether partner antisociality and partner alcoholism status influenced communication. They found that regardless of wives' alcoholism status, couples with an antisocial, alcoholic husband had the highest amount of hostile communication. Hence, similar to the earlier study by Jacob, male partner antisociality was an important variable in predicting negative communication.

Findings from Floyd and colleagues further showed that couples where the male partner was alcoholic but the female partner was not had the highest level of negative communication behaviors. Interestingly, couples where both partners were either both alcoholic or both nonalcoholic showed the highest ratio of positive-to-negative communication behaviors. This suggests that partner discordance in addiction status may moderate communication styles, such that those couples in which partners are concordant with regard to alcoholism status may exhibit better communication than those where the male partner is alcoholic but the female is not.

PARTNER AGGRESSION AND ADDICTION

Intimate partner aggression is shown to be fairly common among individuals with addiction. Studies suggest that the rates of past year intimate partner physical violence among those presenting for addiction treatment is between 50 and 60%. These rates are approximately five times higher than past year intimate partner violence prevalence among demographically similar, nonalcoholic individuals from the community. Intimate partner verbal aggression is also shown to be substantially increased among those entering addiction treatment versus demographically similar individuals from the community. Hence, intimate partner aggression is a significant problem among individuals with addictions.

The positive association between intimate partner violence and measures of alcohol and drug use behavior is well documented. Heather Foran and Daniel O'Leary conducted meta-analysis of 50 independent studies to examine the association between intimate partner violence and alcohol use. Findings from this study showed a small, but statistically, significant association between female-to-male intimate partner violence perpetration and female alcohol use. The overall effect size for male-to-female intimate partner violence perpetration and male alcohol use was also significant and was in the small-to-medium effect size range. These results were further qualified by the alcohol–aggression association being dependent on the type of alcohol use measure that was used. Namely, measures of problem drinking produced a larger effect size with aggression in comparison with measures of consumption. Also, measures of drinking quantity produced higher effect size associations with aggression versus measures of drinking frequency. Not surprisingly, these results indicate that more problematic drinking patterns have a stronger association with partner violence.

A meta-analysis by Todd Moore and colleagues examined the relationship between drug use behaviors and intimate partner aggression. Findings from 96 studies indicated a small-to-medium effect size association between drug use behaviors and intimate partner aggression. However, differences were noted in the degree of association, depending on what type of aggression was being considered. Results indicated a significantly lower effect size association between

drug use and psychological aggression versus drug use with physical, sexual, or mixed forms of aggression. Regarding the type of drug that was being assessed, small effect sizes were noted for most drug types, whereas cocaine had a small-to-medium effect size association with aggression. The degree of association between cocaine and aggression was significantly higher versus several other types of drugs and aggression. The pattern of results suggests that while various classes of drugs seem to increase the risk for partner aggression, cocaine may have a more substantial relationship with partner aggressive behaviors relative to other drug classes. Although gender of the drug user was examined as a moderator, no differences were found in the effect size relationships between drug use and partner aggression.

Findings from large-scale, prospective community-based studies suggest that substance use increases risk for intimate partner aggression. In a 3-year, longitudinal study, Kenneth Leonard and Marilyn Senchak found that marital conflict styles along with husband alcohol use were prospectively predictive of later husband violence. In addition, a large-scale, longitudinal study by Maria Testa and others showed that women's drug use increased the likelihood of their experiencing partner violence in both ongoing and new romantic relationships.

Studies have also been conducted to examine variables that differentiate partner violence from nonviolent couples who are diagnosed with an addiction. Both proximal (e.g. intoxication) and distal (e.g. personality characteristics) variables may influence the occurrence of partner aggression among couples with an addiction. In a study of proximal risk factors for partner aggression, Christopher Murphy and colleagues interviewed alcoholic men and their female intimate partners to determine what circumstances were associated with conflicts that escalated to aggression. Participants endorsed the husband's alcohol use as the main topic in the majority of conflictual occurrences. With most conflicts, husbands were reported to have been consuming alcohol during the 12 h preceding the conflict. Hence, it seems that conflicts are typically related to the problematic drinking behavior, and conflicts are likely to occur during drinking episodes. In addition, when violent conflicts arose, husbands were reported to have consumed a higher quantity of alcohol. This may be related to the manner in which higher levels of intoxication lower inhibitions toward socially undesirable behaviors, such as violence.

Other studies have examined distal risk factors for partner violence, including individual and couple-based characteristics among those seeking treatment for alcohol or drug addiction. Studies have generally shown that higher levels of alcohol and drug use and higher levels of substance-related problems increase risk for partner aggression. In addition, an individual characteristic that has been researched among men but not women with addiction is antisociality. Among alcoholic men, higher levels of antisociality are associated with increased likelihood of partner violence perpetration. With regard to relationship factors among couples with addiction, partner violent couples are shown to exhibit less relationship satisfaction and a stronger perception that the addiction is causing relationship problems. In addition, alcoholic couples who engage in partner violence are shown to exhibit poorer behaviorally coded communication strategies versus those who are not violent. In summary, among individuals seeking addiction treatment, having higher addiction problem severity, having an antisocial male partner, and having lower relationship adjustment seems to distinguish couples who are violent from those who are nonviolent.

In a national community sample of couples, Katrin Leadly and others examined whether couple drinking patterns were associated with partner violence. Their results showed that couples exhibiting moderate or frequent drinking had over twice the odds of experiencing partner violence versus couples who abstained from drinking. In addition, couples who exhibited discrepant drinking patterns had over three times the odds of experiencing partner violence than those who abstained. These results were consistent with the pattern of findings from clinical samples that suggest that partner discordance in addiction-related behaviors is related to a range of couple-related problems, including partner violence.

PARTNER'S INFLUENCE ON ONE ANOTHER'S ALCOHOL USE

Understanding the longitudinal course of addictive behaviors within intimate dyads is important because it can increase the understanding of factors that influence the development of addiction, increase the ability to identify those at high risk, and improve the development and refinement of addiction interventions. In a longitudinal study, Kenneth Leonard and Pamela Mudar followed couples shortly after becoming married and through their first year of marriage. In this study, peer and partner drinking, along with other known risk factors for alcohol problems, were examined to determine whether these influenced husband and wife alcohol use behaviors during their first year of marriage. Findings indicated that heavier husband drinking when the couple initially became married was predictive of increased wife's drinking behaviors at their first year anniversary. However, wife's drinking behaviors when

the couple was initially married had no effect on husband's drinking behaviors at their first year anniversary. In addition, peer drinking behaviors when initially married did not affect either partner's drinking behaviors at their first year anniversary. In contrast, heavier husband drinking when the couple was first married was predictive of increased husband and wife involvement with alcohol-using peers at their first year anniversary. These results suggest that husbands' drinking habits seem to drive the drinking habits of their wives early in marriage and influence the degree to which couples engage with an alcohol-using peer group. These findings suggest that targeting husband drinking behaviors early in marriage may be a key component to addressing both partners' alcohol use and potential abuse.

PARTNER INFLUENCE IN THE RECOVERY FROM ADDICTION

Studies suggest that partner behaviors can affect the chances of recovery from addiction. Building on the literature on expressed emotion (EE) and its relationship to relapse in nonaddictive mental health disorders, Timothy O'Farrell and colleagues examined the role of female partner EE in predicting men's recovery from alcoholism after treatment. After controlling for other known relapse risk factors, they found that when compared with those who had low EE partners, alcoholic men who had partners who were high in EE were more likely to relapse, relapsed quicker, and had more heavy drinking during the year after treatment. Similar results were also found in a more recent study. In this more recent study of male alcoholic individuals, Mattson and colleagues found that female-perpetrated psychological aggression toward men with substance use disorders increased the likelihood of relapse during the 6 months after treatment. This result was found after accounting for the negative association between overall relationship satisfaction and relapse, as well as demographic and substance-related risk variables. This suggests that the relationship between EE and psychological aggression with addiction recovery are not a simple by-product of overall relationship adjustment or other recovery risk factors. Similar results have also been found in drug-addicted men, such that higher perceived criticism from female partners predicts higher likelihood of men relapsing to drugs. Hence, partner criticism and psychological aggression seem to decrease the chances that individuals with addiction will be able to sustain sobriety after treatment.

In addition to partner communication strategies influencing likelihood of recovery, partners may unintentionally engage in behaviors that enable the continuation of addictive behaviors. In a sample of heterosexual couples in which one partner exhibited addiction and the other did not, Rob Rotunda and others found that the vast majority of nonaddicted partners engaged in one or more enabling behaviors at some point during the relationship. Some examples of common enabling behaviors included taking over of chores for the addicted partner, drinking or using drugs with the addicted partner, or making excuses to cover the addicted partner's drinking or drug use behaviors. Unfortunately, such behaviors may unintentionally promote the continuation of the addiction by reinforcing addictive behaviors. Hence, these results suggest a clear need to address family member enabling to increase chances at addiction recovery.

THE RELATIONSHIP BETWEEN PARENTAL ADDICTION BEHAVIORS AND THEIR CHILDREN'S OUTCOMES

In addition to examining the association between addictive behaviors and romantic partner relationships, there has also been research to investigate the association between parental addiction and behaviors of their offspring. In this section, we focus on studies that examine how parents' addictive behaviors may affect their offspring's behavior during childhood. However, there is also a body of research examining the intergenerational transmission of addiction and the long-term effect of addiction across multiple generations. For discussion of the intergenerational aspect of addiction and its consequences, we refer interested readers to the article by Campbell in this volume.

There is clear evidence that children of individuals with addictive disorders who are at increased risk to themselves exhibit childhood behavioral disorders. In a large-scale, community sample of adolescent twins, Marmorstein and colleagues found significantly higher rates of various childhood disorders, including conduct disorder, oppositional deviant disorder, attention deficit disorder, and substance use disorders among adolescents who had a parent with alcohol dependence versus those whose parents did not exhibit alcohol dependence. Similarly, having a parent who was dependent on a drug other than cannabis was associated with increased odds of having these childhood disorders as well. Regarding prevalence of specific childhood disorders, the highest prevalence rates were found for oppositional deviant disorder, conduct disorder, and nicotine dependence, such that approximately one-third of the children of a parent with drug dependence other than cannabis exhibited these disorders. Prevalence for these disorders among children of parents with noncannabis drug dependence was almost 10 times the prevalence found

in children whose parents were not dependent on alcohol or drugs. Among children with an alcohol-dependent parent, it was most common to exhibit conduct disorder, with one-quarter of these children having a conduct disorder.

Other longitudinal research supports a connection between alcoholic fathers' drinking and their children's behavioral problems. Andrea Burdzovic Andreas and Timothy O'Farrell examined the frequency of alcoholic fathers' heavy drinking and child behavioral problems in the 12 months before fathers engaging in alcoholism treatment, during treatment, and in the 12 months after treatment. Children in this study ranged from ages 5 to 16. Cluster analysis revealed three patterns of alcoholic fathers' heavy drinking frequency during the course of the study: stable and low, low and increasing, and high and increasing. Children of fathers whose drinking was classified as either stable and low or low and increasing showed significant declines in behavioral problems from pretreatment through the 6 months after treatment. It was noteworthy that children with fathers who exhibited a low and increasing drinking pattern had the most reduction in behavioral problems during their fathers' periods of abstinence. In contrast, children of fathers whose drinking was classified as heavy and increasing showed no changes in behavioral problems from pretreatment through 6 months after treatment, but then had increased behavioral problems from 6 to 12 months after treatment. These results suggest that alcoholic fathers' abstinence is positively related to their children's adjustment over time, whereas continued heavy drinking is associated with increased risk for child behavioral problems.

Other research by Burdzovic Andreas and colleagues demonstrates that fathers' involvement in addiction treatment and self-help may lead to reductions in their children's behavior problems. Children in the study sample had an average age of 13, and the vast majority were age 13 or younger. Results showed that the extent of alcoholism treatment participation predicted posttreatment self-help involvement. Higher self-help involvement after treatment was, in turn, related to fathers achieving higher abstinence after treatment. Alcoholic fathers' abstinence was associated with their children having fewer externalizing behavioral problems after treatment. These researchers also compared children of alcoholic fathers who participated in alcoholism treatment with a demographically matched community sample. Their findings showed that children of alcoholic fathers who remained stably remitted during the 15 months after treatment had significant reductions in externalizing behavioral problems after treatment. In addition, the degree of behavioral problems exhibited by children of remitted alcoholic fathers did not differ from those found in the community sample and were lower than those whose alcoholic fathers had relapsed after treatment. This suggests that addiction treatment and self-help involvement may have collateral benefits for younger, nonadolescent children of individuals with addictions.

Among adolescent children of parents with addictions, there is evidence that addiction remission might mitigate, although not entirely eliminate, the risk for behavioral problems. Laurie Chassin and her research team compared adolescents who had a parent with an alcoholism history with a demographically similar group of adolescents whose parents were nonalcoholic. They found that having a history of parental alcoholism increased risk for adolescents exhibiting internalizing and externalizing behavioral problems and substance-using behaviors. This risk was moderated by the recency of parental alcoholism, such that adolescents whose parent exhibited alcoholism problems within the past 3 years had higher relative risk for internalizing and externalizing behavioral problems versus those whose parents did not have an alcoholism history. In addition, those whose parent exhibited alcoholism problems within the past 3 years had higher relative risk for substance use and problems related to their use versus those whose parents were nonalcoholic. In contrast, those whose parents had a remote history of alcoholism problems before the past 3 years did not differ on risk for externalizing behavioral problems versus those whose parents were nonalcoholic. Adolescents who had a parent with a remote alcoholism history continued to exhibit higher risk for internalizing problems, based on their fathers' reports and had higher risk for recent substance use and lifetime substance-related problems. Hence, the risk for externalizing problems was reduced among those whose parents had remote alcoholism history, while an increased risk for internalizing problems and substance use was present for adolescents with both a recent and remote parental alcoholism history.

In addition to literature supporting a relationship between parental addiction and child behavioral problems, there are also studies suggesting that parental addiction increases the risk for their children being exposed to violence. Research shows that children of parents with addictions have higher rates of exposure to intrafamilial violence, as well as higher rates of exposure to violence that occurs outside of the home. Steven Ondersma and colleagues examined this issue specifically among African American women and their children. They found that after accounting for multiple other factors, including children's behavioral problems, mothers' stress and depression, and neighborhood crime, exposure to alcohol and drugs was

related to children's higher violence exposure. Hence, these results suggest that exposure to alcohol and drugs may confer a unique risk to children having experiences with violence. Although there are known detrimental consequences for children with parents who have addictions and those who are exposed to violence, the combined effects of these risk factors is not well studied. This is unfortunate given that it is well established that addictions and violence commonly co-occur, and these risk factors occurring together are likely to have a detrimental effect on child development.

PATHWAYS FROM PARENTAL ADDICTIVE BEHAVIORS TO THEIR CHILDREN'S BEHAVIORAL PROBLEMS

The relationship between parental addictive behaviors and their children's behavioral problems may be explained by several pathways. In a 3-year longitudinal study, Laurie Chassin and others investigated familial factors that predicted changes in adolescent substance use over time. Using latent growth modeling, they found that having an alcoholic biological father predicted increases in adolescent substance use during this 3-year period. In addition to this direct effect of father alcoholism status, these researchers found that mother and father alcoholism status indirectly influenced adolescent substance use through several complex pathways. For example, having an alcoholic mother was related to less father monitoring behaviors. Less father monitoring behaviors was associated with higher involvement with drug use peers, and involvement in drug-using peers, in turn, predicted increased substance-using behaviors over time. Results suggested that having an alcoholic father also indirectly increased adolescent substance-using behaviors through this and other indirect pathways. Hence, parental alcoholism status might indirectly affect adolescent substance use behaviors through a chain of pathways that lead adolescents to engage with substance-using peers, thereby increasing the likelihood of substance use.

In addition to findings that support the role of parent–child relationships in explaining the link between parental alcoholism and their adolescent children's behaviors, there is evidence from research on younger children that parent–child relationships are important in explaining the effect of parental problem drinking on children's behavioral problems. In a sample of children aged 6–12, Mona El-Sheikh and Joseph Buckhalt found worse family cohesion and adaptability and worse child behavioral problems among alcoholic versus nonalcoholic families. However, children's perceptions of attachment to their parents moderated the link between parental alcoholism and childhood behavioral problems. Specifically, securely attached children were only at increased risk for problems when they had a parent with alcoholism and did not exhibit increased risk for problems when neither parent was alcoholic. This suggests that parental alcoholism may be an important determinant of child problems among securely attached children, whereas insecurely attached children may be prone to exhibit problems even if their parents are not alcoholic. In addition, family adaptability and cohesion buffered the effect of parental alcoholism status on their children's problems such that children who were in families with higher adaptability and cohesion were less negatively affected by having a parent who was alcoholic. These findings show that if families are able to maintain a well-functioning family system despite the challenges introduced by parental alcoholism, they may be able to partially offset the detrimental effects of parental alcoholism on their children's behaviors.

ADULT CHILDREN OF ALCOHOLIC PARENTS

Although the effect of being an adult child of alcoholic parents has received significant attention in the popular media and among some clinicians, drawing conclusions from the research literature is difficult, since studies of adult children of alcoholic parents have mostly relied on adult children of alcoholic parents providing retrospective reports of their parents' drinking behaviors and retrospective reports of their childhood environments. Hence, the causal relationship between childhood factors, including parental drinking during childhood, and adult children's adjustment is unclear.

Nonetheless, studies that have been conducted on adult children of alcoholic parents have tended to show that these individuals have increased risk maladjustment in a number of domains. According to Stephanie Harter's review of the literature, adult children of alcoholic parents are most consistently shown to exhibit increased risk for substance use disorders, antisocial behavior, emotional disorders, low self-esteem, and family problems. Although they seem to be at increased risk for maladjustment, Harter concludes that there is no evidence to support an "adult children of alcoholics" syndrome. Rather, adult children of alcoholic parents seem to be a heterogeneous group that exhibit increased risk for various forms of maladjustment. Although having an alcoholic parent is related to increased risk for adulthood problems, it is not clear the degree to which this increased

risk in having an alcoholic parent is distinct from having a parent with another mental disorder or being exposed to a generally dysfunctional environment in one's family of origin.

In a rare, large-scale, longitudinal study on adult children of alcoholic parents, Karen Jennison and Kenneth Johnson investigated whether having an alcoholic parent and family environmental factors predicted young women's development of alcohol use disorders. They followed women over a 10-year period and found that having an alcoholic parent did increase risk for adult children to develop an alcohol use disorder. However, the magnitude of having an alcoholic parent on their adult children's alcohol use disorder markedly decreased as the children grew older into their twenties and thirties. In addition, the effects of women's marital relationships moderated the influence of having an alcoholic parent on women's alcoholism outcomes. Specifically, women who reported more cohesion and better communication in their current marital relationships were less affected by having an alcoholic parent. Hence, having a supportive and well-functioning marital relationship seems to be an important resource for buffering the risk of having an alcoholic parent.

SUMMARY AND AREAS FOR FUTURE RESEARCH

In summary, there is a clear negative association between addictive behaviors and family functioning. Addictive behaviors are associated with a variety of romantic partner relational problems. Specifically, when compared to couples where neither partner has an addiction, couples in which one or both partners exhibit an addiction are shown to exhibit less relationship satisfaction, poorer communication, and more intimate partner aggression. However, studies also show that it is important to consider the pattern of addictive behaviors between partners, as those couples where one member exhibits addiction and the other partner does not are shown to have worse dyadic functioning versus those where both or neither partner has an addiction. In addition, there is evidence that partner behaviors and relationship factors may help or inhibit the likelihood of recovery from addiction. These findings suggest that partners' roles are clearly important to understanding the course of and recovery from addiction.

Regarding the effect of parental addiction on children, parents' addictive behaviors are shown to be positively related to child behavioral problems. Parents with addictions have children who exhibit a higher risk for mental health disorders versus parents who do not exhibit an addiction. Further, parental addictive behaviors are longitudinally related to childhood behavioral problems, such that more frequent problematic substance use predicts more childhood behavioral problems. Likewise, recovery from addiction and reduction of parental addictive behaviors is related to fewer childhood behavioral problems over time. Studies suggest that dysfunctional parenting behaviors and parent–child relationships may be one pathway through which parental addiction affects children.

Although the connection between addictive behaviors and the family is well established, there is still need for expanded research among various populations exhibiting addiction and its relationship to family dynamics. Family-based addiction research has historically focused on heterosexual dyads where the male partner exhibits an addiction. Additional research is needed to expand the understanding between addiction and family functioning among a more diverse range of populations, including women exhibiting addiction and homosexual couples. Additional research is also needed to examine how family functioning and addictive behaviors unfold over the course of time. This would improve the understanding of the degree to which addictive behaviors erode family functioning and how positive family functioning may serve as a resource to promote recovery.

Although studies have clearly documented a negative relationship between family functioning and addiction, there should be more research to understand pathways through which addiction influences family functioning and vice versa. As described in this article, some of these pathways have been explored in prior research. However, there is need to expand the understanding of how specific risk factors within family relationships affect addictive behaviors and how addictive behaviors influence family dynamics. An example of this need is the lack of research on families in which multiple members exhibit addictions and how this dynamic affects family functioning and addictive behaviors over time.

Finally, additional research is needed to expand the understanding of the relationship between the family and addictions other than alcohol. The majority of family-based addiction research has examined the relationship between alcoholism and various forms of family functioning. Less research has examined the relationship between drug use disorders and family functioning, and there exists a relative paucity of research examining the association between family dynamics and other forms of addiction, including gambling or internet addiction. Therefore, research is needed to better understand how addictions other than alcohol are related to family functioning.

CHAPTER

32

The Intergenerational Transference of Addiction

Justine Campbell, Tian P.S. Oei
University of Queensland, St. Lucia, QLD, Australia

OUTLINE

Economic, mortality, injury, and menta l health statistics demonstrate that addiction is costly from an individual and societal level. Therefore, understanding the mechanisms by which such behaviors are transferred is an important component in creating treatment and prevention strategies for addictive behavior. It is clear from addictive behavior literature and research that the intergenerational transference of addiction has been well established. Estimated rates of alcoholism, smoking, illicit drug use, and gambling reveal that male and female children are more likely to have a father and/or mother who also demonstrate such behaviors compared to offspring in the general population. These results suggest that parents play a major role in the acquisition of addictive behavior in their children. Although evidence shows quite convincingly that the symptoms of addictive behaviors aggregate within families, it remains unclear that by what mechanisms these symptoms are transferred. More specifically, it is unknown whether the transmission of substance misuse or maladaptive behaviors is a direct causal relationship between parental and offspring behaviors, or due to other mediating variables such as genetic, environmental, or cognitive factors.

A number of reviews and studies have focused on the intergenerational "transfer of risk," whereby specific parental behaviors are associated with an increase in the possibility that similar or related problems will occur in the next generation, and have aimed to determine the processes by which this transfer occurs. Various theories have been proposed for the intergenerational transference of addiction; however, the existing dominant explanation for this phenomenon is genetic theory, which proposes that problematic behaviors are transferred from parent to child through biological processes. Nonetheless, this theory has resulted in a number of

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00032-2

unanswered questions suggesting that other influences may also play a part in the transference of the behavior. For example, environmental theorists suggest that influences such as family dysfunction and social class explain a large proportion of the risk. Yet, as with genetic theories, the extent that these factors influence the transmission of addictive behavior within families remains debatable, leaving a large proportion of variance in interfamilial transference unaccounted for.

More recently, cognitive theories of transference have become more prominent and argue that information regarding addiction and its subsequent effects are acquired during childhood, and that parents have a major impact on these acquisition processes and outcomes. In particular, cognitive theories propose that the observation of parental habits contributes to the child's beliefs and expectations of the subsequent effects, which in turn reinforces their future substance use or behavior. It is suggested that the acquired information is retained in the child's long-term memory and then triggered once their own associated behavior begins.

The familial resemblance of addiction has been demonstrated in innumerable family, twin, and adoption studies and has revealed interfamilial similarities for behaviors such as alcohol abuse/dependence; cigarette smoking; illicit substance use; and gambling between first-degree relatives. As such, this chapter will provide a brief overview of existing research for the intergenerational transference of addiction, and delineate the proposed mechanisms for this transmission within high-risk families. Finally, the chapter will conclude by discussing recent findings for the interfamilial transfer of cognitions as a mechanism for this phenomenon.

FAMILIAL SIMILARITIES FOR ADDICTIVE BEHAVIOR

Family Studies

The familial aggregation of addictive behavior has been demonstrated through numerous family, twin, and adoption studies and results from this research has shown that a family history of problematic behaviors is one of the best explanatory predictors of the initiation and maintenance of later problems in both clinical and community samples. For example, a family history of alcohol abuse/dependence has been shown to contribute almost half of the variance in their relative's problematic alcohol symptoms, which is further increased with the familial concentration of alcohol problems. That is, the more relatives with a history of alcohol problems, the greater the risk of their relatives displaying problematic drinking behaviors. In a study of over 8000 first-degree relatives of alcoholic probands, alcohol dependence was found to be two to three times greater than that reported by controls, with overall lifetime risk rates for alcohol dependence of 28.8% for relatives of probands, and 14.4% for controls. These children are also more likely to report coping, enhancement, and conformity among their motivations to drink, and are also likelier to drink alone, drink to induce intoxication, and drink due to the pleasurable taste of alcohol.

Tobacco smoking research has also revealed numerous familial similarities in behavior showing that offspring of persistent smokers have twice the smoking rates as offspring of nonsmokers, and that parental smoking predicts the initiation and quantity of the same behavior in their children. Offspring of parents who commenced their smoking behavior at an early age and are current persistent smokers have been shown to have the highest rate of smoking behavior (47%) compared to offspring of later onset/relapsing parents (30–34%), and abstaining parents (14%). These rates are consistent for parent and offspring cannabis use with first-degree relatives of cannabis abusing probands being almost six times more likely to abuse cannabis than relatives of control individuals. A moderate risk for the transference of gambling behavior also exists with a family history of gambling increasing the risk of offspring gambling behavior twofold (22–29%) compared to those whose parents did not report excessive gambling (9–15%). However, this risk is increased for children who have more than one family member with a gambling problem, and are over four times likelier to report having a gambling problem themselves, particularly if the family members are first-degree relatives.

This provides a strong evidence for the transference of addictive behaviors from parents to offspring and support for the theory that underlying mechanisms function within families to expedite this transference. However, it has been argued that the use of "at-risk" family studies fails to recognize the influence of genetic and environmental factors in the etiology of relative's addictive behavior compared with twin or adoptee studies where more observable genetic markers are available.

Twin and Adoption Studies

Twin studies, like family studies, have also shown that a family history of addiction is a consistent risk factor in developing alcohol dependence. These studies compare similarities between monozygotic (MZ) and dizygotic (DZ) twins of alcoholic parents raised together, and allow for investigations of genetic and environmental influences between individuals with 100% shared genes and those who share only 50% of

their genes. High heritability estimates of addictive behavior have been demonstrated in twin and adoption studies of adolescent tobacco use revealing estimates between 36 and 60%. However, varied results have been revealed for gambling addiction with heritability contributing between 35 and 54% of pathological gambling behavior, yet in contrast, meta-analyses of family and twin studies have only revealed a weak but significant heritability estimate of 16%. Various studies of alcohol abuse/dependence have demonstrated the familial nature of such disorders with MZ–DZ concordance ratios of approximately 2:1. Twin studies of male and female MZ and DZ twin pairs have consistently shown heritability scores for the likelihood of alcohol dependence symptoms ranging from 47 to 64%, with pair correlations for alcohol abuse or dependence (DSM-IV criteria) of 55 and 31% for MZ and DZ twins, respectively.

Gene-environment studies on adopted away children reveal an increased risk for alcohol and substance addiction in adoptees from alcoholic or substance using biological backgrounds (compared to control adoptees), whereas such abuse by the adoptive parents is not associated with greater risk of the same in the adopted child, suggesting a minor influence of environment. However, to further disentangle these results, the inclusion of stepfamilies with a nonalcoholic biological parent, and either an alcoholic or a nonalcoholic stepparent enables further scrutiny of specific hypotheses concerning genetic and environmental influences. Specifically, the inclusion of one nonalcoholic biological rearing parent with one nonbiological (either alcoholic or nonalcoholic) parent can in turn exclude the genetic transmission of alcohol problems in these offspring. As such, having an alcoholic biological parent significantly increases the risk of offspring developing alcohol abuse and dependence symptoms, with associations almost three fold greater for biological than adoptive and stepfamilies. However, results for nonbiological families are less straightforward such that having an alcoholic adoptive mother or an alcoholic stepfather predicts offspring alcohol abuse, therefore suggesting specific environmental transmissions. These heightened risks may therefore be attributed to other psychopathology in the biological parent, which may have contributed to the adopting out of the child, the termination of prior marriages, and/or some form of abuse or neglect by a stepparent.

The findings from twin and adoption studies indicate the importance of a genetic factor in the intergenerational transference of addictive behavior, yet like family studies, these imply that other mediating processes are functioning to initiate the transmission of such problems. Research assessing parent and child gender differences seem to support this suggestion, and imply that other mechanisms are at work rather than just direct genetic similarities or simple observation and imitation of parental role models.

Parent and Child Gender Differences

The familial relationships between parent and child addictive behavior appear to be moderated by parental and offspring gender; however, results appear to be varied when describing the relationship between same-sex and cross-sex parent/child dyads. Specifically, paternal addictions have been associated with greater levels of the same behavior in their sons, while maternal addictive behaviors predicted daughters increased behaviors suggesting a modeling or imitation effect of the same-sex parent. Yet equally, particular adverse behaviors in either parent has been shown to increase the risk of the same in their children; as does cross-sex effects where the parents' behavior has a greater impact on the opposite sex child's behavior; or more frequently, one parent has a stronger influence on both children irrespective of gender. Nonetheless, this implies that whereas addictive behavior symptoms aggregate within families, other processes are operating to mediate this intergenerational transference, and that the direct effects of parental gender and addictive behavior on offspring behavior are not so straightforward.

It has been argued that females are more sensitive to disruptions in their home environment, which may leave them vulnerable to addictive behavior, whereas males are more prone to genetic influences. For example, additive genetic factors have been found to account for approximately 60% of the variance in alcohol use in 17–18-years-old twin males, but only 10% in female twins; however, shared environmental factors accounted for 68% in female alcohol use, but only 23% in male alcohol use. It is therefore important to consider the role of certain social constructs transferred from the same-sex parent when discussing same- and cross-gender relationships in parent to child addiction transference, and how cognitions related to these constructs may be transferred and become significant antecedents in the initiation of problem behavior. Specifically, formation of gender identity and association with either masculine or feminine traits may play a significant part in the development of explicit gender-related styles of addictive behavior. For example, identification with masculine traits or exaggerations of conventional female stereotypes may contribute to the risk of addiction. As such, the motivations to use substances or gamble may differ between sexes, but underlie the transference of cognitions associated with typical gender roles from parents to children. This issue will be explored more thoroughly in a later section.

It is therefore implied that the pressure to conform to traditional gender roles may leave females more vulnerable to maladaptive outcomes due to family dysfunction, whereby their propensity to display interpersonal connectedness and concern for the welfare of others make them more emotionally affected by family discord.

Summary and Critique

Family, twin, and adoption studies have provided strong evidence that the symptoms of addiction aggregates in families, and the intergenerational transference of these problems can be attributed, at least in part, to a genetic mechanism. Many of these analyses have reported heritability statistics of 40 to 60%; with familial concentration of addiction contributing to elevated levels of symptom transference. However, various problems arise insofar that "at-risk" family studies often confound biology and environment such that most families share these elements. The development of twin studies reduced this limitation, arguing that greater similarities would occur between identical twins that share 100% of their genetic material, compared to fraternal twins, who only share 50%. The heritability rates for these studies provide further support for a genetic influence in the transference of addictive behavior, with a twofold risk of problems in identical twins, compared to nonidentical twins. Similarly, adoption and stepfamily studies have revealed that addictive behaviors in the biological parent, but not the nonbiological parents, are frequently associated with a greater risk of similar problems in the adopted or stepchild. Furthermore, the examination of the moderating roles of parent and child gender has indicated that the genetic load for addiction is equivalent in both genders; however, it would appear that conformity to social roles contributes to particular styles of addictive behaviors, particularly in females.

Nonetheless, twin and adoption studies are not without their limitations (although the evidence is mixed), particularly in regards to assortative mating and equal environment assumptions for twin pairs, and pre/post natal influences or selective placement for adoptees. In a meta-analysis of 50 family, twin, and adoption studies of substance use, heritability estimates much lower than those rates normally cited in the literature were revealed. In fact, after restricting those studies that contribute highly to the genetic hypothesis, the heritability scores for the interfamilial transference did not exceed 26%. These findings indicate that up to 70% of the variance in addictive transference is attributable to other factors. Numerous studies have explored various biological, environmental, and cognitive factors to explain the processes by which the transference of alcohol problems is attributable.

MECHANISMS IN THE INTERGENERATIONAL TRANSFERENCE OF ALCOHOL PROBLEMS

Human Genome Studies and Endophenotypes

Family studies have indicated that the human genome influences the risk of developing certain addictions, which has led to a plethora of research examining the effect of specific chromosomal regions and genes to further explain the mechanism for the intergenerational transference of such disorders. These include both linkage and association studies. Linkage studies involve families with multiple affected individuals, and identify variations within segments of DNA and chromosomal regions that are common among family members. The linkage concept suggests that genes located in close proximity to each other are likelier to be inherited together from one parent, than two distal genes. In contrast, association studies are not restricted to family samples and can use unrelated controls to assess the relationship between specific genes and a particular outcome across families. Mixed linkage and association findings of alcohol dependence, substance use, tobacco smoking, and gambling have implicated, among others, the μ-opioid receptor gene; the serotonin transporter gene; the dopamine receptor gene; and GABA receptor genes. However, much of this research has yielded inconsistent results across groups of varying sample size, ethnicity, and clinical diagnoses. Furthermore, given the exhaustive list of proposed genetic markers, restricting the genetic transmission of addictive behavior within families remains indistinct. Nonetheless, despite some ambiguity in the results, the findings from human genome studies support the suggestion that genes operate as a mechanism for the interfamilial transference of addiction, such that similarities in genetic makeup between parents and offspring contribute to similarities in addictive behavior.

Similarly, it is argued that an endophenotype for a disorder should be heritable if there is a direct relationship between it and other susceptibility genes for the disorder. One genetically influenced phenotype that has been associated with increased risk for substance use addiction is the reduction of P300 (P3) amplitude during event-related potential recordings. The P3 is a brain potential which indicates the amount of attentional resources required for encoding new information in working memory. The reduction in this P3 wavelength has shown to be more similar in MZ than DZ alcoholic; however, heritability estimates appear to vary across gender, with percentages around 65% for boys, and 35% for girls, who were also substantially affected by shared environment. A parental transfer risk has been found in children of alcoholic parents

exhibiting reduced P3 amplitude; however, this parental risk effect appears greater in high-risk families, compared to low-risk families who were less likely to be exposed to the negative effects of alcohol or other substance abuse.

Summary and Critique

A plethora of research has provided mixed evidence for a specific gene, or genes, to explain the mechanism of the intergenerational transference of addiction. Similarly, whereas the identification of observable endophenotypes has provided similar heritably estimates as family studies, it is argued that given the polygenic nature of most genetic influences, it is not possible to implicate a specific gene, or gene combination, that contributes to the vulnerability toward specific addictions. Nevertheless, these studies provide some evidence that the role of genetics is a likely contributor to the transference of problematic behavior within families. It is argued however that the impact of biological influences can only be understood when evaluated in the context of environmental contributors, given that these factors have also shown to contribute to a family history of addictive behavior. In other words, the interaction of genetic and environmental influences may increase the risk of children of parents with specific addictions developing similar disorders under certain family environmental circumstances.

GENOTYPE-ENVIRONMENTAL THEORIES

Genotype × Environment (G×E) research that has assessed lifetime prevalence of problematic addictive behaviors has noted that individuals at high genetic risk for substance use, alcoholism, and gambling are usually also exposed to high-risk environments. As such, the intergenerational mechanisms that occur remain ambiguous such that the increased rates of problematic behaviors observed in children of problem drinkers, smokers, substance users, or gamblers do not distinguish whether it is the genetic transference from parents to offspring, poor family functioning due to problematic parental behavior, or a combination of genetic and environmental influences which contribute to the increase in risk in offspring addiction. To explore this, studies assessing the intergenerational effects of addictive behavior often discriminate between those environmental factors that are shared by siblings (SE or *c*), which include parental and family influences, and nonshared environmental factors (NSE or *e*) which are unique to siblings (e.g. peer groups), and the genetic component shared by parents, offspring, and siblings (G or *a*). The majority of research into the transference of addiction within families normally focuses on the first and last of these factors in determining the contribution of genetic and environmental influences. Estimates of the percentage of variance in addictions due to shared environment vary excessively among the literature. For example, several studies assessing shared and unique environmental factors on cannabis use found evidence for shared influences with estimates ranging from 26 to 85%, whereas estimates for cannabis abuse/dependence ranged between 3 and 29%.

Many G×E studies have found however that common environment interacts with heritability estimates according to age, zygosity, and gender. Assorted studies of alcohol transference have reported shared environment estimates between 37 and 71% among adolescent and young adults. Alternatively however, in a large twin study of MZ and DZ male twin pairs, common or shared environment only accounted for 3–11% of the variation in the development of alcohol abuse and dependence, with no major G×E effects.

However, in stark contrast before and after controlling for the effects of sociodemographic and psychiatric predictors on the risk of alcohol dependence, a more recent study found that shared environment did not provide any variance to the disorder. It was conjectured, though this finding did not exclude possible G×E interactions given that the interaction between genetic and shared environmental effects contribute to similarities of biological siblings reared together, but not to unrelated siblings reared together, or to biological siblings reared apart.

It would appear by these results that, as a mechanism, shared environmental factors add little to the explanation of the intergenerational transference of addictive behaviors, with some studies leaving over 90% of the variance in addiction transference in families unaccounted for. Additionally, it would appear that G×E interactions appear greater for unshared environmental factors, suggesting that indirect effects of parental addiction act as a mechanism for the interfamilial transmission of addictive behaviors.

Family Dysfunction

Problematic addictions adversely affect both the global family environment and the psychological well-being of the addicted parent's offspring. These difficulties with both family and personal functioning have resulted in children of addicted parents being recognized as an at-risk population for similar addictions, either directly as a means of coping, or indirectly through the association with deviant peers due to low parental monitoring. However, the process of transference of addictive behaviors from parent to child due to

family dysfunction remains somewhat unclear given that negative family processes may either be the cause or the result of problematic parental behaviors. For instance, in a German alcohol study it was found that a family history of alcoholism was unrelated to adolescent alcohol problems. However, the parental co-occurring psychiatric diagnoses, and the offspring's perceived parental rejection was related to the child's aggression/delinquency, which in turn led to association with substance using peers and thus, to alcohol problems. When those children diagnosed with conduct disorder and/or antisocial personality disorder were removed from the analyses, however, aggression/delinquency was no longer associated with peer group substance use, and therefore no longer acted as a predictor for alcohol use problems. Family psychopathology however remained a significant predictor of alcohol problems suggesting that this factor increases the risk for a range of behavioral and emotional problems in children of alcoholics. It should be noted however that some substance use studies have found no difference in the specificity of problematic family environments between children of substance users and other children exposed to other family stressors such as parental divorce, death, or major illness. This argues against the notion that parental addictive behavior is a sufficient cause for family dysfunction, and that unstable family environment appears to be equally prevalent among families exposed to other significant stressors. Irrespectively, it appears that a dysfunctional family environment operates as a partial mechanism for the intergenerational transference of addiction; however, what remains unclear is whether this process operates directly or indirectly.

Summary and Critique

As shown, a large amount of literature has addressed the relationship between genetic and environmental factors in describing the mechanism for the intergenerational transference of addiction, yet findings remain inconclusive. Specifically, genetic and environment studies have provided estimates from 0 to 71% for shared environment, and inconsistencies remain as to the G×E interaction. Furthermore, the discrepancies in the findings assessing the relationship between varied elements of family dysfunction and the interfamilial transference of addiction seem to suggest that addictive behavior in offspring may operate through other influences resulting from problematic parental addiction.

Overall, the range of biosocial theories have provided some evidence (albeit mixed) for heritable and milieu related influences in the intergenerational transference of addiction. However, this literature leaves a large proportion of the variance in this process unaccounted for. Further, studies show that certain children do not develop addiction disorders despite having a parent with the same disorder, whereas others acquire these regardless of nonaddicted parents. It is therefore suggested that other mechanisms are operating which account for a part of the variance in interfamilial addictive behavior, which may serve as either protective or risk factors. Particularly, it is proposed that specific social learning cognitions regarding the anticipation, expectancy, memory, and modeling of certain behaviors are fundamental in determining addiction in children and young adults.

COGNITIVE PERSPECTIVES

The role of social factors cannot be overlooked as significant antecedents in the initiation of addictive behaviors. However, certain social constructs (e.g. social norms and gender identification) need to be considered simultaneously with the cognitive aspects associated with them and their interactive effects on the intergenerational transference of these problematic behaviors. Specifically, children develop early expectations about gender through observation of parents and then form schemas that influence how they perceive the behaviors of men and women, and in turn, how these behaviors adhere to social norms, most particularly with alcohol consumption, cigarette smoking, and substance use.

Given that gender plays a fundamental role in the formation of identity (and social norms), association with either masculine or feminine traits may be a significant means through which distinctive gender-related styles of substance use or gambling behavior develop. For instance, males typically display a considerably higher prevalence of gambling, drug and alcohol related problems than women, and identification with the masculine role such as dominance, assertiveness, and independence may contribute to this. Alternatively, exaggerations of conventional female stereotypes may encourage females to be submissive, helpless and dependant thus increasing the risk of their addictive behaviors. It should be noted however that convergence in gender behaviors and changes in societal norms related to gender identity has led to similarities in substance use quantities or gambling frequency in both males and females. This would indicate that the changes in perceptions of gender role differentiation may also be mirrored in changes of addictive behavior. As such, the motivations to participate in substance use or gambling (e.g. coping with negative emotions, stress control, social facilitation, adherence to perceived societal norms) may be different in each sex but underlie the transference of cognitions associated with typical gender roles from parents to children.

The increase in the number of young adolescents and adults participation in gambling or risky substance use suggests that antecedent characteristics may exist prior to the individual's first experience with substances or gambling. For instance, when asked to select a small number of lottery tickets from a larger selection, primary school aged children were more likely to utilize random selection and rationalization for selection using reference to favorite, lucky, or important numbers suggesting the use of strategic methods when gambling. Similarly, children as young as 6 years old have shown to possess some understanding of the contextual, motivational, and normative aspects of alcohol consumption and behavior. One study has revealed that by the age of three most children could identify alcohol type by photographs, and that these children held two common alcohol schemas also held by the greater culture: (1) that alcohol consumption is done more by adults than children and (2) that alcohol consumption is done more by males than females.

Based on these findings, it has been argued that a large proportion of intra-family addictive behaviors may occur through the transference of associated cognitions. Previous alcohol and tobacco smoking research seems to support this possibility and indicates that adolescent's perception of their parents' approval or disapproval of their substance use was related to the child's drinking or smoking habits, such that perceived parental disapproval was associated with increased self-efficacy for refusing alcohol and/or cigarettes, and lower consumption.

EXPECTANCIES AND REFUSAL SELF-EFFICACY

Oei and Baldwin have proposed a cognitive theory to explain the development and maintenance of problem drinking within an individual. It is argued that this model can be extended to explain the relationship between parental addiction and related offspring behavior. For example, this model examines the relationship between Alcohol Expectancies (AE) and Drinking Refusal Self-Efficacy, which are beliefs about specific outcomes and self-control behavior associated with alcohol consumption. The theory proposes a two-process model of alcohol use and abuse: (1) an acquisition phase, based on instrumental learning or modeling processes in which AE are formed, and (2) a maintenance phase based on classical conditioning, in which unconscious conditioned processes automatically initiates a drinking response. In terms of an interfamilial transference of addiction, expectancies as to the effect of a particular addictive behavior originate as a result of parental modeling, and once these cognitions become established they guide the child's behavior when exposed to the factor (i.e. alcohol, substances, gambling). Once initiated these expectancies are reinforced, thus leading to the maintenance of addictive behavior.

Expectancies are generally expressed in the form of contingencies, or "if…then" statements (e.g. If I drink alcohol/use substances/gamble etc… then I will be happy/sad/rich/poor). These expectancies predetermine the individual's choice to undertake (or not undertake) specific behaviors and also their subsequent actions, which is driven by the anticipation of the ensuing effects such as increased sociability or tension reduction. Successive confirmation of these expectancies can reinforce the behavior and, in the case of optimistic outcomes, place the individual at risk of persistent problem behavior. In contrast, self-efficacy has been defined as the perceived ability to refuse a substance or participate in a behavior in a specific situation (e.g. with friends; feeling sad), rather than whether or not one chooses to commit this behavior. Findings from previous research would suggest that the constructs of expectancies and self-efficacy form the foundations of the transfer of addictive behavior between generations, and have repeatedly been demonstrated in alcohol, smoking, and gambling research.

THE INTERGENERATIONAL TRANSFERENCE OF ADDICTION RELATED COGNITIONS

The formation of cognitions prior to actual experience indicates that the knowledge forming these beliefs is derived from sources other than actual addictive behavior. For children, arguably the most accessible and significant models displaying such behaviors are their parents. It has been suggested in previous literature that exposure to parental behavior influences the child's behavior directly through imitation and modeling; however, adoption studies on substance use transference suggest that risk for intergenerational transmission is elevated even in the absence of contact with the substance using parent, making the argument for observation as a requirement for transmission debatable.

It has been suggested that children with a family history of addictive behaviors differ from those without a family history in terms of their cognitive expectations regarding the particular substance or behavior's effects. Research assessing the intergenerational transference of gambling related cognitions has revealed that parental gambling beliefs were directly related to the same in their children, which subsequently predicted their offspring's gambling behavior. Additionally,

expectancies have been shown to differ between offspring of alcoholic parents and offspring from nonalcoholic families, such that adolescents with a family history of alcohol misuse expected more enhanced cognitive and motor abilities. This would imply that children adopt their parents' expectancies regarding the perceived advantageous effects of certain behavior, without the influence of their own similar experiences. For example, it has been proposed that children may acquire the expectation of enhanced functioning via their alcohol abusing parents' self-report of improved performance while drinking, or via the child's observation of the parents' reduction in withdrawal symptoms, once alcohol consumption is resumed. This argument has been supported by the finding that offspring at high risk of developing alcoholism (i.e. presence of alcoholic father and uncle) held beliefs about the effects of alcohol that were similar to their parents, compared to low-risk controls.

Less is known however about the transference of self-efficacy beliefs between parents and children with very sparse research being conducted to investigate this occurrence. Some research that may provide tentative evidence for the transference of addiction related self-efficacy beliefs are studies exploring the effect of self-fulfilling prophecies on children's alcohol use behavior. These studies revealed that parents' beliefs about their offspring's drinking self-efficacy were predictive of their children's alcohol use behavior such that unfavorable beliefs significantly predicted their children's increased alcohol consumption. Similarly, other substance use research has revealed that parental smoking self-efficacy and beliefs about youth smoking were related to both theirs and their children's cigarette smoking behavior. These studies found that parents reporting lower smoking self-efficacy and higher pro-social youth smoking beliefs tended to have children who were regular smokers. Whereas these studies provide some speculative indication that parental self-efficacy beliefs may transfer within families, they do indicate that parents' beliefs about substance use may at least indirectly contribute to their children's behavior.

What appears to be more likely however is that whereas observation of parents' addictive behavior appears to initiate the development of expectancies in children prior to their first experience with a particular substance or behavior, it is the understanding and adoption of similar related beliefs and self-efficacy as their parents that maintains children's actions as adolescents and young adults. Specifically, whereas parents' expectancies do indeed contribute to children's cognitions, they play a greater role in impacting their offspring's personal self-related beliefs regarding their substance use or behavior, as opposed to their beliefs about the effects or outcome of the behavior itself. This suggests an interaction between children's awareness of their parents' expectancies, and their parent's behavior associated with these expectancies (see Fig. 32.1).

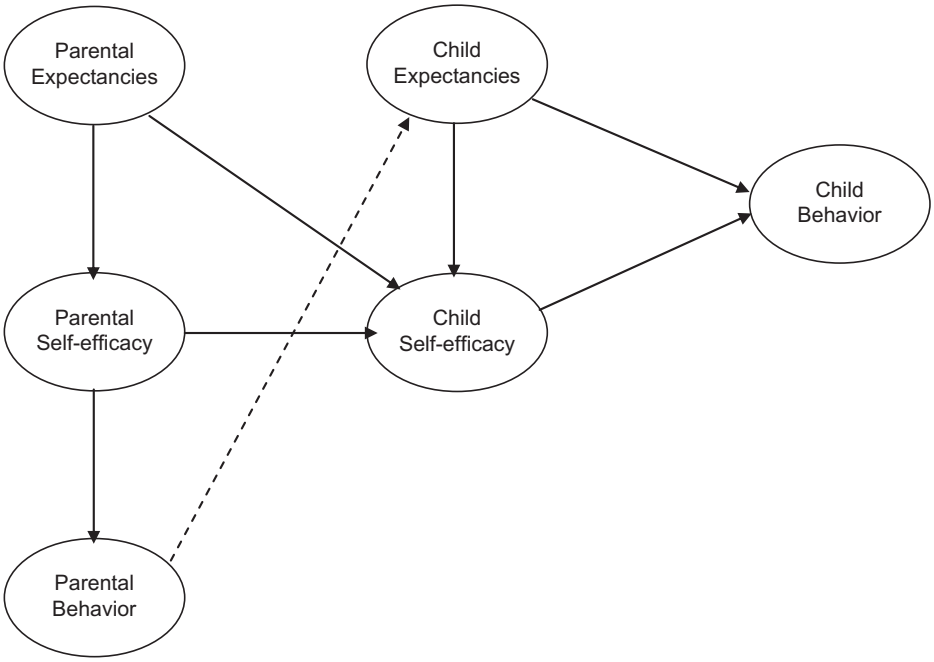

FIGURE 32.1 The intergenerational transference of addiction cognitions indicating the early development of expectancies via the observation of parental behavior (dotted line) and the maintenance of the behavior via reinforcement of expectancies and the understanding and adoption of similar parental beliefs and expectancies (full lines).

This emphasizes the importance of appropriate parental communication regarding the use of substances or gambling on their children's ongoing behavior. This is evidenced by the fact that parental communications regarding appropriate lawful substance use or gambling behavior are more likely to be internalized by their offspring within amiable and supportive parent–child relationships, whereas familial problematic behaviors have been shown to be related to poor family communication. As such, the independent roles of expectancies and refusal self-efficacy have great implications for the prevention and treatment of problematic and addictive behaviors rather than one overarching remedy. Maladaptive cognitions regarding positive outcomes of excessive substance use or gambling could be challenged and altered prior to the onset of the child's first experience with the behavior, whereas recognition of lower self-efficacy beliefs could be managed through familiarization and understanding of cue states, and the development of strategies for avoiding specific situations in the future. Whereas this suggestion may not be revolutionary, the integration of addiction prevention and treatment into a multi-systemic, family-oriented treatment and prevention therapy has the capacity to deal with tertiary problems in parents while simultaneously concentrating on primary or secondary prevention with their offspring. Strategies such as educating parents as to their role in the transference of addiction related messages to their offspring may reduce children's expectancies and self-efficacy beliefs prior to the onset of their first substance use or gambling experience.

CONCLUDING COMMENTS

The contributions of research to the "transfer of risk" literature regarding addictive behaviors within families has provided further understanding of the extent in which our cognitions impact upon others beliefs and behavior, specifically when the individual is vulnerable to suggestion and likely to adopt similar beliefs and behavior merely through observation. The findings also suggest that the development and maintenance of a specific behavior does not unconsciously occur as a result of direct mimicry or imitation, nor does this behavior remain uninfluenced by these same cognitive processes throughout our lifetime.

What is more likely, and demonstrated in the model, is that the development and transfer of addiction requires some aspect of an observable behavior. That is, although such communication expresses parent's beliefs related to the addiction, it is argued that it is the observation of the associated behavior that establishes these cognitions in their offspring. This indicates that parental behavior is important in the initiation of their younger offspring's related expectancies; however, once these cognitions are established, it is parental cognitions that become more prevalent in the maintenance of their child's cognitions and resultant addictive behavior throughout adolescence and young adulthood.

Nonetheless, it is proposed that the current argument has contributed to current literature by extending and strengthening an already well-developed theoretical framework to examine the complex relationships between parent and child addictive behaviors, and their role in predicting future problematic behavior. The challenge for future research is to determine the applicability of this model to multiple generations and to what extent this impact has on more problematic addictions, and even more importantly, the contributions that this theory has on prevention and treatment outcomes.

