Cultures have some traits in common with each other within clusters of characteristic behavior. All societies progress through an identical series of distinct evolutionary stages, which Tylor proposed in his writings. Tylor (in Gillies, n.d.) stated that “human culture developed through three stages—that of savagery, barbarism and civilization” (p. 1). Morgan (1877) was one of the first to provide a written analysis by collecting questionnaires about Native Americans and other U.S. groups. These questionnaires provided a basis for Morgan to formulate additional ideas and theories on this subject. This type of research provided a framework for other anthropologists who followed Morgan and completed extensive documented research on individuals and their cultures.

As we take into account recent steps in understanding culture, there must also be a discussion of the role archaeology reveals. Archaeology is the systematic study of past cultures recognizing that the remains of a culture and their adaptations to that environment provide a look into what occurred previously. This type of research must be able to establish what happened, when it happened, and how these occurrences affect how the specific culture is evolving today. Of course, language or linguistics plays an integral part in anthropology. Record keeping and the ability to accurately document and explain data compiled during research are essential.

Spencer, a philosopher who lived in the 19th century, believed that society had strong and weak individuals. Spencer, an Englishman, followed the theories of social evolutionists in believing that the weaker characters in a society should not be included or considered a part of the

group. Frazer, an English anthropologist, also supported the social evolutionist movement and Spencer’s ideology. Frazer’s major work, for which he is widely known, is titled *The Golden Bough* (1890). This publication details the evolution of religion, and it was the first book to bring together as much information on this topic. The evolutionists thought that man’s social and cultural history could be arranged in a sequence of developments and that populations of people progressed at different rates.

This philosophy was disputed by the next generation of scientists in the 20th century, the followers of anthropologist Franz Boas:

Boas and his students tended to emphasize the variety of local cultural traditions and the accidental course of their development. Some of his most creative associates came to see cultural anthropology as one of the humanities, and this became the dominant cast of American cultural anthropology in the last decades of the twentieth century. (Kuper, 1996, p. 25)

In all corners of the world, studies involving different cultures affect research.

German and Russian anthropologists also provided valuable theories on cross-cultural analysis. As a society grows, the overlap in disciplines becomes more apparent. Cross-cultural studies detail the significance of compiling statistical data accurately. Only when an unbiased account of evaluating cultures worldwide is instituted can there be a true analysis of cultures and disciplines nationwide.

Theory

Tylor stated that culture is “that complex whole which includes knowledge, belief, art, morals, customs and any other capabilities and habits acquired by man as a member of society” (Lassiter, 2002, p. 42). In Tylor’s book *Primitive Culture* (1871), the author focuses on belief systems, which were frequently noted by writers during this period. However, Tylor believed that the development of culture is unilineal since the process was not instant but evolved over a longtime period. He continued to do research in England as other anthropologists formulated similar and other very different theories; he is attributed with conceptualizing a more advanced picture of the early hunters and gatherers. His three stages of evolution did contribute to the understanding of other cultural evolutionists.

Morgan presented a systematic way of analyzing cultures. He was the first to use a written discourse in the form of questionnaires. The questionnaires were used to collect data about kinship relationships of numerous American groups, such as Native Americans. This information helped to substantiate the intellect and strong sense of survival of the Native Americans.

Without substantial facts, the early evolutionists believed that the Europeans were the most advanced culture existing

in this world. Boas wrote from completely different viewpoint of the cultures and cultural traits. The historical particularists explained that a culture's traits had to be analyzed in terms of the society lived in. This approach proved significant as scientists continued to seek broader guidelines to measure similarities, differences, growth, and changes of numerous groups/cultures. Murdock developed a "measure of cultural complexity among ethnographically known cultures. The measure looks at 10 different features of the culture, including its technology, economy, political system and population density" (Ember, Ember, & Peregrine, 2002, p. 28).