Peer Influences on Addiction

Clayton Neighbors [*], *Dawn W. Foster* [*], *Nicole Fossos* [$]

[*] University of Houston, Houston, TX, USA, [$] University of Washington, Seattle, WA, USA

OUTLINE

OVERVIEW

Peer influences, and social influences more generally, are among the most powerful determinants of behavior. With respect to addiction, peer influences seem to be most salient during the period from adolescence to young adulthood and appear to diminish as individuals become more oriented toward work and family. This does not mean that peer influences are no longer important, but that they tend to be less salient and less likely to be focused around addictive behaviors. There are certainly exceptions to the typical gradually decreasing influence of peers on addiction, but for the purposes of this article we refer to processes that have been most often studied among adolescents and young adults. The article begins with a brief review of several theories related to peer influence. The review of theories is intended to provide context and ways to synthesize thinking about peer influence. Next, we discuss direct and indirect influences on addictive behaviors. Direct peer influences range from polite requests to overt commands. Indirect peer influences are more subtle, including modeling (this involves observation and imitation) and perceived norms (subjective views on what is normal). Finally, we discuss resistance to peer influence and conclude with a brief summary.

THEORIES OF PEER INFLUENCE

In this section, we briefly summarize the major theories of peer influence and consider their relevance to alcohol and drug use. Several social influence theories have not been extensively examined in the context of peer influences on addiction but are clearly relevant. Theories of social influence have considerable overlap with each other and there are relatively few contradictions among theories in this domain. Rather, considering the different theories of social influence seems

Principles of Addiction, Volume 1
DOI: http://dx.doi.org/10.1016/B978-0-12-398336-7.00033-4

analogous to viewing an object from different angles and vantages. Certain attributes are more prominent from some perspectives versus others, whereas some attributes are observable only from a particular vantage. We believe that familiarity with multiple theories of social influence is likely to provide the broadest and most comprehensive theoretical understanding of peer influences on addiction. Thus, we provide brief overviews, with more or less detail of multiple theories, which vary in the extent to which they have been empirically applied to addiction.

Social Comparison Theory

Social Comparison Theory describes the causes and consequences of comparing oneself to others. The theory was proposed by Leon Festinger in 1954 as a formal theory with nine hypotheses and eight corollaries. It has remained a dominant theory of social influence and the central theories related to social influence. An initial presumption of this theory was that people compare themselves with others because they want to gauge themselves accurately, especially when objective criteria are not available. Thus, we look to others to help us determine how we should behave. Subsequent research has revealed multiple motivations and functions of social comparisons. Social comparisons can be used to bolster self-esteem or justify behavior (e.g. "I may drink and smoke pot every now and then but at least I'm not like Craig, who can't go a whole day without getting high."). Social comparisons can also function as aspirations in comparisons with those whom we wish to be like (e.g. "I wish I could drink as much as Suzanne without getting totally obliterated," or, "I wish I could quit smoking like Marvin did."). Other motivations include wanting to form a common bond with others, altruism, and self-destruction. The impact of any given social comparison depends on a number of factors including the motivation for making the comparison, relationship to the comparison target, centrality of the comparison dimension to one's sense of self, and direction of comparison. Comparisons with others whom we perceive as being better than we are on a given comparison dimension tend to make us feel worse about ourselves unless we see the comparison target as a source of inspiration. A comparison suggesting that everyone else seems to have fun when they are drinking but I get out of hand and do things I feel embarrassed about later is likely to result in negative affect and self-admonishment. In contrast, an AA newcomer getting a 30 day sobriety chip may be inspired by a fellow member receiving a 6-month sobriety chip. Comparisons can also be made in the opposite direction with others who are worse than we are on some dimension. These types of comparisons can make us feel better about ourselves unless we empathize with the comparison target. A comparison such as "I may drink a lot, but at least I don't drink as much as Nate" may provide justification and affirmation of one's own drinking behavior. On the other hand, comparing ourselves to a friend, with whom we have regularly used substances, who just got busted, may not make us feel so good. Another dimension of social comparison that has been extensively examined is the choice of comparison targets. People may choose comparison targets based on their ability to inspire us or to make us feel better about ourselves. Consistent with social identity (see below), comparisons to others with whom we most strongly identify often have the greatest influences on our behavior. Social comparisons with friends or coworkers will likely have more influence on our behaviors than comparisons with strangers.

Theory of Planned Behavior/Reasoned Action

Theory of Planned Behavior/Reasoned Action was proposed by Ajzen and Fishbein and suggests that behavior is determined by intentions, attitudes (beliefs about a behavior), and subjective norms (beliefs about others' attitudes toward a behavior). The theory was later expanded to the Theory of Planned Behavior wherein perceived behavioral control (beliefs about one's ability to perform a behavior) and behavioral intentions predict behavior. More extensive consideration of these theories are provided elsewhere in this encyclopedia, but the construct of subjective norms is worth additional consideration here. The construct of subjective norms is analogous to the injunctive norm component of other social norms theories and is one operationalization of the more general construct of social norms. Subjective norms refer specifically to how others whom we care about would feel about us engaging in a particular behavior (e.g. "Most people that are important to me think that I should not smoke cigarettes."). According to the theories of reasoned action and planned behavior, if I believe that important people in my life would disapprove if I smoked cigarettes, I should be less likely to intend to smoke cigarettes and subsequently less likely to actually smoke cigarettes. Subjective norms are distinct from other operationalizations of social norms in two ways. They focus exclusively on important others as the reference group and the behavior of relevance is on the perceiver's behavior rather than the behavior in general. Thus, the question is not about the extent to which I think others about whom I care approve or disapprove of smoking but rather the extent to which I think others about whom I care approve or disapprove of MY smoking. This may seem like a small and subtle distinction, and in many cases it probably is. However, in other cases it

may be an important distinction. For example, parents with moderate or favorable views on legalization of marijuana may be less approving of marijuana use by their teenage daughter. While subjective norms and injunctive norms share overlapping features, injunctive norms are framed such that they are inherently consistent with Social Identity Theory and Social Impact Theory (see below) and do not include the stipulations regarding the reference group (important others) or the specification that the behavior in question be the person's own behavior.

Social Identity Theory

Social Identity Theory considers how group membership is incorporated into our self-concept and how this affects our views of other members and nonmembers of our groups as well as members of rival groups. The theory has been used extensively in considering in-group favoritism and out-group discrimination but has received only minimal attention with respect to substance use. Specifically, social identity has been found to moderate the influence of others on substance use. For example, perceptions of the prevalence and approval of drinking among other members of one's group have been found to be more strongly associated with one's own drinking when the individual identifies more closely with the group. Identification with others augments their influence on us. In considering social groups among high school students, an athlete should be more influenced by other athletes, whereas drama club students should be more influenced by other drama club students. Identification with other substance users is highly correlated with personal substance use behavior. This is likely due in part to selection (substance users seek affiliation with other substance users) and socialization (affiliation with other substance users influences substance use). In sum, the people with whom we most strongly identify have the largest influence on our behavior.

Social Impact Theory

Social Impact Theory proposes three variables which are presumed to predict the degree of social influence that a particular source may have. According to this theory, social influence is the product of the strength, immediacy, and number of persuasive agents. Here, strength refers to how much we care about the person or persons who may be attempting to influence us or with whom we are comparing our behavior. This strength dimension is similar to social identity and its inclusion as a predictor of social influence is consistent with most theories of social influence. Immediacy and number are relatively unique factors proposed by the Social Impact Theory. Immediacy refers to proximity of the source or sources of influence. Potential sources of influence are more powerful when they are more proximal than when they are more distal. For example, according to this theory, a teen is likely to have greater difficulty resisting peer influence to smoke a joint in person (e.g. friend pulls out a joint and says, "Look what I have. Do you want to smoke it with me?") than the same request by email or by phone text message. Number refers to the number of independent sources of social influence. More sources of social influence are more persuasive than fewer. Thus, according to the theory, all other things being equal, three friends encouraging a young adult to do tequila shots would be more persuasive than one friend. Basic research on Social Impact Theory suggests that the influence of number diminishes at about four or five independent sources. In sum, Social Impact Theory can be viewed as a theoretical extension of Social Comparison and Social Identity Theories with a unique focus on the proximity and number of sources of influence.

Prototype/Willingness Model

Prototype/Willingness Model is an extension of the Theory of Reasoned Action and posits two paths, a reasoned path and a social reaction path, to engaging in risky behaviors such as substance use. The reasoned path represents an intentional style of processing whereby actions are premeditated and are a function of behavioral intentions. In turn, intentions to engage in a behavior are influenced by one's attitudes and perceptions of other's attitudes toward the behavior (i.e. subjective norms). In contrast, the social reaction path represents a heuristic-based style of processing suggesting that there are times when behavior is unintended and occurs in situations that facilitate risky behaviors such as substance use. The theory suggests that in some risky situations, it is not reasoned decision making (behavioral intentions), but behavioral willingness that determines decisions to engage in substance use. For example, an adolescent may have no predetermined intentions to smoke marijuana but may be perfectly willing to, should an opportunity or situation arise. Similarly, an individual may have no intentions of using a hard drug (e.g. crack cocaine or methamphetamine) but be willing to try it if the occasion arises. Risk prototypes refer to our impressions of individuals who engage in particular behaviors and are presumed to predict behavioral willingness. For example, an individual with a favorable prototype of recreational cocaine users would presumably be more willing to try cocaine in a situation where it becomes available than someone with a less-favorable prototype.

One of the assumptions underlying this theory is that while a person chooses to engage in substance use, substance use often is not planned or even intended. A second assumption is that individuals have distinct social images/representations (prototypes) of the type of person their age who engages in substance use (typology of a person rather than description). These prototypes are associated with behavioral willingness such that the more favorable the image of a substance user, the more likely they are to engage in substance use and to accept the social consequences of being seen as a substance user. An additional assumption of the Prototype/Willingness Model is that the relationship between intentions and behavior becomes stronger than the relationship between willingness and behavior over time.

Problem Behavior Theory and Peer Cluster Theory

Problem Behavior Theory and Peer Cluster theories have both had significant impact on our understanding of adolescent substance use and have been influential in shaping more recent perspectives. Problem Behavior Theory was originally proposed by Richard Jessor as a way of predicting proneness to deviance (unconventionality) and suggests multiple variables that instigate or prevent problem behaviors, and the balance between these variables predict engagement in problem behavior. Variables which instigate deviance have been defined as risk factors, whereas those which prevent or reduce the likelihood of problematic behaviors have been defined as protective factors. Problem behaviors are defined by age and societal norms. For example, consuming two beers at the age of 10 is conceptualized as problem behavior and a social norms transgression; however, consuming two beers at the age of 26 is typically not considered problematic. Deviance proneness leads to a wide range of problem behaviors, and these behaviors positively relate to each other and negatively correlate with conventional or prosocial behaviors. In addition, deviant behaviors in youth are a predictor of behavior problems in adulthood.

Peer Cluster Theory proposes that engagement in behaviors such as substance use is supported or discouraged by interactions with peers. The peer cluster is distinct from the peer group and is defined as a small unit of peers that shape attitudes and influence behaviors to a greater extent than other social network factors. The peer cluster has a powerful effect on an individual and interventions targeting risky behaviors such as addiction to illicit drugs are effective when the individual is separated from the peer cluster or the intervention targets the peer cluster directly.

Deviance Regulation Theory

Deviance Regulation Theory is a recent addition to the literature related to peer influence and has been evaluated only in a handful of studies. The theory provides compelling arguments suggesting that individuals are influenced more by deviance from the norm, rather than by conformity to others. That is, behavior is most influenced by our desire to stand out (deviate) from others in positive ways and not to stand out in negative ways. This is a novel perspective in contrast to most theories of peer influence which implicitly assume that individuals desire to actively conform or to fit in with their peers. The perceived attitudes or subjective norms of the relevant reference group and one's own attitudes, in combination with the situational context, determine what counts as deviating in positive versus negative ways. For example, being the only nondrinker at a fraternity keg party may represent negative distinction, whereas consuming the largest quantity of cheap beer while doing a keg stand at the same party may constitute positive distinction. What is viewed as positive and negative is relative to the individual, reference group, and situation. The theory has novel implications regarding message framing for peer influence based prevention strategies.

Messages that target behaviors viewed as common and healthy should emphasize the consequences of not engaging in the healthy behavior. Messages that target behaviors viewed as common and unhealthy should emphasize the benefits of not engaging in the unhealthy behavior. Messages that target behaviors viewed as uncommon and healthy should emphasize the benefits of engaging in the healthy behavior. Finally, messages that target behaviors viewed as uncommon and unhealthy should emphasize the consequences of engaging in the unhealthy behavior. In each case, the theory proposes that the key is to focus on deviance, rather than conformity, with praise for positive distinction and reproach for negative distinction. The theory has much intuitive appeal and may help explain failures of some public campaigns targeting addictive behaviors.

Social Learning Theory and Social Cognitive Theory

Social Learning Theory applies to several human behavior theories in which the acquisition and maintenance of behaviors such as addictive behaviors depend on the connections between personal factors, environmental factors, and the behavior. Social Learning/Cognitive Theory, to which Albert Bandura greatly contributed, focuses on several key constructs including differential reinforcement, vicarious learning, cognitive processes, and reciprocal determinism.

Differential reinforcement takes place when a behavior results in positive or negative consequences received from the environment or the self. This helps explain why behaviors may change with the environment. Note that consequences to behavior are often social consequences. For example, a teenager using cocaine with peers at a party may receive social approval; however, the same behavior, if observed or discovered by parents or other authorities would likely result in strong disapproval and additional unwanted consequences for the teenager. The likelihood that this teenager will engage in cocaine use is greater if he or she has a positive perception and has less disapproving attitudes toward cocaine use.

Vicarious learning, or modeling, occurs by observation of others' behavior, attitudes, and outcomes of the behavior and can increase the likelihood of the observer engaging in the behavior. Role models such as peers and parents affect expectancies, evaluations, and self-efficacy related to the observed behavior. Thus, even as the consequences we associate with our own behavior shape our future behavior, observing others' consequences associated with their behavior can also shape our behavior (see below for more detail).

Cognitive processes include encoding, organizing, and retrieving information, and these are postulated to regulate behavior and environmental events. An individual cognitively processes information from the environment and determines their behavioral response. Self-regulation can be defined as the ability to arrange environmental incentives and apply consequences. Thus, self-regulation need not be limited to one's ability to choose how to respond in specific situations but can also be applied to one's ability to make choices that affect the degree of exposure to specific influences. For example, if Clyde does not want to smoke marijuana and realizes that he has difficulty saying no to Paul or Mike, he can avoid Paul and Mike as a means of regulating his behavior. A related construct is self-efficacy, which can be defined as the belief that one can engage in a specific behavior and/or produce a specific desired outcome. Self-efficacy can be thought of as context-specific confidence. The extent to which Clyde believes he will be able to resist an offer to smoke marijuana is an example of self-efficacy. Self-efficacy effects and is affected by behavior. The more confidence Clyde has in his ability to resist peer influence, the more successful he will be in doing so. In turn, successful instances of resistance will increase self-efficacy to resist in the future. Furthermore, seeing a peer resist influence can boost one's self-efficacy in resisting peer influence.

Reciprocal determinism describes the associations between behavior and environmental and personal factors, each of which is affected by the other two factors. For example, peers and social environments affect subsequent smoking behaviors, and vice versa.

DIRECT AND INDIRECT INFLUENCES

Peers can contribute to addictive behaviors by way of direct (active) or indirect (passive) influences. Direct influences range from polite gestures such as "would you like a cigarette?" to overt commands such as "finish your beer." Refusal of these direct commands, especially when surrounded by peers, may result in feelings of inferiority, loss of social ease, fear of rejection and exclusion, and actual rejection or exclusion. In contrast, indirect peer influences are more subtle, and these include modeling, which is the imitation of observed behavior. For example, if someone were to observe a group of their friends using marijuana, that person would be more likely to imitate and even adopt this behavior.

Environmental influences such as social expectations contribute greatly to addictive behaviors. Research on alcohol use indicates that social expectations have a substantial influence on the association between peer and own alcohol use. An example of this phenomenon is the divergent social expectations for male and female college students with regard to drinking. In general, men are expected to drink more than women and men who drink more than other men are viewed more favorably than women who drink more than other women. In addition, although women are generally offered more drinks than their male counterparts, research indicates that women turn down offered drinks more often than men.

MODELING

Modeling – a form of indirect influence – is defined as imitation of another's behavior, presumably based on perceived contingencies of engaging in the behavior. For example, seeing another person receive social reinforcement for smoking marijuana would increase the probability that the viewer will try marijuana. During early life stages of childhood and adolescence, influential models include parents and other family members. However, during teen and adult stages of life, peers become more influential. Models with particular influence are peers such as siblings, classmates, coworkers, and friends.

Modeling research studies sometimes involve the use of confederates. A confederate is someone who participates in the experiment but has key knowledge of the nature of the study. This person is an actor who is not recognized by other participants in the study as

the hand of the researcher. A series of alcohol studies in modeling utilizing confederates have shown that participants' level of consumption of alcoholic beverages is affected by the drinking behavior of those around them. For instance, "drink matching" is the phenomenon that occurs when participants match the rate of drinking and the beverage selection of the confederate. Therefore, if the confederate chose to drink a beer rather than a cocktail, and drank half of the beer in 10 minutes, the participant would be likely to also select and consume his or her drink in a corresponding manner. To illustrate, if John were to attend a wedding during which the majority of guests were slowly sipping wine, John would likely follow their example, and similarly sip wine slowly, as opposed to doing shots or chugging beer.

Research indicates that family history and gender may play a part in susceptibility to indirect influences such as modeling. Males have been shown to better match confederates' drinking rates than females. Furthermore, having a family history of drinking problems increases the likelihood of matching to a greater degree. Thus, family history appears to moderate the susceptibility to indirect social influences on drinking. However, research shows that when the participant is with a group of sociable versus unsociable peers, the participant is likely to match the drinking rate of the group's majority, regardless of family history.

Modeling also applies to behaviors other than alcohol consumption. Indirect influences are applicable to a variety of behaviors ranging from deviant addictive behaviors like tobacco and marijuana use to socially acceptable behaviors like physical activity. For example, if someone had a group of friends who regularly exercised and approved of exercise, that person would likely be subjected to the indirect influence of modeling and at the very least, this person would probably feel some degree of pressure to adopt this behavior. Related to modeling and indirect influences, it is important to point out that individuals often have expectancies about addictive behaviors before they ever try them. For example, elementary students report alcohol expectancies before ever trying alcohol.

SOCIAL NORMS

Social norms generally refer to implicit or explicit rules regarding appropriate behavior. They provide a common framework for understanding and interpreting behavior. They represent shared values, some constant and some variable, across cultures and historical periods. Examples of social norms include wearing clothing, taking turns when talking, and not picking one's nose in public. Many of our customs and laws are designed to enforce prominent social norms, whereas others are governed more by social approval and disapproval. Social norms have a profound impact on our behavior. In some instances, such as substance use among young adults, social norms appear to be among the strongest and most consistent predictors of behavior.

Research has shown a significant link between perceived norms and addictive behaviors. For example, students who perceive that those around them support alcohol use and consume excessive alcohol are more likely to use alcohol themselves. Males tend to perceive greater support for alcohol use in their peers than females, putting males at a higher risk for succumbing to alcohol-related peer influences. Social norms have been more precisely defined upon two dimensions: perceived versus actual and descriptive versus injunctive.

Perceived versus Actual Norms

An important distinction in thinking about social norms is the difference between one's perception of the social norm and the actual social norm. This distinction is important for at least two reasons. First, we are not influenced by reality *per se*, but by our perception of reality, thus it is perceived norms, rather than actual norms that influence behavior. Second, perceptions are rarely a perfect reflection of reality. Thus, perceptions of what others approve of may or may not accurately reflect what others actually approve of. Similarly, perceptions or estimates of how many others engage in a given behavior are often inaccurate. A teen's perception that "everyone else is doing it" is almost certainly an overestimate for most behaviors in which this argument might be offered as justification for engaging in the behavior. With respect to addictive behaviors, much research has revealed systematic biases in perceived norms, particularly among, but not limited to, adolescents and young adults. When asked to estimate the level of approval and/or the prevalence of a given risk behavior such as heavy drinking, smoking, marijuana use, or other substance use, there is a strong tendency for people to overestimate, and the greater they overestimate, the more likely the perceiver is to engage in the behavior him/herself. That is, most individuals overestimate the approval of heavy drinking but heavy drinkers overestimate more than lighter drinkers or abstainers. There is also some evidence that suggests people underestimate the use of protective behaviors, such as using a designated driver.

The systematic misperception of social norms has profound implications. Behavior is heavily influenced

by perceptions of others' approval and misperceptions are often in the direction of viewing unhealthy behaviors as being more widely accepted or more prevalent. Thus, individuals may initially engage in risky behavior largely because they believe that others are engaging in the behavior or that others strongly approve of the behavior, when in fact few others may be engaging in the behavior and the level of approval may be quite low. Thus, a primary motivator of engaging in addictive behaviors is often based on faulty presumptions regarding social norms.

There are multiple possible explanations for the systematic bias between perceived and actual norms of addictive behaviors, which are not mutually exclusive. One explanation for misperception is that excessive behaviors tend to be more salient and/or memorable. Consider a party in which 100 people are present and 99 of them are either not drinking at all or are having one or two drinks and behaving appropriately. We are more likely to remember the one who is in the bathroom vomiting because he is drunk than the 99 who are behaving appropriately. When we remember the party, it is the inappropriate behavior that we remember. Relatedly, when we talk to others about the party we are less likely to talk about the 99 who were behaving appropriately but are more likely to talk about the one who was excessive. Thus, salience of excessive behavior distorts our representation of events and affects communication about behavior. Another possible explanation which has been found in some studies is a general reluctance to voice disapproval of excessive behaviors. Because silence is viewed as consent, if one person is endorsing the harmlessness of marijuana in a crowd of people, even if most people privately disapprove but are reluctant to voice their opinion, observers are likely to assume that most of those listening share approval of marijuana use. Justification and self-serving biases are other possible explanations for the bias between perceived and actual norms. Individuals who engage in excessive behavior may feel justified (i.e. less guilty) when they overestimate the prevalence of those behaviors among their peers. Similarly, individuals who do not engage in addictive behaviors, or who do so infrequently, may enhance their self-view by assuming that they are relatively unique in their abstinence or moderation. All of these explanations likely play some role in misperception, and their relative contribution may vary by behavior.

Descriptive versus Injunctive Norms

Social norms have also been described as being of two types: descriptive and injunctive. Descriptive norms, also called popular norms and behavioral norms, refer to the prevalence, quantity, and/or frequency of a given behavior. Believing that most college students engage in heavy drinking would be an example of a perceived descriptive norm. Injunctive norms refer to degree of approval or disapproval of a given behavior. They are similar to subjective norms described above but do not necessarily focus on one's own behavior or important others as a reference group. Believing that most people strongly disapprove of drinking and driving would be an example of an injunctive norm. Descriptive and injunctive norms are moderately correlated and independently associated with behavior. Recent work suggests that descriptive and injunctive norms often interact such that perceiving a behavior like smoking to be common (descriptive norm) is more strongly associated with behavior when perceived approval for the behavior (injunctive norm) is also high. Thus, an individual who believes most others disapprove of smoking will be less likely to smoke even if he or she sees many people smoking. In sum, perceived descriptive and injunctive norms are both positively associated with behavior.

RESISTANCE

Research indicates that although direct and indirect peer influences can be powerful indicators of future behavior, not everyone exposed to these influences succumbs to them. People with greater ability to resist to direct peer influence are those who are more socially confident, competent, and less socially insecure or anxious. To reiterate this, a mature, confident person with a supportive family and an established group of friends who maintains consistent, strong disapproval of drug use would be more resilient to active and passive offers of drugs even if that person were to attend a school where drug use was the norm or go to a party where drug abuse was prevalent.

Social inoculation is a construct which suggests that exposure to behaviors or attitudes heightens resilience to counterarguments. Social inoculation is thought to further increase one's resistance to the persuasive forces of social influence. For example, if a teacher wanted to inoculate his class against drug abuse, he could educate his students about the prevalence and health effects of drug use and allow the students to observe and engage in role playing the refusal of offered drugs. By doing so, the teacher would be inoculating his class against the direct and indirect influences regarding drug use, with the hope that if the students later receive drug offers from peers, they will be equipped with adequate resistance to refuse those offers.

IATROGENIC EFFECTS

Although friendships are viewed as positive relationships, these relationships can have inadvertent adverse effects due to negative peer influence. These are called iatrogenic effects. Group interventions that target behavioral problems like substance abuse have shown that iatrogenic effects can have negative outcomes for vulnerable participants. These negative outcomes can range from adoption of addictive behaviors to maladjustment as an adult. Peer aggregation among deviant individuals can promote deviancy training, which increases the likelihood of future addictive behavior. Deviancy training refers to processes by which adolescents and young adults expand their knowledge and repertoire of deviant behaviors as a function of interacting with more deviant peers. Potential mediators of deviancy regulation include normalization of less extreme behaviors, transmission of ideas, and encouragement and competition of extreme behaviors. For example, in an inpatient treatment setting, an adolescent may make friends with peers who have engaged in more extreme behaviors, and/or who present novel methods and ideas related to substance use. Moreover, exposure to deviant peers may increase accessibility of substances following treatment.

Iatrogenic effects present a challenge, but this challenge can be overcome. Although iatrogenic effects are significant, there is little evidence of these effects across research studies. Therefore, this effect is not as extensive as initially thought. Furthermore, iatrogenic effects can be constructively exploited, resulting in positive outcomes such as a decrease in problem behavior. Mixing prosocial and high-risk peers is an effective way of positively harnessing iatrogenic effects. Recent studies indicate that supportive peer involvement effectively reduces the problem behavior, especially for pairs of two people (dyads) rather than in a group setting. For example, the smoking cessation intervention would be more effective when pairing a smoker with a supportive nonsmoker, or pairing a heavy smoker with a light smoker.

SUMMARY

In summary, peer influences on addiction are central to the initiation of substance use and engagement in addictive behaviors. Peer influences seem to peak in adolescence and young adulthood. This is not to say that peers do not have a substantial influence later in life but the nature of peer relationships change considerably as emerging adults begin to transition into adult roles and responsibilities. Even when peer influences seem most evident earlier in the developmental course of life, they also seem more evident in the early developmental trajectory of addiction. Substance dependence typically includes nonsocial use and nonsocial motivations for use (e.g. tension reduction and withdrawal avoidance).

Peer influence is embedded within the larger context of social influences. A broad review of social influence theories suggests several common themes. Social influences can be explicit but they are often implicit and based on our imperfect beliefs about others' expectations of us. Moreover, others' expectations do not influence us, but rather our beliefs about others' expectations, and these are often quite inaccurate. Another common theme is that the degree of influence that others have on our behavior depends on how much we care about or identify with them. People whom we care nothing about are less likely to influence us than those with whom we closely identify. A third theme is that what is viewed as good and bad is relative to the social group. Being able to drink large quantities of alcohol is good for some and not good for others. Finally, social influences are often governed by social consequences. We observe how people respond to our own and others' behaviors and those responses accordingly increase or decrease the likelihood of future behaviors.

SEE ALSO

Cognitive Factors in Addictive Processes

Glossary

Heuristic efficient, simple rules that are learned or hard coded by evolutionary processes that explain how people make judgments, solve problems, and make decisions. Generally, heuristics are effective but can lead to biases or errors in some cases.

Iatrogenic effects inadvertent negative or adverse effects resulting from advice or treatment.

Reference group a group that acts as a frame of reference to which another group is compared when evaluating qualities such as behaviors and attitudes.

Binge Drinking

Brian Borsari

Brown University, Providence, RI, USA

OUTLINE

CURRENT DEFINITION OF BINGE DRINKING

The term binge drinking has appeared in print for many years, although a precise definition did not exist. In 2004, The National Institute of Alcohol Abuse and Alcoholism (NIAAA) attempted to reduce the ambiguity of previous definitions used in popular society by proposing a definition of binge drinking. On February 5, 2004, the NIAAA National Advisory Council approved the following definition for binge drinking, which had been put forth by a special task force that had been assigned the responsibility of defining binge drinking and differentiating it from other patterns of alcohol use. This task force met in a 2-day workshop held in November 2003, in which experts in neurology, psychology, and physiology discussed how to best define and measure binge drinking. The following definition resulted from these efforts:

> *A binge is a pattern of drinking alcohol that brings blood alcohol concentration to 0.08 g% or above. For the typical adult, this pattern corresponds to consuming five or more drinks (male), or four or more drinks (female) in about 2 h. Binge drinking is clearly dangerous for the drinker and for society.*

This definition was accompanied by the following clarifications: (1) a "drink" refers to half an ounce of alcohol (e.g. one 12oz. beer, one 5oz. glass of wine, or one 1.5oz. shot of distilled spirits); (2) binge drinking is different from risky drinking (reaching a peak BAC of 0.05 g% to 0.08 g%) and a bender (2 or more days of sustained heavy drinking); (3) for some individuals (e.g. older people or people taking other drugs or certain medications), the number of drinks needed to reach a binge-level BAC is lower than the "typical adult"; (4) people with risk factors for the development of alcoholism have increased risk with any level of consumption; (5) for pregnant women, any drinking presents risk to the fetus; and (6) drinking by persons under the age of 21 is illegal.

Since this announcement was published in the NIAAA newsletter, this has been the standard definition for binge drinking in the United States, and it has been adopted in other countries as well, especially in the context of adolescent and college drinking research.

HISTORY OF THE TERM

Multiple definitions of binge drinking exist and the meaning of the term varies according to the source and the era. For example, the Oxford English Dictionary defines binge drinking as the consumption of an excessive amount of alcohol in a short time, Collins English Dictionary defines it as the practice of drinking excessive amounts of alcohol regularly, and Dictionary.com describes the behavior as the consumption of dangerously large quantities of alcoholic beverages in one sitting. All three of these definitions indicate that binge drinking occurs in one occasion, but these definitions fail to provide a concrete definition of what excessive amounts, regularly, and dangerously large.

Until approximately 20 years ago, a binge was often thought of to be an intense, multiday or week-long period of drinking that often was done in a solitary fashion. The purpose of binge drinking was to become intoxicated, and a loss of control was a component of such a binge drinking episode. The binge was often accompanied by significant consequences such as blackouts, injuries and often ended in incarceration or inpatient treatment. Although a binge was occasionally referred to as a single event, the amounts were usually extreme (e.g. 12 or more drinks). Furthermore, binge drinking episodes, or binges, would often be separated by extended periods of sobriety.

The conceptualization of a binge as a discrete episode of extreme drinking is consistent with Jellinek's epsilon alcoholism, or periodic alcoholism, marked by the individual's primary drinking style being binge drinking. This form of alcoholism was relatively rare, however, and Jellinek suggested that it might have been a symptom of another disorder. Further confusion was caused by the fact that binge drinking episodes could occur in the context of other types of alcoholism: alpha (psychological dependence on alcohol), beta (alcohol-related consequences such as cirrhosis occur in the absence of psychological or physiological dependence, proposed to occur in cultures in which heavy drinking is accepted), gamma (progression from psychological to physiological dependence with loss of control), and delta (psychological and physiological dependence without lack of control). Further confusing the issue was the term bender, or bender alcoholics. Benders were popularly conceptualized as a drinking bouts of 48 h or more, with a failure to meet work, family, or other obligations.

Therefore, for many years, the terms binge drinking and bender were used colloquially and in research in the United States. Through the 1980s, the term binge drinking was used to describe a single incident of drinking five or more drinks per occasion in research, but there was still no formal consensus on the definition of the term. However, the term became popular in the media and in research in relation to college students started in the early to mid-1990s. Specifically, Dr Henry Wechsler of the Harvard School of Public Health had started to conduct large-scale surveys of college student alcohol use – the College Alcohol Survey. Dr Wechsler had been studying heavy drinking in college students for over a decade and had first used the term in a 1991 report. The College Alcohol Survey, funded by grants from the Robert Wood Johnson Foundation, permitted a large-scale examination of this phenomenon. The CAS surveyed over 50,000 students at 140 colleges and universities in the United States. The first of these surveys was conducted in 1993, and subsequent surveys were conducted in 1997, 1999, and 2001. Originally defined as having five drinks per occasion, the definition was later amended to five drinks on one occasion for men and four drinks on one occasion for women. Through the many research articles published on the topic from this data, and subsequent research, "binge drinking" was conceptualized as the threshold for which alcohol-related harms became significantly more likely for the drinker, as well as those who share the college environment with the drinker. These "secondary effects" were also a source of concern for school administrators, and a commonly cited reason to increase prevention and intervention efforts on college campuses.

As the term binge drinking appeared with greater frequency in research and the popular press, often coinciding with the release of results of another CAS survey, there was considerable debate about the definition of binge drinking. One benefit of the term binge drinking is the potential to quickly provide descriptive information about a drinking episode. However, opponents of the term binge drinking definition argued that the use of the term binge drinking was not always synonymous with intoxication prior to NIAAA's definition in 2004 and that this threshold was not an appropriate marker of excessive drinking for everyone. In addition, the use of the term binge drinking in the media was believed to sensationalize alcohol use to the point where it might contribute to inaccurate normative perceptions about the frequency of heavy intoxication. Therefore, there was (and continues to be) debate regarding the definition of binge drinking that is markedly different from the historical definition. Synonyms of the term binge drinking were introduced to differentiate the historical and the current definition for binge drinking, and these synonyms included heavy episodic drinking, risky drinking episode, harmful drinking, dangerous drinking, excessive drinking, and problem drinking.

Concurrent with the focus on binge drinking in the United States, there was a large-scale refinement of the phrase binge drinking as researchers and policy makers

around the world attempted to define what exactly constituted binge drinking. As a result, efforts were made to shift the focus to single days, or single drinking occasions, and also to determine how many drinks needed to be consumed to constitute a binge. However, to date, there is no worldwide consensus on the amount of alcohol that needs to be consumed to qualify as a binge drinking episode. Indeed, global cutoffs include a half bottle of spirits or two bottles of wine on one occasion (Sweden); double the daily recommended amount of alcohol – about 2–3 drinks (or 1 or 2 for women) (England); six bottles of beer (Finland); and 6 or more units of alcohol (women) and 10 or more units of alcohol for men (United Kingdom).

In addition to a lack of consensus regarding the amount of alcohol required to constitute a binge, there was still omitted information that directly influences the degree of intoxication, related risks, and cultural issues. First, a time frame in which the alcohol was consumed was not specified. For example, the threshold of drinks could be attained in 5 min or 5 h, with clear implications on the degree of intoxication. Later, the phrase in one sitting was often included but did not completely address the issue. Second, the body weight of the individual was not taken into account. As a result, the degree of intoxication from a binge drinking episode was difficult to discern. Third, there have been no attempts to account for the effect of previous or concurrent food consumption on intoxication. Finally, the motivation for binge drinking can vary – in some situations getting intoxicated is the desired outcome (e.g. in college students) and in others situations binge drinking may be unintentional or related to mental illness. Taken together, these issues make it difficult to precisely interpret research assessing binge drinking episodes. That said, researchers around the world continue to examine different drink cutoffs and definitions for binge drinking, seeking to find the definition that best links levels of intoxication with consequences.

The term binge drinker has often been used, but the precise definition of what makes someone a binge drinker has remained vague. Therefore, there have been various attempts to define a binge drinker by the frequency of binge drinking episodes he/she engages in over a certain time period. Time frames used to capture binge drinking have ranged from the past week to the past year. Overall, a 6-month time frame has been determined by many to be most informative in linking binge drinking to alcohol-related consequences. Dr Wechsler and colleagues further differentiated between binge drinkers (one or two binge drinking episodes in the past 2 weeks) and frequent binge drinkers (three or more binge episodes in the past two weeks). However, this definition has not been universally accepted.

Because of the lack of a stable definition of the term binge drinking, care must be taken to clearly define binge drinking when interpreting or disseminating research findings, especially from different studies. However, as the definition of binge drinking has been clarified over the past 30 years, research has implemented the item into interviews and surveys with a variety of populations. It is possible to identify some trends in the literature on binge drinking (defined in most studies as five or more drinks on one occasion for men and women).

BINGE DRINKING IN ADOLESCENTS

Binge drinking typically peaks in adolescence and declines. Examination of large-scale surveys assessing binge drinking indicated an overall decrease in binge drinking in adolescents and young adults over the past 30 years. However, there was one exception: the rates of binge drinking in college students remained stable. One of the common findings in the research with college students was that often the binge drinking observed on campus was a continuation of binge drinking that had occurred in high school. Some other trends were apparent, as well: women seem to be engaging in binge drinking more, and binge drinking decreased among minority men (but not women).

Research with adolescents consistently indicates that binge drinking is related to injuries, violence, driving while intoxicated, unsafe sexual practices, and death. In addition, binge drinking is the most common style of drinking among adolescents, accounting for over 90% of the alcohol consumed by high school students. This is of concern, as establishing this pattern of alcohol use early in life may lead to continued binge drinking throughout the lifespan, as well as increase the risk for developing alcohol dependence. The association of binge drinking with the concurrent use of other substances, such as tobacco, has also been repeatedly observed.

Recent research has raised worries about the long-term effects of binge drinking on the developing brain; specifically, adolescent brains may be more susceptible to damage from binge drinking than those of adults. Specifically, research has indicated that binge drinking (2–3 times per month, at least 4–5 drinks per occasion) can negatively influence adolescents' performance on thinking and memory tests. Furthermore, it seems that binge drinking may influence the white matter in the brain, making communication among brain cells less efficient. Other areas of the brain, such as the hippocampus, may also be compromised by binge drinking. The long-term effects of this impairment, and whether

it can be partially or totally reversed, have yet to be determined.

BINGE DRINKING IN YOUNG ADULTS

Binge drinking is most prevalent in the 18- to 20-year-olds, and this behavior appears to be especially prevalent in college students. Large-scale surveys indicate that approximately 68% of all college students drank alcohol in the past month, and 40% of college students engage in binge drinking. Recent studies indicate that alcohol use by college students has increased in the late 1990s and early 2000; for example, cross-sectional data showed a 16% increase in the proportion of students who engage in frequent heavy episodic drinking ($\geq$3 in the past two weeks) between 1993 and 2001. Heavy episodic drinking is related to numerous alcohol-related consequences in college students, including academic difficulties, property damage, risky sexual activity, blackouts, alcohol poisoning, and death.

In 2009 and 2010, attention was placed on drinking behaviors labeled extreme binge drinking or industrial-strength bingeing. This practice involves drinking very large quantities of alcohol (10 or more drinks) over a short time (less than an hour), in order to achieve high levels of drunkenness. This practice has yet to receive any formal research attention, however, so its prevalence and associated risks are not known. However, the emergence of this practice indicates that binge drinking and its conceptualization will continue to evolve.

BINGE DRINKING IN ADULTS

The consequences associated with binge drinking in adolescents and college students extend into adulthood. Binge drinking is common in adults, and more than 50% of the alcohol consumed by adults is consumed in the context of binge drinking episodes. In addition, men tend to binge drink more than women, accounting for as many as 81% of adult binge drinking episodes.

BINGE DRINKING IN THE ELDERLY

Binge drinking rates are lowest in adults aged 65 and older, although the majority of the risks associated with younger adults are still present in this population (e.g. drinking and driving, injuries). There may be a unique consequence in this population; however, preliminary evidence suggests that binge drinking may be associated with the onset of dementia. Consistent with younger adults, men are more likely to binge drink, and Caucasian men are most likely to binge drink, followed by Hispanic and African American men. This trend is reversed in women, with African American women exhibiting more binge drinking than Caucasian or Hispanic women. For both men and women, however, social isolation and the lack of an observed connection between psychological distress and binge drinking may make detection and intervention difficult by family, friends, and caregivers.

GENDER DIFFERENCES IN BINGE DRINKING

Across all age groups, men consistently report higher levels of binge drinking than women, even with the gender-specific definition. Binge drinking in pregnant women can cause significant danger to the fetus such as fetal alcohol spectrum disorders (a risk also relevant to adolescents and young adults).

ETHNIC DIFFERENCES IN BINGE DRINKING

Surveys across all age groups indicate, with little fluctuation, that Caucasians binge drink more than any other racial group. Hispanics report the second-highest rates of binge drinking, followed by African Americans. Asians exhibit the lowest rates of binge drinking, although research has indicated that among Asian subgroups, Koreans and Filipinos report the highest rates of binge drinking.

CULTURAL DIFFERENCES IN BINGE DRINKING

Alcohol has a role in each culture, and the practice of binge drinking has different levels of acceptance depending on the culture in which it occurs. For example, in China, binge drinking rates are generally quite low (e.g. 4% of the population). However, at banquets, official functions, or business meetings, many rounds of spirits are often consumed with the toast of gambei (dry glass). The refusal to drink can be interpreted as an insult, leading to social or business repercussions. This pattern of consumption can lead to extreme intoxication, and the deaths of several government officials led the Chinese Communist Party to develop a formal code of conduct for officials as well as ban lavish weddings and funerals in 2010. However, binge drinking is also becoming more prevalent in adolescents and young adults in China.

A similar pattern of binge drinking is also found in Japan, where business meetings are often accompanied with heavy drinking. A common saying iki-iki-iki (drink-up, drink-up) is a verbal cue to have individuals finish their drink in one gulp. Alcohol is highly prevalent in Japanese culture, and binge drinking is seen as part of business. Refusing offers to drink with one's boss may lead to not being promoted. In the larger culture, becoming intoxicated is seen as a way to relax, speak one's mind, or get to know others. Public drunkenness is also more highly tolerated in Japan than other countries. Certain times of the year are also associated with heavy drinking, particularly nenmatsu (the year's end) and nenshhi (the year's beginning). Japanese alcohol consumption has decreased since peaking in the late 1990s, partially attributed to an aging population and a change in societal norms toward binge drinking.

In Europe, eastern and northern Europeans seem to engage in, and be more accepting of, binge drinking and drunkenness. For example, drinking to get drunk is commonly practiced in the United Kingdom, and in Russia binge drinking (zapoy) usually consists of two days of continuous drunkenness. In contrast, southern Europe – France, Italy, and the Mediterranean counterparts – are less tolerant of binge drinking and public drunkenness.

PREVENTION AND INTERVENTION EFFORTS

As the definition of binge drinking has evolved, as have the efforts to reduce or stop this behavior in individuals of all ages. These efforts include educating healthcare workers about detecting binge drinking and informing patients about its associated risks, raising the drinking age, limiting access to alcohol, and the increased enforcement of drinking and driving laws. As the concern about binge drinking on college campuses increased throughout the 1990s in the United States, social norms marketing (SNM) campaigns became a widespread approach to address binge drinking in college students. This approach proposes that heavy drinking in students is influenced by their misperception of other students' drinking. Therefore, using mass media to educate students about actual rates of binge drinking (if lower than the perceived rates) will therefore reduce on-campus alcohol use, as the students would feel less pressure to conform to the perceived norm. In this way, SNM campaigns attempted to change the culture of heavy drinking on college campuses. Results for this approach have been mixed. In clinical settings, individual and group brief motivational interventions (BMIs) typically provided to individuals currently engaging in binge drinking and experiencing problems, provide skills to resist offers of alcohol from peers, alternate behaviors to drinking, and educate the individual about the risks associated with binge drinking. These interventions have been administered in a wide variety of contexts, formats, and settings, and research indicates a consistent small to moderate effects on the frequency of binge drinking and related consequences. One area of particular innovation is web-based interventions, which have demonstrated efficacy with college students and adults and have fostered continued efforts to refine approaches to screening, assessment, and intervention through the internet.

Glossary

BMIs brief motivational interventions.

Binge this term has had a variety of interpretations, but commonly conceptualized to be an intense episode of drinking, the purpose of which was to become intoxicated.

Binge drinking this term has had various definitions over the years, but was formally defined in 2004 by the National Institute of Alcohol Abuse and Alcoholism. A pattern of drinking alcohol that brings blood alcohol concentration to 0.08 g% or above. For the typical adult, this pattern corresponds to consuming five or more drinks (male), or four or more drinks (female) in about 2 h. Binge drinking is clearly dangerous for the drinker and for society. This definition has not been accepted universally by clinician and researchers, however.

Binge drinker as defined by Dr Wechsler, binge drinkers are individuals who have had five or more drinks in a row (four drinks for females) at least once in a 2-week period. This definition of a binge drinker has been further refined to take into account the frequency of binge drinking. Specifically, an occasional binge drinker is defined as an individual who has had five or more drinks in a row (four drinks for females) once or twice in a 2-week period, and a frequent binge drinker is an individual who has had five or more drinks in a row (four drinks for females) three or more times in a 2-week period.

Bender a two or more days episode of heavy drinking, often accompanied by blackouts or loss of consciousness.

Heavy episodic drinking term used to describe a drinking incident that leads to drunkenness, and the amount consumed varies among definitions.

NIAAA National Institute of Alcohol Abuse and Alcoholism.

Risky alcohol use defined in 2004 by the National Institute of Alcohol Abuse and Alcoholism as a drinking event in which an individual's peak blood alcohol level of 0.05 g% is obtained.

CHAPTER

35

Alcohol's Effects on Sexual Arousal and Sexual Functioning

William H. George, Amanda K. Gilmore

University of Washington, Seattle, WA, USA

OUTLINE

OVERVIEW

Alcohol and sexuality are closely linked in art, history, popular culture, anecdotal experience, and clinical lore. The sheer ubiquity and durability of these linkages suggest that something about drinking alcohol systematically co-occurs with or systematically influences something about sexual responding. Scientists have investigated these possibilities using a variety of research methods including questionnaire surveys, personal interviews, and laboratory experiments. Research findings indicate that alcohol is reliably associated with and can exert a causal impact on a variety of sexual processes and outcomes, including – for example – the degree to which one perceives situations and events as sexual in nature and one's willingness to engage in risky sexual decisions, such as unprotected intercourse with a new partner. However, there is a more basic question that potentially underpins these connections from alcohol to sexual processes and outcomes: How does acute or chronic drinking affect sexual functioning? That is, does alcohol intoxication affect sexual desire, arousal, orgasm, and sexual pain; if so, how; and do these potential effects contribute to clinically diagnosable levels of distress? These questions are the focus of the current chapter.

Alcohol is related to variability in sexual functioning in both men and women. The relationship between alcohol and sexual functioning is so evident in both community and clinical samples that the disorder *Substance-Induced Sexual Dysfunction* is in the Diagnostic and Statistical Manual of Mental Disorders, fourth edition text revision. Survey research indicates that women report more problems with sexual functioning than men. However, alcohol use rates are typically higher among men than women. In studies with men,

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00035-8

heavy drinking and alcohol abuse have been found to be associated with more sexual dysfunction and less sexual satisfaction, yet these effects are thought to diminish with sobriety. In studies with women, heavy drinking and alcohol abuse have been associated with sexual dysfunction. However, these studies only imply an association and do not indicate causality. Therefore, it is important to examine both survey and experimental research when discussing alcohol's impact on sexual functioning. For example, it is possible that an individual may use alcohol to cope with a sexual dysfunction because of popularly held beliefs that alcohol enhances sexuality. However, because alcohol can have the opposite effect on sexual functioning, alcohol use to cope with sexual dysfunction may actually decrease sexual functioning. This chapter will discuss the relationship between alcohol and sexual functioning. Because sexual functioning differs based on gender, we will examine research regarding men and women separately.

DEFINITIONS

It is worthwhile to specify several definitions at the outset. *Sexual functioning* can be defined as a normative sexual response including sexual desire, sexual excitement and arousal, orgasm, and resolution. For the purposes of this chapter, we will focus on sexual function in relation to sexual desire, sexual arousal, orgasm, and sexual pain. *Sexual dysfunctions* are defined as disturbances in the normal sexual response that also cause distress and difficulties interpersonally. In contemplating alcohol's effects on sexual functioning, it is important to distinguish between acute alcohol consumption versus chronic consumption. Acute consumption refers to the amount of alcohol consumed in a singular index drinking episode and the resultant effects of alcohol on sexual responding in the context of that index episode. Acute alcohol consumption is operationalized differently in survey and interview studies compared to experimental studies. In survey and interview studies, acute alcohol consumption refers to retrospective reports of the amount consumed in an episode and the sexual events occurring during or after the drinking episode. Alternatively, in experiments, acute consumption is operationalized by having research participants come into a controlled laboratory setting and ingest beverages containing predetermined dosages of alcohol designed to result in precisely targeted blood alcohol concentrations. In contrast with survey and interview studies, which yield primarily correlational findings, such experiments on acute alcohol effects have been uniquely informative about the existence and nature of alcohol's causal impact on sexual functioning. Chronic alcohol consumption refers to the amount of alcohol consumed habitually over time and is operationalized based on research participants' retrospective reporting. These studies, while less informative about causality, have been uniquely informative about alcohol's associations with sexual functioning in real life – as opposed to strictly laboratory settings. Within the domain of chronic alcohol consumption, it is important to distinguish two levels of problematic drinking: *Alcohol abuse* and *alcohol dependence,* which are diagnosable clinical conditions. Alcohol abuse refers to chronic use that results in a number of social, emotional, or physical problems. Alcohol dependence, the more severe condition of the two, refers to chronic use that results in numerous problems and is often accompanied by physical dependence and alcohol tolerance symptoms.

ALCOHOL AND SEXUAL DESIRE

Women

Approximately 30% of women in the United States are affected by problems with sexual desire to a clinical level. The current research on women's alcohol use and sexual desire is limited, and the few studies that have examined this relationship have had contradictory findings and consist predominately of descriptive and survey research. The majority of research has found that alcohol is related to increased sexual desire in women. However, studies have also found the opposite effect as well as null effects on sexual desire. Studies supporting the finding that alcohol is related to increased sexual desire have included both alcohol dependent samples and community samples without alcohol problems. One study specifically examined red wine intake in Italian women and found that women who reported moderate daily red wine intake also reported higher levels of sexual desire compared to women who did not drink alcohol. Studies finding the opposite effect, that alcohol inhibits sexual desire, have primarily been women with alcohol problems. One study found that although alcohol-dependent women were more likely to believe that alcohol enhanced sex compared to women who were not alcohol dependent, they were also more likely to have a lack of interest in sex. Finally, one study using an epidemiological sample found that inhibited sexual desire was not associated with alcohol use for men or women. No study that we are aware of has examined alcohol and women's sexual desire in an experimental paradigm.

We currently do not know why there are contradictory findings of alcohol's effect on women's sexual desire. One possible reason may be sex-related alcohol expectancies (beliefs women hold about the effects of

alcohol on sex). It is a commonly held belief that alcohol increases sexual desire and enhances sex, thus a woman might experience more sexual desire when intoxicated if she holds that belief. However, experiments indicate that physiologically, alcohol typically has an inhibiting effect on the sexual functioning cycle of arousal and orgasm. It is possible that studies finding that alcohol increases sexual desire are capturing an alcohol expectancy effect. However, further research using experimental designs would be useful to gain a better understanding of these contradictory findings.

Men

Approximately 15% of men are affected by problems with sexual desire to a clinical level. While there has been extensive research on the relationship between alcohol and sexual arousal, little is known scientifically about the relationship between alcohol and men's sexual desire, except that chronic heavy drinking can reduce sexual interest and desire. Anecdotal and clinical indications are that acute alcohol intoxication has a disinhibitory effect, increasing men's sexual interest and desire. Cross-sectional survey research indicates that men – and women – generally expect that alcohol disinhibits and enhances sexual feelings and behaviors. Men experience this as true for self and for others, as true in the past, and as likely to be true in the future. Only a handful of relevant experimental studies have been conducted. Although sexual desire was not assessed *per se*, experimental findings have indicated that acute alcohol consumption variables – including placebos, low to moderate dosages, explicit situational alcohol cues, and implicit alcohol priming cues – result in heterosexual men reporting and exhibiting greater interest in erotic material, reporting greater arousal, and rating women as more sexually attractive. Thus, at present, it seems clear that men expect that acute alcohol increases sexual desire and when exposed to alcohol acutely they respond more strongly on indices related to sexual desire. More experimental research is needed, which directly measures sexual desire independent of arousal and evaluates alcohol's direct effects on desire.

ALCOHOL AND SEXUAL AROUSAL

Women

Approximately 10–30% of women in the United States report problems with sexual arousal to a clinical level. Research on alcohol and sexual arousal in women has included both survey and experimental studies. Similar to research on women's sexual desire, the few survey studies that have examined sexual arousal and alcohol use in women have had mixed findings. One study comparing alcohol-dependent women in treatment to community women without alcohol problems found that alcohol-dependent women were more likely to have a lack of arousal compared to the women with no alcohol problems. In a daily diary study, alcohol was found to have no effect on arousal. However, in another diary study, it was found that alcohol use was related to sexual arousal during the post- and inter-menstrual phases of the menstrual cycle. Although the survey research examining the relationship between sexual arousal and alcohol use in women has been contradictory, two studies suggest that sexual arousal increases with sobriety in women. This suggests that it is possible for women to recover from an alcohol-induced diminution of sexual arousal by becoming sober.

Experimental research has also focused on alcohol's effects on sexual arousal. These studies have focused both on self-reported sexual arousal and genital arousal. As of 2011, a total of 15 experiments have examined self-reported sexual arousal in the context of acute alcohol intoxication. The majority, specifically 13 out of 15, of these studies found that alcohol intoxication increased self-reported arousal in women. The effect of alcohol has been more pronounced with higher dosages, but the effect was present at a variety of doses. In addition, the effect has been shown with a variety of different stimuli including erotic films, vignettes, and slides. As discussed with respect to sexual desire, one explanation for alcohol's effect on increasing self-reported sexual arousal in women is alcohol expectancy theory. This theory suggests a self-fulfilling prophecy whereby individuals who hold the belief that alcohol increases sexual arousal are more likely to perceive that alcohol enhances sexual arousal in alcohol-involved sexual situations than those who do not hold that belief. A second explanation for increased self-reported sexual arousal may be alcohol myopia theory, which asserts that alcohol-induced cognitive impairment constricts the range of cues one is capable of attending to in a situation. Alcohol myopia theory would therefore posit that intoxicated individuals may focus more intently on salient sexual cues such as erotic stimuli than sober individuals and consequently experience themselves as more aroused. A third possible explanation for the increase in self-reported sexual arousal when intoxicated with low levels of alcohol may be an increase in testosterone levels. Acute alcohol research conducted with Finnish women has found that alcohol's effects on self-reported sexual arousal occur in specific phases of the menstrual cycle. These findings together suggest that perhaps alcohol's effects on self-reported sexual arousal may be related to testosterone levels. These potential explanations for how low to moderate dosages of alcohol can

enhance women's self-reported sexual arousal warrant further research.

Nevertheless, regardless of the explanation, it seems clear that low to moderate dosages of alcohol result in women feeling and reporting more sexual arousal than if they were sober. Paradoxically, it seems that this effect can occur concurrently while alcohol is actually attenuating genital arousal. That is, in some experiments, women reported post-drinking increases in sexual arousal; yet, they also exhibited alcohol-induced decreases in physiologically measured genital arousal. This paradox is not surprising given the low agreement generally between women's self-report and genital measures across all sexual arousal studies (not just alcohol studies). In a review of studies examining the correspondence between self-report versus genital arousal, self-report and genital measures correlated substantially lower for women ($r = .26$) than for men ($r = .66$). Therefore, although paradoxical, it is not contradictory empirically that alcohol can have opposite effects on women's self-reported versus genital arousal.

Experiments evaluating alcohol's effects on genital arousal typically use a vaginal photoplethysmograph as measurement. This device uses light to detect the amount of blood flow in the vaginal walls, an index of lubrication and arousal. Of 10 such experiments that have been reported to date, 6 found that alcohol attenuated women's genital arousal and 4 found no evidence of attenuation. In two recent illustrative experiments with women between the ages of 21 and 35 years, the effects of two alcohol dosages (.08 and .10 mg%) were evaluated in the context of instructions to control arousal by either maximizing or suppressing it while viewing an erotic film. At the lower dosage, which is widely recognized as substantially intoxicating in that it is the legal criterion for drunk driving and it is widely associated with generalized impairment, alcohol did not attenuate genital arousal. Furthermore, women exhibited greater genital arousal under conditions of being instructed to maximize arousal than to suppress arousal. These findings were interesting in demonstrating that, despite being intoxicated and despite the generically low correspondence between subjective and genital arousal, women were able to exert control over their genital arousal. However, at the high dosage, alcohol did attenuate women's genital arousal and no arousal control was evident. Thus, it seems clear that alcohol can attenuate women's genital arousal and this effect is most evident at very high dosages. As noted earlier, the mechanisms responsible for this attenuation effect have not been clearly identified. It has been presumed that the mechanisms are strictly physiological. However, this has not been established and psychological mechanisms have not been ruled out.

Looking across both the self-report and genital studies, it appears reasonable to contend that until the blood alcohol content exceeds .08 mg%, women are likely to exhibit an arousal response pattern characterized by enhanced self-reported sexual arousal, no alcohol-induced diminution in genital arousal, and an effective capability to control their arousal response volitionally. These considerations suggest that women's post-drinking sexual responses are subject to considerable variability and are not dictated by physiological imperatives or limits. However, this variability apparently decreases at higher dosages where it appears that intoxication effects may become less conducive to positive sexual responding and experience. Potentially, physiology related to high alcohol levels may overwhelm the sexuality-related response systems.

A few studies have found that alcohol is indirectly associated with sexual risk through self-reported sexual arousal, suggesting that alcohol's effects on sexual arousal can have an impact on other aspects of women's sexual health. In addition, more recent studies have found that a history of child sexual abuse or adult sexual assault also has an impact on sexual arousal. Because a history of sexual assault is also associated with increased alcohol use, these two factors may co-occur and have an impact on women's sexual arousal.

Men

Considerable research has been conducted examining the relationship between acute alcohol use and men's sexual arousal. Appraising this research necessitates highlighting key methodological distinctions critical to delineating and understanding the association between alcohol use and men's arousal. These include acute versus chronic alcohol consumption effects and alcohol's physiological effects versus its learned – expectancy – effects.

Regarding chronic alcohol consumption, it has become well established that regular consumption of high amounts of alcohol has been consistently linked with impaired erectile functioning and associated sexual dysfunctions in men. Samples of alcoholic men exhibit greater prevalence of erectile disorder than nonalcoholic samples. Similarly, among samples of men seeking treatment for erectile dysfunction, moderate to high alcohol use has been associated with worse sexual function. Perhaps because of such findings obtained with alcoholic and sexually dysfunctional men, it has been presumed that chronic consumption of low and moderate amounts of alcohol also had deleterious effects on erectile functioning for all men. This presumption was in spite of survey findings and ample anecdotal evidence indicating that modest alcohol consumption was associated with enhanced sexual functioning.

However, two recent review papers evaluating numerous population-based studies examining the effects of chronic alcohol consumption on erectile functioning have indicated that these survey and anecdotal findings have merit. Indeed, in both review papers, authors concluded that consuming low to moderate alcohol amounts actually offered some protection against experiencing erectile dysfunction. This finding is more in keeping with survey and anecdotal evidence and suggests that chronic drinking becomes a problem for erectile responding only when consumption amounts are high.

Thus, recent evidence has ushered a shift in our understanding of chronic alcohol consumption and erectile functioning, from appraising all consumption as deleterious to recognizing nondeleterious effects – and perhaps even salutary effects – for low to moderate consumption. There has been a similar shift in our understanding of the effects of acute alcohol consumption on erectile functioning. While it once seemed conclusive that moderate to high doses of alcohol administered acutely attenuated men's erectile responding, recent research has illuminated more limiting and qualifying parameters on this so-called attenuation effect.

Acute Alcohol Attenuation of Erectile Responding: Then and Now

Approximately two dozen highly controlled laboratory experiments have been conducted examining the effects of acute alcohol consumption on erectile responding. Evidence of an attenuation effect – alcohol reduces erection magnitude – was initially established based on findings from three of four experiments published in 1976. In these pioneering experiments, young (mostly college) men were administered alcoholic or nonalcoholic drinks and presented with explicit sexual stimuli while erectile responding was assessed using a strain gauge to measure penile circumference – an indicator of erection magnitude. The findings revealed that, except at very low dosages, alcohol attenuated erectile response. Intoxicated men had shown less penile tumescence and presumably less erection magnitude than sober men. Another early study showed that alcohol also increased the amount of time it took to achieve orgasm. After this pioneering work, alcohol-induced attenuation of erectile responding became axiomatic. Three subsequent reports corroborated this finding.

Two aspects of this attenuation effect were especially noteworthy. First, it cohered with what were understood, at the time, to be the attenuating effects of chronic alcohol consumption. Thus, the scientific conclusion seemed cohesive and unambiguous: Both chronic drinking and acute (except for very low dosages) drinking undermine erectile performance. This conclusion, of course, rendered as counterfactual the longstanding lore about alcohol's aphrodisiac qualities disinhibiting men's sexual responding. Second, in light of the emerging work on alcohol expectancy effects in the 1970s, the attenuation effect seemed to contribute to completing a cohesive narrative capable of resolving the old Shakespearean paradox about alcohol and sex: "Lechery, sir, it [drink] provokes, and unprovokes: it provokes the desire, but it takes away the performance" (Macbeth, 2.3.32). Specifically, it seemed that alcohol's salutary – "it provokes" – effects were attributable to its psychological expectancy properties, whereas it's deleterious – "it unprovokes" – effects were attributable to its pharmacological properties.

The influential role of alcohol expectancies on men's post-drinking erectile response was identified with experiments using the balanced placebo design. It is a method for evaluating the independent and interactive influences of alcohol's physiological and psychological or expectancy effects. Two properties of drinking are manipulated systematically in the laboratory: expected alcohol content (expectancy) and actual alcohol content. Led to expect alcoholic or nonalcoholic drinks, half the research participants receive alcohol and half do not. Thus, the design has four groups: (1) Expect alcohol/receive alcohol, (2) expect alcohol/receive none, (3) expect no alcohol/receive none, and (4) expect no alcohol/receive alcohol. Use of drink "look/taste alikes" (e.g. vodka-tonic versus tonic or beer versus nonalcoholic beer) and limiting dosage to a low level ($<.05$ mg%) make the deception necessitated in groups 2 and 4 possible. Landmark experiments showed that men in the expect alcohol conditions exhibited greater erectile response compared to men in expect no alcohol conditions and actual alcohol content was inconsequential. The absence of an alcohol attenuation effect was likely due to the relatively low alcohol dosages necessitated by the balanced placebo design.

This expectancy enhancement effect seemed clear: Men who think they are drinking alcohol report and exhibit more erectile arousal than men who do not. The effect is best attributed to the self-fulfilling prophecy analysis outlined earlier. Also, consistent with this analysis, the expectancy enhancement effect on various sexual responses becomes more pronounced among men as a function of the strength of their *a priori* belief in alcohol's sexually enhancing or disinhibiting powers. Relatedly, survey studies using alcohol expectancy questionnaires have also shown that post-drinking sexual responding and sexual risk-taking are greater among men – and women – who more strongly endorsed faith in alcohol's aphrodisiac properties.

The expectancy enhancement effect was somewhat of a breakthrough in that the effect of "drink" on men's arousal could now be seen as consistent with the general

sexual disinhibition outcomes understood as commonplace in conventional wisdom. However, because people drink real drinks in the real world outside of the laboratory, there was an explanatory problem: The pharmacologically driven attenuation remained unreconciled with the anecdotal lore and empirical trends attesting to post-drinking sexual enhancement and disinhibition. This led to careful re-examination of the attenuation effect.

Critics noted that the attenuation effect was not universal. As additional studies accumulated, it emerged that attenuation effects were occurring in less than half of the relevant experiments. Also, in a study evaluating the highest dose reported to date (.15 mg%), alcohol attenuation of erectile arousal was not evident at all among men during sleep. Furthermore, methodological problems were identified, which may have artifactually fostered attenuation evidence in earlier studies.

In a recent set of experiments, these methodological problems were corrected and the attenuation effect was re-examined. Using men between the ages of 21 and 35 years recruited from the community, researchers evaluated the effects of two alcohol dosages (.08 and .10 mg%) in the context of instructions to control arousal by either maximizing or suppressing it while viewing an erotic film. At the lower dosage, alcohol did not attenuate genital arousal. However, alcohol interacted with arousal instructions to influence the latency to arousal onset. Specifically, sober men instructed to maximize arousal became aroused more quickly than did sober men instructed to suppress it. Intoxicated men did not show this distinction, suggesting that alcohol lessened their ability to control the onset of their arousal. At the higher dosage, alcohol did have an attenuating effect on men's peak genital arousal, but no effect on other erectile measures. In other related findings, three dosages (.06, 08, .10 mg%) were evaluated during exposure to an eroticized story depicting an attractive sexual situation and no alcohol attenuation effects were detected.

The most striking outcome of these recent findings is that, contrary to earlier attenuation findings, relatively high dosages of alcohol had limited impact on men's erectile responding. At the highest dosage, an alcohol attenuation effect did emerge, but it was confined to one of five measures. Specifically, alcohol reduced peak circumference change, but it did not affect average circumference change, latency to change onset, latency to peak change, or self-reported arousal. This circumscribed effect, when considered in the context of previous null effects at high dosages with wakeful and sleeping men, posed a challenge for the long held view that acute heavy drinking diminishes erectile performance. These data suggest that alcohol's attenuating effects necessitate higher blood alcohol content levels to manifest and are more topographically specific than previously thought – affecting mainly peak response. Also, alcohol's attenuating effects on erectile functioning were appearing to be more context dependent than previously recognized. A contextual factor that emerged as influential for response latency indices was the instructional demand to maximize versus suppress arousal. Generally, it was appearing that there was little basis here to view alcohol – in this range of acute dosages – as necessarily interfering with sexual response, for sexually functional men. It may be that the attenuation effect holds true only at the higher degrees of intoxication, much higher than .10%, which – while relatively rare in laboratory experimentation – may be common in men's real life encounters.

That said, an important consideration is limb of the blood alcohol curve, that is, whether the blood alcohol level is ascending or descending. In all of the above studies, except the sleep study, investigators sought to assess alcohol's effects on the ascending limb or peak portions of the blood alcohol curve rather than on the descending limb. Less is known about descending limb effects. Generally, ascending alcohol effects are characterized by heightened cognitive and motor impairment, euphoric mood, and stimulation; while descending effects are characterized by reduced cognitive and motor impairment, dysphoric mood, and fatigue. In the one study dedicated to examining alcohol's genital arousal effects on the descending limb among wakeful (rather than sleeping) men, an attenuating effect was evident at a moderate dosage, but again only in a narrowly confined way. Men in the alcohol condition (.08%) exhibited less genital arousal than no alcohol controls, but only when instructed to maximize arousal and only on one of three erectile measures. This finding indicated again that attenuation effects may be more limited than previously thought and also that the threshold for attenuation effects may be somewhat lower on the descending than ascending limb of the alcohol curve. The latter point is consistent with the idea that the descending limb could be especially prone to potentiate alcohol attenuation effects, because of the diffuse systemic inertia (dysphoria and fatigue) associated with descending blood alcohol. A potential implication of this finding is that in circumstances where men are deliberately exerting conscious effort to become maximally aroused, alcohol likely undermines peak erectile response for quite some time after drinking has ended and intoxication subsides. An interesting twist to these findings was that intoxicated men instructed to suppress their arousal exhibited more genital arousal than intoxicated men instructed to maximize their arousal. By implication, in circumstances where men are deliberately trying to resist becoming aroused, being on the descending alcohol limb may hamper their effectiveness at resistance. Reduced

effectiveness at suppressing arousal in conjunction with alcohol's tendency to heighten risk-taking could result in an increased likelihood of pursuing sexual activity in circumstances – such as nonconsensual or disease risk situations – where sexual pursuit should be curtailed.

Acute Episodic Erectile Failure

Consistent with the research finding that high levels of acute alcohol intoxication can attenuate erectile functioning, there are clinical and anecdotal reports of men experiencing erectile failure during episodes of heavy drinking. Phrases such as "whisky dick," "beer dick," and "brewer's droop" have emerged colloquially to characterize and label this phenomenon. While the causal mechanism would clearly seem to be physiological, there are significant clinical and psychological implications. First, frequent episodes of alcohol-induced erectile failure may signal the presence or development of alcohol abuse or alcohol dependence disorders and could serve as a prompt for seeking addiction evaluation and treatment. Second, even a single episode can contribute to the development of an erectile disorder. Specifically, if the episode is not accurately attributed to alcohol; but if instead it is misattributed to psychological concerns about virility, sexual potency, or partner issues then a recurrent pattern of erectile failure can develop and persist. Although initially caused by physiological processes, this pattern can become psychogenic in nature. For instance, subsequent alcohol-free sexual encounters can become characterized by partner conflict and performance anxiety about repeated erectile failure, both of which can drive emotional and cognitive distractibility that, in turn, disrupt normal erectile responding. Under these circumstances, alcohol moderation or abstinence and psychological and/or pharmacological treatment for erectile disorder may be advised.

Erectile Dysfunction Medications

A final note about alcohol and erectile functioning concerns medications used to treat erectile disorder. There is growing evidence that medications such as Viagra (Sildenafil) and Cialis (Tadalafil) are often used in conjunction with alcohol, both legally and illicitly. Among men diagnosed as suffering from erectile disorder, alcohol dependence or both, these medications appear to improve sexual functioning. Among sexually functioning nonalcoholic men, these medications are often used recreationally during drinking episodes, a pattern that has been especially observed in research findings with gay men. Little is known empirically about the interactive effects on sexual functioning of consuming alcohol with these drugs and research is warranted.

ALCOHOL AND ORGASM

Women

Approximately 25% of women report problems with orgasm to a clinical level. Overall, there is little research on alcohol and orgasm in women. To our knowledge, there is virtually no research examining the relationship between alcohol and problems with orgasm to a clinical level. The majority of studies, although few, examining the relationship between alcohol and orgasm has found that alcohol is related to more inconsistent orgasms or less orgasms overall in women. Heavy alcohol use, alcohol dependence, and alcohol use before sex are related to both higher rates of lack of orgasm and more inconsistent orgasms in women. In addition, alcohol abstinence increases the ability to achieve an orgasm. In contrast, one study using daily diaries did not support the finding that alcohol is related to orgasm in women.

To our knowledge, only one study has examined the effect of acute alcohol ingestion on orgasms in women. This study was conducted in the 1980s and had less than 20 participants, all of which were college students. It was found that latency to orgasm was longer and subjective intensity of orgasm was decreased for women with higher blood alcohol concentrations. However, it was also found that women with moderate and high levels of intoxication reported more pleasurable orgasms.

Men

Although 20–30% of men report orgasm problems indicative of premature ejaculation disorders, there has been practically no research on alcohol and male orgasm. In one study reported more than 30 years ago, sexually functional college men exhibited increased orgasm latency after drinking. Latency increased linearly with alcohol level (.03, .06, .09 mg%). Unlike with women, men's subjective orgasm ratings decreased with alcohol. Men reported less sexual arousal, orgasmic pleasure, and orgasm intensity with increasing alcohol dosage. However, the authors noted that this effect "may be viewed as a beneficial consequence" because "sexual intercourse would be prolonged for both partners."

SEXUAL PAIN IN WOMEN

There is very little research on the relationship between alcohol and sexual pain in women. The few studies that have examined this relationship are survey studies and the findings were consistent: alcohol use is

associated with more sexual pain. Also, one study found that clinical levels of sexual pain decreased with sobriety in a study of alcohol-dependent women. Because this research is only correlational, the direction of any causal connection is unclear: It is possible that women with sexual pain drink to ease the pain. However, there is not enough research to understand the relationship between alcohol use and sexual pain.

SUGGESTIONS FOR FUTURE RESEARCH

Important knowledge gaps remain concerning alcohol and sexual functioning. First, while sexual desire is a key construct in sexual functioning theory and clinical diagnostic scholarship, very little is known empirically about alcohol and sexual desire. Sexual desire is obviously an important motivational construct. A call for expanding research dedicated to elucidating how alcohol consumption affects this motivation and – reciprocally, how sexual desire can affect drinking – is clearly warranted. For instance, there are suggestions that people may sometimes drink alcohol as a way of heightening sexual desire or as a way of coping with anticipated sexual encounters. The latter is a pattern apparent among victims of sexual abuse and assault. However, very little is known about these phenomena. Second, regarding arousal, more work is needed specifying the physiological mechanisms accounting for alcohol's attenuation effects on arousal. Third, also regarding arousal, isolated experimental findings from the 1980s revealed that sexual stimulation and arousal can fuel increased drinking and suggested that further experimentation would be valuable. Fourth, little is known about alcohol and women's sexual pain disorders. Fifth, the preponderance of research on alcohol and sexual arousal has focused on men. Although research evidence related to alcohol and women's arousal has expanded exponentially in the last five years, many unaddressed questions remain to be formulated and pursued. Finally, the vast majority of research, especially experiments, on alcohol and sexual functioning have not considered the importance of variation due to culture, ethnicity, and sexual orientation. Research is needed to clarify whether the patterns observed among majority samples have full or qualified generalizability to minority populations, where stigmatization issues could play a role.

CONCLUSIONS

Alcohol's ubiquitous and durable association with sexual functioning will undoubtedly persist, as will sustained intellectual effort in understanding the nature of this relationship and its benefits and costs. Relevant science and clinical scholarship has provided a mix of impressionistic data, robust empirical trends, and recent clarifications to established conclusions. Impressionistically speaking, there is consensus that acute alcohol consumption in moderation enhances sexual desire, fosters greater arousal, and slows orgasmic response thereby prolonging intercourse. Empirically, several patterns are evident. First, heavy chronic alcohol consumption impairs sexual functioning and contributes to sexual dysfunctions, especially in men. Second, although there has been relatively little empirical research – especially experiments, acute alcohol consumption appears to be associated positively with sexual desire and related indices. Third, heavy acute consumption attenuates men's and women's genital responding. Also, in men, there are anecdotal and clinical indications that heavy acute consumption can cause episodic erectile failure, which can contribute to psychogenic erectile disorder. Fourth, contrary to earlier impressions and scientific conclusions, chronic and acute alcohol consumption in low to moderate dosages does not appear to impair sexual arousal. Regarding chronic consumption, recent analyses of population-based studies suggest that chronic non-heavy alcohol consumption may offer protection against erectile dysfunction. Regarding acute consumption, recent experiments have clarified that alcohol-induced attenuation of genital responding does not become reliably evident until the blood alcohol level exceeds .10 mg% on the ascending limb for both men and women or exceeds .08 mg% on the descending limb for men. Fifth, it is clear that alcohol's effects are not entirely physiologically driven and that alcohol's psychological properties – especially alcohol expectancies – play an important role in sexual functioning. Sixth, it seems clear that alcohol's role in sexual functioning directly and indirectly impacts other dimensions of sexual health, such as disease-related risk-taking. Regarding future research, as noted earlier, important knowledge gaps remain concerning alcohol and sexual functioning, especially concerning sexual desire and women's sexual arousal. As a final note, there has been insufficient attention to the benefits of alcohol's association with sexual functioning. With the understandable focus on problems and costs associated with alcohol-involved sexuality, the potential contributions of alcohol-involved sexuality to sexual health and overall well-being have gone largely unnoted and unexamined. As depicted in commonplace cultural images such as wedding night champagne, romantic dinner wine, and bikini beach tropical drinks, alcohol-involved sexuality can be a delight! This perspective, given its relation to human health and prosperity, also merits intellectual and research attention.

Substance Induced Myopia

Nora E. Noel, Jennifer A. Heaton, Brian P. Brown

University of North Carolina Wilmington, Wilmington, NC, USA

OUTLINE

DEFINITION

Substance Induced Myopia (or Substance Myopia) refers to a model often used to explain the acute effects of a psychoactive substance on a person's subsequent behavior in a particular situation. The idea is that when taken in a significant dose, the substance interferes with attentional processes and narrows a person's ability to perceive and comprehend all the stimuli in the environment (hence the term myopia used as an analogy to eye disorders). According to the myopia model, the higher the dose of a substance beyond a critical threshold, the more it interferes with information processing, leading the person to rely on only the most salient cues in the environment to interpret the situation. Generally, the model is referred to as alcohol myopia because the vast majority of the relevant research examines the effects of alcohol on behavior. However, from a hypothetical standpoint, intoxication with any psychoactive substance that limits attention could have a similar effect.

DEVELOPMENT OF THE MODEL

The term alcohol myopia was first coined by Claude Steele and Robert Josephs in a 1990 article in the *American Psychologist*. They were searching for an explanation for alcohol's inconsistent effects on disinhibition as well as a related factor, anxiety reduction. A commonly assumed mechanism for alcohol's association with risk-taking or engaging in socially unacceptable behavior is that intoxication temporarily interferes with one's inhibitions that might normally have kept these behaviors in check. The disinhibition hypothesis posits that under normal circumstances one is inhibited by anxiety from breaking social conventions or exposing oneself to danger. Alcohol intoxication is believed to reduce that anxiety, thereby disinhibiting the person's behavior. Much anecdotal evidence exists that show when people drink, they can become uncharacteristically nasty, unpleasant, aggressive, extroverted, sexual, and so on. As Tara MacDonald and her colleagues put it, common sense flies "out the window" and intoxicated people may engage in many risky behaviors that while sober they would not consider. Such behaviors include driving under the influence of alcohol or drugs, having sex without protection, or starting a fight with a large stranger. However, when tested under controlled conditions, such as in a laboratory, alcohol intoxication does not appear to disinhibit behavior consistently. Often, people do report less anxiety

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00036-X

when they are intoxicated, but sometimes, unpredictably, they do not. In fact, people may become even more depressed or anxious when drinking and, in some investigations, intoxication can be associated with more prudent or altruistic behavior than sobriety.

Likewise, a large amount of research on the tension-reducing effects of acute doses of alcohol (see the encyclopedia entry on the tension-reduction hypothesis) previously had shown that drinking alcohol can reduce tension or anxiety, but sometimes it does not. Tension reduction in response to alcohol intoxication is an unreliable and often unpredictable consequence. Moreover, as noted above, sometimes drinking even leads to increased tension, anxiety or depression, much to the disappointment of the person drinking for the purpose of tension reduction.

To explain the inconsistent effects of intoxication Steele and Josephs proposed a cognitive mechanism (they called alcohol myopia) which they said predicted alcohol's effects better than a disinhibition model. They defined alcohol myopia as "a state of shortsightedness in which superficially understood, immediate aspects of experience have a disproportionate influence on behavior and emotion, a state in which we can see the tree, albeit more dimly, but miss the forest altogether."

By way of explanation, an overarching principle of social cognitive research is that people's responses to a social situation are largely influenced by how they interpret the vast array of stimuli or cues they perceive in the situation. Given the same social situation, a person may make vastly different interpretations depending on the stimuli to which he or she attends. The person's response is then guided by their interpretation.

For example, suppose a man at a party becomes interested in a woman and attempts to strike up a conversation with her. She might react by ignoring him completely or even being hostile. Such a communication would be easy to interpret and he could move on to talk to someone else. On the other hand, if she responds to his overtures with conversation, smiles and laughter at his jokes, the interaction becomes ambiguous. Is she just being polite? Is she interested, but cautious? Is she attracted to him, too?

To answer these questions, he must observe her actions and the external situation to make a judgment about how he will respond to her. Obviously, it would be impossible for a person to allocate attention to every stimulus in an environment. Instead, the man focuses on his internal and the external cues in the situation that he deems important (or salient) stimuli and he filters out irrelevant cues. His internal state (he is interested in her) and his history of interacting with women may influence part of this filtering. Note that attentional filtering is a relatively automatic (non-conscious) ongoing process that happens rapidly (in milliseconds). Quite a bit of cognitive-psychological research demonstrates that even under ordinary circumstances people can miss what should be very obvious stimuli and events if they do not fit with their expectations. For example, inattentional blindness refers to the failure to perceive an event that would be quite noticeable while engaged in an attention-demanding task. The published scientific research is compelling, but the phenomenon is also famously demonstrated by the short video posted on You Tube in which the viewer is asked to count the number of ball passes a basketball team makes. Most viewers watch the team and at the end of the video seem completely unaware that a large man in a bear costume walked right through the center of the action. After the bear is pointed out, he is very obvious on the second viewing.

Thus, people are already selectively screening stimuli, often guided by what they expect, or want, to see. If we return to the man at the party, he is busy attending to social cues that could signal that the attractive woman is mutually attracted to him, unaware that he is selectively screening information he will use in his decisional process. He will use his filtered information to decide how to behave with her.

According to the alcohol myopia model, if the man is or becomes intoxicated, he will be cognitively impaired, thus having an even more limited capacity to process information. The selection filter becomes tighter, narrower, and he will be capable of attending to only the most salient cues, as determined by his internal state or, perhaps, some extremely obvious cues in the situation. He is more likely to miss other important information. Thus, if sober, he might notice that she is smiling (very evident or salient to him) but also be aware that subtly she is making eye contact with other people and appears to be edging away from him. She is probably not interested in conversing with him. However, if alcohol intoxication narrows his attentional processing (i.e. he experiences alcohol myopia), he is likely to interpret her social cues incorrectly, focusing only on her salient smiling behavior, and assume that she welcomes his company. His subsequent behavior with her might be socially inappropriate and very unwelcome.

To further illustrate how the myopic state might function, several researchers suggest that intoxicated men present a higher risk of sexual aggression than sober men because they focus only on their own internal sexual arousal, attending most closely to any positive behaviors exhibited by the woman, while failing to perceive or process any discouraging or negative behavior on her part. The latter cues are

usually less salient because they do not fit with his expectations.

BEHAVIORS THOUGHT TO BE AFFECTED BY ALCOHOL MYOPIA

Researchers have conceptualized alcohol myopia as the explanation for a fairly long and varied list of alcohol-related behavior. Initially, Steele and Josephs used the concept to explain alcohol's inconsistent effect on anxiety, hypothesizing that in a situation where there are no distracting or more salient stimuli, intoxication may cause people to focus on the obvious, salient anxiety-producing stimuli and become more anxious, rather than less anxious after drinking. Their experiments supported their hypothesis by showing that when intoxicated people focused on an impending anxiety-provoking event, they became more anxious, but, in contrast, when intoxicated participants were given a distracting task, more attention-demanding than the anxiety-provoking event, they became less anxious. Similarly, results of some observational and survey studies suggest that people may drink to escape or relieve depression (e.g. drown their sorrows), only to find themselves more depressed (e.g. crying in my beer) as they become more intoxicated. Thus, proponents of the alcohol myopia model have suggested that merely drinking, without engaging in an attention-grabbing distraction, leads to a focus on the person's internal state of depression, which then intensifies.

Other researchers have hypothesized that alcohol myopia plays a key role in alcohol-related aggression. Laboratory studies support the idea that alcohol consumption may increase aggression because the intoxicated individual focuses on reasons for fighting (e.g. "This person insulted me." "This person stepped ahead of me in line." "This person bumped me intentionally."). Reasons for fighting are often quite salient in a drinking situation such as a loud bar or party. According to the model, the alcohol-myopic person loses awareness of less obvious circumstances, both external (e.g. "That person has friends here.") and internal (e.g. "I don't want to fight with someone. I'd rather just have a quiet evening.") that might normally limit their aggression. He or she then reacts with aggression.

In a similar vein, many researchers suggest that alcohol-related sexual aggression increases when cues for the instigation of sexual behavior are more salient than cues inhibiting sex. According to the model, the intoxicated sexually aroused man might believe that he has the right to demand or force sex from his partner, perhaps because he thinks that the she instigated sex. Her sexual cues are salient to him and her protests are not. Moreover, several studies of risky sex, such as having sex with an unknown partner or without a condom, support the idea that when both parties are intoxicated they are likely to focus exclusively on their sexual arousal (the salient stimulus) and ignore less salient concerns such as becoming involved with an inappropriate partner, becoming pregnant, or acquiring a sexually transmitted disease. When sober, they might express this as, "What was I thinking?" An alcohol myopia model can provide a plausible *post hoc* explanation.

One set of alcohol myopia studies that is particularly interesting suggests a compelling explanation for driving under the influence while intoxicated with alcohol or other impairing substances. Sober college students who have been exposed to drunk-driving prevention campaigns often strongly endorse the belief that driving while impaired is irresponsible and dangerous. Even in anonymous surveys, many state that they intend to avoid drinking and driving. However, both laboratory and field studies show that when they actually are intoxicated, their responses change. Once their Blood Alcohol Level reaches a critical threshold (usually about 0.06%), they are much more likely to say that they intend to drive, particularly if their interviewer emphasizes that their intended destination (usually home) is not far away or follows a very familiar route. In such circumstances, the alcohol myopia model suggests that the desire to drive the car to an easy destination becomes paramount (salient) and the possible dangers (distant in time and likelihood) are discounted or ignored. An important further implication of this model is that it predicts (up to the point of incapacity) that the more intoxicated the person, the more likely he or she is to decide to drive while intoxicated. In fact, it predicts that the most intoxicated people are the ones most determined to drive themselves home.

Gambling, smoking, overeating, and other such risky or unhealthy behaviors while intoxicated have been studied as examples of alcohol myopia. Most of this work has been field studies or surveys and questionnaires, so the findings lack the experimental rigor that laboratory studies could have. Nonetheless, myopia seems such a universally applied and appealing explanation that the number and variety of intoxicated behaviors attributed to alcohol myopia continues to grow. Recently, one group of researchers even suggested that they often found association between suicidal behavior and intoxication might result from alcohol myopia intensifying suicidal or self-destructive thoughts.

DOES ALCOHOL MYOPIA EXPLAIN HOW INTOXICATION CAN LEAD TO MORE PRUDENT BEHAVIOR?

Demonstrating that intoxication is associated with poor decisions and discounting of negative consequences

is not, in itself, differential support for an alcohol myopia versus a disinhibition explanation. Evidence providing more compelling support for alcohol myopia comes from the studies mentioned above that show a counterintuitive increase of inhibitory effects associated with acute intoxication. A disinhibition model predicts increased risky behavior, regardless of environmental cues, whereas an alcohol myopia model differentially predicts decreased risky behavior if the most salient cues in the situation promote caution rather than risk.

As an example, one research group reported a series of experiments with a strong inhibitory cue (a hand stamp reading "AIDS Kills"). Volunteers had their hands stamped before they went out to socialize for the evening. Contrary to what most people would expect, it was the intoxicated participants whose hands were stamped before they went out who reported more safe sex practices than sober participants with the same hand stamp. In contrast, when participants had no hand stamp (or had a slightly less inhibitory one that read "Safe Sex") the results were reversed: sober participants were more likely than intoxicated participants to report using protective strategies. A disinhibition hypothesis would have predicted only that intoxication would lead to riskier behavior regardless of the hand stamp, so these results are more consistent with an alcohol myopia model. Hypothetically, if a person had a frightening, intense message (AIDS Kills) stamped on the back of a hand, intoxication caused such an intense focus on the message that they were more aware of it than of other external cues.

Other researchers have reported controlled studies in which intoxication was associated with more positive behavior than sobriety, again depending on which cues were most salient in the environment. Given the right stimuli, for example, intoxicated participants were more likely to be generous and helpful to others than sober participants. These results have all been interpreted as evidence that the intoxicated participants were focusing more on the emphasized very salient needs of others rather than less salient positive aspects of saving their money.

GOING BEYOND ALCOHOL: SUBSTANCE MYOPIA?

To date, although alcohol myopia appears quite embedded in the scientific literature, very few studies or papers address other psychoactive substances as a source of myopia. One reported laboratory study of nicotine effects was consistent with a nicotine myopia explanation, but otherwise, no controlled studies of any substance other than alcohol were found.

Expanding myopia research to encompass other substances could be a promising method of explaining differential use as well as differential acute effects of substance use. After all, alcohol myopia explanations of behavior are linked theoretically to attention allocation models in cognitive psychology (see the discussion of inattentional blindness above). Attention allocation models are well supported in the laboratory and have been applied to a much wider range of behavior than alcohol or Substance Induced Myopia. Substance myopia research might even be characterized as a subset of attention allocation research, thus arguing even more strongly for laboratory demonstrations of parallel effects and connections with more comprehensive models of perception and decision-making. So why are so few laboratory studies of substance myopia effects published?

One explanation for the lack of published substance myopia studies may be that they simply have not been tried. The cost of doing laboratory drug administration research certainly limits feasibility. Rigorous study of the acute effects of intoxication requires administration of the substance in a controlled setting in controlled doses. The expensive involved (e.g. ensuring participants' safety and comfort until the substance has dissipated) may limit researchers' ability, interest, and efforts to investigate these possibilities.

Of course, a second possible explanation is that studies with other substances have been done, but negative or non-significant results limit their likelihood of publication. This point will enter into the discussion below.

LIMITATIONS OF MYOPIA-BASED EXPLANATION

On the surface, alcohol myopia appears to have garnered much empirical support as an explanation of intoxicated behavior. However, this show of support may be misleading. Many of the studies cited as evidence for the myopia model are *post hoc* explanations of how associated factors may relate to one another. Findings that intoxicated people engage in risky and negative behaviors do not provide differential support for the alcohol myopia model versus the more parsimonious disinhibition explanation that it was intended to replace. The burden of support for the myopia model really falls on two types of studies: (1) those showing that counterintuitive behavior can occur during intoxication if the situational cues are manipulated and (2) those showing that distraction plays a key role in the behavior of acutely intoxicated people (e.g. the original studies by Steele and Josephs, described above). As noted above, such studies do not appear in great

abundance in the literature, so the support for the myopia model as a simple explanation is not as strong as many authors tend to suggest.

Further, a few published experiments, despite careful design and execution, have reported finding no evidence for myopia. At least one of these laboratory-based experiments examining sexual aggression suggests that a more complex model of disinhibition incorporating prior individual differences in participants' attitudes may better predict such behavior than does the alcohol myopia model (relying on situational cues). Critics of these experiments have suggested that perhaps the inhibitory cues used in the studies were not salient, but this is somewhat of a disingenuous and possibly circular argument. Alcohol myopia is actually a two-step process. First, certain cues must be salient or obvious enough to capture the participant's attention. Second, intoxication should result in a stronger focus on those cues versus others in the environment. As discussed above in reference to attention allocation, whether a cue is salient or not depends upon the eye, or rather the brain, of the beholder (i.e. the participant). A researcher cannot declare that certain cues were salient on the basis of how the participant behaved when under the influence of alcohol. Cue saliency is an important basic element of the model and should be assessed with the specific participants in every such experimental protocol. In fact, very few studies of the alcohol myopia model have reported a separate assessment of cue saliency. Interestingly, the experiment reported above that failed to find an alcohol myopia effect on sexual aggression did, in fact, report research demonstrating salience of the inhibitory cues with the target participant sample.

On a more general level, questions about natural cue saliency have been raised in support of the myopia model on the occasions whenever non-supportive results have been reported. One contention is that instigatory cues (e.g. cues to initiate sex and aggression) are naturally more salient than inhibitory cues and will always command more attention when they are present (no matter how intense the inhibitory cues may be). Again, because saliency is not often assessed separately in any of these experiments, further study is needed before such an argument can be accepted.

To date, the use of the myopia model to predict and to even modify antisocial types of behavior lacks support. A recent review used the principles of an alcohol myopia model to suggest methods of decreasing alcohol-related aggression incidents, but no empirical data were presented to support these possibilities. If the model is going to be useful beyond providing explanations of behavior, research on modifying behavior is sorely needed.

Finally, another limitation of myopia research is the ongoing definition and redefinition of intoxicated myopia. Currently, there are at least two variations of the model that have developed from studies of intoxicated aggression versus studies of the use of alcohol to relieve anxiety and depression. The two similar lines of research (both using the same terms) can lead to occasional confusion, especially when findings seem to fit with one model variation but not the other. Because all of the variations tend to rely on the same principles, we have presented this introduction to myopia as a relatively unitary model.

CONCLUSIONS

Substance Induced Myopia presents a cognitively based model of intoxicated behavior that has wide appeal, as evidenced by the number of times that it is cited *post hoc* to explain seemingly uncharacteristic actions of people when they are intoxicated. Alcohol myopia, in particular, has been used to understand intoxicated people's decisions to drive after drinking, engage in risky sex, behave aggressively toward others, do dangerous stunts, behave suicidally, become sexually assaultive, and so on. The major premise of the myopia model is that the more intoxicated they become, the more people will focus on the most salient cues or stimuli in the environment to guide their behavior.

Despite its wide acceptance, empirical support for the myopia model is not as strong as it initially appears. The best support comes from studies showing counterintuitive behavior when cues are manipulated and other studies showing that distraction is associated with relief of negative emotions (e.g. depression and anxiety) when a person is intoxicated. More research is needed especially to determine if the fundamental premises are supported (e.g. which cues are more salient than others? Are instigatory cues always more salient than inhibitory cues?). Additionally, research with psychoactive drugs beyond alcohol is necessary to establish if a myopia model is a more universal substance myopia model. Finally, and most importantly, research is needed to show that substance myopia models can reliably and accurately predict intoxicated behavior. Only then can it be useful in modifying the risky, dangerous, and unpleasant behaviors that it is meant to explain.

Glossary

Attention allocation an active (but often non-conscious) process through which people direct their focus to specific stimuli in their immediate environment. No one can possibly focus on all the stimuli that impinge on the senses, so certain stimuli are selected for focus.

Disinhibition inhibition describes a learned process through which a person is thought to restrain certain behavior, because the behavior might be considered socially inappropriate, potentially dangerous, hurtful to others, and so on. Consequently, disinhibition describes behavior hypothesized to occur when those restraints are lifted or temporarily disabled. A prominent explanation for alcohol and other drugs' effects on behavior is that the substances disinhibit a person's behavior.

Drug administration laboratory studies studies in which precisely controlled doses of drugs (including alcohol) are administered to human or non-human subjects for purposes of measuring a variety of responses to those drugs. Such studies are necessary to establish cause-and-effect relationships between the substance at different doses and the participant's behavioral responses. They are conducted in a controlled setting (usually a laboratory, although the laboratory might closely resemble a bar) in order to preserve the internal validity of the experiment by eliminating potential confounding variables. The controlled setting also protects the safety and welfare of participants by closely monitoring them until they are no longer intoxicated.

Field or observational studies (of substance use) studies in which behavior associated with substance use is observed in a setting more naturalistic than the controlled laboratory. Factors associated with the substance, such as those preceding, occurring concurrently with or following consumption of the substance can be assessed. One advantage of such studies is that they can provide input to help formulate specific hypotheses about drug effects that can subsequently be tested in the laboratory. A disadvantage is that such studies can only test the strength of associations because independent variables cannot be manipulated by the researcher.

Inattentional blindness the inability to "see" an object or event even though it is obvious when pointed out. Humans have a limited capacity for attention (see "attention allocation" above), so certain stimuli may not be perceived, even though they are in plain sight. Studies of inattentional blindness and associated studies of change blindness demonstrate that the mind's selection of attentional stimuli is a very active process, but most people are not aware of the process (i.e. it is non-conscious).

Inhibitory cues stimuli in the environment that signal the need for (or advisability of) restraining one's behavior and not acting upon impulse.

Instigatory cues stimuli in the environment that signal the likely availability of certain highly desired or highly rewarding consequences, such as tasty food and sexual satisfaction.

Intoxication a psychophysiological state induced by the ingestion of a psychoactive substance. Once the substance has crossed the blood–brain barrier, it may disrupt normal brain functioning in a variety of ways. Some of these disruptions appear to be pleasurable, at least initially, and probably drive the desire to consume more of the substance, even though some of the effects are harmful or potentially harmful. Intoxication is a vague term and has been used to describe only slight disruption of functioning (usually associated with a low dose of the substance) as well as extreme disruption.

***Post hoc* explanation** a hypothesis or set of hypotheses suggested "after the fact" that attempts to account for a particular event that has already happened. *Post hoc* explanations or hypotheses may be an interesting or intriguing method of generating testable hypotheses, but they capitalize on chance and cannot demonstrate cause-and-effect relationships. Such a demonstration requires a second step: using the *post hoc* hypothesis to generate and test an *a priori* hypothesis.

Tension-reduction hypothesis a prominent hypothesis regarding reasons for alcohol and other drug use that is broken down into two premises: (1) people use alcohol in order to relieve or reduce tension and (2) alcohol does, in fact, relieve or reduce tension. Two different kinds of studies are needed to test the two parts of the hypothesis. First, if a person is in an unpleasant state of tension (vaguely defined), will he or she drink more than someone who is not in a state of tension? Second, if a person is in a state of tension, can a dose of alcohol (versus a placebo) reduce or relieve that state? Empirical support for the hypothesis has been mixed, depending on how tension is defined, how dose is defined, how relief or reduction is demonstrated, and so on.

Salient (stimuli or cues) the stimuli in the environment most likely to capture the person's attention. Sometimes researchers define salient stimuli as the most obvious stimuli. However, given demonstrations of inattentional blindness, for example, salience might be difficult to define easily.

OUTLINE

THE METACOGNITIVE MODEL OF PSYCHOPATHOLOGY

Defining Metacognition

Metacognition is defined as "thinking about thinking." Flavell expanded this definition further, referring to the knowledge and processes involved in the appraisal, monitoring or control of cognition. The theory and application of metacognition evolved from developmental psychology but has since been applied across other domains, including ageing, memory, neuropsychology, and psychopathology. The great majority of theorists would agree in drawing a distinction between three basic aspects of metacognition: metacognitive knowledge, metacognitive experiences, and metacognitive control strategies. Metacognitive knowledge refers to the information that individuals hold about their own cognition and about strategies which impact on it. This knowledge provides a plan or guide for processing, the rules of which may be more (explicit) or less (implicit) amenable to conscious awareness and verbal expression. Metacognitive experiences involve the application of this knowledge to generate online appraisals and interpretations of specific mental events and processes. Metacognitive control strategies involve the execution of responses to control the activities of one's cognitive system.

The Self-regulatory Executive Function (S-REF) Model of Psychopathology

In 1996 Adrian Wells and Gerald Matthews proposed the self-regulatory executive function (S-REF) model (presented in Fig. 37.1), a metacognitive architecture

Principles of Addiction, Volume 1

for conceptualizing psychopathology based on three interacting levels of cognition.

In this model the first level consists of stimulus-driven processing networks which operate outside conscious awareness and can give rise to products which intrude into consciousness. Examples of these products may include affective (e.g. low mood), cognitive (e.g. negative thoughts), and physiological (e.g. palpitations) intrusions.

The second level of the model consists of the S-REF, an online, voluntary and conscious processing of actions and thoughts aimed at maintaining cognitive self-regulation in response to intrusions. Under adaptive conditions, S-REF activity is limited to short bursts. In these instances, an individual is able to select an appropriate strategy for either task-focused coping or modification of beliefs to successfully achieve adaptive cognitive self-regulation. However, when the individual is vulnerable to psychological disorder they may become locked in a cycle of processing known as the cognitive attentional syndrome (CAS). CAS configurations involve attentional bias toward threat, maladaptive coping behaviors, extended thinking (e.g. desire thinking, rumination, and worry) and thought control strategies. According to the S-REF model, these configurations are problematic because they cause negative thoughts and emotions to persist, and fail to modify dysfunctional self-beliefs, increasing the accessibility of negative information. The activation and persistence of the CAS in response to affective, cognitive, and physiological intrusions is dependent upon access to stored self-knowledge, which is contained in the third level of the model.

The self-knowledge at the third level of the S-REF model consists of metacognitive beliefs and associated plans for processing. Metacognitive beliefs are divided into two broad sets: (1) positive beliefs about coping strategies which impact on mental states, such as "Brooding will help me sort out things in my mind," or "Worrying will help me solve the problem"; and (2) negative beliefs concerning the significance, controllability and danger of particular types of thoughts, for example "It is bad to think thought X" or "I need to control thought X." The S-REF model broadly purports that positive metacognitive beliefs are linked with the activation of the CAS and negative metacognitive beliefs with its perseveration.

The S-REF model emphasizes the importance of the processes which generate, monitor, and maintain cognitions, rather than focusing upon the content of cognitions. Individuals are understood to select and implement coping plans based on metacognitive beliefs which may focus attention toward disorder congruent information or lead to the selection of unhelpful coping styles. This may establish a vicious cycle where the faulty blueprint is consistently applied to alleviate processes appraised as distressing but a successful resolution fails to be achieved. Rather than evaluating and updating the stored knowledge to adapt the blueprint accordingly, the individual continues to apply the faulty blueprint believing this will eventually facilitate cognitive self-regulation. Over time the combination of applying the same blueprint and failing to achieve a self-regulatory goal leads to the development of an internal dissonance characterized by negative appraisals toward the selected coping strategies and internal experiences more generally. Failure to achieve the goal may be linked to negative appraisals of the person's current state based on self-knowledge, unrealistic goals for cognitive self-regulation, external factors, or the application of inappropriate coping strategies.

APPLYING THE S-REF MODEL TO SUBSTANCE MISUSE

Recently, Marcantonio Spada and colleagues have applied the S-REF model to substance misuse. They proposed a triphasic formulation where metacognitive beliefs and the CAS operate across three phases: pre-substance use, substance use, and post-substance use. According to the formulation, the content of metacognitive beliefs and CAS configurations vary by phase,

person, and nature of the substance misuse presentation (e.g. severity, duration, and comorbidity).

The Pre-substance Use Phase

In the pre-substance use phase, individuals typically experience an intrusion (e.g. a craving, image, memory, or thought) that is associated with a strong positive or negative affective response, such as anxiety or excitement. The experience of this affective response is then appraised through the activation of metacognitive beliefs that in turn initiate the CAS with the aim of restoring arousal levels to a normative state. The activation of the CAS, however, leads to the escalation of negative affective responses and craving which in turn increase the likelihood of substance use initiation. Spada and colleagues argue that CAS configurations in this phase are predominantly characterized by extended thinking in the form of desire thinking and perseverative thinking (rumination and worry).

Desire thinking was described by David Kavanagh and colleagues as a voluntary cognitive process involving the elaboration of thoughts about a desired target: They particularly emphasized the motivational role of imagery. Recently, Gabriele Caselli and Marcantonio Spada made further distinctions between verbal (repetitive self-talk regarding the need to achieve the desired target and self-motivated statements) and imaginal (construction of mental images of the desired target or of its context of consumption) types of desire thinking. This thinking style has also been described as a preference or as a reaction to preference awareness. The target of desire thinking may be an activity, an object, or a state. Perseverative thinking is characterized by heightened self-focused attention involving persistent, recyclic and generic internal questioning regarding the causes, consequences and symptoms of one's negative affect (rumination) or attempts to engage in mental problem-solving on an issue with an uncertain outcome (worry).

A variety of studies undertaken by Spada and colleagues have demonstrated that negative metacognitive beliefs about the need to control thoughts and lack of cognitive confidence predict alcohol and nicotine misuse. Items relating to the "need for control thoughts" refer to beliefs that certain thoughts will lead to negative consequences unless they are not controlled. Items relating to "lack of cognitive confidence" represent metacognitive knowledge about the ineffectiveness of memory and judgment, and reflect diminished confidence in coping. The combination of these two forms of metacognitive knowledge may lead the individual to ruminate and worry about intrusions exacerbating negative affect and increasing the probability of substance use as a means of escaping the CAS and achieving, albeit temporarily, a degree of mental control. In support of this view research has demonstrated that rumination longitudinally predicts levels of alcohol use and category membership as a problem drinker. Several studies have also supported the association between high levels of worry and the tendency to use alcohol in order to reduce the worry process itself, especially among patients with alcohol use disorders.

A further cognitive strategy linked to the CAS which has been shown to increase negative affective responses and prolong extended thinking is thought suppression. Several studies have found that suppressing unwanted thoughts can lead to a paradoxical increase in these thoughts. Similarly, across substances such as tobacco and alcohol, attempt to control or suppress thoughts can lead to an increase in the frequency of unwanted intrusions and increased accessibility of substance-related information. The strategy therefore represents a counterproductive approach to reducing or managing substance-related urges or intrusions. Even where individuals report being able to effectively suppress unwanted thoughts this typically imposes an increased cognitive load that would detract from optimal cognitive performance when sustained over a prolonged period. Thought suppression has therefore been described as an unsuccessful attempt at coping with unwanted thoughts that typically increases psychological distress and therefore the likelihood of substance initiation.

In the pre-substance use phase the triphasic formulation emphasizes the importance of desire thinking in conjunction with the perseverative thinking and thought suppression as outlined above. Recent research by Caselli and Spada found that individuals who misuse substances hold both positive and negative metacognitive beliefs about desire thinking. Positive metacognitive beliefs concern the usefulness of desire thinking in controlling negative thoughts and emotion, in increasing positive sensations, in improving executive control over behavior, and in planning how to reach goals. These beliefs may be involved in the initiation of the desire thinking process as a form of coping with intrusions. Negative metacognitive beliefs concern the uncontrollability of desire thinking, and its negative impact on executive control over behavior, self-image and cognitive performance. These beliefs may play a role in propagating negative affect once a desire thinking episode has started, which in turn can contribute to the perseveration of desire thinking, leading to an increase in the sense of deprivation (as the substance target is elaborated upon but not achieved) and a greater likelihood of substance use initiation.

Depending on the individual and the substance of choice the activation of CAS configurations aimed at managing undesirable internal experiences may lead to escalations in cognitive–affective dysregulation and therefore increase the likelihood of substance use aimed

at restoring the normative state within the regulatory system.

The Substance Use Phase

In the substance use phase, positive metacognitive beliefs about substance use, which relate to the benefits of substance use as a cognitive–affective regulation strategy, are activated in response to an intrusion or following the activation of the CAS in the pre-substance use phase. These beliefs appear to play a central role in motivating individuals to engage in substance use. In addition to the activation of positive metacogn itive beliefs about substance use, a reduction in metacognitive monitoring appears to occur in this phase. Metacognitive monitoring refers to the monitoring of cognitive–affective change and proximity to goals (cognitive–affective regulation) as substance use proceeds. It relates to the individual's capacity for monitoring and reflecting upon cognitive processes to oversee the regulatory function of the S-REF system. Ineffective metacognitive monitoring reduces the flow of goal-progress information available for processing and simultaneously limits the opportunity to identify a stop signal that could guide action. For specific substances, such as alcohol, use itself will lead to a disruption in metacognitive monitoring. For example, an individual may hold positive metacognitive beliefs about the benefits of alcohol helping them to gain control over worrying thoughts. However, the alcohol impairs the individual's capacity to both reflect upon their internal state and monitor progress toward their goal of reducing their worrying thoughts. As this metacognitive monitoring is reduced, the person may or may not achieve their initial goal, but are unable to identify the stop signals that could guide them toward cessation which could result in prolonged use. During and following a substance use episode, this use is appraised as both uncontrollable and dangerous, contributing to an escalation of negative affect and triggering overuse of the substance.

In the S-REF model it is suggested that the central driver of this phase is the activation of positive metacognitive beliefs about substance use combined with reduced metacognitive monitoring, resulting in a pattern of behavior which is difficult to regulate as the individual loses sight of their objective (i.e. cognitive–affective regulation). While the activation of positive metacognitive beliefs about substance use contributes to triggering substance use, reduced metacognitive monitoring may prolong the substance use episode.

The Post-substance Use Phase

In the post-substance use phase the affective, cognitive, and physiological consequences of substance use are proposed to act as triggers for the activation of positive metacognitive beliefs about the benefits of cognitive reflection and post-event processing. The triphasic formulation suggests that such activation initiates perseverative thinking in the form of rumination and worry regarding substance use. As this process unfolds a growing number of intrusions may be generated which, in turn, activate metacognitive beliefs about the uncontrollability and danger of substance use thinking and related intrusions. This sequence may lead to escalations in craving and negative affect eventually bringing the individual to engage in further substance use as a means of self-regulation.

METACOGNITIVE THERAPY (MCT) FOR SUBSTANCE MISUSE

Adrian Wells and colleagues developed MCT as a transdiagnostic treatment approach for a range of psychological disorders. Empirical evidence supports the application of MCT for the treatment of generalized anxiety disorder, major depressive disorder, obsessive–compulsive disorder, and post-traumatic stress disorder. MCT consists primarily of a series of treatment components aimed at interrupting the CAS, including meta-level socialization procedures, shifting to a metacognitive mode of processing, modifying metacognitive beliefs, postponement of conceptual processes, attention modification (attention training technique (ATT) and situational attentional refocusing (SAR)), detached mindfulness and development of new plans for processing. The order of priority for delivering these treatment components varies in accordance to clinical presentations. What follows is an outline of MCT assessment and case formulation in substance misuse and examples of how the different treatment components of MCT can be used.

Assessment of Metacognition (AMC)

The primary purpose of the assessment phase is to gather information that will enable the development of an idiosyncratic case conceptualisation based on the triphasic formulation of the S-REF applied to substance misuse. Three forms of assessment that are relevant for substance misuse are outlined below:

The AMC Analysis

The AMC analysis provides a stepwise approach to assessment and case conceptualisation. The "A" represents an intrusion and this is followed by "M," the activation of a metacognitive plan. The plan consists of metacognitive beliefs and proceduralized blueprints

that guide coping and which may contribute to the CAS. In turn this leads to "C," the emotional consequences. In a brief example, the "A" is an intrusive thought about being socially inadequate. The metacognitive plan consists of (1) evaluating the thought as a significant intrusion that needs to be controlled; (2) worrying about whether the thought will persist; (3) activating beliefs about the benefits of using alcohol to control the thought; and (4) focusing on instrumental strategies for initiating substance use rather than monitoring internal states. The consequences include feeling anxious and ultimately using alcohol.

Metacognitive Profiling

The main goal of metacognitive profiling is to elicit the nature of the processing routines and metacognitive beliefs that are activated within the individual's metacognitive plan when faced with stressful or emotive situations. Metacognitive profiling may start by asking the client to describe a recent episode when they used a substance, paying particular attention to intrusions experienced before substance use was initiated. The assessment proceeds by focusing on metacognitive beliefs about the intrusion and about thought control processes. The nature of goals (typically cognitive–affective regulation) and cognitive processes that may play a role in achieving the goals (attention, memory, and judgment) are also explored.

Metacognitive-focused Psychometric Instruments

A variety of self-report instruments designed to assess metacognitive beliefs and aspects of the CAS typically aid the assessment process and facilitate the development of an idiosyncratic case formulation. These are summarized in Table 37.1.

Case Conceptualisation and Meta-level Socialization

The triphasic formulation of the S-REF model in substance misuse represents the basis for conceptualizing different CAS configurations and MCT pathways. Three key areas need to be specified across the triphasic spectrum: triggers, metacognitive beliefs, and CAS configurations. These key areas then need to be synthesized into a formulation of the client's substance use and fed back to them as a visual flowchart. The client will then have the opportunity to agree or disagree with the various components and modify them until a broad agreement is reached as to the formulation of the substance misuse.

The balance of focus on a given phase would depend on the severity and duration of the substance use presentation together with the client's level of awareness and treatment goals. For example, the pre-substance use phase may feature more prominently in occasional and irregular users or those who are in the early stages of

TABLE 37.1 Metacognitive-focused Psychometric Instruments

Instrument	Developers	Constructs assessed
Metacognitions Questionnaire (MCQ-30)	Wells and Cartwright-Hatton (2004)	Positive metacognitive beliefs about worry, negative metacognitive beliefs about the uncontrollability and danger of thoughts, cognitive confidence, negative metacognitive beliefs about the need to control thoughts and cognitive self-consciousness.
Positive alcohol metacognitions scale (PAMS) and negative alcohol metacognitions scale (NAMS)	Spada and Wells (2008)	Metacognitive beliefs pertaining to alcohol use.
Thought Control Questionnaire (TCQ)	Wells and Davies (1994)	Elements of the CAS, including strategies for controlling intrusions (distraction, punishment, reappraisal, social control, and worry).
Ruminative Responses Scale of the Response Style Questionnaire (RRS-RSQ)	Nolen-Hoeksema and Morrow (1991)	Rumination.
Penn State Worry Questionnaire (PSWQ)	Meyer, Miller, Metzger, and Borkovec (1990)	Worry.
Desire Thinking Questionnaire (DTQ)	Caselli and Spada (2011)	Imaginal and verbal aspects of desire thinking.
Alcohol Craving Experience Questionnaire (ACEQ)	Statham, Connor, Kavanagh et al. (2011)	Sensory aspects of craving (imagining taste, smell or sensations of drinking and intrusive cognitions associated with craving) when craving was maximal during the previous week (ACE-S: strength), and frequency of desire-related thoughts in the past week (ACE-F: frequency).

using to cope with negative effect. It may also play a central role for individuals attempting to remain abstinent but who have not addressed their pre-substance use mode of processing. In this sense it could represent a core theme for MCT focused on relapse prevention. The pre-substance use phase may have become highly "automated" in individuals with dependency and/or low levels of awareness. For these individuals the substance use phase would be the primary focus of formulation and treatment. Finally, the post-substance use phase may be of central importance when there is a chronic and persistent presentation with a history of relapses combined with a good awareness regarding the substance use problem.

Treatment Components

The overarching goal in MCT is to socialize the client to the role of the CAS in maintaining their current difficulties; specifically, in the case of substance misuse how: (1) desire thinking and perseverative thinking deepen distress and may lead to substance use; (2) metacognitive monitoring may lead to the perseveration of substance use; and (3) perseverative thinking about the substance increases negative effect and the possibility of further use. It is also important to highlight how the CAS prevents self-knowledge from being updated, particularly in the form of metacognitive beliefs.

Specific interventions need to be adapted to the principal target phase. All phases share the main treatment components (detached mindfulness, attention modification, modifying metacognitive beliefs and developing new plan for processing, defined below) but there are differences in each phase. Interventions for the pre-substance use phase need to focus on interrupting extended thinking, particularly desire thinking, and associated metacognitive beliefs. Interventions for the substance use phase need to primarily target attention modification (in particular the enhancement of metacognitive monitoring) and the challenging of positive and negative metacognitive beliefs about substance use. Developing new plans of processing to cope with negative affective states would be central to this phase as well as the pre-substance use phase. Finally, interventions for the post-substance use phase should promote a direct change in substance-related perseverative thinking (rumination and worry) and the modification of associated metacognitive beliefs.

Shifting to a Metacognitive Mode of Processing and Detached Mindfulness

This consists of developing new forms of awareness about cognitive events and processes. Clients are helped to see that the problem is not the occurrence of these events *per se* but their relationship to them, metacognitive appraisal of their impact upon the internal regulatory system, and strategies used to manage them. These internal events can range from craving and memories to thoughts, emotions, and physiological sensations. The detached mindfulness strategies are aimed at helping clients to move to an observing stance (or a metacognitive mode) with respect to their internal states. Detached mindfulness comprises two features: (1) mindfulness – an awareness of the internal experience; and (2) detachment – the suspension of any conceptual or coping activity in response to internal events and the separation of sense of self from the thought. Detached mindfulness is not a symptom management technique; it is intended to amplify the array of flexible responses to internal events. Detached mindfulness involves encouraging the client to observe their cravings, images, memories, and thoughts without trying to control or change them. These strategies are introduced using standard metaphors suggested by Adrian Wells and colleagues, such as taking the observer stance like watching clouds float across the sky or being a passenger on a train station watching trains go by, encouraging the client to relate to these cognitive events differently.

Attention Modification

This component involves the use of two strategies. In 1990 Adrian Wells developed the ATT, which aims to develop the individual's executive control over the allocation of their attentional resources. In terms of individuals with substance misuse, rather than automatically focusing their attention upon internal and external substance use cues, through ATT they may learn that they are able to choose to allocate their attention to non-substance related cues. The strategy involves asking the client to focus on a visual fixation point and to keep his or her gaze on this point. While doing this the client is directed to focus his or her attention on at least three competing sounds close by. The client's attention is moved between these sounds first slowly, and then rapidly and finally the client is encouraged to maintain attention on all of the sounds simultaneously. This pattern is repeated with at least three sounds outside the room and then at least three sounds far away. The clients are asked to practice this at least twice a day for 10–15 min.

The second strategy developed in 2000 by Wells involves SAR and aims to increase the flow of new and adaptive information into awareness so the individual is better able to update erroneous metacognitive beliefs (for example about uncontrollability). One application of SAR would entail encouraging the client to purposefully direct their attention onto substance cues and refrain from conceptual elaboration of substance-related pleasant memories and images. This could be combined

with fostering divided attention skills (e.g. extending the attention focus to include new and adaptive flow of information from the environment). Another application of SAR would involve enhancing metacognitive monitoring. The client could be asked to focus on the impact of substance use on internal states as a substance use episode unfolds. This scenario aims to provide a means of amplifying self-attention thus increasing the flow of goal-progress information into processing and increasing the possibility of substance use discontinuation.

Modifying Metacognitive Beliefs

In MCT applied to substance misuse, it is paramount to modify both negative and positive metacognitive beliefs. Negative metacognitive beliefs are usually tackled first as they tend to maintain the CAS. Examples of negative metacognitive beliefs may relate to various domains, including cognitive–affective states (e.g. "Anger is not good as it will lead me to lose control of my mind;" "My craving experiences are uncontrollable") or aspects of the CAS (maladaptive behavioral and thought control strategies –e.g. desire thinking, perseverative thinking, and substance use). Strategies for tackling negative metacognitive beliefs could include de-catastrophizing their significance through verbal reattribution (e.g. "What is the evidence for and against the idea that your cravings are uncontrollable?"), the facilitation of skills which promote a direct change in aspects of the CAS (for instance, interventions aimed at interrupting desire thinking, rumination, and worry) and practicing detached mindfulness. Positive metacognitive beliefs (e.g. "If I imagine the object I desire my mood will lift;" "If I ruminate I will find a solution;" "Using will help me gain control of my mind") are linked to the activation of unhelpful coping strategies. Modifying these beliefs starts with verbal reattribution such as an advantages–disadvantages analysis (e.g. "What are the advantages and disadvantages of thinking that drinking makes you gain control?"). This is followed by the exploration of better methods for achieving the advantages highlighted. Continuing on a similar theme, the client can be asked to explore the effectiveness of their chosen strategy in achieving their goal (e.g. cognitive–affective regulation).

In addition to these interventions, clients can develop a number of behavioral experiments to test their metacognitive beliefs. For example, clients may present with metacognitive belief where they believe that if they have an intrusion (e.g. craving) they need to act on it. A behavioral experiment could be devised by linking this metacognitive belief with a detached mindfulness activity. That is, clients can be exposed to the intrusion and then apply the detached mindfulness where they observe their internal state without acting on it. After this activity the clients are encouraged to reflect on their reaction to experiencing the intrusion.

Development of New Plans for Processing

Clients are encouraged to identify their use of coping strategies and then to not engage in them but to engage in healthy alternatives. This is done initially in session and then between sessions when clients experience internal states associated with use. For example, if clients are using distraction or thought suppression when they initially start experiencing unwanted intrusions, then rather than avoid these intrusions, they are encouraged to use detached mindfulness to just observe the experience without acting on it.

Substance misuse is seen as one of a number of behavioral coping strategies aimed at managing the individual's internal states. Clients are encouraged to identify their unhelpful behavioral coping strategies and then to not engage in them. For example, rather than avoid people or places which may trigger unwanted intrusions, clients will be encouraged to meet with these people and go to these places while using detached mindfulness or SAR.

SUMMARY

Metacognitive theory applied to psychopathology and substance misuse argues that the development and maintenance of problems may be linked to the monitoring, appraisal or control of internal cognitive processes. The S-REF model provides a conceptual framework to illustrate how stored knowledge and beliefs a person holds about their own thinking processes may influence the activation of plans for coping in response to cues or triggers from the environment. The emphasis of the model is upon the human drive to maintain cognitive regulation. In vulnerable individuals the configurations that are initiated to maintain this regulatory function can be unhelpful and maladaptive, leading to the development of a vicious circle consisting of negative patterns of responding which perpetuate cognitive–affective distress. Extending this model further, the recently developed triphasic formulation of substance misuse details a three-stage process that allows for the application of metacognitive theory to substance misuse.

During the pre-substance use phase the formulation suggests that cues trigger an affective response, leading to the activation of metacognitive beliefs regarding that internal state. The metacognitive beliefs guide the activation of the individual's blueprint for coping and this could include engagement in extended thinking (consisting of desire thinking and/or perseverative thinking), leading to the establishment of the vicious circle or CAS

and increasing the likelihood of cravings and substance use initiation. Due to this priming in phase 1 and the possible activation of positive metacognitive beliefs about the potential benefits of substance use for reestablishing internal regulatory control, the person may be more likely to shift to the second phase of the formulation. In addition, substance use simultaneously reduces the individual's capacity to track the regulatory state of the system by reducing metacognitive monitoring through the effects of the substance. In the post-substance use phase, the individual is proposed to select substance use perseverative thinking in response to the activation of positive metacognitive beliefs about the benefits of rumination and worry as post-event processing strategies. Perseverative processing of this nature is likely to lead to the activation of negative metacognitive beliefs regarding uncontrollability and danger as the person appraises further escalations in cognitive–affective distress. Strategies applied by the individual in this post-substance use phase could therefore increase the likelihood of future use to cope with ongoing distress.

MCT has shown to be effective in the treatment of various anxiety and mood disorders. The principles of metacognitive theory underpinning the triphasic formulation present a number of key components for therapeutic intervention that should be addressed according to the target phase. These include the interruption of extended thinking, challenging and restructuring of metacognitive beliefs, attention modification strategies, and the development of novel ways to manage and process negative internal states.

The triphasic formulation was developed based on empirical studies to date and offers a conceptual framework for the application of metacognitive theory to our understanding of substance misuse. Further research examining the interaction of metacognitive knowledge, plans for extended thinking and the relationship with internal and external triggers is required to consolidate this metacognitive framework. However, it offers a novel development that brings together our understanding of cognitive and affective distress in the development and maintenance of substance use disorders and provides a promising pathway for therapeutic intervention.

CHAPTER

38

Maturing Out

Andrew K. Littlefield, Rachel P. Winograd
Psychology Building, Columbia, MO, USA

OUTLINE

INTRODUCTION

Perhaps contrasting with popular notions, substance use disorders (SUDs) are largely disorders of young adulthood. Data from several large epidemiological studies indicate that the peak prevalence of SUDs, such as alcohol use disorders (AUDs), occurs during the early twenties and then drops precipitously with age. That is, many of the young adults who experience SUDs during young adulthood later remit (often without receiving treatment). This process of normative decline in problematic substance use is referred to as maturing out.

In this chapter, empirical data depicting the rise and fall in the prevalence of SUDs in young adulthood will be summarized. Specifically, theories describing potential mechanisms that contribute to the peak substance use observed during late adolescence/early adulthood will be described. In conjunction, theories that depict processes that contribute to maturing out will be covered. Finally, important considerations relevant to the phenomenon of maturing out will be highlighted.

DEFINITIONS OF SUDs

Before describing maturing out in more detail, it is important to note current conceptualizations of SUDs. The *Diagnostic and Statistical Manual*, version IV-TR, defines two major classes of SUDs: substance dependence and substance abuse. The diagnostic criteria for dependence is defined as "a maladaptive pattern of use, leading to clinically significant impairment or distress, as manifested by three (or more) of the

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00038-3

following symptoms occurring at any time in the same 12-month period: (1) tolerance; (2) withdrawal; (3) the substance is often taken in larger amounts or over a longer period than intended; (4) a persistent desire or unsuccessful efforts to cut down or control substance use; (5) a great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects; (6) important social, occupational, or recreational activities are given up or reduced because of substance use; and (7) the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance" (p 197).

The DSM-IV defines substance abuse as "a maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by one (or more) of the following occurring within a 12-month period: (1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home; (2) recurrent substance use in situations in which it is physically hazardous; (3) recurrent substance-related legal problems; and (4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance" (p 198). These general criteria are applied to the diagnoses for specific substances (e.g. AUDs). According to the DSM-IV's diagnostic hierarchy, individuals who meet criteria for dependence for a given substance do not receive diagnoses for substance abuse, implying that dependence is the more severe of the two SUDs. However, for reasons that are beyond the scope of this chapter, the abuse/dependence distinction will most likely be eliminated in future versions of the DSM, resulting in the combination of the two classes of SUDs into one substance use disorder diagnosis.

DOCUMENTING MATURING OUT

Several studies have documented the peak prevalence of substance use and related negative consequences that occur during the early twenties before declining with age. For example, data from the Monitoring the Future study suggest that heavy drinking (i.e. drinking five or more drinks in a row in the past 2 weeks) peaks at ages 21–22 and then decreases linearly with age.

Numerous epidemiological studies have documented the rise and fall of SUDs during the third and fourth decades of life. Nationally representative data (for the United States) from the National Epidemiologic Study on Alcohol and Related Conditions (NESARC) clearly indicates that the peak prevalence of SUDs, such as AUDs, occurs during young adulthood and declines sharply with age. Notably, many of the individuals who recover from AUDs do not abstain from drinking but rather continue to consume alcohol at more moderate levels. Although some research suggests that heavy drinking among blacks and Hispanics may peak later compared to whites, and that the overall rates of AUDs differ among various racial-ethnic groups, the tendency for AUDs to decline with age is consistent among whites, blacks, Native Americans, Asians, and Hispanics. Similarly, NESARC data indicate that the past 12-month prevalence for drug use disorders (abuse and/or dependence for a broad range of substances including cannabis, cocaine, and heroin) is significantly higher in younger age cohorts (see Fig. 38.1). Thus, age-related declines in prevalence seem to be robust across substances and, at least in the United States, across racial-ethnic groups.

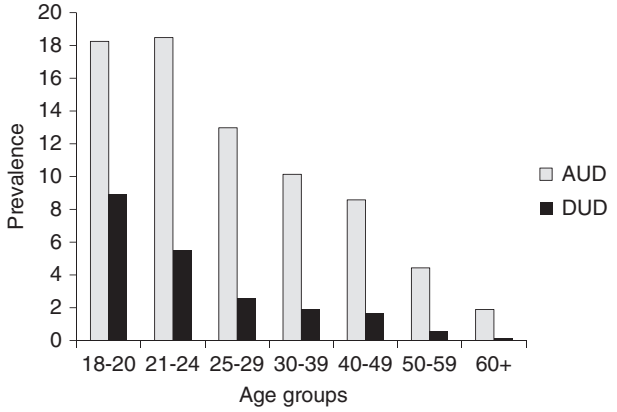

FIGURE 38.1 Prevalence of alcohol use disorders (AUDs) and drug use disorders (DUDs) from ages 18 to 60 in NESARC data.

THEORETICAL MODELS OF MATURING OUT

There are two essential questions regarding the phenomenon of maturing out: why does the peak prevalence of SUDs tend to occur in the early twenties, and why is there a dramatic normative decrease in both substance use and SUDs across the third and fourth decades of life? Potential explanations that have been provided by theorists and researchers are summarized below.

WHY DOES THE PEAK PREVALENCE OF SUDs OCCUR IN THE EARLY TWENTIES?

Several reasons have been proffered to explain the high rates of substance use and misuse that occur during the transition between late adolescence and adulthood.

Theorist Jeffery Arnett referred to the transition from late adolescence to adulthood as emerging adulthood, and describes it as a unique developmental period in which several factors contribute to problematic substance use.

According to Arnett, emerging adulthood lasts approximately from ages 18 to 25, though it can extend throughout the twenties and beyond for some individuals, depending on completion of developmental milestones such as marriage and parenthood. Arnett noted significant demographic changes over the past half-century in industrialized countries, such as prolonged educational pursuits and subsequent delayed entry into the workforce. This more recent focus on higher education could contribute to a later adoption of adult roles for some individuals. Indeed, compared to previous generations, both men and women are currently getting married and having children at later ages. Arnett suggests these demographic shifts result in the developmental period of emerging adulthood that is characterized by instability, self-focusing, feeling "in-between" adolescent and adult, increased optimism about the future, and identity exploration. As each one of these factors may contribute to delayed acquisition of adult roles, so too might they contribute to the increased use and misuse of substances.

For example, there are various forms of instability that are evident during emerging adulthood. As documented by Arnett's research, individuals frequently change residence, romantic partner, and educational and job status during emerging adulthood. As Arnett explains, this instability could result in anxiety and sadness, resulting in some emerging adults to use substances to "self-medicate" these negative emotions.

Emerging adulthood is also a time of exceptional self-focus. As opposed to adolescents (who are governed by parents and teachers) and adults (who have commitments to work and family), emerging adults have relatively few daily obligations to other people. As described by Arnett, self-focusing results in more volatile and ephemeral social networks and friendships, which in turn creates an overall lack of imposed social control compared to other age periods. This lack of social control coupled with relatively fewer responsibilities may also explain the heightened substance use during emerging adulthood.

Feeling "in-between" adolescence and adulthood is common during emerging adulthood. Arnett's research suggests that emerging adults consider reducing substance use and associated risk behaviors (e.g. drunk driving) as crucial criteria for adulthood, even more so than the adult transitions of graduating from college and getting married. However, since emerging adults feel "in-between" adolescence and adulthood, many may consider that this age period is a time where substance use is relatively acceptable compared to later age periods. In line with this perception of acceptability, research suggests that perceived norms of substance use is one of the strongest correlates of substance use behaviors among emerging adults. In fact, many emerging adults overestimate rates of peer substance use compared to their own use as well as the general acceptance of substance use and related behaviors. These beliefs may explain why many people engage in substance use during emerging adulthood but not later in life.

Arnett also describes emerging adulthood as the "age of possibilities," that is, a time period when people believe that they can make dramatic changes in their life and optimism for the future is exceptionally high. This optimistic bias, according to Arnett, may result in emerging adults to discount the myriad negative consequences associated with substance use, resulting in increased substance use during this age period. Supporting this conjecture, research suggests that many emerging adults base their decision to drink on perceived positive expectancies of substance use rather than potential risks. Further, Arnett hypothesizes that many emerging adults will have a high sense of well-being and use substances based on enthusiasm, whreas some emerging adults have a lower sense of well-being and use substance to cope with negative emotions. Supporting this notion, a large body of empirical literature suggests that alcohol use is increased among individuals who endorse relatively high levels of enhancement (e.g. I drink to have fun) and coping (e.g. I drink to relieve negative moods) motives to drink compared with individuals with lower levels of these motives. Further, alcohol problems are indirectly related to enhancement motives through increased alcohol, whereas coping motives directly predict alcohol-related problems. Thus, individuals who report higher motivations to drink tend to consume higher amounts of alcohol and subsequently experience more alcohol-related problems.

As Arnett describes, identity explorations may include emerging adults' desire to have a wide range of experiences before transitioning into adulthood, including experimenting with various substances. Further, distress related to forming a stable identity may result in some emerging adults to use substances as a means of coping with identity confusion (though there is limited existing empirical evidence to support this notion). Related to identity exploration, levels of sensation seeking (i.e. the pursuit of novel and intense experiences), a significant predictor of substance use, tend to be higher during emerging adulthood compared to later ages (see section "Why do People Tend to Mature Out of Substance Use?" for further discussion). Therefore, identity explorations that are common during emerging adulthood may contribute to the high prevalence of SUDs.

In line with Arnett's description of increased sensation seeking during emerging adulthood is a burgeoning collection of research that suggests overall mean levels of personality traits related to substance use are higher during emerging adulthood than perhaps during any other age period. For example, traits related to impulsivity (a broad construct that is related to making rash decisions and sensation seeking) and neuroticism (the tendency to experience negative emotional states) correspond to the increased use and misuse of a range of substances. For many individuals, these traits may be most pronounced during emerging adulthood and directly and indirectly relate to problematic substance involvement. For example, numerous studies have documented that individuals higher in traits related to impulsivity and neuroticism are more likely to have greater motivation to use alcohol. These motives in turn predict both alcohol use as well as alcohol-related problems. As will be described in more detail later in the chapter, changes in personality and motives across time may also influence the maturing out of substances.

In summary, the peak prevalence of substance use and SUDs occurs during emerging adulthood. This age period is marked by several factors that are conducive to substance use, such as increased freedom and exploration (compared to adolescence) and decreased responsibilities (compared to adulthood). Further, compared to older age groups, personality characteristics that are linked to substance use motives, substance use, and associated negative consequences seem to be relatively high during this timeframe. These features may help explain why substance use and misuse is the highest during emerging adulthood.

WHY DO PEOPLE TEND TO MATURE OUT OF SUBSTANCE USE?

As noted above, theorists and researchers have provided several explanations of the heightened use and misuse of substances that is observed during emerging adulthood. There is also a large body of work describing why there is a sharp decrease in substance use across the twenties and into the thirties. Primary findings from this literature are summarized below.

ADULT ROLE ATTAINMENT AND ROLE INCOMPATIBILITY THEORY

The most prominent explanation as to why many individuals mature out of problematic substance use is the attainment of adult roles. Numerous studies have documented that transitions into full-time employment, marriage, and parenthood are linked to decreased substance use and substance-related problems, especially alcohol use and misuse.

The link between adult role attainment and reduced problematic substance involvement may reflect selection or socialization processes. That is, the link between adult roles and maturing out might reflect the tendency of SUD remitters to later adopt adult roles (i.e. self-select). Contrastingly, adult roles may influence substance use through socialization processes, such as bringing about increased responsibilities, which result in substance use reduction for individuals who enter into these roles.

Work by Denise Kandel and Kazuo Yamaguchi suggests that both role selection and role socialization processes influence substance use. For example, findings suggest that marijuana use is associated with delayed entry into marriage and parenthood (i.e. a selection effect). Marriage and parenthood are also associated with increased rates of stopping marijuana use (i.e. a socialization effect). Additionally, using a longitudinal sample of college students, Kenneth Sher and colleagues concluded that the socialization effect of marriage on later AUDs seems to be more plausible than role selection effects of AUD on later marriage. Data taken from NESARC suggest that the relation between decreased alcohol dependence and getting married and having children reflect socialization processes, whereas the effects of school and work transitions were more consistent with selection effects.

Yamaguchi and Kandel proposed that the link between decreased substance involvement and adult roles could be attributed to role incompatibility, that is, adult roles associated with increased responsibility, such as marriage and parenthood, are "incompatible" with heavy substance use. For example, as Patrick O'Malley noted, marriage and parenthood result in numerous changes in social and recreational activities that are not conducive to maintaining a heavy drinking lifestyle. Specifically, compared to single individuals, those who are married attend fewer social functions that are compatible with substance use, such as parties and gatherings at bars. Increased responsibilities associated with child rearing also result in limited time for social activities involving substance use. Indeed, O'Malley noted that parenthood "is the key event" that propels men to reduce their drinking. Further, many women reduce their substance use during pregnancy because of concerns that substances such as alcohol can harm the developing fetus. Thus, many individuals seem to reduce their substance use in the presence of increased responsibilities and reduced free time that are brought about through the assumption of adult roles.

IS PERSONALITY CHANGE ASSOCIATED WITH MATURING OUT?

Although much of the research involving the maturing out of problematic substance involvement has focused on adult role obtainment, more recent work suggests that changes in personality may also be an important developmental factor. Despite personality being traditionally considered a stable, enduring construct, numerous studies have empirically documented mean level changes in personality across time and especially during emerging adulthood. These changes tend toward increased maturity, with people typically becoming less impulsive and more emotionally stable with age. This tendency has been referred to as the maturity principle. As with decreased substance use, increases in traits associated with maturity have been linked to adult role attainment and experiencing satisfaction in adult roles, such as marital and occupational satisfaction.

Recent work by Andrew Littlefield, Phillip Wood, and Kenneth Sher suggests that individual differences in personality change seem to influence the tendency to mature out of alcohol-related problems. That is, despite normative trends, there seems to be significant individual differences in both the tendency to mature out of problematic substance use and to experience increased psychological maturity. Thus, not all individuals show reductions in substance use and misuse or display beneficial changes in personality. Using longitudinal data from a cohort of college students, Littlefield and colleagues demonstrated that changes in neuroticism and impulsivity were linked to changes in alcohol problems from ages 18 to 35. Findings suggested that individuals who displayed sharper declines in neuroticism and impulsivity across this period also were more likely to undergo steeper decreases in alcohol problems. Subsequent analyses suggested these relations remained significantly linked even when adjusting for the influence of marriage and parenthood, demonstrating the unique importance of personality change in addition to the adoption of adult roles.

Using data from the same longitudinal sample, Littlefield and colleagues recently demonstrated that a group of individuals characterized by considerable decreases in impulsivity from ages 18 to 25 were more likely to show decreases in alcohol consumption and alcohol-related problems when compared to other groups with high and relatively stable levels of impulsivity. These findings suggest that individuals with relatively high levels of impulsivity who do not show significant decreases in that trait may be less likely to mature out of problematic alcohol involvement. These findings are consistent with recent longitudinal data suggesting that individuals who stopped smoking between the ages of 18 and 26 made corresponding larger increases in constraint (a construct considered to be the antithesis of impulsivity) and more pronounced decreases in negative emotionality compared to other individuals.

Individual differences in personality change also seem to influence changes in drinking motives, which in turn influence the tendency to experience alcohol-related problems. Individuals who exhibit more rapid decreases in impulsivity and neuroticism during emerging adulthood also seem to display larger decreases in coping motives to use alcohol. These reductions in coping motives predict more pronounced declines in alcohol-related problems. Thus, changes in personality and reasons for drinking seem to contribute to the maturing out of problematic alcohol involvement and most likely other substances as well.

Another potential, though somewhat speculative, explanation of the decline of substance use after emerging adulthood is the ongoing cognitive neurodevelopment that occurs during this timeframe. There is significant development in the prefrontal cortex during adolescence and emerging adulthood. These changes are thought to coincide with subsequent development of several processes, including affect regulation, self-control, cognitive control, and regulating behavior in general. Thus, declines in substance use after emerging adulthood, as well as the ostensibly adaptive personality changes detailed above, may be due in part to cognitive development.

In summary, the normative acquisition of roles associated with adulthood seems to strongly relate to the maturing out of substance use. This relationship likely reflects both role selection and role socialization processes. Just as the relatively lower amounts of responsibility and relatively higher amounts of freedom associated with emerging adulthood are conducive to substance use and misuse, the increasing responsibilities and time demands associated with adulthood seem to be largely incompatible with a heavy substance using lifestyle. Individuals also seem to undergo changes in personality during emerging adulthood, and changes in certain personality constructs seem to relate to changes in motives to use substances and decreased substance involvement. Normative cognitive neurodevelopment may also contribute to the maturing out of substance-related problems. In reality, changes in role status, personality, substance use motives, and cognition, as well as other factors, most likely affect each other and interact to produce dynamic, complicated influences on substance use behaviors (Table 38.1).

TABLE 38.1 Factors Potentially Contributing to Peak SUDs during Emerging Adulthood and Factors Potentially Contributing to Maturing Out

Factors potentially contributing to heightened substance use during emerging adulthood	Factors potentially contributing to declining substance use during early adulthood
• Increased freedom/relatively less responsibilities	• Adult role attainment/ increasing responsibilities
• Instability in roles, residence	• Role incompatibility
• Increased self-focus, decreased social demands	• Increased social demands
• Feeling "in-between" adolescence and adulthood	• Neurocognitive development
• Decreased focus on negative outcomes	• Decreased motives to use substances
• Identity exploration	• Identifying as an adult
• Social acceptance of substance use	• Decreased social acceptance of substance use
• Heightened levels of risky personality traits	• Decreases in risky personality traits

MATURING OUT: NORMATIVE BUT NOT UNIVERSAL

As described briefly above, there is considerable variability in the developmental course of SUDs. That is, although the normative trend is for rates of substance use and misuse to peak during the early twenties before declining with age, many individuals do not follow this typical pattern. For example, even among substance users, many individuals are not diagnosed with an SUD during emerging adulthood or later in life. Other individuals do not undergo normative decreases in problematic substance use but rather display chronic patterns of heavy use and SUDs across their lifespan. Still others experience SUDs and problematic substance use off and on at various intervals during their life. Thus, although the maturing out of substance use seems to be the norm (at least in the United States and other industrialized countries – see section "Cultural Differences" for further discussion), it by no means reflects the developmental course of substance use for all individuals.

ADULT ROLES DO NOT ALWAYS LEAD TO DECREASED SUBSTANCE INVOLVEMENT

Although transitions into adult roles seem to be a crucial element of maturing out, not all individuals who engage in adult roles reduce problematic substance involvement. Despite the harms associated with substance use during pregnancy, not all women quit (or even reduce) substance use habits when carrying a child; therefore, parenthood does result in reduced substance use in everyone. NESARC data suggest that entry into marriage is significantly associated with nonabstinent recovery (i.e. low-risk drinking) from alcohol dependence for many people. However, some individuals remained dependent after getting married and these individuals were less likely to subsequently recover from alcohol dependence. Additionally, though becoming a parent doubled the likelihood of becoming abstinent (i.e. eliminating alcohol use), this influence of parenthood was decreased among individuals who remained dependent after three or more years of starting full-time work. Therefore, not all individuals seem to mature out of SUDs after undergoing adult role transitions.

There are several reasons why adult role transitions may not always lead to reductions in substance involvement. Some occupations may be more conducive to substance use and misuse than others, and thus occupational obtainment may not always lead to decreased substance use. Occupational obtainment may also result in increased stress, which may result in increased substance use to cope with job-related stress. Positive assortative mating (the tendency for individuals to marry individuals with similar characteristics) may result in couples comprised of individuals who both engage in problematic substance use. Such relationships may not facilitate reduced substance use and, in some cases, may promote it.

For example, Kenneth Lenoard and his colleague Gregory Homish found that individuals with antisocial characteristics, a family history of alcoholism, higher levels of negative affect, and positive alcohol expectancies were more likely to engage in postmarital drinking. Drinking after marriage was influenced by partner drinking for both men and women. Decreased relationship quality (which may or may not be related to substance use) also seemed to predict later alcohol problems. The social network of the married couple may also moderate the influence of marriage on subsequent substance involvement. Leonard and Homish showed that the number of "drinking buddies" (i.e. social contacts that primarily involve activities associated with alcohol consumption) for both husbands and wives were longitudinally linked to both heavy drinking and alcohol problems. Taken together, these findings suggest that the characteristics of the individuals entering into marriage, as well as the nature of the marital relationship, moderate the protective influence of marriage on substance use.

There is also some evidence that the protective influence associated with adult role transitions may be

limited to certain age periods. Results from a meta-analysis of several studies suggested that never marrying was significantly related to increased alcohol consumption for men aged 18–39 but not older men. Findings also suggested that marriage/divorce was related to decreased/increased alcohol consumption in young but not older women. Thus, the specific age period in which adult transitions occur may alter the influence of adult roles on substance use.

DEVELOPMENTALLY LIMITED SUDs CAN STILL BE DESTRUCTIVE

Research documenting the phenomenon of maturing out suggests that many, if not most, individuals with SUDs during late adolescence and emerging adulthood later recover. Notably, this does not suggest developmentally limited SUDs are somehow benign. Extreme substance use, especially in the case of alcohol, is strongly linked to many of the injuries and deaths that occur during emerging adulthood. Many of the crimes that occur during this time period, such as vandalism, assault, and rape, are also alcohol related. SUDs that occur during emerging adulthood may also have detrimental influences on subsequent occupational and relational obtainment for the individual. Thus, though many individuals recover from SUDs, developmentally limited forms of pathological substance use still result in many negative consequences for societies, families, and individuals.

CULTURAL DIFFERENCES

Although most of the research described in this chapter is based largely on US samples, a meta-analysis of studies from ten different countries has suggested an international presence of maturing out. This pattern was consistent across most countries studied, indicating the cultural robustness of this normative trend. However, it should be noted that the countries included in this study (e.g. Germany, Poland, Switzerland, United Kingdom) are similar to the United States in their levels of Westernization/industrialization; thus, caution should be used when generalizing to other countries and cultures.

Just as legal drinking ages and drinking customs vary among regions, so too does the manner in which people develop and "grow out" of problematic use. For example, in countries with strict religious affiliations, often any amount of substance use is seen as destructive, whereas other regions that view drinking as an intrinsic part of the culture and heritage may have a more lenient stance on alcohol use. Thus, cultural and regional differences may affect the manner in which people mature out. Lastly, there is marked variability in the developmental course of SUDs in most, if not all, countries, with many people and subcultures not necessarily following the patterns and trends discussed throughout this chapter.

MATURING OUT IN EMERGING ADULTHOOD – HIGHER RATES OF RECOVERY OR DECREASED ONSET OF NEW CASES?

Throughout this chapter, the rapid decrease in prevalence of SUDs that occurs during the third decade of life has been discussed in terms of the high rates of recovery experienced by many emerging adults. However, intriguing new analyses from the NESARC data suggest that much of the rapid decline in the past 12-month prevalence of AUDs may be primarily attributable to a decrease in the rates of new onsets (i.e. new cases of AUDs) rather than increased offsets (i.e. recovery from AUDs) that occur during this time period. These findings suggest that SUDs, such as AUDs, may not be highly stable at any age; that is, recovery from SUDs is not limited to emerging adulthood. Rather, decreases in new cases of AUDs seem to occur more frequently in emerging adulthood than any other age group. Notably, these findings still suggest that AUD diagnoses are less persistent (i.e. a larger percentage of individuals with an AUD diagnosis later recover) during emerging adulthood than in other age periods. Overall, these results highlight the importance of understanding the many factors that contribute to acquisition, persistence, and recovery from SUDs during various age periods.

SUMMARY

For many individuals, emerging adulthood represents a time of peak use and misuse of various substances. Substance use during the time period relates to myriad negative consequences that could detrimentally influence life course. Fortunately, many, if not most, of these individuals later mature out of problematic substance use. Notably, these decreases in use typically do not occur in the presence of treatment. Importantly, many individuals continue to use certain substances, such as alcohol, though heavy consumption and negative consequences largely abate. These beneficial decreases are linked to adult role attainment as well as changes in certain personality traits.

Despite these normative trends, there is considerable variability in the developmental course of substance use and associated outcomes. Getting older is not a panacea

for problematic substance involvement. Unfortunately, some individuals continue to engage in risky patterns of consumption and experience negative consequences from substance use throughout their lives. Thus, understanding the contributing factors to risky and potentially chronic patterns of use at all life stages is of paramount importance.

Glossary

Constraint a personality trait characterized by the tendency to reflect and deliberate before acting, and avoiding risky behaviors. Broadly, the opposite of impulsivity.

Emerging adulthood the transition from late adolescence to adulthood (roughly ages 18–25) that is marked by transitions, increased freedom, and identity explorations and in which peak rates of substance use and substance disorders are observed.

Epidemiological a scientific study that focuses on the causes, distribution, and spread of diseases or epidemics within a population.

Impulsivity a broad construct of personality that is characterized by the tendency of individuals to engage in behavior without adequate forethought about the plausible negative consequences of their actions. Broadly, the opposite of constraint.

Individual differences observed differences in individual characteristics and behaviors. For example, the fact that some people abstain from alcohol, whereas others drink heavily reflect individual differences in alcohol consumption.

Maturing out the process of a normative decline in peak problematic substance use that typically occurs across the mid- to late twenties.

Maturity principle the theory that people tend to undergo personality changes associated with increased maturity, such as becoming less impulsive and neurotic, thought to develop with the ability to handle the demands of adult roles.

Neuroticism a personality trait characterized by the enduring tendency to experience negative emotions and emotional states. Often translated to experiences of anger, guilt, anxiety, and depressed mood.

Substance use disorder use of alcohol or other drugs despite problems related to use of the substance. Substance abuse and substance dependence are the primary categories of substance use disorders.

Substance use motives an individual's reasons for using substances (drugs or alcohol). These include both positively reinforcing (e.g. drinking to enhance positive mood) and negatively reinforcing motives (e.g. drinking to cope with negative moods).

Role incompatibility theory a theory that describes the phenomenon when an individual's societal role (e.g. mother) is not compatible with that individual's behaviors (e.g. frequent drinking at bars).

Role selection the process in which individual differences influence the likelihood of assuming a specific role (e.g. emerging adult marijuana users are less likely to subsequently get married).

Role socialization the process in which the assumption of specific roles influence behaviors or other individual characteristics (e.g. marriage tends to result in decreased substance use).

CHAPTER

39

The Effects of Substances on Driving

David J. Hanson

State University of New York, Potsdam, NY, USA

OUTLINE

SUBSTANCES AND DRIVING

Operating motor vehicles involves performing multiple tasks, the demands of which can change continuously. To operate a vehicle safely, a driver must remain alert, make decisions based on ever-changing information present in the environment, and execute maneuvers based on these decisions. This requires adequate visual functioning, information processing, decision-making, and psychomotor skills. The subtlety and complexity of the skills required to operate motor vehicles make them susceptible to impairment from a variety of both licit and illicit substances. However, less commonly recognized is the fact that some substances can enhance driving performance under certain circumstances.

The substances reviewed below are beverage alcohol (ethanol), caffeine, nicotine, cannabis (marijuana), amphetamine, cocaine, opioids (morphine and heroin), carisoprodol and meprobamate, phencyclidine (PCP), gamma-hydroxybutyrate (GHB) and its precursors of gamma-butyrolactone (GBL) and 1,4-BD, toluene, zolpidem (and zaleplon, zopiclone), dextromethorphan, diazepam, diphenhydramine, ketamine, and lysergic acid diethylamide (LSD).

SUBSTANCES

Ethanol

Ethanol, a central nervous system depressant, is a naturally occurring substance that results from the process of fermentation, by which yeast cells convert sugar into carbon dioxide and ethyl alcohol. Fermentation continues until all the sugar has been converted or until the fermenting mixture reaches about 14% by volume. At this point, the level of alcohol causes the yeast cells to die and the fermentation process to end.

Distillation is used to create alcoholic beverages of higher alcohol content or proof. In this process, heating causes the alcohol to vaporize before water; the alcohol vapors are then condensed into liquid ethanol.

Alcohol consumption is virtually always by oral ingestion. Ethanol vapors can be inhaled; however,

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00039-5

alcohol vaporizers are illegal in many jurisdictions and inhaling is a rare practice. It can also be absorbed transdermally, most often by means of enemas. Because both practices are probably unknown to most people, this discussion is limited to oral ingestion. After entering the mouth, a small amount of alcohol is absorbed into the tissues of the mouth and throat. Upon entering the stomach, it is absorbed into the bloodstream rather quickly because it does not need to be digested. Alcohol is a very small, water soluble molecule that quickly enters the bloodstream. About one-fifth of the alcohol consumed is absorbed in the stomach. The majority of alcohol is absorbed into the small intestine. However, a number of factors influence the rate of absorption, including the contents of the stomach. A large amount of food in the stomach dilutes the alcohol and slows its absorption there, and continuing to eat or nibble delays the release of stomach contents into the small intestine, where absorption is much more rapid.

Ethanol in the bloodstream (blood alcohol concentration (BAC), sometimes called blood alcohol level (BAL)) is measured by testing a sample of blood or is estimated by testing samples of exhaled breath. However, the latter method is subject to a number of measurement errors.

The results of either measurement or estimation of BAC are commonly expressed in terms of grams of absolute alcohol per deciliter of whole blood (g/dl). The g/dl notation is usually replaced by "percent" or "%," although it is not a true percentage because the numerical value represents a measure of weight in a measure of volume.

Metabolism occurs at a constant rate of about .015 of BAC per hour. If alcohol consumption exceeds the body's ability to metabolize it, the BAC will rise. After consumption ends, BAC will rise for a period of time before it begins to drop.

Men and women of the same height and weight who consume equal amounts of alcohol over the same length of time will have different BACs. Women have less of the gastric enzyme, alcohol dehydrogenase, which metabolizes about 20–30% of the alcohol in the stomach before it can be absorbed into the bloodstream. Women also have a higher proportion of body fat than men; alcohol is not soluble in fat and so it becomes more concentrated in the bloodstream of women than of men.

Driving-related skills are not all impaired at the same level of BAC. Wakefulness, for example, is generally impaired at lower BAC levels than simple reaction time and most components of visual functioning.

Although there is a fairly high correlation between a person's BAC and alcohol-induced impairment, there are large variations in the degree of impairment between individuals with the same BAC. One reason is that tolerance develops from repeated consumption of ethanol over a long period of time.

Generally unrecognized is the fact that impairment can also be influenced by a person's expectations. For example, impairment in performance of some tasks can occur if people falsely believe that they have been consuming alcohol. Relatedly, their impairment can be minimized if they falsely believe that they have not been consuming alcohol. The following section presents the results of numerous tests of the impairment or non-impairment of driving-related skills at different BAC levels.

Research has examined simple reaction time, which is measured by the length of time taken between a stimulus and the resulting intentional movement that a person makes. It is physiologically fixed in an individual and cannot be improved by practice. It can, however, be reduced by such factors as the ingestion of alcohol. Impairment of simple reaction time has been found at .043 BAC whereas some tests have found none at .080.

Choice reaction time is the time taken between a stimulus and an action that requires a choice. For example, a subject might be asked to give a response that corresponds to the stimulus, such as pressing a key corresponding to a letter if the letter appears on a screen or computer monitor. Tests of choice reaction time involve using multiple stimuli and multiple possible responses, thus requiring greater information processing and decision making than that required in simple reaction time experiments; both speed and accuracy are demanded. Unlike simple reaction time, choice reaction time can be improved by practice but can also be reduced by the ingestion of alcohol. It is more closely related to most actual driving tasks. Choice reaction time has been found to be impaired at a BAC of .020. However, it is more commonly found at BACs of .060 and higher.

Visual functioning includes eye movements, ocular motor control, and contrast sensitivity (ability to discern spatially distinct luminance differences). The brain's control of eye movements is highly vulnerable to the effects of alcohol. In driving, the eyes must focus briefly on important objects in the visual field and track them as they and the vehicle both move. Low BACs interfere with voluntary eye movements, which impairs the ability of eyes to rapidly track a moving target.

The frequency of eye movements and the duration of each fixation or "look" change significantly with increasing BAC levels. Research has examined the effects of alcohol on eye movement while subjects viewed a film of traffic events. The proportion of looks directed to the center of the driving scene increased under the influence of alcohol. As a result, subjects fail to see important peripheral events. Similar findings have been reported from on-the-road research. Impairment of visual functioning has been found at a BAC as low as .026.

Diverse psychomotor skills are required to operate a motor vehicle. Steering (tracking) is a complex psychomotor task in which the negative effects of alcohol on eye-to-hand reaction time are superimposed on the visual effects described above. Body balance and imbalance is also a commonly used indicator of psychomotor impairment by alcohol and is included in roadside sobriety tests. Impairment of psychomotor skills has been detected at .014 but is much more commonly found at BACs of .040 and higher. The driving-related skill of maintaining vigilance is impaired at moderate levels of BAC. It is regularly and consistently found at BACs of .030 and higher.

Alcohol impairs nearly every aspect of information processing by the brain. Alcohol-impaired drivers require more time to read a street sign or to respond to a traffic signal than unimpaired drivers; consequently, they tend to utilize fewer sources of information. Impairment of information processing is only occasionally found below .040 BAC.

Although wakefulness is not a skill, it is an essential condition for safe driving. Drowsy driving as a result of sleep deprivation is demonstrably a contributing factor to traffic crashes. Alcohol exacerbates sleepiness in its sedative effects as a depressant. This may be especially important because most alcohol-related crashes occur at night, which is a time when drivers are more likely to be sleepy. Wakefulness is impaired at BACs as low as .010 and always found at BACs of .035 and higher.

Caffeine

Caffeine is a naturally occurring central nervous system stimulant that temporarily reduces drowsiness and restores alertness. It is most often consumed in brewed beverages prepared from beans of the coffee plant (*Coffee arabica*) or the leaves of the tea bush (*Camellia sinensis*) as well as from various foods and beverages containing products derived from nuts (seeds) of the kola tree (*Sterculioideae cola*).

The drug is used medically to reduce fatigue, restore alertness, reduce drowsiness, and to treat problems sometimes found in premature infants. Caffeine is used recreationally for its taste, its stimulative effects, and to satisfy addiction to the drug. Over-the-counter caffeine tablets are often taken by students when studying for examinations, by people who work or drive for long periods of time, and by athletes to enhance their performance. Numerous studies have demonstrated often dramatic increases in endurance among athletes who consume caffeine. Caffeine has been shown to improve driving performance in actual road tests among drowsy drivers. There is also evidence that caffeine may increase alertness and improve reaction time after alcohol consumption but will not completely counteract alcohol impairment in a driver. Consumption of caffeine does not eliminate the need for sleep; it reduces drowsiness and increases alertness temporarily. This is important because maintaining alertness is important for safe driving. The National Highway Traffic Safety Administration has estimated that each year in the United States, about 100 000 motor vehicle crashes result from drowsy driving.

Nicotine

Nicotine is a naturally occurring central nervous system stimulant found in the leaves of the tobacco plant, *Nicotiana tabacum*. The primary therapeutic use of nicotine is in treating nicotine dependence in order to eliminate smoking and its attendant health risks, although it has many other therapeutic applications. However, the most common use of nicotine is recreational. Recreationally, nicotine is commonly inhaled with tobacco smoke, inhaled as snuff or in spray form, chewed in tobacco or chewing gum, inhaled as vapor (as in electronic cigarettes), placed between the lip and gum (as dipping tobacco or snuff), or absorbed transdermally through skin patches.

Nicotine has been shown to have a significant beneficial effect on athletic performance. It is similar in this regard to caffeine. Nicotine can both invigorate and relax users, depending on how much and how often they use the drug. When smokers want to achieve a stimulating effect, they tend to take short quick puffs, which produce a low level of blood nicotine concentration. When they want to relax, they tend to inhale deeply, which produce a high level of blood nicotine concentration that produces a mild sedative effect. Nicotine is unique in comparison to most other drugs in that it changes from a stimulant to a sedative as dosage increases.

Marijuana (cannabis)

Marijuana refers to the leaves and flowering tops of the hemp plant, *Cannabis sativa*. Cannabis contains substances called cannabinoids. These include tetrahydrocannabinol (THC), which is believed to cause most of the psychoactive effects of cannabis.

Marijuana is the most commonly used illicit drug throughout the world. It is usually smoked but can also be ingested orally. Data from traffic arrests and fatalities indicate that after alcohol, marijuana is the most frequently detected psychoactive substance among driving populations.

At typical recreational doses, the driving-related effects of cannabis include reduced inhibitions, disorientation, distorted perceptions of time and space, reduced

coordination, inability to concentrate, impaired memory, changes in thought formation and expression, drowsiness, and mood changes such as panic and paranoia.

The effects of marijuana vary to some degree with dose. However, it is difficult to establish a clear relationship between a person's THC blood concentration and its effects, including its impairing impact on driving-related skills. The commonly used indicator of psychomotor impairment by alcohol is included in roadside sobriety tests. The influence of any given blood THC concentration and specific effects is heavily influenced by the experience of the user, the individual vulnerability of the user to psychoactive reactions, the expectations of the user as to the effects of marijuana, and the setting of its use.

Although the onset of effects from ingesting marijuana orally take longer, the effects from smoking it are perceived by the user within minutes and peak after a period of between 10 and 30 min. The emotional high typically then lasts about 2 h. Most behavioral effects disappear within 3–5 h after use begins. Nevertheless, some researchers have found effects in some skills such as complex divided attention tasks for as long as 24 h. The more difficult and unpredictable the task, the more likely marijuana will impair performance. Impairment of psychomotor skills can continue after the emotional high has ended. The impairment of selective attention (the ability to disregard irrelevant information) among long-term users, even after abstinence, is adversely effected with increased length of use. Similarly, impairment in information processing speed is impaired with increased frequency of use. In laboratory studies, some drivers have demonstrated the ability to improve performance for brief periods of time by overcompensating for their self-perceived impairment. In real-life driving situations, the greater demands placed on drivers for long periods of time make impairment of driving performance a very serious traffic safety concern.

Combining alcohol consumption with the use of marijuana may produce dramatically greater impairment than does either substance on its own.

Amphetamine

Amphetamine is a powerful central nervous system stimulant, some of the effects of which can enhance the performance of driving-related skills. The drug can increase alertness, enhance the ability to concentrate, increase energy, and improve some cognitive functions including the ability to divide attention effectively.

However, amphetamine also creates tunnel vision, irritability, paranoia, aggressiveness, poor impulse control, psychomotor agitation, greater self-confidence, grandiosity, and strong feelings of power and superiority. These appear to be inconsistent with safe driving. The results of simulated driving after receiving very low doses of amphetamine (10–30 mg) have been inconsistent and may not be representative of driving performance at the doses ordinarily taken by recreational users (typically 100–1000 mg day^{-1}).

Because it reduces sleepiness, amphetamine can lead to insomnia, hours or days after which the user becomes exhausted and falls asleep (the "crash"). Among sleep-deprived persons on amphetamine, enhanced psychomotor skills have been found. However, the effects on cognitive performance appear to be mixed and inconsistent.

Amphetamine has long been, and is still, used by militaries around the world as a performance enhancer. British troops used 72 million amphetamine tablets during World War II and the Royal Air Force used so many that it was said that amphetamine won the Battle of Britain.

Amphetamine is also widely used as a physical and mental performance enhancer by civilians. Some students use it as a study and test-taking aid; it works by increasing energy levels, concentration, and motivation, thus allowing them to study for extended periods of time and to remain alert and concentrated in taking examinations.

Amphetamine is used by some high school, university, and professional athletes to enhance performance. It is also used by some truck and other commercial transportation drivers to increase energy, alertness, and concentration while driving for long periods of time. Like amphetamine, methamphetamine is a central nervous system stimulant. Possible driving-related effects of the drug include increased alertness, faster reaction time, poor coordination, aggression, poor impulse control, paranoia, delusions, and hallucinations.

Although it is sometimes used in the treatment of narcolepsy, attention deficit hyperactivity disorder, and obesity for a period of up to 6 weeks, it is not used for longer periods because of the serious risk of addiction and abuse. Tolerance may develop and users may quickly become addicted and use it with increasing frequency and in increasing doses.

Recreationally, methamphetamine is also used to enhance performance, create intense euphoria, relieve fatigue, increase alertness, self-medicate for depression, and control weight. Users often begin with intranasal or oral use, progress to intravenous use, and occasionally to smoking. Methamphetamine is sometimes used with alcohol or marijuana, especially during withdrawal. Peak blood methamphetamine concentrations occur shortly after intravenous injection, a few minutes after smoking, and several hours after oral ingestion. Effects are less intense after oral ingestion than after smoking or injecting.

Ecstasy is a "designer drug" that is synthesized to produce effects similar to those of amphetamine. Although it is a weaker central nervous system stimulant than amphetamine, it can cause muscular rigidity, tremor, decreases in attention, impaired visual functioning, and reduced ability to divide attention effectively in driving-related tasks.

It is difficult to predict the overall driving-related effects of ecstasy use. Driving simulation tests have found it to be associated with increased speed and more variation in speed. However, some tasks are not influenced whereas others are improved. Lacking in research is attention to the effects of different levels of dosing.

Cocaine

Cocaine is a strong central nervous system stimulant that is sometimes used as a topical local anesthetic for ear, nose, and throat surgery or other medical procedures. Recreationally, it is used to create euphoria, increase alertness, reduce fatigue, and create feelings of well-being and strength.

Cocaine also increases mental focus, mental clarity, and improved performance of some simple tasks. At higher doses it can cause confusion, disorientation, delusions, hallucinations, fear, paranoia, aggression, and antisocial behavior.

Use of cocaine can minimize the adverse effects on performance caused by sleep deprivation and also by the consumption of alcohol. Among people who are not sleep deprived, some research finds no effect on cognitive or psychomotor performance whereas others find enhancement of psychomotor performance, attention, and learning.

Specific effects are not closely associated with specific blood cocaine concentrations because of individual levels of tolerance and other factors. However, the onset of effects is slower and last longer than those of amphetamine.

Opioids (Morphine and Heroin)

Morphine is a naturally occurring substance extracted from the seedpod of the poppy plant, *Papavar somniferum*. Heroin is, in turn, produced from morphine. Both are central nervous system depressants.

Morphine is used medicinally for both acute and chronic pain management and is sometimes used to sedate patients. Heroin can be used as an analgesic and cough suppressant although these are no longer accepted medical uses in the United States and some other countries.

The effects of morphine or heroin depend on the dose, the route of administration (of which there are numerous possibilities), and tolerance. Both drugs can create driving-related effects including euphoria, inability to concentrate, drowsiness, slower reaction time, distractibility, mental clouding, tremors, lethargy, apathy, and depressed consciousness.

The effects of a dose of morphine typically begin within 15 min–1 h and last for 4–6 h. It may cause sedation and significant psychomotor impairment for up to 4 h following a single dose in normal individuals.

The driving performance of cancer patients who received long-term morphine for its analgesic benefits was not considered to be impaired enough by its sedative effects to increase the risk of crashes. Compared with a control group, the patients treated with morphine showed no impairment in vigilance, concentration, divided attention, or psychomotor skills. A small decrease in reaction time was found 3 h after administration of morphine. There are several field reports of driving impairment (weaving, poor vehicle control, poor coordination, slow response to stimuli, delayed reactions, difficultly in following instructions, and falling asleep at the wheel) in instances of drivers who have tested positive for morphine in law enforcement cases of driving while under the influence. However, the blood amphetamine levels are not reported nor is the existence of other drugs in the blood of the impaired drivers indicated.

For heroin, intense euphoria lasts from about 45 s to several minutes, strong effects last about 1–2 h, and then dissipate in 3–5 h. Slowed reaction times up to 4 h in former narcotic addicts have been found in laboratory research. As with amphetamine, high levels of tolerance can develop making effects less pronounced for the same dose in long-term users. Alcohol increases the effects of morphine, including sedation, drowsiness, and decreased motor skills.

Carisoprodol and Meprobamate

Carisoprodol and meprobamate are both central nervous system depressants that are legally available only by prescription. The former is prescribed to relax muscles and the latter is prescribed to reduce anxiety; both are dispensed in tablet form. The driving-related skills affected by either include loss of coordination, sluggish movements, tremor, reduced visual functioning, confusion, disorientation, slowed cognition, and lack of comprehension

The effects of carisoprodol begin within 30 min of ingestion and continue for as long as 4–6 h. The effects of meprobamate last much longer. Single doses of carisoprodol (700 mg) do not appear to effect cognitive or psychomotor performance. However, single doses of meprobamate can impair divided attention, slow reflexes, increase reaction time, and impair coordination.

Signs of cognitive and psychomotor impairment in persons found to be driving under the influence of either carisoprodol or meprobamate include poor perception, impaired reaction time, confusion, disorientation, inattentiveness, slurred speech, slow responses, sleepiness, lack of coordination, and difficulty standing, walking or exiting vehicles.

Similarly, among persons involved in driving under the influence cases who were found to be positive for carisoprodol and/or meprobamate and in which no other drugs were detected, impairment included slow reflexes, disorientation, sleepiness, poor balance, poor coordination, and slurred speech. Driving behaviors that were observed included extreme weaving, striking other vehicles and fixed objects, and hit-and-run accidents of which the driver appeared to be unaware. The greatest impairment was found among those whose combined use of carisoprodol and meprobamate led to high blood concentrations of those drugs.

Alcohol increases the sedation and mental confusion that can be produced by carisoprodol. Alcohol also increases the sleepiness, disorientation, incoherence, and confusion that meprobamate can cause. The use of other central nervous system depressants can also contribute to impairment.

PCP

PCP is a synthetic chemical that is illegally produced or illegally obtained from veterinary sources. It is currently used as a veterinary anesthetic or tranquilizer and used recreationally as a psychedelic and hallucinogen. Recreationally it is smoked, orally ingested, inhaled, injected, absorbed transdermally, and applied in the form of eye drops.

A single dose of PCP appears to create severe impairment of driving-related skills. The effects, which tend to be dose dependent, include blurred vision, impairment of eye–hand coordination, memory impairment, disorientation, disordered thinking, distorted sensory perceptions including distorted perceptions of space, memory impairment, poor concentration, hallucination, combativeness, feelings of power and invincibility, paranoia, and numbness in extremities. Effects generally occur within 1 h after dosage and slowed reaction time has been reported for up to 14 h.

GHB as well as GBL and the Drug 1,4-BD

GHB is a central nervous system depressant that is used medically as a sedative, an anesthetic, a treatment for narcolepsy, and to suppress symptoms of alcohol-dependence withdrawal and opiate withdrawal syndrome.

Recreationally, GHB is used for its effects in creating euphoria, reduced inhibitions, and sedation, and by bodybuilders as a substitute for anabolic steroids.

GHB was first synthesized in 1960 and sold as a food and dietary supplement. Thirty years later, the US Food and Drug Administration (FDA) banned the nonprescription sale of the drug. However, it is easy to produce illegally and ingredient kits with instructions are sold.

Later the FDA issued warnings about the dangers of GBL and 1,4-BD, both of which are used as industrial solvents and as ingredients in a variety of cleaners, paint removers, and degreasers. GBL and 1,4-BD are both rapidly converted into GHB in the body and are used as GHB substitutes. They are marketed as natural diet supplements, “antiaging” drugs, mood enhancers, energizers, as aids in achieving weight loss, and as self-medication for insomnia, anxiety, and depression.

Low doses of GHB do not impair attention, alertness, vigilance, psychomotor coordination, short-term memory, nor increase the effects of low BACs. However, the doses given in laboratory studies have been below those used recreationally.

Driving-related effects at higher doses include visual disturbances, loss of peripheral vision, confusion, reduced inhibitions, drowsiness, combativeness, short-term amnesia, shaking or seizures, and hallucinations. Signs of impaired performance in 24 cases of driving under the influence in which GHB was detected included drowsiness, confusion and disorientation, reduced peripheral vision, incoherent speech, short-term memory loss, lack of balance and unsteady gait, poor coordination, and poor performance of field sobriety tests. The impaired drivers had typically been stopped because of erratic driving, including such things as weaving, ignoring road signs, and near-crashes. The existence of drugs for which the drivers were not tested might have exacerbated the effects of the GHB.

Whereas the effects of amphetamine begin within 10–20 min, peak within 20–45 min, and generally last 2–5 h, there is a longer duration of effects following 1,4-BD ingestion because it metabolizes more slowly to GHB than does GBL.

Toluene

Toluene is a volatile solvent that acts as a central nervous system depressant. It occurs naturally in the tolu tree (*Myroxylon toluiferum*) and crude oil. It is produced during the refining process to make gasoline and other fuels from crude oil, in making coke from coal, and in manufacturing styrene. Toluene is used as a solvent in paints, lacquers, thinners, glues, and nail polish remover. It is also used in industrial processes such as printing and tanning leather.

Toluene has no medical use but is frequently used recreationally for its intoxicating effects. Such use is common among younger adolescents because the product is readily available, inexpensive, and legal, although some states have prohibited its sale to minors.

The driving-related effects of toluene include drowsiness, reduced ability to concentrate, slowed reaction time, distorted perception of time and space, impaired color vision, impaired vigilance, confusion, memory loss, delusions, and hallucinations.

No simple relationship between blood toluene concentrations and degree of impairment has been found.

Zolpidem (and Zaleplon, Zopiclone)

Zolpidem is a central nervous system depressant that is prescribed as a short-term treatment for insomnia. Zaleplon and zopiclone are also used for this purpose. The driving-related effects of each of these three drugs are drowsiness, double vision, slow reflexes, poor coordination, confusion, decreased cognition, difficulty concentrating, memory impairment, and hallucinations.

Effects typically last as long as 4–5 h. However, some effects can last for 8–16 h after heavy doses of any of the drugs. Given the same dosage, zaleplon has a more rapid onset and shorter duration of effects compared with zolpidem, whereas zopiclone has a longer duration of effects.

The recommended dose of zolpidem is 10 mg. Following doses of 10–20 mg, confusion, disorientation, double vision, cognitive impairment (memory, time estimation, memory), and psychomotor impairment can occur. Some of the impairments can last as long as 8 h. A 10–20 mg dose of zaleplon can cause significant impairment for 1–3 h with no effects on actual driving within 5–10 h. A 7.5 mg dose of zopiclone can cause severe effects on actual driving for as long as 10 h.

In five reported cases of driving impairment in which zolpidem was the only drug detected, behavior included erratic driving, slow reflexes, disorientation, confusion, loss of balance and coordination, loss of short-term memory, double vision, poor attention, an inability to stand or walk unassisted, and poor performance on field sobriety tests. In six other cases of driving under the influence of zolpidem, drivers were involved in automobile crashes or drove erratically, and symptoms included slow and slurred speech, unsteady gait, confusion, and disorientation.

Dextromethorphan

Available both by prescription and over-the-counter, dextromethorphan is used for the temporary relief of coughs caused by minor throat and bronchial irritation. It is used recreationally for its ability to create euphoria, elevated mood, dissociation of mind from body, dream-like experiences, and heightened perceptual awareness.

Although adverse effects with recommended doses are rare, slight drowsiness and dizziness can occur. Driving-related effects of higher doses for recreational purposes can include confusion, impaired judgment, psychomotor impairment, disorientation, reduced memory altered perception of time, and both visual and auditory hallucinations.

Combining dextromethorphan with promethazine may cause marked drowsiness or impair the mental or physical abilities necessary to operate a motor vehicle safely.

Diazepam

Diazepam is a central nervous system depressant that has numerous medical uses. Commonly prescribed doses are 5–40 mg daily.

Diazepam is used recreationally as a sedative or to enhance the effects of alcohol or opioids. For example, administration of diazepam 30 min after a dose of oral methadone produces a greater high. Diazepam is also used by cocaine users to increase the threshold at which seizures occur, by heroin users to enhance the effects of heroin, and by both cocaine and heroin users to reduce withdrawal symptoms between doses.

At low doses, diazepam is a moderate tranquilizer causing sleepiness, drowsiness, confusion, and some loss of memory. At high recreational doses, diazepam can produce slurred speech, blurred or double vision, slowed reflexes, disorientation, tremor, and hallucination. Alcohol consumption increases some of the effects of diazepam including drowsiness, sedation, decreased motor skills, and impaired memory.

A single dose of 5–20 mg of diazepam can cause significant impairment in driving-related skills with the greatest effects occurring at approximately 2 h after dosing and lasting for as long as over 4 h. Reported have been decreased attention, reduced divided attention, increased lane crossing, reduced auditory and visual reaction time, increased braking time, decreased eye–hand coordination, and impairment of memory, tracking, vigilance, information retrieval, psychomotor, and cognitive skills. Consumption of small amounts of alcohol additionally reduces impairment.

In drug users, diazepam can lead to greater impairments in psychomotor and cognitive performance, reduced concentration, and amnesia; some effects can last for a period of days. Epidemiological studies have reported a range of increased levels of risks to driving from taking diazepam. These increases have ranged

from twice to several times higher when compared with drug free drivers. The elderly may be at additionally increased risk of a vehicle crash.

Regular use of diazepam will produce tolerance to most of the sedative and adverse effects. Therefore, blood diazepam concentrations are not highly correlated with behavioral effects.

Diphenhydramine

Diphenhydramine is a central nervous system depressant that is used for the relief of allergy symptoms, for cough relief, as a sleep aid, and for the prevention of motion sickness.

The effects of diphenhydramine are increased by alcohol, monoamine oxidase inhibitors (MAOIs), diazepam, hypnotics, sedatives, tranquilizers, and other central nervous system depressants. Alcohol enhances such effects as drowsiness, sedation, and decreased motor skills. Diphenhydramine decreases alertness, reduces vigilance, decreases reaction time, induces drowsiness, reduces working memory, impairs concentration, reduces divided attention, impairs the estimation of time, impairs tracking, decreases learning ability, and reduces psychomotor performance. It impairs tracking, reaction time, and overall driving performance in actual on-the-road tests.

A single therapeutic dose of diphenhydramine can significantly impair psychomotor performance for 4 h and has been found to cause a greater negative impact on driving performance than the consumption of alcohol at a level exceeding the maximum legal BAC limit.

Ketamine

Ketamine is a hallucinogen and dissociative anesthetic that is legally available only by prescription, usually as a veterinary tranquilizer and anesthetic. It is also used occasionally as a short-acting general anesthetic for children and elderly patients.

The drug is used recreationally as a psychedelic and for its dissociative effects. Users have reported that the physical effects of ketamine are similar to those of PCP and that the visual effects are similar to those of LSD. Because it is difficult to synthesize, the ketamine that is used recreationally is usually stolen or illegally diverted from legitimate sources.

Ketamine causes impaired cognition, disorientation, blurred vision, increased distractibility, lack of coordination, increased reaction time, hallucinations, and distorted perceptions of surroundings, time, space, and sound. Effects can last as long as 2 h.

LSD

LSD is a hallucinogen and psychedelic drug that is manufactured from the lysergic acid that occurs naturally in the ergot fungus that grows on wheat and rye. The liquid is typically applied to blotter paper squares, stickers, sugar cubes, candy, or soda crackers. LSD is also available in dropper bottles and in the form of gelatin sheets. There is no medicinal use for LSD; it is used recreationally as a hallucinogen and for its ability to alter perception and mood.

LSD creates hallucinations, reduced reaction time, diminished visual acuity, altered mental state, thought difficulties, delusion, temporary psychosis, and distorted time and space perception. Effects begin within 20–30 min, peak at 2–4 h, and gradually diminish over 6–8 h. Some effects may last longer. Flashbacks may occur suddenly, often without warning, and may occur within a few days or more than a year after use. The effects of LSD are unpredictable and depend on the dose, the user's personality and mood, expectations, and surroundings.

Research suggests that the incidence of LSD in driving under the influence cases is extremely rare.

CONCLUSION

In a recent nation-wide roadside survey in the United States, 11.0% of daytime drivers and 14.4% of nighttime drivers tested positive for drugs, both medicinal and illegal. In the same survey, 0.9% of daytime drivers and 11.2% of nighttime drivers tested positive for alcohol.

It is important to note that testing positive for either alcohol or drugs does not necessarily indicate impairment. However, the evidence does suggest that the problem of drugged driving may be more serious than generally recognized.

Because of its legality, long tradition of use, social acceptability, and general availability, ethanol has long been widely recognized for its ability to impair driving performance. Law enforcement of impaired driving is almost exclusively focused on impairment from alcohol consumption. Law enforcement officers typically do not have the expertise or equipment necessary to test for the presence of other substances. Nor is there strong social or political pressure to do so. Consequently, some drug users report having been repeatedly stopped while driving under the influence of drugs but being released because they did not test positive for alcohol. By not consuming alcohol before driving, drugged drivers can operate their vehicles with virtual impunity. This problem will continue unless there is a significant change in

public perceptions. For over 30 years mothers against drunk driving (MADD) has been a strong leader in raising public awareness of the serious nature of drunken driving, an effective rallyer of moral indignation, a powerful force pushing for stricter laws, a persistent advocate for the strict enforcement of alcohol-impaired driving laws, and a vigilant monitor pressing for punishment of drunken drivers to the fullest extent of the law. However, MADD has simultaneously and consistently opposed any consideration of such traffic safety problems as drugged driving and driving while using a cell phone, which it sees as potentially competing for public attention and funding.

The problem of traffic crashes and the injury and deaths they cause is a very serious one. Dangerous driving has many causes. It includes not only alcohol consumption but also drug use, cell phone use, driving while drowsy, driving while eating, and many other factors, all of which need to be addressed.

A person who is killed in an impaired driving crash is just as dead whether the impairment was caused by alcohol, other substances, or driver inattention.

List of Abbreviations

BAC	blood alcohol concentration
FDA	US Food and Drug Administration
GBL	gamma-butyrolactone
GHB	gamma-hydroxybutyrate
LSD	lysergic acid diethylamide
MADD	mothers against drunk driving
PCP	phencyclidine
THC	tetrahydrocannabinol

Glossary

Blood alcohol concentration (BAC) Blood alcohol concentration, sometimes called blood alcohol level or BAL, is commonly expressed in terms of grams of absolute alcohol per deciliter of whole blood (g dl^{-1}) and measured by testing a sample of blood or is estimated by testing samples of exhaled breath.

Choice reaction time Choice reaction time is the time taken between a stimulus and an action that requires a choice.

Distillation Distillation uses heat to create alcoholic beverages of higher alcohol content or proof, causing the alcohol to vaporize before water; the alcohol vapors are then condensed into concentrated liquid ethanol.

Simple reaction time Simple reaction time is the length of time between a stimulus and the resulting intentional movement that a person makes.

Visual functioning Visual functioning includes eye movements, ocular motor control, and contrast sensitivity (ability to discern spatially distinct luminance differences).

CHAPTER

40

Defining and Assessing Drug Craving

Harold Rosenberg

Bowling Green State University, Bowling Green, OH, USA

OUTLINE

ADVANTAGES OF ASSESSING CRAVING

The experience of craving is commonly reported by substance abusing and dependent smokers, drinkers, and drug takers and is often a target of assessment and intervention in clinical settings. For example, a recent survey of American substance abuse treatment agency directors revealed that clients' experiences of craving are assessed regularly during both intake evaluations and ongoing therapy. Most respondents viewed craving as an important target of treatment, which their agencies addressed during both individual and group therapy sessions, often by providing education about craving, teaching coping skills, and encouraging clients to avoid or leave situations where craving occurs. Almost half of the respondents said their agencies would refer clients for anticraving medications, but only small proportions of respondents indicated that they administered published questionnaires designed to assess craving or offered cue exposure therapy in which clients practice coping with craving in the presence of drug paraphernalia or the sight and smell of their target drug.

Researchers are also interested in being able to assess the subjective experience of urges or craving. For example, researchers depend on being able to manipulate and assess craving to test predictions based on psychological theories of craving such as those summarized below. In addition, craving has been assessed as an outcome variable in the evaluation of psychotherapies such as cue exposure therapy and pharmacological therapies such as drug-replacement medications and purported anticraving medications. Both clinicians and researchers have studied whether craving predicts a drug taker's likelihood of lapse or relapse some days, weeks, or months after assessment.

Recognizing the advantages of being able to assess craving, a variety of methods – including self-reports of subjective craving, self-reports of other behaviors considered indicators of craving, and observation of

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00040-1

behavioral and physiological indicators of craving – have been employed to assess craving for both legal substances such as tobacco and alcohol as well as for illicit substances such as marijuana, heroin, amphetamines, and cocaine.

ELEMENTS IN THE DEFINITION OF CRAVING

Although many clinicians and researchers would agree that craving is an important component of addiction, there is considerable debate regarding just what craving means, what causes it, and how to assess it. Because the content and format of a measure of subjective craving will depend, in part, on how one defines the construct, this chapter begins with an overview of several key issues that arise in the definition and conceptualization of craving. One such issue is where to set the threshold separating a mild interest in drinking or drug taking from an urge or desire that is sufficiently intense to be considered craving.

Another question is whether the definition should reflect a combination of emotional, cognitive, behavioral, and physiological experiences that might indicate craving. For example, craving might be experienced as irritation, anxiety, or dysphoria, in addition to or instead of intense desire. Cognitive experiences of craving might include intrusive thoughts and sensory images of the substance, anticipated relief of withdrawal symptoms or negative mood, and expectations of positive outcomes following intoxication. Overt behavioral indications of craving might include rapid or excessive consumption, undertaking arduous or tedious tasks to acquire a drug, selecting drug consumption over money or other valued goods, and difficulty disengaging one's attention from drug-related stimuli. Psychophysiological correlates of craving might include salivation, changes in respiration and blood pressure, and activation of specific brain regions following exposure to drug-related stimuli. Substance abusers often report different combinations of these emotional, cognitive, behavioral, and physiological experiences when they imagine taking drugs or are exposed to drug-related cues.

Another issue when defining craving concerns its time course. For example, craving may be defined and assessed as a relatively acute and short-lived state whose intensity and experiential components shift rapidly depending on both contextual and intrapersonal factors. Craving may also be defined and measured as if it were a more stable (perhaps even trait-like) inclination or propensity to seek drugs somewhat independent of the time since one's last dose, environmental constraints on consumption, and one's overall intention to abstain or continue using drugs. These are not mutually exclusive conceptualizations of craving, and the degree to which one integrates these two views of craving has implications for the content of a questionnaire or behavioral task, the time period over which respondents' experiences will be measured, and the evaluation of a measure's reliability and validity.

Definitions also differ on the degree to which self-awareness is a component of craving. Using a self-report questionnaire to assess craving assumes respondents are aware of and are able to rate the frequency, duration, or intensity of experiences considered indicative of craving. However, some theories of addiction propose that urges and cravings may be elicited without the person's conscious awareness. Unconscious cravings might not be assessable using direct self-report questionnaires but might be revealed using procedures to assess cognitive, behavioral, and physiological experiences considered indirect or proxy measures of craving. Because these and other theoretical considerations have implications for the assessment of craving, the section below provides a short summary of several key etiological explanations of craving.

ETIOLOGICAL EXPLANATIONS OF CRAVING

Classical Conditioning

Craving is often conceptualized as a conditioned response to either environmental or interoceptive stimuli. Over time and with repeated pairings, initially neutral stimuli may become associated with emotional states and withdrawal symptoms that motivate consumption or with the initial effects of intoxication that follow consumption. These conditioned stimuli include locations where alcohol and drugs are consumed, the sight and smell of one's preferred substance, the presence of other drinkers and drug users, and drug-use paraphernalia. After repeated pairings, exposure to these conditioned stimuli may elicit the now conditioned responses of subclinical withdrawal symptoms and/or anticipated intoxication – both of which may be experienced subjectively as craving. Several of the etiological explanations summarized below assume that psychological or psychophysiological processes ultimately resulting in craving begin with exposure to drug-related cues.

Incentive-Sensitization Model

According to this model, both mildly and powerfully intoxicating substances activate "wanting" and "liking" systems in the brain that, in other contexts, are critical to

the survival of humans and other animals. Repeated drug use alters these brain systems such that relevant neural circuits become "hypersensitive" or overreactive to drug stimuli and drug effects. When exposure to drug-related stimuli activates the wanting system, the organism is more likely to desire and seek drugs but may or may not be aware of a subjective experience of craving. Because one implication of this model is that craving may occur without conscious awareness, indirect or implicit measures reflecting attentional bias for drug cues, willingness to work for drug access, or preference for environments associated with past drug use may reflect craving more reliably than self-report.

Obstacles to Automatized Drug Use

According to this model, craving may arise when stimuli trigger automatic drug seeking that is restrained by environmental obstacles to consumption (e.g. one's drug of choice is not readily available) or is restrained by one's commitment to abstain. The physiological and psychological arousal that occur when one exerts effort to overcome environmental obstacles to consumption, or exerts effort to maintain abstinence, may be experienced subjectively as craving. This model implies that craving will be revealed by measures of physiological and psychological arousal and by reports of conscious intentions to consume one's drug of choice. It also implies that craving will occur only when automatic drug seeking is cued in the presence of either environmental obstacles to consumption or when a drug taker has made a commitment to restrain substance use. In the absence of environmental or intrapersonal obstacles, the outcome of automatized drug seeking is not craving, but consumption.

Elaborated Intrusion Theory

Integrating classical conditioning, neuroscience, and cognitive processing perspectives, this theory proposes that a process resulting in craving begins when intrusive thoughts of a target substance are triggered by factors such as physiological changes (e.g. decreasing blood level of the drug), negative affect (e.g. depression), external cues (e.g. sight or smell of preferred drug), and anticipatory responses (e.g. salivation). Most intrusive thoughts are transitory, but when these thoughts are followed by anticipated pleasure or anticipated relief, mental elaboration of the intrusive thoughts may occur. Elaboration combines internal and external information in working memory to create sensory images of the substance and the subjective experience of desire, and one implication of this model is that both these sensory images and subjective desire may be assessed as indications of craving.

Approach-Avoidance Conflict

Arguing that consumption is influenced by more than just an appetite for or desire to take drugs, this conceptualization proposes that craving, consumption, and abstinence are outcomes of inclinations to use a drug interacting with inclinations to avoid using the substance. This model argues that the relative strength or weakness of an addict's inclinations to avoid or restrain consumption impact behavior as much as the strength of one's desires and intentions to take a drug. Therefore, assessment questionnaires based on this model ask about one's attempts to restrain or regulate consumption as well as asking about one's preoccupation with and temptation to consume a drug.

Analogy to Obsessive-Compulsive Disorder

This model is based on the correspondence between the key features of obsessive-compulsive anxiety disorder (OCD) and substance dependence. Specifically, this model proposes that drug craving is analogous to the unwanted, intrusive, disruptive, and anxiety-provoking thoughts or images (i.e. obsessions), and that excessive smoking, drinking, and drug taking are analogous to the repetitively performed and ritualized behaviors (i.e. compulsions), that characterize OCD. Based on this model, questionnaires have been designed to assess the frequency of, duration of, and distress caused by substance-related thoughts, impulses and images and to measure the degree to which substance use and attempting to control one's consumption has interfered with daily functioning.

SELF-REPORTS OF SUBJECTIVE URGES AND CRAVING

The most common method of assessing subjective craving has been to ask respondents to indicate the intensity of their urge or desire for a substance using one or several rating scales. These rating scales – often referred to as visual analog scales (VAS) – are usually anchored by terms such as "none" or "not at all" and "extreme" or "strongest ever experienced," and the respondent is instructed to make a mark on a 100-mm line (or to circle a numeral) to indicate the degree of urge, craving, or desire for the target drug experienced at that moment (or over some specified period of hours or days). Clinicians and researchers may provide a definition of "urge" or "craving" for respondents, but this is not

usually done and respondents are left to interpret the word and indicate their experience of it without further guidance. Paper-and-pencil forms are often used to have respondents record their craving, but electronic devices such as cell phones and handheld computers may also be used to record and transmit one's ratings.

In light of the many advantages of single-item rating scales, such as ease of administration and scoring, suitability for frequent and repeated administration, and apparent sensitivity to rapid changes in craving, such scales are often used in both laboratory and clinical settings. However, single-item rating scales have several disadvantages as well. One concern is that asking the respondent to provide a global rating of the strength or intensity of his or her "urge" or "craving" oversimplifies a complex and perhaps conflicting set of experiences. In addition, the subjective experience of a 10-point increase in craving from 30 to 40 (on a 100-point scale) may feel rather different than the 10-4point increase from 85 to 95 on such a scale. It is also possible that single-item ratings may fail to assess the experience of subjective urges or cravings if the drug taker interprets such feelings as reflecting another psychological or physiological state, such as anxiety, excitement, frustration, ill health, or withdrawal.

Partly to rectify these disadvantages of single-item rating scales, researchers have developed a number of multi-item questionnaires of craving for a wide variety of substances. Adapted from a recent review of such instruments, Table 40.1 provides a summary of these multi-item questionnaires. For each instrument, the table lists the authors of the source document (column 1), the name of the questionnaire (column 2), the target drug and conceptualization of craving on which the instrument is based (column 3), the number and type of items (column 4), the questionnaire's time frame and response options (column 5), and the number and names of factors/subscales, if relevant (column 6). As Table 40.1 shows, these questionnaires reflect one of four basic conceptualizations of addiction and craving: (1) craving as analogous to OCD; (2) craving as one outcome of an approach-avoidance conflict; (3) craving as a multidimensional experience comprised of conscious desire, intentions to consume, anticipated outcomes, and perceived control; and (4) craving as conscious urges measured in terms of their intensity, frequency, and duration. The selection of a questionnaire will be based, in part, on which of these conceptualizations matches the assessor's view of craving.

As Table 40.1 also shows, these questionnaires vary considerably in their length, with the shortest ones containing only four or five items, some containing 12–15 items, and the longest measures containing either 32 items or 45 items in their original versions. Although more items are likely to increase the internal consistency reliability and enhance the content validity of a questionnaire, longer scales have lower utility if the assessor expects craving to be short-lived or conducts repeated measurement of craving within a laboratory or therapeutic session. A shorter questionnaire is also preferred if one is concerned that reading and responding to multiple items might increase existing craving or might elicit craving not otherwise being experienced at that time. Given the advantages of shorter measures, several research teams have revised lengthier initial versions of their questionnaires, and both the longer and shorter versions are summarized in Table 40.1.

Table 40.1 also reveals that these self-report questionnaires differ regarding the time frame over which craving is assessed (e.g. "now," "past week," "when regularly drinking") or do not specify a time frame. Thus, some instruments assess a current state of craving, some assess craving in the recent past, and others measure a more stable preoccupation with or inclination to take a drug. Questionnaires that ask respondents about their craving over some period of hours or days could pose interpretation problems because the assessor does not know whether the drug taker answered items based on an especially salient or peak experience of craving over the designated time period, based on an attempt to average one's craving experiences over that time period, or based on some other rationale. To address these limitations, those using one of these questionnaires might ask respondents about the stability or variability of craving within the designated time period and whether the experience of craving varied depending on context.

The source articles for many of these questionnaires have reported convergent validity among different multi-item questionnaires or between these questionnaires and single-item VAS ratings of craving. These findings suggest that responses on these different instruments reflect some common underlying experience of craving, but the similarity of items across questionnaires and/or respondents' tendency to answer consistently when asked to complete several questionnaires may also account for the correlations among scores on these measures. Although total or subscale scores on different drug-specific questionnaires are often significantly correlated, the coefficients are not so uniformly large that these scales and questionnaires should be considered completely interchangeable.

In addition to evaluating the convergent validity of their measures, some researchers have also evaluated the construct validity of their self-report scales. One type of investigation is based on the assumption that craving scores should increase as blood level of a drug decreases, and several studies have found that craving is more intense following a period of deprivation. Other experiments have shown that asking participants to think about drug-related scenes increases self-reports

TABLE 40.1 Authors and Features of Multi-item Self-report Craving Questionnaires

Authors (Year)	Name of questionnaire	Drug; Conceptualization	Number and type of items	When craving assessed; Response format	Number and names of factors/subscales
Anton, Moak, and Lantham (1995)	Obsessive-compulsive drinking scale	Alcohol; Obsessive-compulsive	14 (with 2 sets of paired items, higher of which contributes to score)	Not specified; 5 choices per item indicating degree of impairment	Two: Obsessive; Compulsive
Franken, Hendriks, and van den Brink (2002)	Obsessive-compulsive drug use scale	Heroin; Obsessive-compulsive	12 (adapted for heroin from OCDS with some items combined or phrasing changed)	Presumably same as OCDS, but not stated in source article	Three: Thoughts and interference; Desire; Control and resistance
Collins and Lapp (1992)	Temptation and restraint inventory	Alcohol; Approach-avoidance	15 (adapted from other questionnaires)	Not specified; 9-point anchored with "never" and "always"	Two: Cognitive and emotional preoccupation; Cognitive and behavioral control
McEvoy, Stritzke, French, Lang, and Ketterman (2004)	Approach and avoidance of alcohol questionnaire	Alcohol; Approach-avoidance	20 items on Australian version; 14 items on American version	Now; Past 24 h; Past week; 9-point anchored with "not at all" to "very strongly"	Three: Inclined to drink; Resolved to avoid alcohol; Obsessed/Compelled
Ikard, Green, and Horn (1969)	Horn–Waingrow scale	Cigarettes; Multidimensional	23 reflecting psychological model of smoking	Not specified; 5 frequency options for each item: always, frequently, occasionally, seldom, never	Six: Habitual smoking; Addictive smoking; Negative affect reduction; Pleasurable relaxation; Stimulation; Sensorimotor manipulation
Leonard, Harwood, and Blane (1988)	Preoccupation with alcohol scale	Alcohol; Multidimensional	14 (items reflect seeking and increased thoughts of alcohol, active drink seeking, heavy drinking)	Not specified; 7-point anchored with "not at all like me" and "very much like me"	One
Tiffany and Drobes (1991)	Questionnaire of smoking urges	Cigarettes; Multidimensional	32 (from pool of 70) with 8 for each of 4 dimensions (desire, positive outcomes, relief from withdrawal/negative affect, intention)	Now; 7-point anchored with "strongly disagree" and "strongly agree"	Two: Intention, desire, and positive outcomes; Relief from withdrawal and negative emotions and strong desire
Cox, Tiffany, and Christen (2001)	Brief Questionnaire of smoking urges	Cigarettes; Multidimensional	10 out of 32 from QSU described above	Now; 100-point scale anchored with "strongly disagree" and "strongly agree"	Two: Strong desire and intention; Anticipation of relief
Tiffany, Singleton, Haertzen, and Henningfield (1993)	Cocaine craving questionnaire	Cocaine; Multidimensional	67 in initial pool → 45 (many adapted from QSU plus new impaired control items)	Now and General (i.e. average over past week); 7-point anchored with "strongly disagree" and "strongly agree"	Four: Desire and intention; Lack of control; Combined positive and negative expectancies; No clear theme

(*Continued*)

TABLE 40.1 Authors and Features of Multi-item Self-report Craving Questionnaires—cont'd

Authors (Year)	Name of questionnaire	Drug; Conceptualization	Number and type of items	When craving assessed; Response format	Number and names of factors/subscales
Sussner et al. (2006)	Cocaine craving questionnaire-brief	Cocaine; Multidimensional	10 (from 45 on the CCQ above)	Now; 7-point anchored with "strongly disagree" and "strongly agree"	One (10 CCQ-Brief items loaded on the same "general craving" factor on full CCQ)
Singleton, Tiffany, and Henningfield (1994; 1995)	Alcohol craving questionnaire	Alcohol; Multidimensional	45–47 (adapted from QSU plus impaired control items)	Now and general; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Emotionality; Purposefulness; Compulsivity; Expectancy
Raabe, Grusser, Wessa, Podschus, and Flor (2005)	Alcohol craving questionnaire-revised	Alcohol; Multidimensional	30 items retained from 45 in original ACQ	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Two: Urge and intention to drink; Reinforcement
Tiffany, Fields, Singleton, Haertzen, and Henningfield (1993)	Heroin craving questionnaire	Heroin; Multidimensional	45 (adapted from CCQ)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Positive outcomes, intention, craving; Intention and satisfaction; Relief from withdrawal; Lack of control
Ollo et al. (1995)	Questionnaire of cocaine use	Cocaine; Multidimensional	33 (adapted from QSU plus olfactory item)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Anticipation of positive outcomes or relief; Desire and intention to use; Use unpleasant; Uninterested in use
Bohn, Krahn, and Staehler (1995)	Alcohol urge questionnaire	Alcohol; Multidimensional	8 (of 49 in initial pool) loading > 0.70 on primary factor	Now; 7-boxes anchored with "strongly disagree" and "strongly agree"	One (comprised of 4 desire items, 2 positive outcome expectancy items, and 2 impaired control items)
Love, James, and Willner (1998)	Desires for alcohol questionnaire	Alcohol; Multidimensional	36 (based on Clark, unpublished); 14-item short form in same source article	Now; 7-point scale, anchors not provided in source article	Three: Relief from negative states and positive outcomes; Strong desires and intentions; Mild desire and intentions
Heishman, Singleton, and Liquori (2001)	Marijuana craving questionnaire	Marijuana; Multidimensional	47 adapted from previous measures (e.g. ACQ noted above)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Compulsivity or loss of control; Emotionality or anticipated relief negative emotions; Positive outcomes; Immediate intention to use

Heishman et al. (2009)	Marijuana craving questionnaire-short form	Marijuana; Multidimensional	12 (from 47 on the MCQ noted above)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Same four as MCQ: Compulsivity or loss of control; Emotionality or anticipated relief negative emotions; Positive outcomes; Immediate intention to use
Franken, Hendriks, and van den Brink (2002)	Desires for drug questionnaire	Heroin; Multidimensional	36 (adapted from DAQ described above)	Now; 7-point scale, anchors not provided	Three: Desire and intention; Negative reinforcement; Impaired control
Heishman, Singleton, and Moolchan (2003)	Tobacco craving questionnaire	Cigarettes; Multidimensional	45 (32 adapted from QSU, 8 impaired control items; 5 new items)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Relief of negative states; Enjoyment from smoking; Lack of control; Perceived control
Heishman, Singleton, and Pickworth (2008)	Tobacco craving questionnaire-short form	Cigarettes; Multidimensional	12 (3 items from each of the 4 factors in TCQ described above)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Relief of negative states; Enjoyment from smoking; Lack of control; Perceived control
Mol et al. (2003)	Benzodiazepine craving questionnaire	Benzodiazepines; Multidimensional	48 adapted from QSU and CCQ reduced to 32 (deletion of reverse-phrased items) then reduced to 20	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	One (containing 20 items reflecting 5 dimensions: desire, intention, positive expectancies, relief from negative states, control)
James, Davies, and Willner (2004)	Desire for speed questionnaire	Amphetamines; Multidimensional	40 (adapted from DAQ in Love et al., 1998, plus new items on control of amphetamine use)	Now; 7-point scale anchored with "strongly disagree" and "strongly agree"	Four: Expect positive and negative reinforcement; Strong desires and intentions; Mild desires; Impaired control
Ooteman, Koeter, Vserheul, Schippers, and van den Brink (2006)	Jellinek alcohol craving questionnaire	Alcohol; Multidimensional	24 items from initial pool of 129	Now; While regularly drinking; 5-point anchored with "not at all" and "very much"	One with high inter-correlations among 4 dimension-based subscales (Feelings of urge; Uncontrolled thoughts; Temptation; Physical sensations)
Jimenez, Grana, Montes, and Rubio (2009)	Alcohol craving scale based on three factors	Alcohol; Multidimensional	33 items from initial pool of 40	Over past two weeks of consumption before treatment; 4 options (never, rarely, frequently, always) to indicate frequency with which drinking motivated by each item	Three: Positive reinforcement; Negative reinforcement; Loss of control

TABLE 40.1 Authors and Features of Multi-item Self-report Craving Questionnaires—cont'd

Authors (Year)	Name of questionnaire	Drug; Conceptualization	Number and type of items	When craving assessed; Response format	Number and names of factors/subscales
Shiffman and Jarvik (1976)	Shiffman–Jarvik smoking withdrawal questionnaire	Cigarettes; Intensity	6 (of 25 total) that loaded on factor named "craving"	When varies by item (some now, some unspecified); 7-point anchored with "very definitely" and "very definitely not"	One for craving items
Halikas, Kuhn, Crosby, Carlson, and Crea (1991)	Minnesota cocaine craving scale	Cocaine; Intensity, Frequency, Duration	5: Intensity, Frequency/day over past week, Average duration; Change since last week; Effect of medication on craving	Past week; Format varies by item – Intensity: 100 mm VAS; Frequency: 7 choices from none to more-than-20; Duration: 8 choices from 0–5 min to 2 h+	N/A
Voris, Elder, and Sebastian (1991)	Voris cocaine craving scale	Cocaine; Intensity	4: Intense craving-No craving, Depressed-Happy mood, No energy-Too much energy, Feel sick-Feel well	Now; 100 mm VAS for all 4 items	N/A
Weiss, Griffin, and Hufford (1995)	Weiss craving questionnaire	Cocaine; Intensity	5: Current desire; Past 24 h desire; Past 24 h frequency of urge; Past 24 h when cued; Current likelihood if in regular environment	Now; Past 24 h; 9-point with various relevant anchors (e.g. "no desire" and "extremely strong")	One
Flannery, Volpicelli, and Pettinati (1999)	Penn alcohol craving scale	Alcohol; Intensity, Frequency, Duration	5 (frequency/strength/duration of thoughts; ability to resist; overall craving	Past week; 7 item-specific choices reflecting frequency, intensity, duration, difficulty abstaining	One
Kavanagh, May, and Andrade (2009)	Alcohol craving experience questionnaire	Alcohol; Intensity, Frequency, Duration	10 (duration/strength of craving, sensory images, thoughts of drinking)	7 items regarding most recent episode of strong craving; 3 items regarding past 24 h; 5 item-specific choices (e.g. from "weak" or "not at all" to "intense" or "all the time")	One

Adapted from [Rosenberg, 2009. Clinical and laboratory assessment of the subjective experience of drug craving. Clinical Psychology Review, 29, *519–534.]*

of craving on both single-item ratings and multi-item questionnaires. More concrete forms of cue exposure – for example, having drug users look at or handle drug paraphernalia – also elicit reports of elevated craving, usually measured using a single-item self-rating but also occasionally using a multi-item questionnaire.

Research demonstrating the impact of deprivation, drug-related imagery, and exposure to drug photos or paraphernalia on reported craving lends support to the construct validity of self-report questionnaires and VAS ratings. However, despite the practical advantages and theoretical bases for using these three interventions to elicit craving in clinical and laboratory settings, these procedures may not elicit craving or its presumed correlates in every respondent. Furthermore, deprivation and exposure probably elicit a wide variety of emotional and physiological responses in addition to craving, but respondents may attribute such responses to craving rather than other psychological states when craving is the only type of psychological experience about which they are asked. In addition, and probably because it would be difficult to do so, there are no empirical studies evaluating whether cue-elicited craving is subjectively experienced similarly to that which occurs outside the research lab or treatment setting.

As another evaluation of their self-report craving instruments, many investigators have examined the association of single-item and multi-item questionnaire scores with measures of recent consumption, severity of dependence, and number of drug-related problems. One especially innovative investigation compared craving scores as a function of route of drug administration and found that amphetamine abusers who injected the drug reported higher craving than those who smoked or snorted their amphetamines. The association of craving scores with the number of drug-related problems and severity of dependence is often interpreted as lending support to the validity of a questionnaire. However, these associations could also mean that these questionnaires are, in fact, measuring other features of drug addiction (e.g. experience of withdrawal symptoms, negative life consequences) that sometimes covary with, but that many would not consider the same as, the compelling urge or intense desire that defines craving. Depending on one's perspective, associations of self-reported craving with drug consumption and drug-related consequences could be seen as an indication of either good criterion validity or poor discriminant validity.

Limitations of Self-Report Questionnaires

Depending on one's conceptualization of craving, many of these self-report questionnaires may not ask about experiences the clinician, researcher, or drug taker considers indicative of craving. For example, only some questionnaires assess anticipated loss of control, only some include items assessing overt behaviors such as drug seeking, and only several assess bodily sensations that some might consider direct or indirect indications of craving. On the other hand, attempting to represent every thought, emotion, behavior, and physical sensation considered indicative of craving could result in unnecessarily lengthy questionnaires that might be no more reliable and valid than shorter questionnaires.

Self-reports of craving also appear to have limited predictive validity. Specifically, many studies find only a weak correlation between craving measured at a specific point in time (e.g. during intake or at discharge) and one or more aspects of consumption some hours, days, or weeks later. However, other studies report a more robust relationship between craving and subsequent consumption, and further research is needed to evaluate that combination of factors – such as craving, commitment to abstinence, coping ability, and exposure to environmental triggers – that yields the most reliable prediction of posttreatment outcome. We should also recognize that predicting relapse may not be a fair test of any measure of craving given the transitory nature of craving and the multiple influences on consumption in addition to craving.

The validity of craving questionnaires may also be tempered by limitations inherent to almost all self-report questionnaires. These include, for example, intentional and unintentional acquiescence and social desirability biases that might influence a respondent to underreport or overreport one's experience of craving. The quality of self-report measures could also be compromised if respondents limit the amount of effort they exert when reading questionnaire items, when retrieving information about their experiences from memory, and when selecting a response option that best reflects their experience. Craving questionnaires may be especially prone to this type of problem if craving itself disrupts memory and impairs judgment. In addition, assessors and respondents may differ in their understanding or interpretation of questionnaire items, response choices, and rating-scale anchors.

Finally, self-reports of craving might also serve, in at least some cases, as a preconsumption or postconsumption excuse to explain one's purposeful decision to consume a drug. Even if not purposefully misleading, the report of subjective craving may be the story one tells to explain consumption after the fact (e.g. "I must have been craving or I wouldn't have had that first drink"). There has been relatively little research evaluating how these limitations impact the reliability and validity of the instruments listed in Table 40.1, and these questions warrant consideration when one selects – and analyzes the responses from – a self-report questionnaire of craving.

SELF-REPORTS OF OTHER BEHAVIORS CONSIDERED INDIRECT INDICATIONS OF CRAVING

Free-Response Procedure

The free-response or think-aloud procedure allows clinicians and researchers to assess the subjective experience of craving without the use of printed items rated by the participant. The instructions for this procedure are similar to the free association instruction in psychoanalytic therapy because participants are asked to speak their thoughts and feelings aloud without judging how appropriate they might seem; however, in this procedure, substance users free associate during cue exposure or after imagining themselves in a drug-related situation. The participant's verbalizations may be audio- or video-recorded for subsequent content analysis. Advantages of this procedure over printed questionnaires include not having to rely on participants' reading ability or their recall of current or previously experienced craving. Free-response procedures may also reveal unique examples of a respondent's drug-related thoughts and emotions, and video-recording would allow analysis of facial expressions and body posture as subtle signs of craving. However, the think-aloud procedure has its limitations, including the possibility that respondents are unable or unwilling to report every drug-related thought or emotion. There are also practical limitations of recording and transcribing verbalizations for content analysis.

Selection of Drug Access over other Rewards

Designed as a means of assessing the "reinforcement value" of drugs, the multiple-choice procedure (MCP) could be considered an indirect indication of craving. The basic MCP asks respondents to select repeatedly which of two presented options they prefer, typically from a list of choices pairing potential access to a dose of a selected drug against ever-increasing amounts of money (e.g. the choice between a puff on a cigarette or $1.00; next, the choice between a puff on a cigarette or $2.00; next, the choice between a puff on a cigarette or $3.00; etc.). The respondent is informed that, at the conclusion of the testing session, the experimenter will select at random one of the many listed pairs of choices, and the respondent will be given whichever one of the two options (i.e. access to puff on a cigarette or specified amount of money) he/she selected at that choice point. Presumably, the greater one's craving and, therefore, the greater one values possible access to the drug, the more money must be on offer to induce one to switch or crossover from selecting drug access to selecting a specified amount of money. Several studies using this procedure have found higher crossover points when smokers and heroin-dependent patients were drug deprived (and presumably craving more intensely). The MCP holds promise as an easy-to-use and seemingly subtle measure of craving; however, some respondents may always select drug access over money regardless of how weak or strong their craving, and others may select the money option even though they actually prefer the drug. In addition, providing respondents a genuine choice between money and drug access may not be practical or ethical in many clinical and research settings. A more practical though less subtle use of a monetary scale to assess craving has been to ask drug takers how much money they would be willing to spend to obtain a specified dose of their preferred substance.

Drug Dreams

The reported frequency and intensity of drug dreams, and the dreamer's reported reaction to such dreams, could also be considered indirect indications of craving. Depending on one's theoretical orientation, substance-related dreams may be conceptualized as the expression of unconscious wishes to resume drug use, as the processing during sleep of drug cues and craving experienced while awake, or as arousal of neuropsychological systems that underlie both dreams and craving. Although several studies have reported an association between drug dreams and craving while awake, the prognostic value of such dreams as a predictor of lapse or relapse has been mixed. Furthermore, research has yet to assess whether the content of such dreams (e.g. searching for drugs, preparing to consume, refusal of drug offers) and the dreamer's reaction to the dream content (e.g. anxiety, guilt, subjective intoxication, relief that "it was only a dream") reliably precede or follow other indications of craving, drug seeking, and drug use while awake. The value of reports of substance-related dreams as an indirect measure of craving would benefit from further research to assess whether the frequency and content of drug dreams are influenced by presleep drug deprivation and presleep cue exposure designed to induce craving.

OBSERVATION OF BEHAVIORAL AND PHYSIOLOGICAL INDICATORS OF CRAVING

Motoric Behavior

Craving could also be defined in terms of overt behaviors, such as willingness to work for drug access, latency to consume given access, preference for drug-use

environments over other locations, and speed of consumption. Although assessing these behaviors obviates the need to rely on potentially misleading self-report of an internal state of craving, measuring craving only in terms of overt behavior raises other problems. For example, even intense craving does not always result in smoking, drinking, or drug use. Furthermore, both recreational and pathological drug use are influenced by a variety of factors other than craving, including mood, personal consumption goals, availability of the drug, and anticipated outcomes of consumption. In short, the overt behaviors noted above are influenced by more than just craving.

Attentional Bias for Drug Cues

Attention and attentional bias facilitate mental processing of the numerous internal and environmental stimuli to which we are exposed in our everyday lives. There is considerable debate regarding how and why attentional bias occurs among substance abusers, and mixed evidence regarding the reliability and validity of attentional bias for drug-related stimuli as an indication of addiction and predictor of consumption. Nonetheless, attentional bias has been proposed as both a cause and outcome of craving, and performance on attention-related reaction-time tasks such as the addiction-Stroop and dot-probe procedures may serve as proxy measures of subjective craving.

In the addiction-Stroop procedure, drug-related words and "neutral" or contrast words are used as stimuli, and the respondent is asked to name the colors of the ink in which the words are printed (or in which stimulus photos are tinted). A recent meta-analytic review of research using the addiction-Stroop concluded that longer reaction times on this task often distinguish addiction-related words from contrast words, distinguish substance abusers from nonabusers, and predict relapse following a period of abstinence. However, it is not clear how much slower one's reaction time to drug words (vs. contrast words) must be to indicate craving. In addition, performance on the addiction-Stroop could be influenced by several types of cognitive processes in addition to or instead of craving (e.g. reading drug-related words might elicit disruptive anxiety or might activate drug-related memories that distract one from the color-naming task).

Another reaction-time task, the dot-probe procedure, may also be considered a proxy measure of craving. On each of the many trials comprising this task, a drug-related word or picture and a neutral/control word or picture are displayed simultaneously on a computer screen, typically for just a fraction of a second. To control for handedness and other biases, the left–right position of the photos is counterbalanced across trials. After the pair of images is removed from the screen, a probe stimulus such as a dot, arrow, or asterisk appears in the location occupied previously by one or the other of the stimulus pictures. Participants are asked to indicate the position of the probe by pressing one of two response keys as quickly as possible. Attentional bias (and perhaps craving) may be inferred if reaction times are faster when the probe replaces drug-related stimuli than when it replaces neutral stimuli, revealing that one's attention has been "captured" and remains focused on the same side of the screen recently occupied by the drug-related stimulus. Consistent with this hypothesis, a recently published meta-analysis found a significant, though relatively weak, association between subjective craving and various measures of attentional bias (including the dot-probe). Once again, however, the point at which performance on the dot-probe task reflects an urge or craving remains to be delineated. Perhaps attentional bias must remain focused on drug stimuli for at least several seconds for craving to be elicited or intensified, or perhaps only when craving is of sufficient intensity might it result in scanning the environment for and attentional bias to drug-related cues.

Psychophysiological Reactivity

There are several rationales for assessing psychophysiological responses – such as salivation, changes in skin temperature, respiration or blood pressure, increased perspiration, and activation of specific brain regions – as indirect measures of craving. First, self-awareness of subjective craving could itself elicit psychophysiological arousal; secondly, conditioned stimuli previously associated with drug withdrawal or drug consumption could elicit both subjective craving and psychophysiological arousal simultaneously; thirdly, psychophysiological responses of which the person is not consciously aware could serve as conditioned stimuli that elicit craving; and fourthly, self-awareness of changes in physiological arousal could be interpreted by the drug user as subjective craving (e.g. "My palms are sweating, and so I must really need a drink").

Consistent with these rationales, research has found that exposure to drug-related stimuli, compared to neutral/comparison stimuli, often yields changes in measures of both peripheral and cortical functioning. Although physiological reactivity could provide an apparently "objective" measure of either conscious or nonconscious craving, psychophysiological reactivity – like craving itself – is a multi-determined phenomenon influenced by such factors as individual differences in

baseline reactivity and the environmental context in which reactivity is measured. Furthermore, physiological measures have limited clinical applicability given the need for special training to operate recording equipment, safety and esthetic concerns if one collects bodily fluids such as saliva, and the sometimes weak correlation between physiological reactivity, cue exposure, and other presumed measures of craving.

CONCLUSION

Developing and evaluating measures of subjective craving are complicated by questions regarding the emotional, cognitive, behavioral, and physiological components of craving, the threshold separating preference from craving, the degree to which one is interested in an acute and fluctuating experience of craving or a relatively stable preoccupation with or inclination to use a target drug, and the degree to which substance users are aware of and able to report on their motivational state of craving, among others. These questions notwithstanding, researchers and clinicians have a variety of assessment methods from which to choose, including single-item ratings of craving, multi-item questionnaires representing several different conceptualizations of craving, the free-response or think-aloud procedure, reports of drug dreams, observation of drug seeking and drug consumption, performance on reaction time tasks, and physiological reactivity.

Given the diversity of procedures for assessing craving, on what basis might clinicians and researchers choose a specific measure? Each type of assessment procedure has its advantages and disadvantages, and most could be used to measure craving experienced during a period of abstinence, within an ongoing drug-use episode, or during withdrawal. Selection will depend on several factors, including one's theoretical conceptualization of addiction and craving, the time frame over which one wants to assess craving (e.g. right now; over past 24 h; over past week), access to physiological recording equipment, opportunities to observe drug consumption, and the need for quick assessment when conducting repeated measurement or if respondents have limited concentration. Depending on one's setting, the expensive equipment needed for some procedures (e.g. assessment of brain activation), and the ethical and practical limitations of procedures that involve providing access to an illicit drug, will also influence one's selection. Perhaps the best strategy, if it is practical in one's clinical or research setting, is to employ several measures, each assessing different emotional states, cognitions, and behaviors considered indicative of craving.

Finally, as the concept of addiction has been applied beyond substances to apparently "addictive" activities such as gambling, physical exercise, computer use, and viewing sexually explicit material, there have been suggestions that researchers and clinicians also assess urges or cravings for those activities. For example, several of the multi-item self-report instruments listed in Table 40.1 have been modified to assess urges or inclinations to gamble. Further research may reveal that activity-specific modifications of craving questionnaires, and the other self-report, behavioral and physiological procedures outlined above, will improve the assessment and treatment of other types of addictive disorders.

Glossary

Addiction-Stroop procedure task during which participants are asked to read a list of drug-related words and "neutral" or contrast words, and to name the different colors of the ink in which the words are printed. Longer reaction times to drug-related versus contrast words may be interpreted as attentional bias.

Attentional bias reflexive, automatic awareness and cognitive processing of emotionally important stimuli in one's environment.

Craving subjective experience of an intense or compelling urge, desire or inclination to consume a drug.

Cue exposure procedure during which drug takers are shown drug-related photos, videos, or actual paraphernalia to assess cognitive, emotional, or physiological reactions considered indicative of craving (or to provide practice coping with craving).

Dot-probe procedure task involving multiple simultaneous presentations of both a drug-related word or picture and a "neutral" or contrast word or picture, typically for a fraction of a second. Following offset of the stimuli, a probe stimulus such as a dot, arrow, or asterisk appears in the location occupied previously by one or the other of the stimuli. Respondents are asked to indicate the position of the probe by pressing one of two response keys as quickly as possible. Shorter reaction times across those occasions when the drug stimulus and dot appear on the same side of the screen are interpreted as attentional bias.

Drug dreams dreams during which a person imagines seeking, consuming, or refusing drugs; such dreams may be an indirect indication of craving.

Free-response/think-aloud procedure respondents are asked to speak their thoughts and feelings aloud during cue exposure or after imagining themselves in a drug-related situation.

Multi-item craving questionnaire self-report questionnaire containing at least several and often dozens of items asking about various emotional, cognitive, and behavioral experiences considered indicative of craving for a specified substance.

OCD obsessive-compulsive anxiety disorder.

Visual analog scale (VAS) 100-mm line on which the respondent makes a mark to indicate the degree of urge, craving, or desire for the target drug experienced at that moment (or over some specified time period).

Deprivation, Craving, and Affect: Intersecting Constructs in Addiction

Jason A. Oliver, David A. MacQueen, David J. Drobes

Moffitt Cancer Center, University of South Florida, Tampa, FL, USA

OUTLINE

INTRODUCTION

Substance dependence and addictive behavior are complex syndromes, driven by a number of different processes. However, three concepts that are thought to play a central role in nearly every theory of addiction are deprivation/withdrawal, craving, and affect. The experience of drug craving and affective disturbance are key features of drug dependence that are acknowledged by nearly every theory of addiction. Most notably, both symptoms of dependence are markedly pronounced during drug deprivation and are thus characteristics of withdrawal. Though each of these concepts is distinct, they are also inextricably linked and interact in a number of ways. In this chapter, we will review the current state of both psychosocial and neurophysiological evidence derived from both nonhuman animal and human research on these topics. We provide basic definitions and formulations of these topics individually, and then discuss both specific research findings and overarching models that attempt to integrate these concepts.

DEPRIVATION/WITHDRAWAL

Individuals who are deprived of a drug after an extended period of regular use frequently experience a number of symptoms, with the cluster of symptoms being referred to as withdrawal. Withdrawal from substances can include changes in appetite and weight,

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00041-3

nausea, sleep disturbance, sweating, aches and pains, diarrhea, seizures, convulsions, and more. Symptoms can range in severity from minor irritants that may not be perceptible to the individual experiencing them, to serious conditions that carry a risk of permanent injury or death. These symptoms can emerge as early as 30 min to a few hours after the time of last drug use and can persist for days, weeks, or even months. Not all dependent users will experience significant withdrawal symptoms when usage is stopped, and the symptoms they do experience may change over time within a single withdrawal period (i.e. new symptoms appearing 1 week into the deprivation period as others are remitting), or across episodes of withdrawal (i.e. different symptoms experienced from one attempt to stop drug use to another). Different symptoms may follow different time courses during withdrawal, with some symptoms emerging later, or lasting longer. During an episode of withdrawal, administration of the drug to which the individual has become dependent will alleviate the withdrawal syndrome. Although the specific symptoms of withdrawal vary substantially across drug types, and span a variety of domains (e.g. physical, cognitive, etc.), two withdrawal symptoms that occur almost universally across drug types are craving and disturbance in affect.

Tolerance and Withdrawal

A discussion of drug withdrawal requires some understanding of the mechanisms of chemical dependence. Repeated administration of drugs of abuse often results in the development of tolerance, in which the potency of the drug (the amount of the substance required to produce an effect) is reduced across time. Tolerance can be described as a reduction in the physiological or subjective effects of a drug across repeated administrations of the same dose, or as a pattern in which increasing amounts of the substance are needed to achieve the same effects produced previously by lower doses. The mechanisms underlying tolerance can be described as dispositional, functional, or learned/behavioral. Both dispositional and functional tolerances result from physiological responses to the maintained presence of a drug within the system. Dispositional tolerance results from processes that reduce the distribution of the drug to its site of action, such as increased production of enzymes that break down the substance before it can exert its effects. Functional tolerance results from physiological changes that cause sites of action to be less responsive to the presence of the drug. As a direct result of the development of functional and dispositional tolerance, drug abstinence after a period of maintained exposure often results in the production of physiological states opposite of those produced by the drug. This abstinence effect is the withdrawal syndrome referenced above and, as previously noted, is associated with reports of negative affect and drug craving in humans, as well as drug-seeking behaviors in both human and animal models of drug dependence.

CRAVING

Despite the proliferation of research on craving in recent decades, scientists have yet to agree upon a precise definition of craving. It is generally agreed that it is an approach-oriented state that reflects the desire or urge to consume, though there is substantial disagreement over how strong a desire must be to constitute craving. While some view craving and urge as interchangeable terms that exist along a continuum, others reserve the term craving solely for describing extremely strong urges. Craving is generally subdivided into two categories. Tonic craving reflects a generalized state of craving that persists over long periods of time, though potentially fading into the background during periods of active substance use. It is typically linked to an individual's dependence level and is exacerbated by withdrawal. As such, tonic craving can be described in the context of physiological tolerance (dispositional and functional). As physiological tolerance develops, deviations in active levels of the drug present in the body that occur during the course of repeated administration can have more profound withdrawal effects, including increases in tonic craving.

In contrast, phasic (or, cue-elicited) craving is evoked by particular internal or external stimuli, such as the presence of a particular stimulus that is closely associated with prior drug use, a stressor, or even a drug-related thought. Importantly, these two forms of craving appear to be additive. That is, reports of craving are likely to be strongest in situations when cues are present, and withdrawal is being experienced, relative to either situation occurring in isolation. Cue-elicited cravings are typically thought to be relatively short-lived but can be experienced quite intensely. Despite this intensity, it is important to note that while there is substantial evidence linking tonic craving to actual drug use and risk for relapse, phasic craving has produced mixed evidence. While it may seem that craving would be closely linked to actual drug use behavior, and risk for relapse following an attempt to stop drug use, the actual link between craving and drug use appears to be far more complicated. Relationships between craving and drug use are small, or even absent, in many instances of cue-elicited craving.

Recently, scientists have also begun to distinguish between proximal cues, those which are directly related to substance use, such as drug-related paraphernalia or the drug itself, and distal cues, which may be highly individualized and will not necessarily have obvious

ties to substance use for all individuals. Distal cues might be a certain location where a person frequently engages in drug use (e.g. a chair one sits in while drinking), or an object or activity one typically is involved with while substances are being used (e.g. a phone one talks on while smoking).

Physiological Processes and Craving

In addition to self-reported craving, exposure to drug-related environmental stimuli can also be associated with discrete neural, somatic, or autonomic activity, even though no substance has been administered. These physiological responses may reflect the activation of motivational states, or other mechanisms that support drug-seeking behavior. Because cue-elicited cravings are produced by exposure to drug-related stimuli and environments rather than by withdrawal, they are able to produce experiences of craving even after long periods of drug abstinence. As a result, phasic craving produced by learned/behavioral processes are often separated from cravings occurring as a result of active dependence and acute withdrawal (tonic craving). There is evidence that both forms of craving share common neural substrates. Activity in the mesolimbic dopaminergic pathway, consisting of dopaminergic neurons in the ventral tegmental area (VTA) that project upon nucleus accumbens (NA), has been associated with both forms of craving. Because increased activation of this pathway has been consistently associated with the reinforcement (increased frequency) of drug-taking behaviors, these regions have also been assumed to underlie the pleasurable experience of drug use and are often referred to as the "pleasure pathway." It has been suggested that the subjective pleasure derived from drug use can be separated from the experience of drug wanting (craving). This is supported by the observation that repeated administration of abused substances frequently leads to progressive reductions in the self-reported pleasurable effects of the drug (tolerance), while self-reported craving increases across time. Thus, the effects of chronic drug administration on craving may be best described as sensitization, in that repeated delivery of a consistent dose leads to increases in craving both during withdrawal and in response to environmental stimuli.

AFFECT

Definitions

Another withdrawal symptom that is pervasive across drug types is disturbance in affect. Though precise definitions of affect remain a subject of controversy, most scientists now distinguish affect from the related concepts of mood and emotion. Emotion generally refers to brief states that manifest across a variety of component systems (e.g. subjective, behavioral, physiological). These are typically intense despite their transience, are thought to last no more than a few minutes, and frequently occur in response to a discrete, identifiable stimulus. In contrast, moods persist for longer durations (e.g. hours, days, or even weeks), vary more widely in intensity, and do not necessarily manifest across as many component systems as emotions do. Experiencing intense emotional states can have significant physical consequences, such as a substantial increase in heart rate, and therefore are not typically sustainable for extended periods of time. Fortunately, while individuals spend the majority of their existence in one mood state or another, emotions occur less frequently. Affect refers to an overarching construct that encompasses both mood and emotion. Scientists also generally distinguish between short-term changes in affect (i.e. state affect) and the relatively stable individual differences in affect that may persist across years.

Models of Affect

Although research has had some success with defining core affective states, work examining the overall structure of affect has generally supported a dimensional view. That is, rather than moods occurring as discrete, easily separable states, they tend to be highly correlated. Although individuals may identify specific moods (e.g. fear, sadness), these are frequently associated with other negative states, such as guilt, anger, and anxiety. Consequently, models positing a two-dimensional structure of affect have dominated the field. One of these models was developed in an attempt to disentangle the valence component of affect (e.g. happy vs. sad) from the arousal component (e.g. active vs. drowsy). A related model has also been developed, which retains this distinction between the valence and arousal components of affect, but also allows for the simultaneous experience of both positive and negative affects. Thus, an individual can experience both anxiety and excitement surrounding an upcoming event. Finally, though it is not frequently acknowledged in the scientific literature, it should be noted that the distinctions between emotion and mood have clear parallels to those between cue-elicited and tonic forms of craving.

NEGATIVE REINFORCEMENT

Development of Negative Reinforcement Effects

While escalating drug use after initiation is often driven by the direct euphoric effects produced by

drug taking, these euphoric effects generally lessen across time as physiological (functional and dispositional) and learned tolerance develop. As a result of these homeostatic processes, deprivation after the development of tolerance can induce negative states (withdrawal) that are alleviated only by the administration of the same or a related drug. Thus, early models of addiction posited that across time, the motivation for drug use shifts from sensation seeking (euphoria) to alleviation of withdrawal. According to these models, rather than eliciting euphoric effects, drugs were used by dependent individuals primarily to return to baseline mood following increased levels of negative affect due to withdrawal. Given that negative affect symptoms can emerge very quickly after drug use is stopped, affect may be a critical element of withdrawal that motivates continued drug use. The pattern of withdrawal symptoms may also play a role in how distressing they are. The immediacy of certain withdrawal symptoms, such as negative affect, may make them more potent motivators of drug-use behavior than other symptoms that develop slowly across a period of deprivation.

Addiction and Negative Reinforcement

Negative reinforcement models have dominated contemporary theories of addiction. These models have emphasized the role of withdrawal relief or anticipation of withdrawal relief in both craving and drug use. According to these models, drug-seeking and drug use behaviors are rewarded by the removal or avoidance of aversive states associated with withdrawal, which subsequently leads to craving in future situations in which these symptoms are anticipated or experienced. The subjective discomfort of withdrawal may be partially determined by a number of nondrug factors, including differences in genetic makeup, personality, and environment. One area that has received increased attention in recent years is the effects of menstrual cycle phases on withdrawal symptoms for female substance users. Though preliminary, there is evidence that withdrawal symptoms may worsen during the luteal phase of the menstrual cycle. However, disentangling withdrawal symptoms from premenstrual symptoms has proven a significant challenge and further research will be needed before definitive conclusions can be drawn.

Environmental Influences on Negative Reinforcement

As mentioned previously, environmental stimuli that have been associated with drug use can induce drug cravings and drug seeking in humans, as well as physiological effects. Similarly, specific stimuli and environments associated with drug administration can produce drug-seeking behaviors in animals. Evidence from recent animal studies suggests that environmental cues may actually produce stronger cue-elicited drug seeking (sensitization) across lengthier periods of abstinence. For instance, rats trained to self-administer cocaine and then withdrawn from the drug show more drug seeking (production of the trained self-administration behavior) after being returned to the drug administration context the longer the animal has been deprived of the drug. The enhanced effects of prolonged deprivation from abused substances on the production of drug-seeking behavior in response to environmental stimuli exceeds deprivation effects observed with other natural reinforcers (such as sugar) on the later production of trained behaviors in response to environmental stimuli. These observations of increased cue-elicited drug seeking as a function of deprivation period (referred to as incubation) have been associated with increased levels of brain-derived neurotrophic factor (BDNF) – a growth factor that enhances nerve cell growth and survival. Specifically, levels of BDNF have been shown to increase across periods of extended withdrawal in the NA, the VTA, and the amygdala – an effect not seen for other natural reinforcers.

While research on craving incubation in humans remains in its infancy, preliminary evidence suggests that cigarette cravings may incubate across periods of withdrawal. Should the phenomenon be consistently documented in humans, animal models of incubation will no doubt be critical in evaluating the effects of novel compounds that prevent, reverse, or otherwise alter the neuroadaptations underlying the sensitization of drug craving, including longlasting changes in responsiveness of the mesolimbic dopaminergic pathway. Across numerous drugs of abuse, imaging studies in dependent substance users suggest that chronic substance use results in reductions in dopamine release and in dopamine receptor density. When compared with nondependent controls, drug-dependent subjects demonstrate decreased responsiveness of the mesolimbic dopaminergic pathway to both drug administration and other natural rewards. This effect is congruent with the observation that substance-dependent individuals frequently report reduced enjoyment of nondrug-related activities. Anhedonia – an inability to derive pleasure from activities – is a characteristic symptom of depression. Thus, drug-induced changes to intrinsic reward pathways may serve to exacerbate or produce this facet of depression across long-term use.

Negative Reinforcement and Contemporary Theory

One prominent negative reinforcement theory of drug use emphasizes that drug use may be driven by affective withdrawal symptoms that can occur outside of conscious awareness. That is, as withdrawal symptoms begin to develop, an individual may take drugs to avoid experiencing those negative effects even before becoming fully aware that they were emerging. Over time, the addicted individual may become conditioned to expect a reduction in negative affect as a result of drug use because the sensation of relief from negative affect experienced as a result of withdrawal is generalized to other instances of negative affect. Thus, a regular drug user may frequently experience decreases in negative affect as a result of drug use, but this occurs only due to relief of withdrawal symptoms that emerged as a result of regular drug use. However, the individual may believe that drug use is capable of relieving negative affect in other distressing situations independent of withdrawal. In turn, craving can occur as the individual becomes highly motivated to use drugs in order to escape or avoid the experience of negative affect.

SELF-MEDICATION MODELS

One significant challenge for scientists examining negative reinforcement models of addiction has been distinguishing the transient effects of drug withdrawal from offset effects. While true withdrawal symptoms are caused directly by physiological adjustment to the presence (and subsequent absence) of the drug, they may be confounded by underlying, trait-like conditions that were masked by continued drug use. Unlike withdrawal symptoms, these trait effects will not necessarily diminish over time. While not all individuals who become addicted to a drug of abuse suffer from mood and anxiety disorders, rates of drug use are substantially higher among populations with psychiatric illness (including depression) than among individuals without any diagnoses. Moreover, individuals prone to affective disturbances are more likely to experience depression as a result of withdrawal from substances and tend to report greater withdrawal symptoms overall. These individuals may be more highly motivated to use drugs than other drug users, experiencing more frequent and more severe urges. Relatedly, they may have difficulty differentiating withdrawal symptoms from more stable, individual differences. For example, an individual with recurrent major depressive disorder experiencing the onset of a depressive episode may misattribute this decrease in mood to drug withdrawal. As a result, the individual may be more motivated to engage in drug use behavior and their dependence on the drug may increase. Although negative affect is a symptom of withdrawal from all major classes of drugs, misattributions that are more specific to particular drug classes may also play a role in driving drug use behavior. For example, an opioid addict may be unable to differentiate the flu-like aches of opioid withdrawal from an underlying chronic pain condition, and a benzodiazepine addict with chronic insomnia may be unable to differentiate withdrawal-induced insomnia from a return to baseline sleeping difficulties. Of course, functioning can vary widely even in nonclinical samples, and further research will be needed to determine the extent to which individual differences such as personality, genes, and other factors may cause subsets of individuals to experience differential effects resulting from substance use and deprivation.

Interactions of Affect and Cognition

Studies of how mood motivates drug use have not typically examined individual differences in baseline mood. Thus, it is possible that a subset of individuals, such as those with an active mood disorder, would experience a differential benefit of the mood-altering effects of abused substances. Self-medication of cognitive deficits may also occur, as thought to be the case for individuals with a variety of disorders that impair cognition (e.g. Attention Deficit Hyperactivity Disorder). It is important to note that at least in the case of alcohol and nicotine, the effects of the substance on affective state may be mediated by the cognitive effects of the substance. One such study revealed that smoking a cigarette did indeed relieve experimentally induced negative affect, but only when the smokers were given something else to focus their attention on after smoking. Similarly, studies have shown that alcohol may reduce anxiety by decreasing attention to threat cues when distracting stimuli are present.

POSITIVE REINFORCEMENT

Role of Positive Reinforcement in Drug Use

While research on addiction has traditionally emphasized the role of negative reinforcement (e.g. withdrawal relief) in motivating drug use, this contrasts sharply with the well-documented euphoric effects that exist across the majority of substances of abuse. Addiction must progress and tolerance must typically develop in order for significant withdrawal symptoms to emerge, so negative reinforcement models struggle to explain how drug use is motivated early in the course of addiction, before use has escalated. Similarly, negative reinforcement

does not account for the subjective experience of drug addicts, who frequently report drug use to enhance pleasant situations (e.g. parties). A history of euphoric effects as a result of drug use would help explain this association. Research across both animals and humans indicates that drugs of abuse can function similarly to other positive reinforcers, such as food. However, while most substances of abuse have verifiable euphoric effects following use (e.g. cocaine, opiates), this is not true in all cases. Although tobacco smokers subjectively report smoking to enhance positive affect, there is scant evidence to support the idea that nicotine is actually effective in doing so. Rather, the mood-altering effects of nicotine appear to be driven primarily by withdrawal relief, even among lighter smokers. It has also been suggested that the decreased responsiveness to natural rewards (as a result of the development of tolerance within reward pathways) may serve to increase the comparative saliency of direct drug effects, which serve to increase dopamine levels in the mesolimbic dopaminergic pathway. That is, drug use may dampen responses to other rewards, causing a relative increase in the subjective pleasure associated with drug use relative to these other rewards. While chronic drug use generally produces tolerance to drug effects on dopamine release within reward pathways, the administration of drugs (especially with increasing doses) may allow for dopaminergic activity that is comparatively greater than what can be achieved by other natural reinforcers. As a result, chronic substance users can develop a preference for drugs over other rewarding activities. The development of functional tolerance within reward pathways might represent a mechanism through which drug craving/seeking becomes sensitized. Craving may in fact be driven by this sensitization to drug-specific reward, as the pleasurable feeling obtained from the drug may exceed that of alternatives. This hypothesis suggests that drug cravings assessed during periods of dependency and craving during immediate withdrawal will be related to the development of tolerance within reward structures. Thus, the frequency, active dose, and duration of chronic administration will have a direct impact on drug craving during dependence and immediate withdrawal (tonic craving).

Drug Sensitization

If craving is indeed related to neuroadaptations occurring within reward pathways that are consistent across drugs of abuse, then it is also expected that adaptations occurring as a result of administration of one substance should facilitate the development of craving for a second substance. This prediction is supported by evidence from animal studies in which drug-seeking behavior (such as self-administration) is facilitated by prior exposure to drugs. It has been demonstrated in several species that prior administration of a drug can produce enhanced self-administration of the same drug. In addition, a number of studies have now reported cross-sensitization in which the prior administration of one drug enhances measures of craving/drug seeking for another drug with a different mechanism of action. For example, rats pretreated with amphetamine have enhanced preference for contexts associated with the delivery of morphine and vice versa, even though the two drugs act through very disparate mechanisms and have differing profiles of behavioral effects. In animal studies drug craving is inferred by the extent an animal will produce trained behaviors to receive a drug or the animal's preference for contexts associated with drug effects. The implication drawn from this research is that the development of craving for one drug in humans may serve to enhance the development of craving for other abused substances with the same or with different behavioral effects. Such effects have been observed in human research: drugs with euphoric effects can also increase both craving and consumption of other drugs, and these effects may be partially mediated by the original drug's effects on mood. Similarly, presentation of a cue for a specific drug can induce craving for other drugs that are used contemporaneously with the presented drug. Although this effect likely emerges as a result of classical conditioning, cross-drug priming may play a role in establishing the patterns of contemporaneous use that allow this conditioning to occur. Given the frequency with which individuals abuse multiple substances, cross-drug effects may play an important role in the development of secondary addictions and escalation in overall substance use.

EXPECTANCY THEORY

Although researches on the reinforcing aspects of substance use have generally emphasized direct drug effects on relevant motivational processes (i.e. escape/avoidance of aversive states or enhancement of positive states as causes of craving and drug-seeking behavior), they generally fail to explain the initiation of substance use. Beliefs about the effects or outcomes of drug use can develop long before initiation of use. In addition, these beliefs may continue to evolve after initiation, even independent of actual drug effects. That is, people may anticipate certain drug effects and this expectancy may drive behavior even when these expectations are not realistic. In other words, even if drug use may not actually result in the intended effects (i.e., relief of negative affect), the belief that the substance will have this effect might result in craving and motivate drug-seeking

behavior. At least in the case of nicotine, there is evidence that nicotine does not effectively relieve negative affect – except in the case of nicotine withdrawal. Although context (e.g. presence of distractors) may play an important role in moderating this, individuals may generalize their experiences of nicotine relieving negative affect due to withdrawal to other situations involving negative affect. Both personal experiences with a drug, and information gained from other sources of information (e.g. peer users, marketing) play a role in shaping expectancies. Indeed, these expectancies begin to develop at a fairly young age and continue to develop over time. Research indicates that negative expectancies decrease and positive expectancies increase as children enter adolescence, the time when substances are frequently used for the first time. The fact that expected effects of these substances are malleable also makes them a potential target for treatment. There is evidence that reducing the positive expectancies related to drinking can lead to decreased consumption.

AFFECT-INDUCED CRAVING

Previously, withdrawal was discussed as a causal influence that affected both craving and affect. However, it has long been recognized that changes in mood or emotional state can serve as powerful triggers for drug craving independent of withdrawal. Extensive laboratory research has documented that induction of negative affective states, even in the absence of direct substance use cues, can reliably induce drug cravings across a variety of substances (i.e. smoking, alcohol, cocaine). Similarly, stressful or otherwise unpleasant events can produce a high risk for relapse. Research with alcohol indicates that affect may interact with discreet substance use cues to predict drug use behavior above and beyond the level of prediction offered by either cue in isolation. In contrast, there is mixed evidence to support an increase in craving induced by positive affective states. Some research has shown that risk for relapse is also high during celebratory or other pleasant events. However, it has been suggested that this effect is driven by the increased presence of drug-related stimuli in pleasant situations (e.g. alcohol at a party) rather than the positive mood itself. Nonetheless, there is substantial evidence that drugs with potent ability to increase positive mood (e.g. cocaine, alcohol) can increase the likelihood of ingesting other drugs.

Negative Affect, Craving, and Physiology

Because negative affect has long been recognized as a precipitant of craving and drug relapse in humans, attempts have been made to model this phenomenon in animals. Though it is difficult to conceptualize or measure negative affect in nonhumans, animal models of the interaction between stress and drug administration have been fruitful in uncovering the neural mechanisms involved. Such studies have been conducted in a similar manner to those investigating the role of environmental stimuli in drug craving. Animals are trained to produce a behavior (e.g. lever pressing) to receive doses of an abused substance. Subsequently, the animal is deprived of the substance by providing no drug administration after production of the trained behavior. Eventually, animals cease producing the behavior. After a period of time a subgroup of the deprived subjects then receive a stressful stimuli such as a foot shock or a tail pinch. Subjects receiving stressful stimuli tend to begin producing the behavior that previously resulted in drug delivery, while subjects not receiving stress do not. This is referred to as reinstatement, and it has been demonstrated that stressful stimuli can reinstate responding for a range of substances including cocaine, nicotine, alcohol, heroin, and amphetamines. Reinstatement of drug-seeking behavior after stressful stimuli has been associated with increases in stress hormones (corticotrophin releasing factor, CRF) and noradrenaline in the amygdala, a structure associated with fear, negative affect, and emotional processing of memory in humans. In addition, increased levels of CRF, glutamate, and dopamine are observed in the VTA. Selective inactivation of the portions of the amygdala, the prefrontal cortex (involved in reasoning and emotional control), the VTA, and the NA reduces stress-induced reinstatement.

CRAVING AND MIXED AFFECT

Although scientists have traditionally viewed craving as a distinct construct with important ties to affect, recent theorists have posited that craving is itself a form of affective response that reflects an approach-oriented state, similar to how fear is an avoidance-oriented state. Yet, addicts report that craving is a predominantly aversive experience, and research reveals that it is typically correlated with self-reported negative affect. Although craving appears to be universally associated with heightened arousal, context appears to moderate the valence of the craving experience. The availability of the drug may play an important role in determining the valence of craving, as research with cigarette smokers indicates that negative affect is substantially lower following the induction of craving if individuals believe they can smoke immediately afterward. One plausible explanation is that when drugs are immediately available the addict may

anticipate relief, which may be experienced as an appetitive state. In contrast, when drugs are not available, craving may be a frustrating experience and take a more negative tone.

Theories of Craving and Affect

A number of prominent theories of drug addiction help explain how context can modify the affective valence of craving. According to Tiffany's Cognitive Model of Drug Urges and Drug-Use Behavior, drug use becomes automatic as dependence develops, and craving emerges as a result of these automated processes being disrupted. Therefore, while ongoing drug use in contexts where drugs are readily available would not have specific affective consequences in this model, the interruption of drug use will have distinct affective consequences. In situations where drug use is blocked by external circumstances (e.g. a supply of the drug running out), the addict would experience significant frustration and the overall affective response would have a distinctly negative tone. However, in situations where drugs are readily available but use is blocked by internal states (e.g. a desire to stop using), the affective consequences of craving would be better described as ambivalent, rather than strongly negative.

The Elaborated-Intrusion Theory of Desire purports that the specific affective response that craving may take will vary over the course of the experience. While an initial fleeting thought about a drug may be pleasant, this response can shift toward a distinctly negative response as this initial "intrusive" thought is more thoroughly processed and expanded upon. In some respects, this resembles the affective sequence characteristic of obsessive–compulsive disorder. Importantly, attempts to suppress thoughts related to drug use, particularly in situations where the drug is unavailable (e.g. the individual cannot afford to purchase the drug) or drug use is undesirable (e.g. the person is trying to stop using), will paradoxically lead to further cognitive elaboration of drug-related thoughts. At this stage, craving begins to take a predominantly negative tone. Although this negative tone may persist for some time, craving may return to a positive state at times as elaboration of the drug-related thought incorporates memories of positive sensory experiences resulting from past drug use. These intermittent bouts of positive states may serve to maintain the state of craving, even in instances where craving is predominantly negative. Deprivation and withdrawal may also play a key role in this process, by increasing the likelihood of intrusive thoughts and enhancing the intensity of the negative affect experienced. Also critical to this model, the relationship between intrusive thoughts and deprivation is thought to be reciprocal, as intrusions may serve to highlight awareness of deprivation and further increase the motivation to use drugs to mitigate any consequences resulting from that deprived state.

CONCLUSIONS

A great deal of research has demonstrated the critical role that withdrawal, craving, and affect play in the onset, development, and maintenance of substance use and addiction. While defining these constructs has proven exceptionally challenging, it is clear that these constructs intersect in a number of different ways. It is this intersection that forms the core of many prominent models of addiction. This chapter has described several ways in which these concepts interact, including the impact of substance deprivation on craving and affective experience. Even in the absence of acute substance deprivation, sensitization of neural reward pathways plays an important role in the generation of craving and drug use behavior, by heightening the reward value of drugs relative to other rewards. Certain individuals may be more prone to these facets of substance use, due to differences in affective and cognitive processes. Drugs may take advantage of these individual differences, speeding the development of dependence and increasing its severity. However, even in the absence of direct drug effects, the expected benefits of drug use may play an important role in the desire to consume substances of addiction. The motivation to use drugs is indeed a complex process, with affective correlates and consequences that can be moderated by a number of contextual factors.

The influence that research on deprivation, craving, and affect have had on shaping current views of addiction is profound and will likely continue to play an important role in the coming decades. Despite extensive research on the topic of addiction, it is clear that we have barely scratched the surface of a broad conceptual understanding of how addiction develops and is maintained. The majority of the relevant scientific literature has focused on examining individual components of the addictive process, often from the perspective of a single discipline. Recent advances in the fields of genetics, neuroscience, psychology, and others, coupled with an increased focus on transdisciplinary and translational research, will likely lead to important new discoveries, and an increased understanding of core components of addiction. More importantly, increased attention is now being given to how these components interact on neurobiological and behavioral levels to drive substance use and addictive behavior.

Glossary

Brain-derived neurotrophic factor a protein promotes nerve cell growth and survival.

Corticotrophin releasing factor a hormone involved in the stress response.

Dispositional tolerance a decrease in the effects of a drug that result from a decrease in the amount of drug that reaches the site of action.

Functional tolerance a decrease in the effects of a drug that result from physiological changes that cause sites of action to be less responsive to a drug.

Negative reinforcement a process in which the occurrence of a behavior is followed by avoidance from an aversive stimulus, or the removal of a pre-existing aversive stimulus, resulting in an increase in the behavior.

Phasic craving an urge to use a drug that is evoked by internal or external stimuli – typically increasing and decreasing rapidly.

Positive reinforcement a process in which the occurrence of a behavior is followed by presentation of another stimulus, resulting in an increase in the behavior.

Tonic craving a state of craving that persists over long periods of time, tightly coupled with an individual's level of dependence and withdrawal status.

Implicit and Associative Processes in Addiction

*Reinout W. Wiers** *and Alan W. Stacy*[$]

[*]University of Amsterdam, Amsterdam, The Netherlands [$]Claremont Graduate University, Claremont, CA, USA

OUTLINE

WHY DO THINGS THAT HARM?

Why do people engage in addictive behaviors such as smoking, binge drinking, or taking other addictive substances, while they "know" the consequences are harmful and potentially devastating? Research on implicit or associative processes in addiction has addressed this paradox and demonstrated that these choices are influenced by a set of associations in memory that become spontaneously activated, usually under specific conditions. These learned associations are not revealed through self-reflection, introspection, or reasoning processes, yet they guide behavior choices and the development of addictive habits. Hence, implicit cognition approaches have emphasized that there is more to decision making than a weighing of pros and cons of behavioral options. Implicit cognition may be especially powerful in the so-called "hot" situations, for example, when craving is high or in cases when control processes are impaired due to stress, fatigue, or acute alcohol intake. Note that although researchers on implicit cognitive processes in addiction emphasize the importance of these spontaneously activated associative processes, they also recognize that more rational decision making can influence drug decisions, especially when control capacity and motivation are sufficiently available.

ONE PROCESS OR MULTIPLE PROCESSES?

There is some discussion in the literature regarding how to best describe the cognitive processes involved in decision making, both in general and in relation to

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00042-5

addictive behaviors in particular. On one side of the spectrum there are theorists who state that there are two qualitatively different systems (or sets of systems), one reflective, rational, or propositional and one impulsive or associative, which independently influence (addictive) behaviors. On the other side of the spectrum are researchers who view expectancies, attitudes, or intentions as a unifying construct, capturing both associative and propositional processes. In the middle there are a variety of dual-process models, which distinguish between qualitatively different processes (associative versus propositional) and study the interaction of these processes. An influential general dual-process model was proposed by Strack and Deutsch, and many applications to addictive behaviors and proponents of these different perspectives can be found in the *Handbook on Implicit Cognition and Addiction* (see Further Reading). The study of associative processes in addiction can be undertaken both in animals, using controlled and well-studied learning paradigms, and in humans. Although we focus on human research here, we recognize the potential of the study of associative processes in addiction to bridge animal and human research.

DEFINITION

Definitions of implicit cognition vary depending on the discipline and research topic. Adapting a pragmatic approach that spans multiple disciplines (e.g. social and cognitive psychology), implicit cognitive processes are revealed on tests that do not require or encourage the conscious or deliberate recollection of previous events or introspections about the causes of one's behavior. Implicit cognition operates without reflective or deliberative processing or without being aware of the processes underlying behavior. There are many ways in which this nondeliberative process can be spontaneously triggered by a stimulus to influence behavior. Once triggered, an implicit process may influence the concepts that are activated in memory, one's subsequent train of thought, concomitant approach or avoidance tendencies, the accessibility of behavioral choices, and performance on tasks that reflect any of these consequences.

More specifically, processes may be considered implicit or automatic if they are characterized by one or more key qualities or features. De Houwer and colleagues suggest such characteristics include uncontrollability, absence of intentionality, goal independence, absence of awareness, efficiency, and operation even under time constraints. Implicit processes involve one or more of these qualities, suggesting a range of processes that are not necessarily unitary but nonetheless differ from reflective processes in important ways.

INDIRECT TESTS

Measures of implicit cognition use indirect assessment. Participants do not directly answer questions about the target construct. Indirect tests use measures of increased efficiency (e.g. reaction time or physiological measures), word production, or tests of memory performance that include an indirect element. The idea is that self-presentational or self-reflective processes are less likely to be engaged if direct questioning is not used. However, this is not absolute: research on faking of these indirect tests and research that mathematically models the underlying processes have indicated that both associative and controlled processes influence task outcomes. However, it is also clear that it is far easier to influence results on a direct than an indirect test, if a person is motivated to do so. Further, neurological approaches have shown strong evidence that indirect tests can detect associative cognition even when reflective processes are severely impaired and cannot be detected on direct tests.

DIFFERENT PROCESSES

Different implicit processes are distinguished. On the "input" (perceptual) side, an attentional bias for drug-related stimuli has been found for many different drugs, as well as for addictive behaviors not involving substances (e.g. gambling). On the "output" (motor) side, an action tendency to approach drug-related stimuli has been observed for a number of different substances (alcohol, marijuana, smoking, smaller research base as yet). Between input and output, memory associations are studied. As outlined in detail by Strack and Deutsch, these input, output, and mediating processes are viewed as intimately related from the dual-process perspective. Perception automatically triggers a motivational orientation and corresponding action tendencies, and the reverse also holds true: action tendencies can influence motivational orientation, which influence perception. Further, positive alcohol-related memory associations have been found to predict an attentional bias for alcohol, in participants with relatively modest control capacity. Regarding assessment and findings concerning a substance-related attentional bias, *see* Attentional Biases in Craving.

ASSESSMENT AND FINDINGS

Memory Associations

Memory associations can be assessed with a variety of measures that infer association strength on reaction

times in relation to different stimuli, and with a variety of memory association tests that do not rely on reaction times.

Measures of Associations Using Reaction Times

The Implicit Association Test (IAT), developed by Greenwald and colleagues, is the most commonly used RT-test to assess implicit associations. In addiction research, the test assesses individual differences in associations between a substance and two attribute categories (e.g. "positive" versus "negative"). The target category (alcohol or another substance in addiction research) also requires a contrast category (e.g. soft drinks or water for alcohol). On each trial of the task, participants rapidly categorize visually presented stimuli (pictures or words) by pressing one of two response keys. For example, in one phase of the task, they press the left response key when an alcohol-related or a positive stimulus is presented, and the right response key in response to alcohol-unrelated or negative stimuli. In another phase of the task, they press left when an alcohol-unrelated or positive stimulus is presented and the right key when an alcohol-related or negative stimulus is presented. The rationale for the task is that if participants automatically evaluate alcohol as positive rather than negative they should be quicker to respond when "alcohol" and "positive" stimuli share the same response key (as in the first phase in the example) compared to another block of the task where "alcohol" and "negative" words share the same response key (as in the second phase in the example). The IAT has a number of strengths: it is a flexible tool (different associations can be assessed), easy to use, and more reliable than many other implicit measures. Although the validity of the measure sometimes has been criticized, with ongoing debate, there are many studies revealing the test's utility, also in the field of addiction. New varieties of the IAT have been introduced, which may be particularly useful for the assessment of memory associations with substances for which it is hard to find a natural contrast category (e.g. smoking), because in these varieties there is no contrast category (Single Category IAT) or a contrast category that is not used in the instruction to categorize (Brief IAT).

Studies using varieties of the original IAT to assess whether alcohol is more strongly associated with negative than with positive effect found, perhaps surprisingly, consistently stronger associations between alcohol and negative valence than between alcohol and positive valence, in both light and heavy drinkers. However, heavy drinkers demonstrated somewhat less strong negative associations than light drinkers and IAT scores of implicit alcohol attitudes also predicted drinking behavior above the variance explained by explicit measures using the same words. Positive and negative associations can also be assessed separately, in two separate IATs contrasting positive with neutral and negative with neutral words. With these varieties, participants demonstrate both positive and negative associations for alcohol and smoking. Interestingly, the strength of the (relatively weak) positive associations and not the strength of the (relatively strong) negative associations predict unique variance in drinking and smoking behavior above the variance explained by explicit measures. Many studies have now found that relatively strong negative associations to be unrelated to drinking and smoking behavior. This suggests that positive associations may be more personally relevant, while negative associations may primarily reflect the common opinion of the culture or the fact that negative stimuli are generally more salient than positive stimuli. In line with this idea, studies using personalized versions of the IAT have demonstrated positive implicit associations with both alcohol and smoking. In addition to associations with positive and negative valence, researchers have used the IAT to assess other associations with substances, notably, associations with arousal, which were consistently found in heavy and problem drinkers, but not in light drinkers. Researchers have also recently used an IAT to assess automatically activated coping motives. The IAT can also be adapted to assess action tendencies to approach or avoid the substance (see below).

Other reaction time measures have been used to assess substance-related associations, such as varieties of priming measures. In these measures, a prime stimulus is presented briefly before the stimulus to which participants react (for example, by judging whether the second stimulus is a word or not). The advantage of this priming measure is that temporal order can be introduced to the measurement, which is not possible with the IAT and related measures. For example, it can be tested whether negative effect activates the concept of alcohol (or another substance) or whether the substance activates the concept of negative effect. With the varieties of these measures, it has been demonstrated that problem drinkers with high levels of psychiatric distress automatically activate the concept alcohol in reaction to negative effect primes.

Measures of Associations Not Using Reaction Times

Tests of memory associations using word production in addiction typically have used various types of word association tests. Common tests have used free word association, in which the participant lists the first word that comes to mind in response to a cue word, phrase, or picture, or a variant termed controlled

association, in which a category of some type (e.g. verb) is requested using similar instructions. Given that, tests do not directly inquire about the target concept (e.g. drug associations), these tests are indirect and may assess implicit processes. Indeed, consistent evidence across diverse paradigms from memory research shows that word association tests are capable of detecting implicit conceptual memory, and associations uncovered in these tests predict the spontaneous activation of cognitions across a wide range of experimental procedures. Probably the most compelling evidence for the implicit quality of word association tests comes from studies in amnesic participants, who show severely impaired explicit memory but no impairments on tests of implicit memory.

Addiction research began using word association methods comprehensively with the work of Szalay and colleagues. They found different associative structures in drug users versus nonusers and among participants entering versus successfully completing drug treatment. Most of the addiction research using word association conducted after this pioneering work has relied on traditional word association, using either free word association or a form of controlled association termed verb generation; verb generation asks for the first action or behavior that comes to mind in response to the cue, which may be a word, picture, or other stimuli. In the first study using this technique, Stacy and colleagues asked college students to generate the first behavior that came to mind in response to a series of alcohol-related and neutral short phrases. The alcohol-related phrases did not explicitly mention alcohol or its synonyms, but were obtained from college student norms for likely (perceived) positive outcomes of alcohol use (e.g. having fun, feeling good). Strong correlations were found between the generation of alcohol responses and alcohol consumption, even though nothing was asked about alcohol until after the associations were elicited using this indirect assessment. A number of studies have replicated this finding but have also documented the importance of associations between cues (in addition to affective associations) and alcohol as well as other substances. In a meta-analysis by Rooke and colleagues, word association tasks demonstrated the best predictive effects among all indirect tests of alcohol or other drug-related associations studied to date.

Action Tendencies

Motivational theories distinguish between two motivational orientations in relation to specific stimuli: approach and avoidance. Note that a wider perspective on motivation, proposed by Cox and Klinger, also involves broader concerns relevant to substance use, such as other personal concerns (e.g. partner relationships, work, housing, etc.), which may also be assessed with indirect measures (but little work has been done yet to achieve this). We focus here on the more narrow motivational orientation (the tendency to approach alcohol/drug cues). The first is an adapted IAT, where associations with approach versus avoidance are measured by comparing reaction times in a phase where the substance is categorized together with approach-words, with reaction times in a phase where the substance is categorized together with avoid-words. The second measure uses a symbolic approach or avoid movement by a manikin (matchstick Figure), which has to be moved toward the substance in one phase and away from the substance in another phase (reaction times are compared again). The third task involves an actual approach or avoid movement with a joystick, and participants respond to a feature of the stimulus that is unrelated to the contents (e.g. pull joystick in response to pictures tilted to the left, push in response to pictures tilted to the right). With the first measure it has been demonstrated in several studies that heavy drinkers are faster to categorize alcohol words when the same response key is used to categorize approach words than when the same response key is used to categorize avoid words; this facilitative effect on alcohol words is predictive of participants' self-reported craving when faced with an alcoholic beverage. With the symbolic approach avoid task (sometimes referred to with the too general label SRC, which stands for stimulus response compatibility), it has been found that frequent substance users (of alcohol, tobacco, or marijuana) are faster to make the manikin approach of the substance pictures than to make the manikin avoid the substance pictures. This approach bias has been related to indices of the severity of their substance use. In the third assessment task, the approach avoidance task (AAT), participants respond to pictures (substance or not substance-related) presented on a computer screen, by pulling or pushing a joystick. The task incorporates a "zooming mechanism": when the joystick is pulled, the picture size increases on the computer screen, and when it is pushed, it decreases. This zooming mechanism creates a sensation of approach or avoid and disambiguates the task. In several studies the AAT has been used in a so-called irrelevant feature variety, which implies that participants react to a feature of the picture that is unrelated to the contents of the picture (e.g. picture format: landscape or portrait, or pictures are presented with a small tilt to the left or right). For example, participants are instructed to respond with an approach movement (pull the joystick) to all pictures in portrait format and with an avoid movement (push the joystick) to all pictures in landscape format. The pictures in the task include control pictures (e.g. soft drinks, and sometimes also other pictures like landscapes) and critical stimuli (e.g. picture of beer bottle);

the type of picture is not addressed in the instructions. With this variety of the AAT it has been found that heavy drinkers as well as alcoholic patients are faster to approach than to avoid alcohol stimuli. An approach (or avoidance) bias is generally not found for control pictures that are positive (or negative). This could be related to the natural coupling of the stimulus category (appetitive stimuli) to the response used (arm movement). Note that the AAT is more indirect compared to the two tasks discussed previously (IAT, SRC), which both involve the instruction to categorize the substance pictures with approach in one phase of the test and with avoid in another phase. Initial findings of an approach bias for other substances (cigarettes and marijuana) have been reported as well, with an approach bias for marijuana as the best predictor of escalation six months later in problematic users. In addition, training varieties of the AAT have been used recently to change the approach bias for alcohol (see below).

Individual Differences: Trait and State

As noted in the introduction, dual-process models state that many behaviors, including addictive behaviors, are influenced both by automatically activated associative processes and by more controlled reflective processes. The relative extent to which associative and reflective processes determine (addictive) behaviors is likely to differ between people (trait differences) and within a person, depending on the situation (state).

Trait

In a series of studies using different measures of substance associations (open-ended memory associations as well as reaction time measures) and different measures of individual differences in executive control, it was demonstrated that associative measures are a better predictor of substance use in individuals with relatively weak scores in executive control, than in individuals with good scores in executive control. There is also some (more limited) evidence that in individuals with relatively good scores in executive control, explicit expectancies better predict substance use. This dissociation has not only been found repeatedly for substance use outcome measures, it has also been found for related behaviors, such as aggressive tendencies, aggression after alcohol, sexual interest, and candy eating despite attempts to restrain eating. In all of these cases, the target behavior was better predicted by measures of relevant associations in individuals with relatively weaker scores in executive control.

State

There is also an emerging evidence that measures of the relevant associative processes better predict behavior in conditions where the (limited) executive control capacity has been reduced. This can be done by depleting executive control. One way to do this is to first give participants a task that depletes control capacity, such as holding a hand in ice water or by doing a number of difficult cognitive tasks. There is also evidence that an acute dose of alcohol temporarily impairs executive control capacity. As reviewed by Field and colleagues, alcohol not only impairs executive control but it also primes associative appetitive processes. Depending on the situation, this can lead to the consumption of more alcohol than desired before the drinking session, or to an increased chance of performing other behaviors than normally desired, including aggression, overeating, and unsafe sex. As reviewed by Wiers, Houben, and colleagues, this may explain why in some cases after alcohol consumption, common sense may go out of the window. As yet, there is little research on the effects of other substances on associative processes, on the one hand, and executive control processes, on the other hand. In addition, there is little research yet on long-term effects of different substances on these processes, as well as on other relevant cognitive motivational processes (e.g. motivation to engage in school or work). The suggestion from clinical observations as well as animal research is that negative long-term effects are likely.

ORIGINS AND RELATION TO THE DEVELOPMENT OF ADDICTIVE BEHAVIORS

As yet little is known about the origins of implicit cognitive processes involved in addictive behaviors in humans. As reviewed by De Wit and Dickinson, in animal research, there is a rich tradition on different types of associative learning (classical and instrumental conditioning) with recent emphasis on different underlying neural systems involved. Some of these tasks have recently been used in humans as well. Most human research on the origins of associative processes in addiction have used natural existing drug-related stimuli, rather than studying reactions to novel artificial stimuli of which the learning history is controlled, as is done in the animal research. In these studies of natural origins of alcohol- and drug-related association, one important distinction concerns origins before personal initiation of the substance and origins after initiation.

Origins Before Substance Initiation

Some of the most likely origins of implicit associations involve the social environment (parents, peers) and media exposure. Grenard and colleagues found

that the growth in alcohol-related implicit associations in adolescence over time is predicted by earlier reactions to alcohol advertising on television. Alcohol consumption and implicit association growth curves were strongly correlated across early adolescence. There is also some evidence indicating that parents' implicit associations with smoking are related to children's implicit smoking associations, as well as with their smoking behavior. Traits like sensation seeking and impulsivity have also been related to the early initiation of substance use, but to our knowledge it has not been studied to what extent this relationship is mediated by substance-related cognitions.

Origins After Substance Initiation

It is a well-established finding that addictive behaviors are partly explained by genetic factors (*see* Neurogenesis and Addictive Disorders on Neurogenetics of Addiction). There are some first indications that some of these genetic factors may be mediated by cognitive processes. For example, it has been demonstrated that heavy drinkers with a g-allele in the *OPRM1* gene (also associated with strong cue-induced craving) have stronger automatic approach tendencies to alcohol cues than equally heavy drinkers without this allele. Other genetic variations are currently studied in relation to associative processes in addiction, as well as in relation to other psychopathology (e.g. an attentional bias for emotional stimuli in anxiety has been related to varieties of the serotonin transporter gene promoter region (5-HTTLPR) Polymorphism).

In relation to neurobiological models of the development of substance use, some implicit processes (attentional bias, arousal associations, and approach tendencies) have been theoretically linked to the development of a hypersensitive motivational reaction to conditioned stimuli predicting drug use (incentive sensitization, *see* Incentive Salience and the Transition to Addiction). In addition, it has been proposed that some associative processes may be more related to the development of drug-related habits (e.g. cue–behavior associations). Both hypotheses await critical testing.

Development and Causal Role

As yet little is known about the development of implicit cognitive processes in addictive behaviors.

Regarding a causal role of implicit cognitive processes, the current database is limited. It is well established that substance associations differ between heavy and light users or abstainers of the substance and that implicit measures predict variance in the addictive behavior after controlling for explicit predictors (as demonstrated in the meta-analysis of Rooke and colleagues). There is also some evidence of prospective short-term prediction after controlling for previous substance use and explicit cognitions, but this database is more limited. A more direct way to test the causal status of implicit cognitive processes is to directly manipulate them, and to study the effects on the cognitive processes and on behavior. Since these recently developed methods also have therapeutic implications, they are discussed below.

POTENTIAL FOR NEW INTERVENTIONS

Addiction researchers have begun attempts to directly manipulate implicit cognitive processes. This can be done for two reasons: to establish the causal status of the process in an experimental way and for therapeutic reasons. In studies establishing the causal status, it is as informative to experimentally increase a cognitive bias as it is to decrease the same bias and to observe corresponding effects on addictive behaviors. For ethical reasons, these studies are typically performed in nonaddicted participants. In clinical samples, the cognitive substance bias is typically decreased in the experimental group and left unaffected in the control group. The manipulation or retraining of the bias is typically done by using a variety of the task used to assess the same bias, in which a contingency is built in. For example, in an assessment version of the AAT, participants respond to an equal number of alcohol pictures with an approach movement and with an avoidance movement (the difference generates the approach bias for alcohol). In a manipulation version, this contingency is changed; in an avoid-alcohol condition, participants are made to respond with an avoidance movement to most alcohol pictures and with an approach movement to most nonalcohol pictures. Similarly, in an approach-alcohol condition, participants are made to respond with an approach movement to most alcohol pictures, and with an avoid movement to most nonalcohol pictures (not used in clinical studies). In a control condition, often continued assessment is used (equal number of approach and avoid movements to alcohol and nonalcohol pictures) or no assessment. Researchers study the effects of this manipulation on pictures used during the training, as well as to pictures not used during the training (close generalization; same task as used in the training, but different stimuli). They also study further generalization (e.g. performance on another task that attempts to assess the same process), and effects on behavior.

Following the pioneering work in anxiety research, addiction researchers first targeted an attentional bias for a substance (alcohol). Initial studies testing causality by a single session of attentional retraining found corresponding effects on the bias, but no generalization to untrained stimuli or different tasks. However, recent

studies using repeated attentional retraining in problem drinkers and alcoholic patients found generalized effects on the attentional bias and reduced alcohol intake in problem drinkers after training in one study and increased levels of abstinence in alcoholic patients in another better controlled study by Schoenmakers and colleagues. Wiers, Rinck, and colleagues developed a retraining version of the alcohol AAT. In a preclinical study, they found generalized effects on the approach bias for alcohol in students (stronger approach bias in students who had responded with an approach movement to most alcohol stimuli, and reduced approach bias in students who had responded with an avoidance movement to most alcohol stimuli). In students who were successfully trained, they also found corresponding behavioral effects in a taste test: students who had been successfully trained to make a push response to alcohol stimuli, drank less on a subsequent taste test involving different beers. In the first randomized controlled clinical study using this procedure, alcoholic patients were trained in four sessions to avoid alcohol and approach nonalcoholic drinks (experimental condition) or not (control condition), after which the patients participated in regular cognitive behavioral therapy (CBT, *see* Cognitive Behavioral Therapies). This resulted in a strong generalized effect on the automatically activated tendency to approach alcohol in the experimental condition. For example, patients who had been trained to make a push-movement with the joystick in response to alcohol pictures, also associated alcohol words more strongly with avoidance than with approach on an IAT, while patients in the control group continued to associate alcohol words more strongly with approach-words than with avoidance-words. Moreover, patients in the experimental condition were 13% more likely to be abstinent 1 year later than patients in the control condition.

In addition to first experimental studies targeting an attentional bias and approach bias, researchers have initiated attempts to change substance-related associations. This can be done by consistently coupling the substance to negative (repulsive) pictures, a form of evaluative conditioning. In two studies, Houben and colleagues coupled alcohol pictures with negative pictures (experimental condition), which was not done in the control condition (alcohol pictures were coupled to neutral pictures). In both studies, participants in the experimental condition drank less in the week after the experiment than before, which was not the case in control participants. In one of the studies, it was also shown that the experimental condition had stronger negative alcohol associations after the experiment than the control condition (using an IAT). To the best of our knowledge, evaluative conditioning has not yet been used in clinical samples, but it bears resemblance to aversive conditioning procedures used earlier in the treatment of alcoholism (unfortunately often in poorly designed research).

Note that it is well possible that existing CBT may result in changes in substance associations, but these are often not measured in studies of CBT effects. One study that did assess the effects of a specific form of CBT (a so-called expectancy challenge) on alcohol associations (in addition to explicit expectancies) found that while this intervention resulted in the anticipated changes in explicit expectancies, there was little change in alcohol associations. However, there may also be other ways to use explicit instruction to change the likelihood of the desirable over the undesirable behavior occurring in a specific situation. This may be done, for example, by forming the so-called implementation intentions: if situation X, then behavior Y. For example, if I drive, then I order nonalcoholic drinks.

CONCLUSION

There is ample evidence that implicit or associative processes play an important role in addictive behaviors, despite the fact that there are many open questions in this relatively young field of research. There are different indirect methods to assess these processes, some relying on reaction times, some not. With both types of measures, it has been found that substance associations predict unique variance in substance use, also after controlling for explicit cognitive processes. In addition, there is evidence that heavy substance use is related to an approach bias for that substance (as well as an attentional bias for the substance, discussed more extensively in Attentional Biases in Craving). Most research has studied associative processes involved in alcohol use and misuse, some in cigarette and marijuana smoking and few have studied associative processes related to other substance use and misuse. In addition, little is known yet about the development of associative processes in relation to the development of addictive behaviors. There is an emerging evidence that associative processes better predict substance use and related behaviors in individuals with relatively limited executive control abilities (either as a trait or as a state). Finally, there are promising first studies that demonstrate that it is possible to modify associative processes in addiction. These findings are not only important for establishing causality of these processes but also hold promise for novel interventions, as initial studies demonstrate.

OUTLINE

CUE REACTIVITY

Rates of relapse across all classes of addictive substance are high (substance covers alcohol and nicotine as well as illicit substances; see Fig. 43.1). For example, up to 70% of alcohol-dependent individuals relapse within 3–6 months of receiving treatment, while up to 90% of attempts to quit smoking fail within a year. Relapse rates for opiates, 12 months following residential treatment, are approximately 65–70%. A risk factor believed to be important in substance-related behaviors (defined here as substance-seeking and self-administration) is cue reactivity. When an individual comes into contact with a stimulus (cue, e.g. alcohol advertisements, the sight and smell of cigarettes, other substance users) associated with the substance, psychological and physiological reactions can occur, which may trigger substance-related behaviors. Substance cues can increase self-reported craving and self-administration behaviors in both dependent and nondependent populations and the degree of cue reactivity may predict individual differences in the risk of relapse. However, the evidence is inconsistent: cue reactivity is not always observed, and the predicted relationships between cue reactivity and other variables, such as severity of

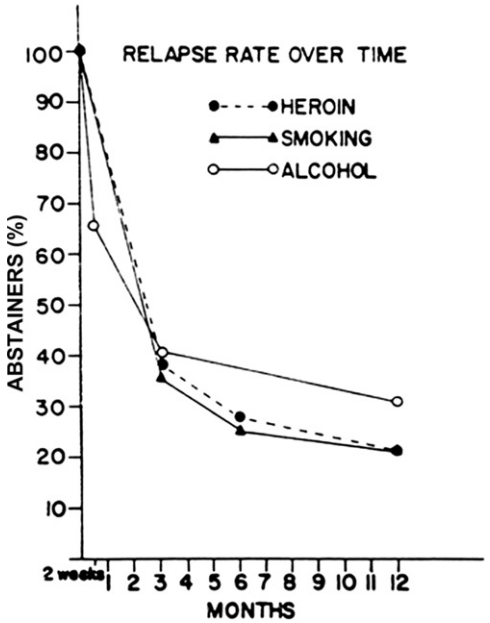

FIGURE 43.1 Relapse rate over time for heroin, smoking, and alcohol. *Reproduced with permission from Hunt, W.A., Barnett, L.W., Branch, L.G. 1971. Relapse rates in addiction programs. Journal of Clinical Psychology, 27, 455–456.*

dependence or prospective substance use, are not always present.

Cue reactivity paradigms measure the effect of both discrete (e.g. a glass of wine or a tone paired with substance administration) and contextual (e.g. the pub, operant chamber) cues on a range of measures. Cue reactivity effects have been found on measures of self-report (e.g. desire and craving), automatic cognitive responses (e.g. approach tendencies, attentional bias), self-administration (e.g. ad lib administration, speed of consumption), motivation (e.g. operant responding), physiological (e.g. heart rate, skin conductance) and pharmacological (e.g. dopamine) responses, and increased activation in discrete regions of the brain (e.g. ventral striatum, anterior cingulate cortex).

As substance dependence is necessarily preceded by a period of time in which the substance is administered on a regular basis, often in predictable environments and when in the presence of discrete cues, conditioning-based accounts of cue reactivity have been highly influential in this area. However, other cognitive theories have provided different insights and identified several cognitive biases that are likely to be involved in cue reactivity. As the neurobiological basis of cue reactivity has been mapped, it is clear that reactivity involves a complex system of interrelated processes. Finally, it is important to gauge how cue reactivity can be applied to clinical aspects of addiction and inform treatment.

CONDITIONING AND LEARNING THEORIES

It was originally suggested that, as dependence on a substance developed, withdrawal symptoms (unconditioned responses) would be experienced and cues (conditioned stimuli) associated with substance administration would come to elicit withdrawal-like responses (conditioned responses; see Fig. 43.2). Substance use is, in this theoretical account, defined as an operant behavior that alleviates withdrawal symptoms (avoidance or escape learning), and each successful reduction of negative effect reinforces substance use. These withdrawal-based, negative reinforcement theories were originally formulated due to anecdotal reports from opiate addicts who claimed to experience withdrawal-like symptoms when coming into contact with opiate-related cues (e.g. previous substance-related contexts).

Both human and animal models have shown that, if withdrawal is accompanied by a conditioned stimulus (e.g. a tone or odor), the conditioned stimulus alone can precipitate withdrawal. However, cues associated with substances have also been found to alleviate withdrawal symptoms. Although the ability of cues to trigger withdrawal symptomatology is important, the key issue is whether this is related to maintenance of problematic substance use and relapse. There is a substantial amount of research that fails to find these relationships. For example, some addicts never abstain long enough for conditioned withdrawal to develop yet they persist in self-administering substances. In addition, anecdotal reports suggest that only a minority of heroin addicts experience conditioned withdrawal, and even fewer report relapse as a result of this effect.

In a similar vein, it has been proposed that, through attempts to maintain homeostasis, opponent processes (physiological and affective responses that work in direct opposition to the effects of the substance itself) develop in anticipation of, and to counteract, the effects of the substance (see Fig. 43.2). These opponent processes may underlie the development of tolerance and support the administration of greater substance doses to experience the desired effects. If opponent processes can be conditioned, substance cues associated with the substance's central effects could trigger the opponent process and reduce the perceived effects of the substance, or be perceived as withdrawal in the absence of substance administration. The absence of a conditioned opponent process has been put forward as a reason for why fatal overdoses occur in experienced substance users when they have administered a substance in an environment free from the usual substance cues. Importantly, both the theories of conditioned withdrawal and conditioned opponent processes argue that physiological changes are key in activating substance urges, and that these urges motivate substance intake to reduce these physiological changes. However, as with conditioned withdrawal, evidence for opponent processes is also lacking and research fails to show a strong relationship between physiological changes in response to cues and self-reported craving for substances.

Competing theories postulate that cues take on positive incentive properties and trigger substance-like effects (see Fig. 43.2). General incentive motivational frameworks propose that cues can develop conditioned incentive properties in their own right and elicit motivational states. These motivational states may support specific types of behavior and can interact with internal states. For example, the sight of a cold can of beer may elicit a desire to drink alcohol, which triggers approach and consummatory behaviors; however, this effect may be greater in a person who is also thirsty. In terms of withdrawal, instead of negative reinforcement *per se*, the withdrawal state makes the incentive value of the substance so great that substance use prevails. When applying these general ideas to addiction, substance-associated cues could elicit substance-like, as opposed

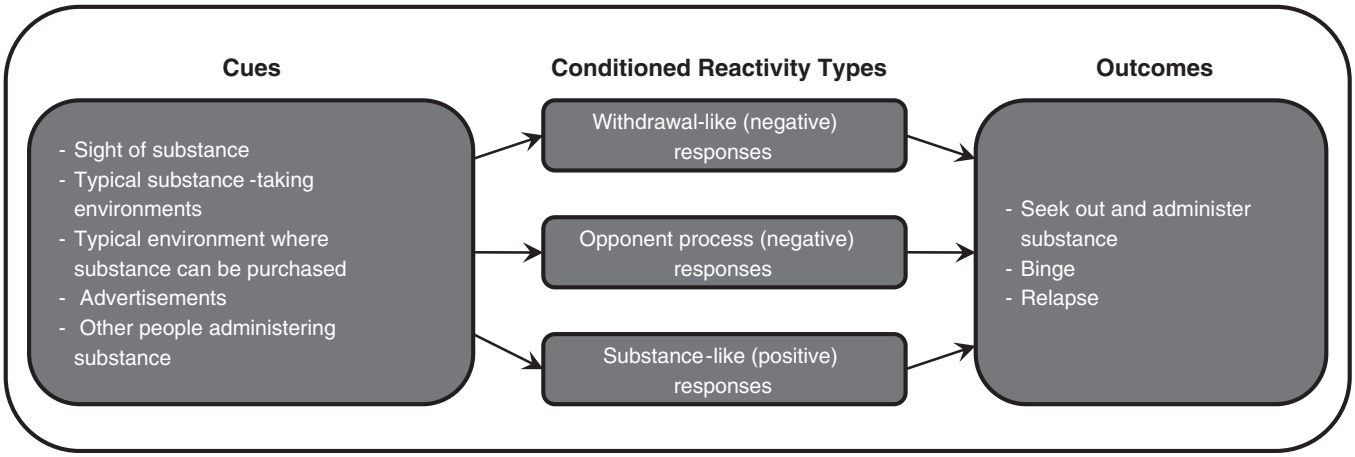

FIGURE 43.2 Typical types of cues, possible cue reactions according to major conditioning theories of addiction, and potential outcomes from cue exposure.

to substance-opposite, effects. Animal models have found that cues associated with opiate administration can produce hyperthermia, which mimics the actual substance effect, rather than hypothermia, which is a withdrawal effect.

The evidence concerning single process theories (i.e. those that focus on positive or negative reinforcement, and substance-like or substance-opposite effects) with regard to cue reactivity shows inconsistencies between direction of cue effect and differences in effect sizes across substance classes. For example, significant decreases in skin temperature reactivity have been found in opiate and cocaine addicts but not in alcoholics and dependent smokers. Self-reported desire in the presence of substance cues often increases significantly across all substance types, but effect sizes are inconsistent for opiate- and smoking-dependent populations.

Another key area addressed by learning theories is whether substance behavior is habit-like or goal-directed. Habit-like behavior is thought to be based upon stimulus–response associations, in which behavior (e.g. substance intake) is triggered by a cue with little or no mediation by the intention to engage in substance use, or anticipated outcomes of substance use. Goal-directed behavior involves stimulus–outcome–response associations, in which the cue triggers an expectancy of the outcome, which then triggers behavior. Devaluation paradigms are often used to compare these two learning processes and some animal models have indicated that substance rewards act differently to natural rewards. When food or substance outcomes have been devalued (e.g. through being paired with an aversive consequence or state-specific satiety), some research has found that animals will stop responding for the former but not the latter. These findings indicate that, whereas food-seeking behavior is goal-directed (i.e. governed by an expectancy of the outcome), substance-seeking behavior is insensitive to the devaluation effect, indicating a habit-like stimulus–response association. However, human research has yielded somewhat different results. Nicotine devaluation, by satiety, reduces cigarette-responding, as would be expected by a goal-directed theory, but the presence of a cigarette cue abolishes this devaluation effect and substance-seeking responses occur regardless of the substance's incentive value. This research demonstrates the Pavlovian-to-instrumental-transfer (PIT) effect in cue reactivity; conditioned stimuli (traditionally associated with stimulus–reward associations) for a given reward can elicit operant responding for that reward (response–outcome associations). When a substance cue is presented in extinction (no response outcome), the behavioral response (substance-seeking) is elicited, suggesting that the cue activates an expectancy of a specific outcome (e.g. alcohol) but not necessarily the current incentive value of that outcome.

Such findings indicate that although substance-related behavior involves both goal-directed and habit-like learning, it may also be particularly susceptible to the influence of cues. This possibility lends itself to the compulsive nature of addiction and fits with findings that cues can trigger relapse in individuals, even though they are aware of the significant adverse consequences of returning to substance use. Such possibilities may predict that treatments that emphasize the negative consequences of substance use may be limited in their efficacy. In addition, the finding that cues can trigger substance-related behavior, with scant regard to the value of the substance, may help explain the claims that craving elicited by cues is not consistently related to relapse risk. The effects of cues on substance behaviors may bypass craving mechanisms, which may be more associated with the perceived value of the substance, and trigger administration behaviors in a more automatic fashion. However, systematic

investigation of the relationship between cue-induced craving and relapse is still needed to resolve this issue.

Due to the discrepancies in results, theoretical accounts of substance use moved toward dual process theories with an increased focus on more complex learning processes and, initially, there were two primary versions: motivation and expectation. The motivation framework suggests that cues (e.g. an exteroceptive stimulus or an interoceptive state) can motivate a response and that the response outcome (e.g. a new state) can provide feedback to strengthen this association. Alternatively, the expectation framework argues that the cue first activates an expectation of the response outcome, which then triggers the response. The actual response outcome can then feedback on to the expectation (see Fig. 43.3). As the latter model incorporates outcome expectancies, the expectation framework better fits with the finding that if the outcome is devalued or revalued, the response for that outcome is decreased or increased, respectively. However, the model does not directly explain the possibility that cues may trigger a general outcome expectancy, which does not take into account the current value of the outcome.

Although most recent major theories of substance dependence acknowledge a role of conditioning, not all theories assume that conditioning is sufficient to explain substance use and relapse. In its simplest form, conditioning theories argue that over time, cues can elicit physiological responses and/or motivational states (e.g. urges, cravings), which promote substance use. However, there is a lack of consistent evidence that self-reported urges or physiological reactivity account for a significant amount of the variance seen within actual substance use. Severity of dependence is not always correlated with degree of cue reactivity, as would be predicted by a conditioning account, and not all dependent individuals experience cue reactivity. In addition, substance use, whether as an example of "everyday usage" or relapse, involves a number of aspects. For example, deciding to purchase a bottle of wine while shopping may take into account a number of factors including price, preexisting plans, substance-related memories, and, in the individual trying to abstain, perceived self-control.

COGNITIVE THEORIES

At the more basic level, it has been suggested that urges simply reflect a state of physiological arousal and that the details of this state have been cognitively interpreted and labeled as "urges" by the individual. Any substance cue may trigger arousal and the individual may perceive the cue as associated with substance administration (e.g. a former heroin addict may take a walk in a park where he/she used to shoot up, this context may trigger both arousal and memories of past substance use). These two processes may result in the individual interpreting the arousal as craving, which triggers substance intake. These propositions come from a general "cognitive labelling theory," which argues that the cognitive and contextual/cue state that the individual is in is key to the interpretation of arousal. In addition, arousal can have effects on other processes, including focusing attention, and emotional influences on decision making, which could result in attentional bias for substance cues and disrupted rational decision making regarding substance use. Although no detailed arousal theory of addiction exists, it is fair to assume that the greater the physiological arousal, the greater

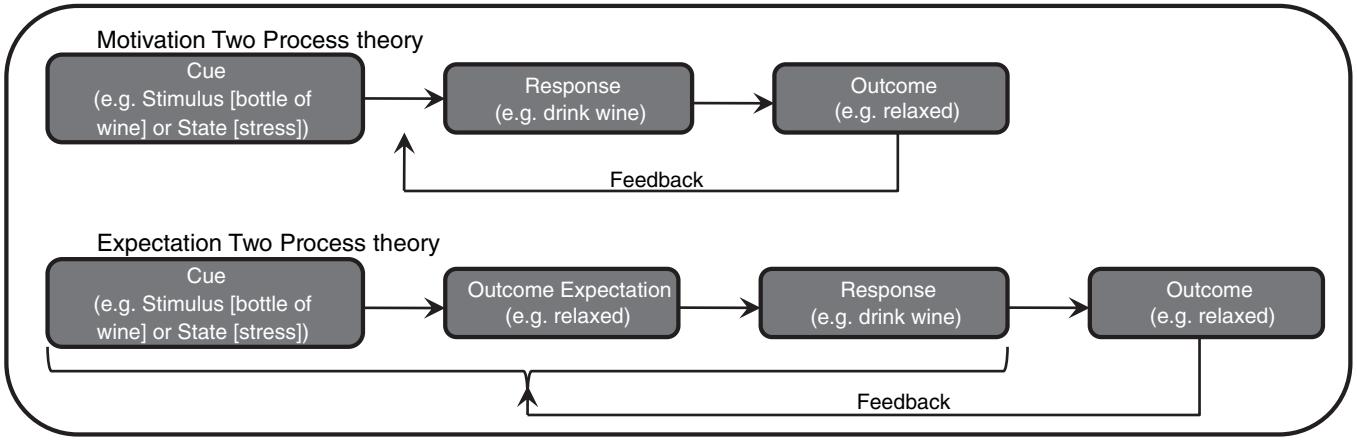

FIGURE 43.3 Outline of the motivation and expectation dual process theories. The motivation theory suggests that outcome of a response can feedback and strengthen the stimulus–response association. The expectation theory suggests that the cue stimulates an expectancy of the outcome, which then triggers a response (stimulus–outcome–response). The outcome therefore feedbacks on to this association and can affect the nature of responses made in future to the cue.

the perceived craving. However, as discussed above, clear relationships between physiological cue reactivity, craving, and substance intake have not been supported by the literature.

Some cognitive-behavioral theories argue that cues can trigger craving by highlighting the positive effects of the substance and, if powerful enough, this craving will translate into substance use. Outcome expectancies concerning the positive and negative reinforcing effects of substances are related to greater substance administration, more positive cue rating, and responding to cues with greater craving in dependent and non-dependent populations. An additional element to several cognitive theories is abstinence self-efficacy, which is the extent to which a person believes themselves capable of maintaining abstinence. Addicts with low abstinence self-efficacy are more likely to report higher levels of craving in the presence of cues. It is possible that the association between low abstinence self-efficacy and cue-induced craving reflects an impaired level of cognitive control, such that cues are able to have a greater effect on substance-related thoughts and behavior. Although this possibility needs further study, it is possible that low abstinence self-efficacy and cue reactivity may interact and promote relapse.

During the last two decades cognitive theories have become more complex. The "dual affect" theory argued that substance urges represent either positive affect, associated with appetitive motivational systems, or negative affect, related to withdrawal systems, and that these two frameworks of cognitive urges were mutually inhibitory. The dual affect theory proposed that substance administration, availability, and cues could activate a positive appetitive state and result in excessive and compulsive substance intake and polysubstance use. In addition, withdrawal, withdrawal-related cues, and aversive cues and states (e.g. stress) could trigger a "negative affect urge" framework and drive substance use. These urge frameworks were thought to be incorporated into larger propositional networks that contained information on salient cues and responses to these cues. The theory argued that as the conditions of the eliciting stimuli better matched the prototype, the stronger the network activation. In addition, as activation of some elements of the network occurs, the activation threshold for other propositional elements would be decreased. This suggestion can be related to cross-substance cue reactivity, for example, if an individual usually drinks, smokes, or takes cocaine while in a positive affective state, coming into contact with positively reinforcing alcohol cues will increase the likelihood of smoking and cocaine behaviors as well as drinking. There are a number of problems with the original dual affect theory. Evidence does not support mutually inhibitory affective systems, for instance, individuals who report positive reinforcing substance-related expectancies also tend to report high levels of negative reinforcing expectancies. In addition, increasing urge does not consistently increase measures of cue reactivity, and this lack of association is found both when measuring relationships within a substance class (e.g. urges for heroin may not increase heroin cue reactivity) and across substance classes (e.g. urges for alcohol do not always increase cigarette cue reactivity).

A prominent cognitive theory of addiction, the cognitive urge and automaticity model, proposes that, over time, behaviors associated with substance use become automatic (see Fig. 43.4). According to this theory, substance-related behaviors are stored in memory as "automatized action schemata" and these action plans contain information on behavioral sequences/procedures (e.g. how to open a bottle and then pour a glass

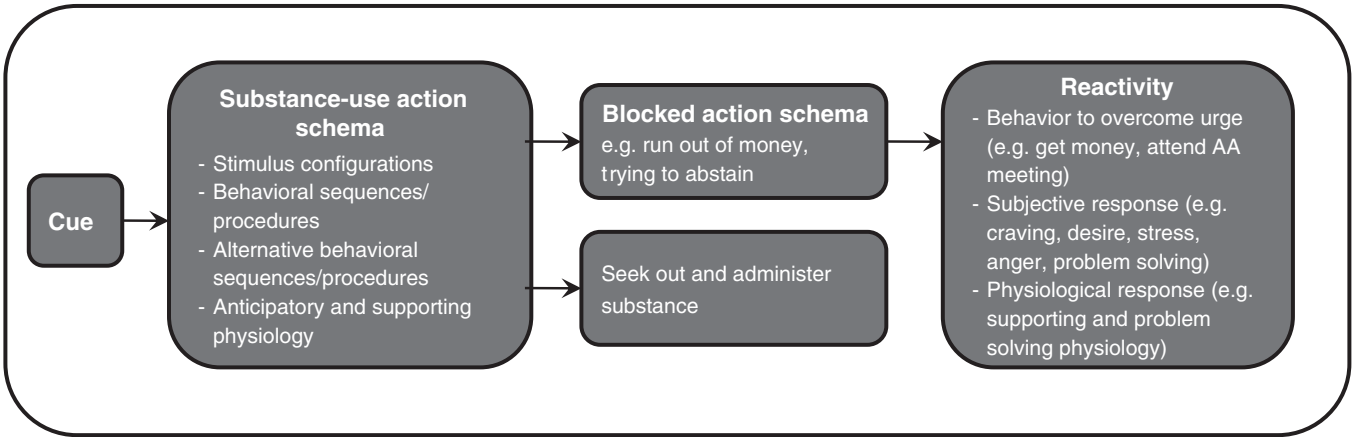

FIGURE 43.4 Cues can elicit automatic action schema which trigger substance-seeking and administration behaviors quickly and effortlessly. If these actions are blocked, effortful processes are activated to deal with this impediment and the individual may experience craving.

of wine, or find a vein before injecting heroin) and cues (e.g. a local pub, a state of stress, pharmacological effects of substance ingestion) which could trigger automatized behaviors (e.g. substance administration). In addition, the action plans incorporate physiological responses that support the behavior, and alternative behavioral sequences which could be triggered to ensure the behavioral goal is achieved even in the presence of obstacles (e.g. if a lighter fails to work, use matches). Repetition results in behavior becoming automatic, this is to say effortless, fast, and impervious to introspection. At a neuronal level, pathways are strengthened and activation thresholds decrease so that corresponding behaviors can be triggered easily and can occur quickly. Key to this model is that an urge reflects a nonautomatic process and only occurs if automatic substance-related behaviors are interrupted for some reason (e.g. no money, trying to abstain). These nonautomatic processes are the trigger for substance urges rather than the cue itself. This theory may be better able to account for studies which show that cue exposure fails to elicit reactivity as assessed by traditional measures (e.g. self-report, physiological reactions, behavior), although studies addressing this assumption are scarce. This cognitive theory is entirely consistent with other addiction models that emphasise habit-like processes, in the sense that cue-elicited effects are theorised to be relatively autonomous of the current motivational state of the individual.

BIASES IN AUTOMATIC PROCESSING OF SUBSTANCE CUES

The impetus for this work has come from theoretical models that emphasise the importance of automatic cognitive processes as an essential mediating step that can account for the effects of substance-related cues on craving and substance-related behavior. It has been argued that substance users find it difficult to ignore substance-related cues in their environment, which exacerbates subjective craving in response to those cues, and this in turn leads to substance-seeking behavior. Additionally, attentional bias for substance cues may occur as a consequence of a dysfunctional, dopamine mediated incentive learning process, which causes substance-related cues to grab the attention and elicit automatic approach responses, ultimately resulting in increased craving and substance-seeking behavior.

Attentional bias refers to the observation that substance-related cues can "grab" or "hold" the selective attention of substance users. Studies using the addiction Stroop task have demonstrated that users of alcohol, tobacco, cannabis, cocaine, and heroin are slow to name the color in which substance-related words are presented and this impairment increases across levels of substance usage. This suggests that substance abusers find it difficult to disregard task-irrelevant alcohol-related cues, which leads to an impairment in the primary task (color naming). Other studies have used the visual dot probe task, often combined with eye movement monitoring, which provides more direct measures of visuo-spatial attention. Results obtained from this task demonstrate that substance abusers (including heavy drinkers, heroin users, and tobacco smokers) are faster to respond to probes that appear in the location of substance-related pictures compared to probes that appear in the location of control pictures. These populations also maintain their gaze for longer on substance-related pictures, which suggests that substance abusers bias their spatial attention toward the location of the substance cues. However, some nicotine research has found attentional bias, as measured by the visual dot probe task, to be greater in lighter, compared with heavier, smokers. It is possible that this reflects a shift from goal-directed to more habit-like behavior, indicating that attentional bias plays a less important role in heavier substance use.

More sophisticated measures of biases in selective attention have emerged in recent years, such as the P300 component of event-related brain potentials, and these have also been applied to demonstrate attentional biases in addiction. Although the P300 is often found to be blunted in response to general stimuli in substance-dependent populations, P300 amplitude has found to be greater in reaction to substance-specific cues. In addition, P300 amplitude has been found to positively correlate with self-reported substance craving and, therefore, may demonstrate the motivational significance of substance cues.

Another cognitive process which may be important in the development of substance use disorders is "appraisal," that is, how a person appraises the importance of interoceptive or exteroceptive cues in relation to current behavior and goals. Some cognitive models suggest that as addiction progresses, appraisal biases develop which result in information being processed in accord with an individual's goals (e.g. substance taking). Appraisal is likely to be affected by attentional biases and "interpretative biases," whereby ambiguous situations or states (e.g. physiological arousal) will be interpreted within a substance-relevant context. Research shows that ambiguous stimuli are more likely to be interpreted as alcohol-related in those who drink more and score higher on measures of alcohol use disorders. Some cognitive models presume that it is the attention to, and the appraisal and interpretation of the cue that is crucial in cue reactivity, rather than the cue itself. This proposal may explain why some research fails to

find congruent relationships between traditional measures of cue reactivity and craving. For example, if cognitive processes are focused on the exteroceptive cue but not on the internal autonomic state, then physiological measures of reactivity will be minimal and not relate to self-reported craving. Individual differences may exist concerning what type of cue effect (e.g. behavior, affective, physiological) is focused on and so, if this is accepted, cue reactivity may actually be diverse across individuals and levels of substance use disorder. More research is needed to investigate these possibilities, however, it does highlight a theoretical shift from physiological and subjective responses to substance-related cues (as reviewed in the previous sections), to subtle biases in the cognitive processing of those cues.

At present, there is no evidence to suggest that attentional biases operate below the threshold of conscious awareness, although results obtained using the alcohol Stroop task suggest that distraction that is created by alcohol-related cues occurs automatically, and is difficult to control or impede. However, it is interesting to note that in visual dot probe task studies, heavy drinkers tend to show attentional biases for alcohol stimuli only when they are presented for relatively long exposure durations (500 ms or more) but not when they are presented briefly (e.g. 200 ms). As such, attentional bias among heavy drinkers who are not seeking treatment may primarily reflect a bias in the maintenance of attention, or delayed disengagement of attention from alcohol-related cues. By contrast, in alcohol-dependent inpatients (compared to nonalcoholic controls), attentional biases are seen for briefly-presented (50 ms) alcohol-related stimuli, and the magnitude of this effect is related to the severity of alcohol dependence. Also, among alcohol-dependent inpatients, if the stimuli are presented for long periods of time, attentional avoidance of those stimuli is seen. The approach-avoidance pattern of attentional bias that is observed among treatment-seeking alcoholics may reflect motivational conflict or ambivalence: the initial orienting may reflect sensitization of the incentive value of alcohol, whereas the subsequent avoidance may occur because alcohol-related cues are aversive when presented in a treatment context. Overall, the relationship between craving and attentional bias tends to be quite weak, however, research suggests that the association between subjective craving and the latter component of attentional bias (delayed disengagement of attention) is stronger than the relationship with the earlier component (rapid initial orienting). Given this, the approach-avoidance pattern of attentional bias among patients in treatment may actually reflect the aversive properties of alcohol cues in the treatment context (leading to rapid initial orienting toward alcohol cues) coupled with diminished subjective craving (leading to a diminution or even reversal of the bias to maintain attention on alcohol-related cues).

Substance-related cues also elicit automatic approach tendencies in substance abusers. For example, in the stimulus–response compatibility task, participants are required to rapidly categorise substance-related and neutral pictures by moving a manikin either toward or away from the pictures as quickly as possible. In one block of the task, participants are required to make the manikin approach substance-related pictures and avoid neutral pictures; in a different block of the task, these instructions are reversed. Substance abusers (but not control participants) are faster when required to approach, rather than avoid substance-related pictures, and this has been demonstrated in heavy drinkers, tobacco smokers, and cannabis users. The mechanisms that underlie these effects are presently a matter of debate: substance-related cues may trigger an automatic approach response as would be predicted by the cognitive urge and automaticity model discussed earlier, which results in participants being faster when required to respond to those cues by performing a (motivationally compatible) approach response rather than an (motivationally incompatible) avoidance response. An alternative explanation is that these results reflect strengthened underlying associations between the concepts of "substance" and "approach" in substance abusers, therefore one might not expect substance-related cues to elicit an automatic approach tendency unless the substance-relatedness of those cues was explicitly encoded. Nonetheless, experimental manipulation of automatic response tendencies elicited by alcohol-related cues can have a causal influence on drinking behavior in the laboratory, which suggests that these automatic approach responses may have a causal effect on substance-seeking behavior.

The research on cognitive biases in addiction has helped demonstrate the complexities of cue reactivity and highlight how biases may change across contexts (e.g. in treatment and nontreatment environments) and, therefore, how cue reactivity may also differ. Factors which impact on how cue reactivity is translated into behavior need to be identified by future experimental research and applied to clinical populations and treatment interventions.

NEUROBIOLOGY OF CUE REACTIVITY

Recently, functional neuroimaging studies have revealed the neural substrates of cue reactivity and associated cognitive biases. These studies have identified a number of brain areas which are involved in cue reactivity, including the mesolimbic dopaminergic pathways (reward, motivation) as well as the amygdala (memory),

anterior cingulate cortex (attention), dorsolateral prefrontal cortex (inhibitory control), orbitofrontal cortex (reward, motivation, decision making), hippocampus (memory), and thalamus (memory and attention).

Meta-analysis shows that there is considerable overlap in the neural substrates for cue reactivity to the most studied substances (i.e. nicotine-, alcohol- and cocaine-related cue reactivity). Cue reactivity activates the ventral striatum, anterior cingulate cortex, and the left pallidum. Importantly, these are also the areas that seem to be involved in self-reported craving. Although the search for the neural substrates of the cognitive bias associated with cue reactivity – using Stroop-related tasks – has just begun, it seems that the dorsal anterior cingulate cortex, the superior parietal gyrus, and the superior temporal gyrus play a role. These are brain regions associated with top–down processing, suggesting that substance-dependent individuals have to employ more attentional resources to focus on alternative tasks when substance cues are present.

Functional magnetic resonance imaging research shows that non-dependent student populations, with some evidence of substance problems, respond to substance cues differently to neutral cues. The similarities between these findings with those from dependent populations suggest that neural-based cue reactivity may develop very quickly as hazardous substance use progresses, or that such reactivity may reflect a pre-existing risk for substance problems. In addition, some research has found associations between cue-induced brain activation and craving only in moderate, not severely, dependent populations. This may indicate a shift from goal-directed substance behavior to habit-like behavior, the latter perhaps being more likely to occur with or without cues.

Although the majority of research suggests a complex system of neural activity in response to cues, which integrates areas involved in incentive salience, attention, memory, information processing, decision-making, and goal-directed behavior, there remain discrepancies within the literature. One issue is that the perceived availability of a substance differs across cue reactivity studies, and this may be one determinant of inconsistent results. For instance, if the participant expects to smoke after completing a nicotine cue reactivity task, this will likely affect processes of expectancy and preparedness which will be apparent in neural activity. Treatment-seeking dependent populations are trying to resist substance use, and are using their cognitive resources to resist relapse, so results must be interpreted in light of the current goals of the participant (e.g. treatment-seeking, not treatment-seeking). Another issue is the specific substance under study. Although there are many common neural substrates involved in cue reactivity across substances, there are also some substance-specific differences. All these factors will impact on the nature of the cue reactivity observed and needs to be taken into account when identifying the clinical application of such research.

CLINICAL APPLICATIONS

Perhaps the most researched cognitive and behavioral treatment to have emerged from the cue reactivity literature is cue exposure during extinction; by removing the reward associated with a conditioned stimulus or an operant response, an organism eventually stops expecting, or responding for, the reward. The effect of extinction has been found to reduce reactivity to a wide range of substance cues, however, rather than the original association being unlearned, a number of observed phenomena suggest that the original learning persists but that new learning also takes place. Firstly, the conditioned response can be "reinstated" if the unconditioned stimulus is encountered following extinction. "Renewal" of the conditioned response can occur when the context differs from that of the extinction environment. For example, if acquisition (e.g. context A) and extinction (e.g. context B) of an association occur in different environments, then renewal may be observed if the organism re-enters context A (ABA renewal effect). In fact, renewal of the conditioned response may be seen in any environment that differs from the extinction context (ABC renewal effect). The conditioned response can also show "spontaneous recovery" when the organism comes into contact with a cue after a prolonged period of time. Finally, organisms will learn extinguished associations more quickly than new associations, indicating that the original association is still intact (i.e. "rapid reacquisition"). In its current form, cue exposure treatment does not seem to have a significantly beneficial effect on relapse rates. Taken together, these findings suggest that to increase the efficacy of cue exposure treatment, exposure sessions would need to be conducted across a wide range of different environments and for a prolonged period of time, to help ensure the new learning can be generalised and strong enough to compete with the original cue–substance associations.

Currently, "talking therapies" are the standard psychosocial treatment for addiction, and these include cognitive behavioral therapy, motivational interviewing, and group therapy. When comparing standard treatment with standard plus cue exposure treatment, research tends to find that the inclusion of cue exposure increases the patient's self-efficacy regarding their ability to resist substances in high-risk contexts. However, even when a decrease is observed in cue

reactivity following exposure treatment, there is not always a decrease in craving or relapse and some research finds higher relapse rates following cue exposure treatment. In addition, a reduction in cue reactivity has been observed irrespective of treatment type, therefore, reduced cue reactivity may be a general effect of treatment procedures.

Given the behavioral methods needed to increase the generalisation and strength of new associations developed during treatment, the cost-effectiveness of successful cue exposure treatment is questionable. This has resulted in research aimed at identifying pharmacological agents which may enhance cue exposure treatment. D-cycloserine (d-4-amino-3-isoxazolidinone) is a glycine partial agonist which activates the N-methyl D-aspartate (NMDA) receptor complex, a type of ionotropic glutamate receptor. The NMDA-glutamate synapses are crucial in learning and memory, and NMDA antagonists can block learning, therefore, exciting these connections during learning may strengthen new associations. The effects of D-cycloserine on learning diminish as the time between extinction procedures and D-cycloserine administration increases, suggesting that D-cycloserine is facilitating acquisition and/or consolidation of the new association. In addition, animal models have shown some generalisability of effects. If animals learn two conditioned associations and complete extinction trials to just one of these, administration of D-cycloserine can also reduce responding to the nonextinguished conditioned stimulus. This finding indicates that extinction-based addiction treatments used in conjunction with D-cycloserine may result in more general extinction effects which may, in turn, reduce the types of environment in which cues can precipitate substance use. However, other work has found the effects of D-cycloserine to be context-specific and more recent cue reactivity studies in humans have failed to find a beneficial effect of D-cycloserine. Although it is unclear whether treatments which focus on the learned associations in addiction are likely to result in significant decreases in intake levels and relapse, it is apparent that the key to making such treatments efficacious is to make their effects generalise to multiple contexts.

Other pharmacological agents which may offer therapeutic benefit via effects on cue reactivity processes include naltrexone, a μ-opioid receptor antagonist. Treatment with naltrexone, compared with placebo, can reduce self-reported urge following substance cue exposure. Other main pharmacotherapies for alcoholism include acamprosate (which has some of its effects on the gamma-aminobutyric acid system) and disulfiram (inhibits alcohol metabolism), however, findings are equivocal in terms of the impact these drugs have on cue reactivity. Recently, the efficacy of drug treatments has been linked, at least partly, to the genetic profile of the individual. This research is in its infancy and it remains to be determined which functional genetic variants are associated with different pathways into substance problems (e.g. via cue reactivity, impaired inhibitory control). However, some research has indicated that an amino acid substitution (Asn40 to Asp40), caused by the rs1799971 polymorphism on exon 1 of the OPRM1 gene, is associated with cue reactivity. The Asp40 variant leads to a μ-receptor subtype with up to three times greater binding of β-endorphin than the more common Asn40 variant, and craving in response to alcohol cue exposure is more pronounced in carriers of the Asp40 variant. In addition, evidence suggests that naltrexone may have more efficacious general treatment effects in carriers of the Asp40 variant. Although an association between the Asp40 variant and cue reactivity has yet to be fully established, the research illustrates, in principle, that genotype might modulate cue reactivity and thereby treatment response.

Models which see cue reactivity as a more unique response pattern, difference across individuals, suggest that the cognitive mechanisms (e.g. appraisal, beliefs, expectancies, biases) held by the individual need to be mapped so that interventions can be more targeted. Although in general, reducing attentional and approach biases to substance cues may provide some therapeutic benefit, understanding the individual differences which affect the development and nature of such biases should improve the efficacy of any bias-based treatments. Some studies suggest that attentional bias has a causal role in alcohol drinking, and some positive treatment results have been found, suggesting attentional bias retraining may be a suitable target for treatment development. However, other work has failed to replicate early successes and has called into question the causal role of biases in substance use.

SUMMARY

Cue reactivity covers a wide range of subjective, physiological, and neurochemical responses, and can be observed in social, hazardous, and dependent substance populations. The state changes that occur during cue exposure are likely to contribute to initiation and maintenance of substance use in a significant number of people, however, cue reactivity is neither necessary nor sufficient to account for the chronic relapsing nature of addiction. Perhaps one important finding is that cues appear to have an effect on behavior which is relatively autonomous from the actual incentive value of the substance. Such findings should inform treatments aimed at educating people about the dangers and negative consequences of substance use.

Although the early conditioning and learning research within this area has been invaluable, it is clear that cue reactivity is complex and highly individual, involving both substance-like and substance-opposite effects. More recent research highlights the potentially important role that cognitive biases may play in cue reactivity, and identifying how and why these development offers a promising area for future research which may help better predict cue reactivity across different populations and environments.

Given the potential importance of cue reactivity, treatments based on cue exposure have delivered disappointing results. Future work may benefit from developing exposure treatments which also include cognitive bias retraining, ensuring that the various processes involved in reactivity are recognised. The possibility that pharmacological and cue exposure treatments may work synergistically is important. However, the growing awareness of how individual factors (e.g. genetics) affect treatment response indicates that some kind of screening process is required. Screening treatment-seeking individuals should help target treatments and increase their cost-effectiveness, whether these are treatments based upon the evidence from cue reactivity research or not.

Glossary

Approach bias an automatic tendency to approach substance-related stimuli.

Attentional bias an automatic tendency to direct attention toward substance-related stimuli.

Automaticity the process by which behavior is elicited in the absence of intention to perform the behavior. Automatized behavior tends to be stimulus bound and difficult to inhibit.

Classical/pavlovian conditioning a learning process in which a previously neutral stimulus (conditioned stimulus) becomes associated with a biologically significant stimulus (unconditioned stimulus) which naturally elicits a response (unconditioned response). As a result, the conditioned stimulus comes to produce a response (conditioned response) by itself.

Cue exposure treatment a treatment approach in which patients are exposed to cues associated with their addiction (e.g. a glass of wine, a wrap of cocaine) in the absence of substance administration. The aim of cue exposure treatment is to extinguish associations between the cues and substance effects.

Cue reactivity a phenomenon in which exposure to substance cues produces a range of physiological (e.g. alterations in heart rate, respiration, and temperature) and psychological (e.g. substance-related expectations and substance-relevant cognitive biases) responses, which motivates the individual to seek out and administer substances. Cue reactivity is believed to play a role in initiating and maintaining substance use and may be an antecedent for relapse.

Negative reinforcement the process in which a behavior is more likely to be repeated if that behavior leads to reduction or removal of a negative affective state.

Operant/Instrumental conditioning a learning process in which an association is learned between a response and an outcome. Cues can act as a discriminative stimulus and trigger the response, either through direct stimulus–response or stimulus–outcome(expectancy)–response associations.

Pavlovian-to-instrumental transfer (PIT) a learning process involving two phases: a classical/pavlovian conditioning stage, in which a conditioned stimulus (e.g. a cue) is associated with an unconditioned stimulus, and an instrumental conditioning stage where an association is made between a response and an outcome which matches the unconditioned stimulus. Following these two stages, the conditioned stimulus (cue) can elicit the response for the outcome (unconditioned stimulus).

Positive reinforcement the process in which a behavior is more likely to be repeated if that behavior leads to an increase in positive effect.

Craving and Expectancies

Ross McD. Young

Institute of Health and Biomedical Innovation, Queensland University of Technology, QLD, Australia

Many will try a range of substances in adolescence or early adulthood, but only a small proportion will go on to develop problematic use. As such, the experience of a substance misuse problem is not something that most individuals can identify with personally. However, the experience of craving an object or activity and the importance of making predictions about the expected consequences of our future behavior are concepts that have universal significance. While we accept the use of the term craving in everyday conversation, there has been a considerable scientific debate about the semantics of craving. Regarding addictive behavior, there is a general agreement that craving reflects a desire or urge to consume a substance – to either experience pleasure or provide relief from discomfort. This aligns with clinical experience, where those with drug dependence commonly report a sensation they call craving that parallels this definition. On this basis alone, craving is worthy of consideration in models of addiction.

The wish or urge to consume a substance that we refer to as craving is a broad cognitive-emotional construct. Craving is acknowledged in many models of alcohol and other drug use as contributing to the development and maintenance of drug-related problems. As such it features in some definitions of dependence, including that of the International Classification of Diseases, ICD-10. However, craving is not experienced by all drug users, and even those with severe dependence can report an absence of craving. Disentangling individual differences that may contribute to craving is therefore important. Craving is shaped via learning processes, but there are also important neurobiological factors that have a primary influence on craving state.

Craving is acquired via direct experience with a drug as a consequence of prior consumption. The stronger intensity of craving experienced for some drugs may also be a feature of their use and be instrumental in maintaining addiction to the drug, for example in the case of heroin or nicotine dependence, where craving and associated physical symptoms may be marked. In contrast, physical symptoms are not as prominent in stimulant withdrawal. It can be difficult to differentiate intense craving from the emergence of the withdrawal state, and while both may be related, the withdrawal state typically has a predictable time course and emergence of a complex array of symptoms. Craving may be one of these. The withdrawal syndrome, or elements of withdrawal, is not simply a consequence of declining drug concentrations, excessive CNS receptor stimulation, and tolerance, but is also related to conditioning mechanisms that pair environmental cues with drug administration. Thus, craving can be viewed as a phenomenon that while independent of withdrawal, is a component of the subjective experience of withdrawal related to drug deprivation for many drug users.

The desire for a drug does not exist in the absence of consideration of the perceived consequences of drug ingestion. These drug outcomes are more complex than simply the relief of withdrawal or a general sense of drug reward. Indeed, both desire to use and anticipation of reinforcing outcomes related to use could be present in individuals where no withdrawal symptoms are experienced. Consideration of these subjective drug outcomes has included exploration of motives, attitudes, intentions, and expectancies. Outcome expectancies (or expectations) reported by drug users are acquired as a result of both indirect and direct experiences of drug use. Unlike craving, drug expectancies can be present before the first use of a substance. These expectancies represent a more finely grained cognitive construct than the cognitive–affective construct of craving, as they relate to an array of specific outcomes and consequences that may occur once a drug has been taken. Drug expectancies are typically described as substance-specific, for example as alcohol

http://dx.doi.org/10.1016/B978-0-12-398336-7.00044-9

expectancies or cannabis expectancies, as various drugs have different outcomes due to their pharmacological properties, typical modes of use and environments of administration. Given that these expectancies link anticipated ingestion of a drug with a subsequent outcome, they are viewed as learned *if–then* contingencies. For example, *if* I were to drink now, *then* I would feel sadness (a negative expectancy); or *if* I were to smoke a cigarette now, *then* I would feel more relaxed (a positive expectancy). Expectancies have relevance in the spectrum of use from prior to first consumption to dependence. Prior to first use expectancies are acquired via observation, modeling, and vicarious reinforcement. In dependent use, they are potentially based on decades of direct experience with a substance. For example, expectancies of alcohol as a social lubricant or reliever of stress have been identified in children as young as 5 years of age, and coalesce with actual drinking experience in adolescence. The nature of the drug expectancies an individual holds is predictive of subsequent drinking behavior patterns. Tension reduction expectancies are markers of risky consumption of several drugs including alcohol, cannabis, and heroin. Once acquired via direct experience with the drug, this memory network of positive expectancies can be primed by internal or external drug-associated cues. Primed expectancies are thought to guide subsequent drug use.

Drug expectancies are not the only cognitions that are likely to shape use, or be relevant in a consideration of craving. Efficacy expectations that relate to the expected confidence with which a substance might be refused in some future circumstance are also important. In a similar way to drug outcome expectancies, there are several domains of drug refusal self-efficacy, and they have also been identified in adolescents with minimal experience with alcohol. Drug refusal self-efficacy expectancies can impact consumption decisions, future use, and the nature of problems associated with consumption. There is a good evidence that drug expectancies and refusal self-efficacy operate in concert, and that both an individual's drug expectancies and confidence in refusal are probable casual factors in drug consumption. Most of the data regarding drug expectancies are from studies of alcohol expectancies: there is a stronger body of work across several drug classes supporting the importance of self-efficacy beliefs.

Triggers of craving include expectancy, with some models viewing this memory of the rewarding effects of use combining with an underlying negative affective state to generate drug urge. Urges are likely to ulitize attentional capacity, making expectancies and other associated cognitive outputs such as images more difficult to shift from working memory. These cues can be internally generated via expectancy once established and can create a powerful motivational state to use.

Craving, once considered an epiphenomenon, is now along with drug expectancy seen as an important aspect of drug motivation. Despite craving being commonly reported by those with drug dependence as a core feature of their experience, the emphasis on craving in models of addiction has been in and out of fashion over the last 60 years. A key debate has been around whether craving represents a meaningful causal factor in the development of addiction. The challenges of measurement have also been a key impediment to progress. The disease model of the 1950s and 1960s emphasized craving as a physical manifestation of the disease of addiction. Behavioral models, which emerged in the 1970s, saw a reconceptualization of craving, but there was still considerable disagreement regarding issues of definition and the threshold when desire for a substance was strong enough to be considered a craving state. There was little consensus as to whether or not the concept was of value. However, a commonly held definition of craving relating to the "subjective desire for the effects of a drug" views it as a potential summary index of potential reinforcement.

The renaissance of craving as a construct has spawned several theories since the 1980s. Some have posited craving as a consequence of unconscious cognitive processes, which only come into awareness when the automatic process of drug intake in those with established dependence is disrupted. This emphasizes cognitive processes where introspection is limited, or not possible at all. Others, based on classical conditioning processes, view craving as a consequence of seeking to alleviate drug withdrawal and clearly consider that self-reports of craving are reliable given that the drug is negatively reinforcing. In many ways these are a psychological extension of the earlier medical model, where aversive consequences were emphasized, but in addition they examine the contribution of learning to withdrawal-related craving. These models, unlike those of earlier medical models, do not view craving as "physiologically inevitable." Environmental cues associated with drug use can, through conditioned association, elicit a significant withdrawal response. For example, a heroin user can, by being simply present in an environment such as a "shooting gallery" where they typically inject, experience situational withdrawal discomfort including physical symptoms and a longing for the drug.

Subsets of conditioning-based models of craving describe homeostatic processes that exert their effect over time as tolerance to the appetitive effects of the drug. These effects occur along with the emergence of compensatory responses. The compensatory responses are opposite to the effects of the drug (e.g. if the drug is anxiolytic, or anxiety relieving, then the compensatory response would be anxiogenic, or anxiety inducing).

These compensatory responses are hypothesized to be the basis of withdrawal and contribute to craving for withdrawal relief. The relative balance of positive and negative expectancy would be a likely reflection of these dynamic changes over time, particularly for such striking subjective effects as a shift from anxiolytic to anxiogenic outcomes. If models emphasizing these opponent processes were ubiquitous, it would be unlikely that positive expectancies would remain in those with significant dependence, as the compensatory responses would have predominated over the appetitive effects and the experience of use would become aversive. Severely dependent users typically still report positive expectations of use, although this is in the face of increasingly strong negative expectancies.

A contrary view to models based on withdrawal relief is that environmental cues are associated with drug administration as signals of reward. This has led to two sets of models regarding craving, which emphasize conditioned cues as either signals of anticipated positive reinforcement (also called craving type-1) or signals of withdrawal (also called craving type-2). There is evidence to support both types of model: both types of craving coexist and may vary between drugs and level of dependence.

The theories that underpin craving clearly influence, and are influenced by, the measurement of the phenomenon of craving itself. Given the approaches previously mentioned, which are predicated on withdrawal relief or reward, there are measures that conform to each of these two types of craving, but most measure both. Simple single item measures and multifactorial scales exist, and the more sophisticated measures based on withdrawal and reward models do not necessarily have better utility in predicting dependence or relapse. Most of the available drug-specific measures are of alcohol craving. Scale content may include obsessive and intrusive thoughts about alcohol, the intensity of the compulsive urge to drink and sensory aspects of craving. Typically these measures are summarized by two to four factors, but replication of underlying factor structures has been a challenge, limiting the selection of a preferred definition or measure. Despite these measurement challenges, across the body of measures in use, craving is consistently associated with dependence severity and poorer prognosis. Craving exists in nondependent drinkers, and while multifactorial scale structures have been replicated in those with less developed or absent problems, the predictive utility of craving measures under these circumstances is restricted. Whether this is due to scales being less sensitive to craving of lower intensity or whether there are qualitative differences in craving in those who are not drug dependent compared to those with dependence, is unclear. Additional challenges are evident in tapping the more subtle manifestations of emergent craving, as measured by self-report questionnaires in those without established dependence. These measures have stronger validity in those with drug dependence. In dependent users, imagery may be a particularly important component of craving, with stronger craving being associated with more intense sensory imagery, for example of the sight, taste, or smell of alcohol.

Given the role of positive and negative expectancies as reflections of the motivation to use drugs, it is likely that both reward and relief craving are present at different stages of the evolution of dependence to a varying degree, with relief predominating in cases of more severe dependence. Cognitive models of craving have emphasized higher order learning that is both potentially positively and negatively reinforcing and are thus of direct relevance to a consideration of drug expectancies. Indirect evidence exists to support the role of changes in cognitive processing in a craving state which may prime expectancies. For example, smokers in withdrawal focus more on smoking-related stimuli and on the positive consequences of use in their nicotine-deprived state, indicating that both craving and expectancy are linked.

The potential to integrate our understanding of craving and expectancy has been advanced by better knowledge of the brain processes that underlie addiction. Psychobiological addiction research has expanded our notions of learning related to drug use by explicating the underlying physiological mechanisms of reward. Contemporary advances in molecular biology and neuroimaging have driven this. This emergent understanding forms a sound basis to examine potential links between craving and expectancy learning.

There is strong evidence that craving is influenced by several neurotransmitters including dopamine, gamma-aminobutyric acid (GABA, the primary inhibitory neurotransmitter), endogenous opioids, glutamate, and serotonin. All drugs of abuse, except the benzodiazepines, impair dopamine reuptake, enhance dopamine release, or reduce dopamine breakdown. For example, cocaine blocks the active reuptake of dopamine via the dopamine transporter in the shell of the nucleus accumbens (NAcc), a structure in the ventral striatum implicated in reward prediction and adaptive behavior expression. This impaired reuptake increases dopamine availability in the synaptic cleft resulting in stronger signals of reward. Brainstem neurons rich in dopamine D2 receptors (DRD2), particularly in the ventral tegmental area (VTA), have a strong role in approach and avoidance learning and the mediation of reward. These receptors are stimulated by drug ingestion via enhanced dopamine release. This dopamine system has been extensively investigated in the development

of addictive behavior. Projections extend from the VTA to the NAcc and orbitofrontal cortex (OFC), and collectively this is often referred to as the dopamine "reward pathway." GABAergic interneurons (which are stimulated by benzodiazepines and thus indirectly influence dopamine release in the VTA) are embedded within midbrain dopamine neurons and this region also contains localized glutamatergic neurocircuitry. Collectively this reward pathway integrates inputs from several key structures involved in sensory processing, memory, motivation, and planning (e.g. from the amygdala, which responds to the intensity of cues related to reward or punishment) and it projects to higher order cognitive centers (e.g. OFC) to promote associative learning. This reward pathway and the neurotransmitters that influence it provide a plausible link between the affective component of craving and the conscious cognitions of expectancy, given the signals of incentive salience generated.

Animal studies have confirmed the importance of the neurotrophin, the brain-derived neurotrophic factor, and the secreted protein glial cell-line derived neurotrophic factor, in the synaptic and structural plasticity of mesolimbic dopamine neurons. This operates via the production of drug-related experience-dependent dendritic spine proliferation. The richness of these connections is in essence a marker of previous drug-related learning built via operant conditioning and represents learned associations. The enriched connective network of the mesocorticolimbic dopamine system and its effect on the reward pathway enhances the "natural" function of this system of performance monitoring based on external feedback. Importantly, dopamine is released to the drug-associated cue rather than the reward itself.

Conditioned place preference studies provide a useful experimental paradigm to examine operant learning. They measure the relative probability that animals that have been administered drugs via operant conditioning paradigms return to environments where the drug was administered, as opposed to an alternative environment where drugs have not been administered, when they are given a choice. This place preference has been examined using dopamine agonist drugs administered during operant trials (where learning is enhanced) and dopamine antagonist drugs (where learning is impaired). Other studies have used rodents that have been specifically genetically bred with an absence of DRD2 (D2 knockouts) and this drug experience dependent learning is completely absent. These studies support the mediation of crucial learning processes related to possible if–then contingencies and desire via dopamine release. The potential for drugs of abuse to stimulate brain pathways that have evolved to facilitate approach and avoidance reward learning to enhance survival, as well as to create dynamic changes in synaptic connectivity based on drug use, is a core component in the development of addiction. For example, stronger amphetamine-induced dopamine release in midbrain structures in humans has been examined via neuroimaging and is associated with increased drug-related "wanting" and novelty seeking. Importantly, this increased dopamine release is correlated with more positive subjective ratings of the effects of amphetamine. Neuroendocrine human and animal studies indicate the complexity of these processes extend beyond the neurotransmitters noted and involve endocrine effects where leptin, ghrelin, and thyroid stimulating hormone (peptides and hormones involved in food seeking) are also associated with drug seeking or acute craving. This observation occurs particularly in human studies examining those with an early onset of dependence. Collectively, these results further support the notion that processes that subsume learning about natural reinforcers related to improved survival via effective reward learning are the underlying key elements of drug reinforcement.

Examining these processes in more detail has commonly involved the manipulation of brain reward systems pharmacologically, and examining individual differences in response. Bromocriptine, a specific DRD2 agonist used in the treatment of Parkinson's Disease, a disorder on diminished dopamine function, boosts reward learning and related responses in the striatum of those with the A1+ allelic version (Taq 1A) of the DRD2 gene (also called the Ankyrin repeat and kinase containing 1 or ANKK1 gene). No similar enhancement occurs in A1− individuals who do not possess this allele. The DRD2 agonist drug cabergoline has produced similar striatal responses. A1+ carriers also have a significantly lower concentration of DRD2 in several midbrain structures including the NAcc and striatum. They also have fewer postsynaptic D2 autoreceptors in the striatum. These autoreceptors act to dampen dopamine release, so when they have diminished function related to this genetic marker, the likely result is a greater tonic release of dopamine from dopamine agonist drugs of abuse. A1+ allelic status is probably a broadly based risk factor, rather than specific for any drug or class of drugs, as individuals with this allele are more impulsive and show more drug-related physical and psychological comorbidity due to their impulsivity. For example, A1+ individuals who abuse heroin and are intravenous drug users are more likely to be infected with Hepatitis C, presumably due to a lessened delay of gratification despite sterile injecting equipment being unavailable.

Psychobiological models also illuminate the affective element of craving. Disruptions in midbrain neurotransmitter systems related to chronic drug use, particularly

alterations in NAcc dopamine and serotonin activity, and increased corticotropin releasing factor in the central nucleus of the amygdala, contribute to a negative affective response. This is a key component of craving and it may also influence expectancy development. There is an increased firing of subgroups of dopamine neurons in the VTA in response to stress, which may constitute a stimulus for further drug seeking. Indeed, the importance of dopamine in craving and reducing negative effect has been confirmed via placebo-controlled study using bromocriptine. Craving for alcohol was reduced in those receiving the active drug, but only if they were A1+ in terms of DRD2 gene status. A similar effect was evident for anxiety reduction, but over a different time course, indicating that craving (as measured by a single item craving scale) and anxiety could be differentiated. Clearly both were influenced by dopamine. No effect was evident for those with A1− status or those administered placebo.

Both translational and reverse translational research have extended our knowledge of drug reinforcement and craving. There is a strong emphasis on translational research in the delivery of treatment for physical and psychological disorders to ensure that the benefits of theoretical findings are incorporated into the delivery of more effective and efficient care. The psychobiological research already discussed is beginning to produce better outcomes, particularly through the development of medications that alter the systems that give rise to drug reward and craving. Other evidence to support underlying neurobiological processes that contribute to addiction comes from the trials of medications used to treat addiction themselves.

The role of GABA has been confirmed in several studies of baclofen, a $GABA_B$ receptor agonist, which results in decreases in craving, anxiety, and alcohol consumption. Baclofen also reduces dopamine release in the dorsal and ventral striatum in animal experiments.

Mu-opioid receptors are associated with reward and are present in the VTA. These VTA receptors when activated by endogenous opiates or opiate drugs of abuse inhibit GABA, thus reducing their inhibitory effect on dopamine. Increases in mu-opioid receptors over time are associated with alcohol and cocaine craving. Naltrexone, a mu-opioid receptor antagonist, is an effective treatment for alcohol dependence when combined with psychosocial treatment and appears to operate via reductions in craving when exposed to alcohol-related cues. This may then make those seeking treatment more receptive to skills acquisition including cognitive skills aimed at reducing positive expectancies. Those receiving naltrexone also reported less interest in drinking and a reduction in alcohol-related "highs" if they lapsed during the course of treatment, than did those on placebo. This prevents the escalation of a lapse to a relapse.

Glutamate, the most common excitatory neurotransmitter in the brain, stimulates the glutamatergic N-methyl-D-aspartate (NMDA) receptor and projections from the prefrontal cortex, amygdala, and hippocampus to the NAcc release dopamine, including indirectly via the VTA. In a similar manner to the increased dendritic spines on dopamine VTA neurons that are responsible for conditioned association learning during cued drug administration, the richness of these glutamatergic connections with the NAcc with dopaminergic afferents from the VTA increase as a product of previous drug exposure. This is a thought to contribute to drug-seeking behavior. Acamprosate acts at the NMDA receptor and enhances GABAergic inhibition. There is some evidence that acamprosate reduces craving for alcohol but this has not been consistently replicated. It may act via reducing excitatory responses to alcohol-related cues.

The outcomes of psychological intervention trials have also been illuminating in terms of refining our understanding of the role of desire and subjective outcomes. Psychological treatments based on exposure theory provide repeated unreinforced exposure to drug-related cues predicated as the primary means of reducing craving. There is evidence that exposure trials of at least 15 min are necessary for benefit. However, differential effects between cue exposure and other effective treatments such as cognitive behavior therapy (CBT) have not been evident. Typically habituation within exposure sessions and across trials has been demonstrated, but this has also been evident from CBT, suggesting that the reduction of craving due to environmental exposure may be common to multiple psychological therapies. Alternative treatments based on models contrary to the principles of cue exposure can also reduce craving. Mindfulness-based relapse prevention involves the teaching of skills to observe emotional and cognitive states such as craving through relaxation and other exercises without reacting in the habitual manner. The goal is to be more aware of responses rather than to extinguish them. Mindfulness appears to break the association between negative effect and craving. Following usual care incorporating 12-step and psychoeducational approaches, craving and negative affective states are still related after completion of therapy. In mindfulness-based therapy, repeated unreinforced exposure to the internal negative affective state, rather than to an external cue, may be an important advance in more effectively creating new learned associations.

Drug expectancies reflect conditioned associations and drug reward mechanisms. Expectancy studies have mapped the potential domains of reinforcement and have examined underlying processes associated with dependence such as salience, tolerance, and craving. As previously noted, positive expectancies are

consistently related, in their number and strength, to reports of drug consumption. The brain processes underlying learning and the acquisition of addiction have direct relevance to the development of drug expectancies. For example, $GABA_A$ receptor beta-3 subunit allele status is associated with alcohol expectancy related to negative effect, linking GABA-related genetic influences with self-reported alcohol outcomes. This genetic influence extends beyond the central nervous system to the effectiveness of alcohol metabolism and outcome expectancies. ALDH2*2 status confers protection against alcohol dependence through an aversive response to alcohol via the accumulation of acetaldehyde. Acetaldehyde is a toxic metabolic product of alcohol that causes increased heart rate, flushing, and nausea and in most individuals is rapidly metabolized. Presence of the ALDH2*2 allele is associated with lessened positive expectancies about alcohol, again indicating a relationship between individual differences in physiological mechanisms related to drug response and beliefs about drinking outcomes.

It is also assumed that drug expectancies are conditioned to cues because of their temporal link with drug consumption and are subsequently reinforced by drug ingestion itself, and this temporal effect is likely to be more distal from the act of drug use than craving itself. Primed expectancies prior to drug consumption are also likely to elicit or strengthen the acute experience of craving. In one study, cross-sectional data indicated that positive opiate expectancies are predictive of reward craving in opiate-dependent individuals, but a similar effect for alcohol expectancy was not evident for alcohol dependence. By contrast, a lack of positive coping strategies was predictive of high relief craving in opiate dependence, and high reward craving in alcohol dependence.

The in vivo study of drug effects offers some key benefits related to experimental control. Analog studies involving the administration of alcohol to those without alcohol dependence typically use convenience samples of undergraduate students. They do not support a strong role for craving but typically support the influence of alcohol expectancies on in vivo drinking behavior.

Manipulation of positive expectancies to decrease expectancy intensity through laboratory or therapeutic procedures shows a casual relationship with lowered consumption. For ethical and practical reasons these studies have typically focused on alcohol. Procedures designed to decrease expectancies are called expectancy challenges (EC). EC manipulations of positive expectancies have usually taken place in simulated bars, with college or undergraduate students. Most often, participants have been young adults with a short drinking history of moderate to heavy alcohol consumption rather than dependence.

In an EC procedure, a socially pleasant atmosphere is generated in the laboratory bar, and drinks are made available to participants. In the tradition of other alcohol research using placebo-controlled designs, half of the participants are given an alcoholic beverage, and the other half are given a placebo, which tastes and smells of alcohol but has no alcoholic content. In some studies all beverages have been placebo. The socially pleasant atmosphere is designed on the basis of these environmental cues to elicit both positive alcohol expectancies and craving.

In an early EC two sessions were separated by 5 days, where male participants were administered either alcohol or a placebo. In the first session, word games were played and turns were taken through the group with the session designed to facilitate social interaction. The second session had a sociosexual theme. Photographs of female models from magazine advertisements were displayed one by one, and discussions of their relative attractiveness took place to arrive at a consensus judgment. Toward the end of these sessions, participants were asked to guess who had consumed drinks containing alcohol and who had consumed a placebo beverage. Mistaken judgments were used to demonstrate that expecting that alcohol had been consumed could cause an individual to behave as though alcohol had actually been consumed. The importance of alcohol expectancies in generating what was otherwise considered to be an alcohol-related pharmacological response alone was the theme of the discussion. The goal was to disrupt the association between drinking and expectancy. In the final session, these initial observations were summarized, and the role of alcohol expectancies in driving future consumption was emphasized. As a consequence of the EC, heavy drinkers reported weaker endorsement of sexual and social alcohol expectancies and reduced their alcohol consumption. No measures of craving were taken, but based on the nature of the population, craving was likely to have been weak. Changes in positive expectancies and consumption were not evident in a control group exposed to a standard college prevention program instead of the three EC sessions, or in a control group that completed only before and after measures. Moderate drinkers exposed to EC reported no change in consumption. Subsequent studies have replicated the effect for social and sexual expectancies, but changes in expectancies related to affective and cognitive arousal did not occur. Equally, there has been replication for males but not for females, unless they are heavy drinkers. Using more traditional methods of CBT can also diminish the strength of the positive expectancies and increase the strength of negative expectancies, particularly those related to social enhancement.

The motivational systems that shape drug use include cue-related information, expectancies, and signals of

drug availability. In addition to altering expectancies to change this motivational system, it is viable to target urges in those with the most risky expectancies. Naltrexone, the mu-opioid antagonist used as relapse prevention agent, has been studied in this regard. Naltrexone can diminish the urge to drink in hazardous drinkers who do not have manifest dependence, but only in those with high positive expectancies. In other words the maximum benefit of naltrexone appears to be when positive expectancies are primed. The treatment implications of this finding in those with established dependence have yet to be explored.

Taken together, these findings show that positive alcohol expectancies can be reduced through EC in those with alcohol abuse. However, even in the absence of expectancy change, given the motivational network that incorporates craving and expectancy, reducing the urge to drink in those with strongly positive expectancies via effective pharmacotherapy shows promise.

Drug refusal self-efficacy, drug expectancies, and craving collectively shape drug use motivation. A lapse is likely to reflect multiple influences ranging from craving to impulsive decision making. The notion that the final decision was caused by a lack of belief in personal agency is common. For example, "I didn't have the confidence to refuse an offer of cannabis and just gave in to temptation." Social learning theory describes the acquisition and maintenance of all human behavior, including alcohol use, as derived from two related but independently operating expectations: outcome expectancies, such as alcohol expectancies which have already been described and self-efficacy expectancies. Self-efficacy expectancies reflect an individual's belief in their capacity to regulate a specific behavior, and these expectancies reflect the person's situational confidence. They may influence effort in the face of a challenge directly or interact with the person's mood state: they may, for instance, both induce and be undermined by depression.

There are self-efficacy measures for several drugs of misuse, with some important common elements across different classes. The broad nature of self-efficacy domains identified via factor analysis is almost identical across different drugs of abuse, despite their different pharmacological actions. A common factor in alcohol, cannabis, heroin, and nicotine self-efficacy involves difficulties in resisting substances in situations where a person needs emotional relief. Challenges to self-efficacy in social pressure situations are also evident with alcohol, nicotine, and cannabis users. Drinking refusal self-efficacy has been associated with adolescent and university student drinking patterns in cross-sectional studies. Cross-sectional data from adults seeking help have confirmed that self-efficacy is more strongly associated with the number of occasions of alcohol consumption than with the quantity consumed on a specific occasion, indicating that these beliefs may be more important in the initiation of substance use on any given occasion relating to alcohol-related cues.

There is good evidence for the influence on the development of self-efficacy beliefs, from learning related to the reward pathway. For example, those who have DRD2 gene A1+ status show diminished drinking refusal self-efficacy in situations of social pressure, compared with their A1− counterparts. Importantly, those with A1+ allelic status report an earlier age of onset of alcohol-related problems, which is in turn associated with lower drinking refusal self-efficacy and subsequent level of alcohol consumption and dependence. The association of A1+ status with lower drinking refusal self-efficacy, but not with greater alcohol expectancy, underscores the importance of these reward systems in shaping "wanting" to drink as opposed to "liking." "Wanting" is likely to driven by the cue-conditioned pulsatile dopamine release in the VTA. Furthermore, using the "reward value" of alcohol (how rewarding do you expect it to be to have alcohol presented to you today) as a summary index of "wanting" explains additional statistical variance in craving over and above prior drinking behavior and personality.

Despite the more limited predictive utility of craving in those without misuse, research that examines the association of craving and expectancy and involves the presentation of alcohol tends to be conducted in convenience samples without significant drug problems. As previously discussed, this is for ethical and practical reasons and usually involves college or undergraduate students. Some of this work has confirmed an association between the ratings of valence, dominance, and effect associated with alcohol-related cues and of craving with alcohol expectancy strength. Other studies have failed to find a relationship between expectancy strength and reactivity to alcohol-related cues.

Substance abuse treatment research has historically focussed more on "what treatments work" rather than "why they work." There have been repeated claims since the 1980s that effective treatment increases patients' self-efficacy. Self-efficacy expectancies are likely to develop through past experiences; enactive mastery; vicarious learning from peers, parents, social reference groups, and the media; and emotional experiences. The least effective influence on self-efficacy is verbal persuasion. Confirming the mechanisms responsible for clinical improvement has proved elusive, and mechanisms to date have typically been inferred rather than definitively identified. There is a large body of work indicating that CBT, based on social learning principles, is effective. CBT specifically attempts to bolster self-efficacy through teaching effective problem solving

skills, rehearsal, and skills to challenge dysfunctional expectancies. CBT fares no better than other bona fide treatments when direct comparisons are made. Thus, techniques designed to enhance social skills, challenge maladaptive cognitions, and teach drinking refusal skills do not show comparative benefit over techniques that do not purport to operate via cognitive-behavioral mechanisms. CBT studies have not identified reliable behavioral or cognitive mediators of treatment outcome, including self-efficacy.

When alcohol expectancy and self-efficacy are examined together, self-efficacy beliefs appear to be stronger predictors than expectancy of alcohol consumption at posttreatment. However, some studies have failed to find evidence for a predictive role of self-efficacy. Self-efficacy predicts relapse to heavy drinking over the first few months post abstinence, and is typically a more effective predictor of posttreatment relapse than expectancies over periods ranging from 6 months to 2 years. Reductions in positive alcohol expectancy and increases in self-efficacy have been demonstrated in a handful of studies, but they have not concurrently examined craving. Self-efficacy has predictive power for heavy drinking over 12 months in those who are taking the anti-craving drug *naltrexone* over and above effects related to craving reduction.

Craving itself can be elicited by alcohol expectancies, and imagery scripts based on positive alcohol expectancies have been used as an experimental paradigm to investigate craving, where urge and strength of personally held alcohol expectancies were related. The strength of craving in alcohol-dependent individuals from the experimental use of imaginal cues, based on autobiographical memories of craving, is as strong as those from actual exposure. Craving and expectancy may work in concert to enable behavior change under these circumstances. For example, effective CBT has been associated with expectancy change, particularly related to social and relationship relevant domains. Abstinence across 12 weeks of CBT is associated with reductions in assertion and sexual enhancement expectancy and increases in social pressure self-efficacy. Extinction of craving may be enhanced via exposure to social situations where drinking was previously undertaken as a consequence of increased confidence to resist alcohol in these environments.

These processes are not fixed: the priming of expectancies and craving requires information of drug availability. For example, the craving experience in drug-dependent individuals within inpatient settings is significantly less intense than in those who are continuing to use drugs in their usual settings. While there are multiple confounds acting on this relationship, there is a good evidence from nicotine dependence studies that craving for nicotine varies as a function of being told that there is a potential opportunity to smoke a cigarette versus being told that smoking is not possible. The impact of exposure to smoking-related cues is attenuated when smokers believe that there is little opportunity to smoke in the near future as compared with being informed that smoking would be possible soon. Cues may elicit craving via expectancies that include the broad expectancy of the possibility to access substances. These processes are not independent of the reward processes already described. There is brain imaging evidence that greater OFC activation in substance users who considered that the opportunity to use was imminent, compared with those for whom use was not possible and were trying to remain abstinent. In smokers who were not attempting to cease smoking, a subsequent opportunity to smoke during cue exposure resulted in greater brain activation, including in several subregions of OFC, than the activation in those who were told that cigarettes were not available. However, there was no association between this instructional expectancy set and craving. In a similar manner, these instructional expectancies regarding availability partially mediate attentional bias to smoking-related cues. The generation of drug expectancies may also involve particular subregions of frontal cortex. Again on the basis of neuroimaging, individual decision making under risk is negatively associated with dorsomedial prefrontal cortex (DMPC) activation and positively associated with ventromedial prefrontal cortex (VMPC). Those with strong activation of VMPC are more sensitive to reward on that basis display a higher probability of risky decision making.

SUMMARY

The motivation to use drugs is influenced both by the beliefs we hold about the consequences of drug ingestion and by the urge to use. Drug expectancies in conjunction with an array of other internal and external cues can elicit craving. Craving is a cognitive-emotional state of desire to use drugs that many dependent drug users experience, and it can relate to both the avoidance of an aversive state and seeking reward. Both types of craving coexist and are potentially related to drug expectancies although the experience of craving is more closely temporally linked to drug use itself. Individual differences in the neurobiology of reward related to genetics and learning history influence both craving and expectancy development. Drug expectancy, refusal self-efficacy, and craving can all be stimulated by external drug-related cues in the presence of signals of drug availability.

Craving has fallen in and out of fashion, but has been given more credence over recent years as an important

component in models of drug use, given its neurobiological validation. Although not directly compared in research studies, drug expectancies appear to develop first via observational learning and then both craving and expectancy develop as a consequence of use itself. Both craving and expectancy are shaped via brain processes that signal the presence of reward and facilitate associative learning. While these processes are complex and involve multiple neurotransmitters, dopamine has a central role. Drug expectancies and drinking refusal self-efficacy can work together as part of the same memory network to influence the acute initiation of drug use. There is a growing body of work confirming viable ways of altering expectancy and craving. In the absence of expectancy challenge, diminishing motivation via craving reduction in the context of strong expectancies may be a future useful treatment. The treatment implications of integrating expectancy and craving are yet to be fully realized.

VMPC ventromedial prefrontal cortex
VTA ventral tegmental area

Glossary

Allele a variant, or form, of a gene.
Autoreceptor a presynaptic receptor on a neuron that is sensitive to neurotransmitters produced by that neuron, providing a feedback loop that controls neurotransmitter release.
Drug expectancy a belief about the likely behavioral, cognitive or emotional effect of a drug on the person.
Drug refusal self-efficacy confidence in being able to refuse drugs that are offered in specific circumstances (e.g. under social pressure).
Glial cells cells that surround and protect neurons, providing oxygen and nutrients. Their role in neurotransmission is still being explicated.
Mesocorticolimbic pathway a dopamine pathway from the midbrain to the frontal cortex, that has been implicated in the salience of incentives or rewards.
Neurotrophins growth factor proteins that modulate the functioning and life cycle of neurons.

Attentional Biases in Craving

Jon May

School of Psychology, University of Plymouth, Drake Circus, Plymouth, UK

OUTLINE

ATTENTIONAL BIASES IN CRAVING

In everyday terms, an attentional bias might be interpreted simply as a tendency to attend more toward some thing than others, and it would thus seem straightforward to conclude that people who are dependent upon a substance will pay more attention toward it, and notice it more in their environment, particularly if they are currently craving it. Within cognitive psychology, however, facilitated recognition or responding to a cue is described as priming, and can arise for many different reasons, including prior exposure, motivation, overlearning, or general activation of mental representations (*see* Cognitive Factors in Addictive Processes by Neighbors). In this context, attentional bias has a more precise meaning, since it reflects a bias within the attentional processes themselves, and it has been argued that this may represent a change in mental functioning that causes or maintains substance dependence. If this is the case, then therapeutic approaches that modify such biases may help alleviate craving, and hence assist abstinence attempts. Theories that see addictive behavior as an automatic response (such as Tiffany's view that drug-seeking behavior is driven by the activation of overlearnt action schemas, with craving occurring when these schemas are blocked or inhibited) would predict a strong relationship between attentional bias and craving, and also between attentional bias and drug use.

An alternative possibility is that attentional biases do not play a causal role in craving, either being a consequence of craving, or being caused by the same processes that lead to craving, and so while they may attenuate as craving is reduced, attempts to modify them directly will not have any direct impact upon craving, substance use, or addiction. For example, Robinson & Berridge's Incentive Sensitization hypothesis suggests that use of addictive substances leads to neurological changes in the brain making users hypersensitive to drug-related cues (*see* Incentive Salience and the Transition to Addiction by Robinson, Berridge, & Robinson). While these changes might lead to both an increased desire for the drug, and an increased tendency to attend to drug cues, modifying the attentional bias would not be expected to reverse the drug-related neurological changes, even if it had behavioral effects in the form of reduced addictive behavior or reports of subjective craving.

A more cognitive interpretation is that an attentional bias to substance-related cues might lead to increased conscious awareness of the substance, and hence a subjective state of craving that distracts the individual from other tasks, motivating drug-seeking behavior. This link between automatic and controlled cognition is a key component of, for example, the Elaborated Intrusion Theory of desire proposed by Kavanagh, Andrade, and May (EI Theory). Where other theories of addiction emphasize the automatic or bottom-up control of

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00045-0

drug-seeking behavior, EI Theory gives conscious strategic behavior a mediating role. Automatic processes, including attentional biases, lead to intrusive thoughts about substance use, but craving only occurs if the individual cognitively elaborates the initial thought, especially through substance-related sensory imagery (*see* Sensory Imagery in Craving by Andrade). Conscious thoughts of substance use may in turn moderate attentional allocation, confounding attempts to measure purely automatic attentional biases in deprived substance users or those manipulated into states of high craving. While EI Theory predicts a relationship between attentional bias and craving, the link is one of many, and is not direct or one-way.

A better understanding of the relationship between addiction, craving, and attentional biases would be very useful in identifying the relative contributions that explicit, conscious processes (such as craving) and implicit, automatic processes (such as attentional biases) play in addiction (for a detailed account of implicit processing, *see* Implicit and Associative Processes in Addiction by Wiers and Stacy). One difficulty in untangling the causal relationships is that many attentional bias studies using substance-related materials do not measure craving, or do not measure it at the same time as the attentional bias measure. Often they simply show differences between dependent and non-dependent groups. Other studies may compare substance-dependent participants who have or have not been deprived, or who have been exposed to cues relevant to a substance. Increasingly, the role of craving is being recognized, and short scales that simply ask participants to rate how strongly they are experiencing an urge to use or consume a substance are administered several times during studies, allowing baseline craving and changes during the study to be assessed. In a recent review of such studies of visual attentional bias, Field, Munafò, and Franken concluded that while a correlation between visual attentional biases and craving did exist, it was weaker than might be expected from theories that give attention a direct role in driving drug-seeking behavior.

Historical Aspects

Attentional bias was initially described and developed theoretically within the context of affective disorders, and in particular anxiety, by Andrew Mathews, Colin MacLeod, and colleagues at St George's Hospital in London. Their work had focused upon the role that negative schemas of thought might play in anxiety. It had long been recognized that depressed people tended to interpret the world around them in a negative manner, giving negative interpretations to everyday events that other people might see as neutral or even positive. When asked to recall events, they would include more negative material or events than non-depressed people, and would tend to dwell on or ruminate on these thoughts. Early work on attentional biases evolved as an attempt to explain differences in the patterns of findings between depressed and anxious people.

In the 1960s, Aaron Beck had proposed a cognitive model of affective disorders that focused upon the negative content of thoughts, in contrast to the then-dominant behaviorist model that saw emotional problems as a set of learned responses to stressful or threatening situations. The model was criticized for lacking an explanation of how these negative thoughts came about or were processed: without such an explanation, the model was difficult to test empirically. Using the then-dominant cognitive concepts, Gordon Bower proposed an associative network-based model of mood and memory, in which emotional states were represented as nodes within a general semantic memory network, alongside other nodes representing events and memories. When one memory or node was activated, it would in turn activate any nodes to which it was connected or associated. In this model, affective disorders resulted from a richer linking of negative emotional nodes to other memories, such that almost every thought or stimulus would spread activation to negative emotions.

This model allowed empirical, hypothesis driven research to take place which confirmed the predictions of memory biases in depression, especially explicit biases, where people were asked to search memory for answers. For anxiety, however, the results were different. Instead of explicit memory biases, it seemed that implicit memory biases were typically being found.

Taken together with anecdotal evidence from clinicians about anxiety patients being hypervigilant for threat cues in their environment, it seemed that instead of a memory bias, anxiety might be linked to an attentional bias. Mark Williams recounted the cases of a bird phobic who was unable to walk down her high street in case the butcher's shop there had a display of poultry in the window, and of a welder who obsessively scanned through newspapers looking for reports of disasters. For these people, their elevated levels of stress and anxiety could be seen as a natural and correct response to the highly threatening world that they found themselves in, for the more they searched the world for instances of the things they feared, the more they found them.

Stroop Task

Initial studies on attentional bias used two methodologies taken from experimental psychology, one based on Stroop's color-name interference effect, and the other on

dividing auditory attention in dichotic listening tasks. Stroop had asked people to name the color of the ink that had been used to print various color names. When the color name and the ink matched, people were fast to do this task; but when the color name was different to the ink, reading speed slowed and errors increased, due to the tendency people had to read out the color name instead of naming the ink.

The Emotional Stroop was a variant upon this in that emotional words were printed in different colors. Gordon Bower reported an experiment that he had carried out with Gerald Clore in which participants who had been induced into an emotional state were slower to name the ink color of emotional phrases than neutral phrases, whereas participants in a neutral mood named the colors of all phrases equally and rapidly. Fraser Watts and his colleagues adapted the test to show that spider phobics were slower to color-name words associated with spiders, and C. Ray found that students were slower to color-name words related to examination anxiety than neutral words, when tested just before their exams.

To see if this effect was specific to anxiety or if it was involved in other motivational states, other researchers looked at the effect of food deprivation on color-naming food-related words, and found similar results. By using substance-related words instead of emotional words, a task known as the Addiction Stroop was developed. In one of the first reports of an Addiction Stroop, Gross and colleagues showed that smokers who had abstained overnight were slower to color-name smoking-related words than neutral words, while non-abstinent smokers showed the opposite pattern. This finding is important because it does not just distinguish between dependent and non-dependent participants, but shows that the level of deprivation is associated with the interference effect.

The Addiction Stroop is attractive because it is easy to use. In its simplest form it can be prepared as a printed sheet of around 30 words, and the time taken to color name the entire sheet recorded, and divided by the number of words used (see Fig. 45.1). The effect is then the difference in time per word obtained for a sheet of substance-related words and a set of neutral words – although to control for category effects the neutral words should ideally all be drawn from a coherent set, such as furniture or transport words. More complex versions of the task can be conducted using computer-based presentation, in which words can be presented individually for precise durations, allowing masking to be used (neutral stimuli presented before or after the cue). Stimuli can be presented in blocks or mixed with neutral stimuli.

However, the task is controversial and difficult to interpret. Slower naming speeds on any Stroop test could be due to the difficulty of inhibiting processing

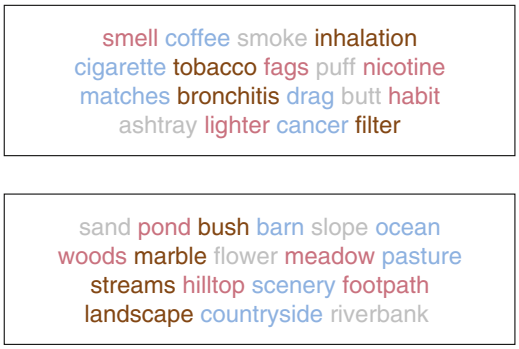

FIGURE 45.1 Addiction Stroop task – an example of an Addiction Stroop task using sets of 18 smoking-related and environmental words. Participants name the ink color of each word (pink, gray, blue, or brown), and the effect is measured by the difference between the mean naming time for the two sets. Smokers craving cigarettes would take longer to color name the smoking words than the environmental words. *Word sets used by Waters, A.J. and Feyerabend, C., 2000. Determinants and effects of attentional bias in smokers.* Psychology of Addictive Behaviors, 14(2), *111–120.*

of the word content, as originally suggested, or due to a gradual build up of associated thoughts due to the use of repeated salient words from a single category. Even if the effect is due to individual words, one or two verbal stumbles in a set of 30 words are sufficient to create an overall difference in color-naming time. It is not clear that the test is measuring anything about attention at all, and even if it is, it is not a pure test.

In a comprehensive meta-analytic review of the use of Addiction Stroop tests, Cox, Fadardi, and Pothos found 18 studies using alcohol cues, 11 smoking cues, 3 drug abuse cues, and 1 gambling cues. While they found that variations in the method of presentation affected the sensitivity of the task to addiction-related attentional bias, the task did reliably show such an effect, and the effect was increased by manipulations that induced or elicited addiction-related thoughts. Increases in the amount of use, or the desire to use, substances also increased the effect. However, they also noted that no study had explicitly measured craving at the same time as administering the Stroop task, although one study reported correlations between heroin craving in the prior week and interference on a heroin-Stroop task. It seems that the task is sensitive to the increased activation of substance-related concepts, and while it seems highly plausible that this is also related to craving, the link is not yet proven.

Cox, Fadardi, and Pothos make a number of recommendations for studies using Addiction Stroop tasks. Four colors should be used, and in computer-based tasks, requiring participants to say the color name out aloud in addition to pressing response keys enhances the effect. Stimulus words need to be chosen carefully so that there are no associations with color, and the neutral words should form categories that really are

neutral, with no emotionally charged content. The addiction and neutral categories should contain an equal number of words, and should be balanced for frequency and length. Blocked presentation is also preferred over intermixed presentations in computer-based testing, but if intermixed presentation is to be used both the addiction and neutral words need to be preceded by additional neutral filler words to reduce the chance of effects from one trial persisting into the next trial (which is presumably a factor in the increased sensitivity of blocked presentation). They also recommend that very short and very long tasks should be avoided, and although they make no recommendation about the appropriate number of trials per category, the median number of words per category in the reviewed studies was 12, with each word being used four times, for a total of 48 trials per category.

Dual Task Procedures

Another, more obviously attentional, early approach to measuring attentional biases used a dual task procedure known as dichotic listening, in which different audio streams are played to each ear over headphones. The basic design requires people to perform some primary task upon the stream played in one ear, the 'attended' channel, and then tries to assess how much they are distracted by events played in the other 'unattended' ear. This can be measured by a decrease in performance upon the primary task, or by an increased ability to detect the 'unattended' events.

Dual task paradigms are widely used in experimental psychology to study the degree to which different mental faculties are independent of one another (if the two tasks do not interfere), or load upon shared resources (if they do interfere). In the context of attention research, the assumption that attention cannot be divided but must switch between tasks, sources of information, or spatial locations means that an attentional bias can be detected if performance on the primary attended task is reduced more by addiction-related content in the unattended channel than by neutral content.

Mathews and MacLeod adapted the dichotic listening task and asked anxious and non-anxious control participants to shadow (i.e. to repeat while listening) eight stories played to one ear, while ignoring word lists read in the other ear. Some of these lists contained threatening words and others were entirely neutral. They hypothesized that the anxious participants would have their attention drawn toward the unattended threat lists, but not to the neutral lists, and to measure this participants were also asked to complete a simple reaction time task by pressing a response button whenever a cue appeared on a computer screen. As predicted, the response times for the non-anxious participants were unaffected by the word list content, at around 500 ms, whereas the anxious participants took 600 ms to respond during the neutral word lists and 680 ms during the threatening word lists. Following the task, participants all reported being unaware of the unattended word lists, and memory tests for the words used in the unattended lists indicated no recall. This indicates that the attentional bias toward the threatening words was preconscious and not a result of increasing awareness during the task.

In an addiction context, Sayette and Hufford found that manual responses to tones were slower when deprived and non-deprived smokers were holding and looking at a lit cigarette in their other hand (at around 350 ms) than if they were holding and looking at a similarly sized spool of electrical tape (300 ms). They also measured self-reported craving, and found that in the group of smokers who had been deprived of cigarettes and then exposed to cigarette cues, there was a significant relationship between craving and the amount of slowing in response times; non-abstinent smokers and abstinent smokers who had not been exposed to cigarette cues did not show this association. This suggests that the attentional bias was due to the cigarette exposure, and not to deprivation, but that when smokers were also deprived, the strength of their craving was associated with an increased attentional bias. The craving seems to enhance an attentional bias brought about by awareness of cigarette cues, rather than the cues inducing an attentional bias that leads to craving.

As with the Stroop effect, it is not clear that dual tasks are a purely attentional effect, because the repeated presentation of negative or threatening material might have a cumulative effect upon mood, which might in turn affect responses or performance on a primary task. Similarly, presenting cues related to substance use might trigger associated thoughts about that substance that could also distract a dependent participant and affect their performance, without the cues themselves being selectively attended to.

Visual Probe Tasks

Andrew Mathews and Colin MacLeod turned to the attentional literature to search for a purer measure of attention, and adapted a visual cueing technique developed by Michael Posner. In what has come to be called the dot probe or visual probe task, two cues are presented simultaneously in different parts of a computer screen (see Fig. 45.2). When the cues disappear, one of them may be replaced by a small probe or target, often a dot, and the participant has to respond to this probe. There are many ways on which the task can vary, as described

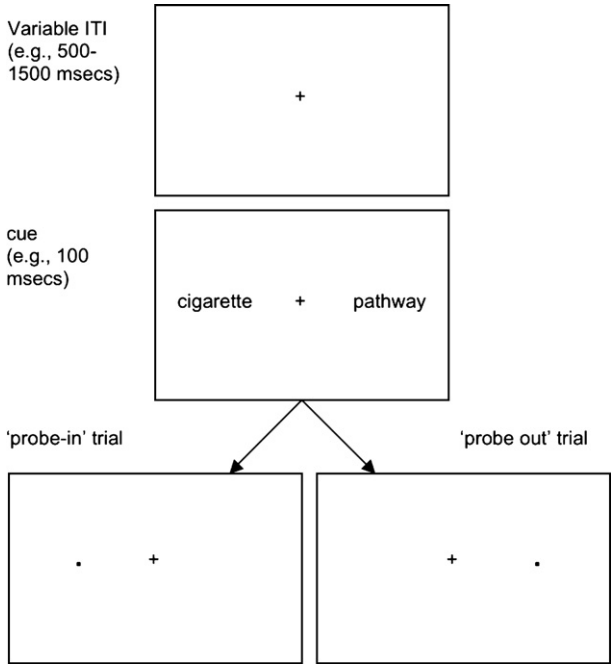

FIGURE 45.2 Visual probe task – a trial from a typical visual probe task, using smoking-related and neutral stimuli. The participant is asked to look at the fixation cross, and to press one response button when they see a dot appear on the left of the screen, and a different button if it appears on the right. Deprived and craving smokers' responses are faster on 'probe in' trials when the probe letter is displayed in the location of a prior cue that is smoking related than on 'probe out' trials, when it follows the neutral cue, indicating an attentional bias toward the smoking cues. The opposite pattern (avoidance of smoking cues) may be found for non-smokers.

below, but a key feature is the simultaneous onset of two stimuli which thus compete for attentional resources. If one of them is especially salient in some way (e.g. a threat word for anxious people, or a substance-related word for users of that substance) then participants' attention may be drawn toward the location of that cue. Response latencies to probes that appear in this location will therefore tend to be faster than those presented in the location of the other cue. The difference in latencies between the two locations gives an index of attentional bias.

The basic task is quite flexible in that it can use verbal or pictorial cues, which can be separated horizontally or vertically by differing amounts, and presented either subliminally (i.e. for less than 50 ms), very briefly but supraliminally (between 50 and 500 ms), or for much longer periods which allow the participant to attend to, look at, and then look away from the cue. Participants can be asked to fixate on a central location before the cues appear, and not to look at them, or be allowed to move their gaze. The probe (and critical cues) can appear on all trials, or on a subset; and the probe can require a simple detection response or (more usually) a binary decision, contingent upon probe location or probe content. These variations are all interesting from a theoretical analysis of the functional location of the effect within the cognitive system: but the presence of the effect is robust – if at times small, being measured in milliseconds.

Mathews and Macleod's first study reporting the use of this task found that anxious participants responded 45 ms faster to threat location probes than non-threat location probes, whereas the non-anxious participants were 24 ms slower. In fact, the tendency of the supposedly neutral control group to show an avoidant, rather than a neutral, pattern of responding, is a frequent finding in anxiety studies, which suggests that normal behavior involves avoidance of threat. Over the last 25 years, variants of the visual probe task have been widely used in studies of affective disorders, especially anxiety, but also in other motivational contexts, including addiction.

The use of two cues in the visual probe task is based upon the idea that attention can only be focused upon one spatial location (or stream of information) at a time, and so using two simultaneous cues forces the two cues to compete for attention. Sensitivity to any differences in attentional bias toward the experimental cue is increased, whereas the onset of a single cue always attracts attention. A related procedure in which only one cue is presented at a time has also been used, and is called the attentional cueing task (see Fig. 45.3). Because attention is inevitably allocated toward the

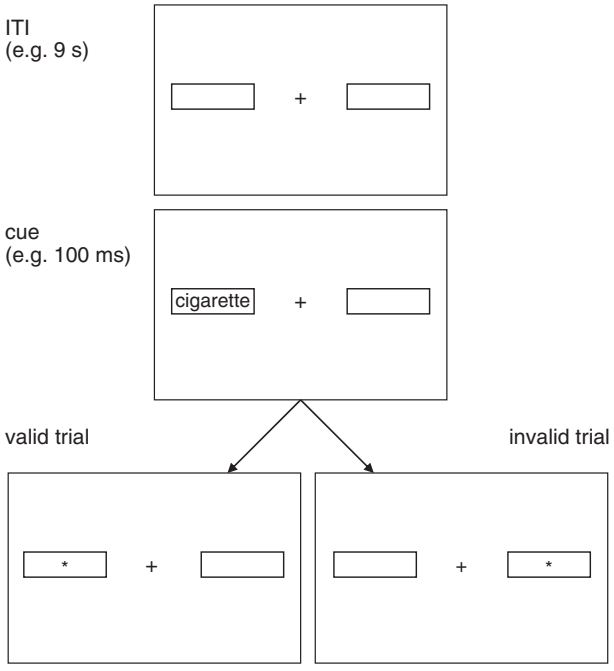

FIGURE 45.3 Attentional cueing task – a trial from a typical attentional cueing task. Unlike the visual probe task, only one cue is presented at a time. Participants are asked to respond as quickly as possible when they detect a probe, and substance users show slower response on invalid than on valid trials. Note the longer inter-trial interval (ITI) required compared to the visual probe task.

single cue, it is more sensitive to differences in disengagement of attention from the cue, or post-attentional avoidance.

Field and Cox recently reviewed the findings from attentional cueing and visual probe studies on users of alcohol, cannabis, cocaine, heroin, and tobacco. While they found that in general, substance users tended to show an attentional bias toward their substance, two patterns stood out. First, subliminal cues, which were not reportable by participants and so not available for conscious processing, did not lead to attentional bias. Secondly, alcoholics who were undergoing treatment showed a pattern of avoidance, with slower detection of probes in the location of alcohol cues. This would seem to indicate that, as with the Stroop task, attentional bias effects in addiction may be due to explicit, conscious processing rather than very early, automatic processing: this is the opposite to the findings from the anxiety literature.

New Methodological Developments

As the attentional literature evolves, tasks developed there can be adapted to measure attentional biases in more sophisticated ways. For example, some researchers are now using the attentional blink phenomenon in which the ability to detect a briefly presented target within a sequence of distractors is impaired if it closely follows a distractor that is salient in some way (typically, being visually similar to the target). While this phenomenon has been extensively studied using varying visual stimuli to explore visual attention, Barnard and colleagues used words as stimuli to show that increasing the semantic relatedness between distractor words and the target category could also lead to attentional blink effects, showing that the effect is not purely caused by visual effects but that meaning is also important. Other researchers have also shown that emotionally valenced targets are less prone to the effect, which suggests that they are more able to regain attention following a distraction event. Addiction researchers have now used the task to show that smokers show smaller attentional blinks for smoking-related targets than for non-smoking targets. Although these studies have not yet assessed different levels of craving, they suggest that this task might be another useful way of measuring the degree and timeframe of attentional biases.

Other researchers are making increased use of eye-tracking tasks, in which shifts in gaze direction are measured. While gaze direction follows the allocation of attention, and so can be used as an indirect measure, it is not identical to attention. Studies using eye tracking, however, have shown that substance users gaze for longer at substance-related cues, as if they find it hard to move their attention away from them. These techniques can usefully be combined with visual probe tasks, to separate trials involving explicit changes in gaze direction from those that do not: if attentional biases can still be found in the absence of changes in gaze direction, then relatively early components of attention would be contributing to the effect (see below for further details).

It is possible that with better understanding of the neurological and electrophysiological correlates of attention, that methods may be developed to assess attentional biases using neuroimaging data or event-related potentials (ERPs). ERP studies measure the electrical activity on the scalp caused by a small area of the cortex following the presentation of a stimulus. Characteristic patterns of positive and negative changes in voltage above and below a resting state indicate processing, and a positive wave occurring approximately 300 ms after stimulus presentation has been found to be associated with attention, and in particular the detection of salient events. Studies have shown associations between craving and the size and timing of these components of ERPs to substance-related pictures for heroin users, smokers, and alcoholics.

Models of Attentional Bias

In the use of the visual probe task in anxiety, it has been established that attentional biases can be due to a combination of pre-attentive, attentional, and post-attentional factors.

Pre-attentive effects occur very rapidly and can be detected with subliminal cues, typically presented for less than 50 ms. These effects serve to prepare a shift of attention toward the location of the relevant cue, and so increase the speed with which attention can subsequently be directed toward a probe occurring in the same location as the salient cue (in the attention literature, moving attention toward an object or event is known as engagement, so these pre-attentive effects occur before engagement but facilitate it). Anxiety produces reliable, if small, pre-attentive effects, but it seems that general motivational states such as hunger do not. This could be due to a lower salience of food-related stimuli for hungry participants, compared to negative or threatening words for anxious participants, or it could reflect an underlying difference in the cause of attentional biases in addiction and anxiety.