Followers of Darwinism believed in the theory of natural selection whereby the frequency of human traits has evolved over time. Charles Darwin wrote in his publications, such as *The Descent of Man* (1871), that "every species is composed of a great variety of individuals some of which are better adapted to their environment than others. . . . Without variations, one kind of characteristic could not be favored over another" (Ember, 2002, p. 34). Darwin also believed in heritability recognizing that offspring inherit traits from their parents. Individuals that are better adapted in their environment produce more offspring year after year. The stronger individuals extend these traits to their offspring, and the results are stronger offspring and stronger generations of people in the family structure. A new species emerges when changes in traits or geographical barriers result in the reproductive isolation of a population.

Various scientists in the 1930s and 1940s added genetics as a factor in understanding culture. In 1972, Niles Eldredge and Stephen Jay Gould wrote that evolution moves quicker than scientists earlier believed. There are various schools of thought about evolution and these beliefs have affected how we presently study culture.

Anthropologists have discovered stone tools over 2 million years old in regions of East Africa. This discovery led scientists to develop certain timelines according to humankind's ability to control and survive in its surroundings. In this chapter on cross-cultural studies, it is necessary to discuss the beginning of culture. Culture is a set of learned behaviors. Adaptation and change are a part of culture: "Cultural change regularly occurs as new and beneficial means of adaptation are developed and shared" (Ember, 2002, p. 108).

The German-born anthropologist Boas did not accept the evolutionist theories. Rather, he challenged the beliefs that Western culture was considered a higher form than others. These anthropologists were in the forefront of cultural relativism, acknowledging that a society's customs and ideas should be explained within the context of that environment. Boas's work was viewed with significance by researchers.

William Graham Sumner, a sociologist and economist, was instrumental in introducing concepts of folkways and mores in *Folkways* (1906). Sumner was a follower of Darwinism, believing that most fit members of society survived; thus, the biologically strong lived longer. This belief supports the Darwinian theory of cultural evolution.

However, Sumner was an avid proponent of using ethnographic methodology in research.

Another anthropologist, Alfred Louis Kroeber, published numerous works on culture and culture growth. He was an American who early in his career studied the Native American Indians of California and believed in the study of human culture as a discipline in itself. Thereby, Kroeber helped to express the need for the emergence of anthropology as a necessary academic area to be studied.

These anthropologists advanced the major theories of cross-cultural studies. Morgan used interviews and questionnaires in his kinship research (1871). Tylor (1889) was the first to attempt statistical cross-cultural analysis. Murdock in his world-renown HRAF (1930s and 1940s) coded ethnographies of over 300 cultures. Levinson published *A Guide to Social Theory: World Wide Cross-Cultural Tests* (1977), and Murdock published *Atlas of World Cultures* (1980). These are a few of the major works that revealed the need and importance of taking an analytical look at methods of research and cultures.

Methods

Researchers have taken a more cautious look at methods of obtaining data in the social sciences. Anthropologists have especially noted that some past observations were not performed exactly accurately. Some processes now used by scientists include regional comparisons, holocultural analysis, controlled comparisons, and coding. The two major methods of research in this field of study are the comparative method using scientific principles, explicit theory and details, research and sampling procedures, and data and tests available for authentication. As scientists have experimented and been challenged in their research methods, a greater attempt to make this research accurate and consistent has emerged. The second major method of research is the use of the hypothesis. The hypothesis and the variations recorded must withstand testing. In hologetic research, information is based on firsthand, ideographic accounts of single populations. In Thompson's writings, he notes that the "modern cross-cultural survey method emphasizing deductive theory-testing represents a logical development. A leading proponent of this method notes that the main idea of holocultural study usually is to test an existing theory by means of worldwide correlations. The increasing use of computers has greatly facilitated cross-cultural comparisons in social anthropology, as well as in history, sociology and economics" (Thompson & Roper, 1980, pp. 907–908).

While, the holistic approach permits anthropologists to develop a complex understanding of entire societies, anthropology also adds another dimension of analysis through cross-cultural comparison. When examining any particular society, the anthropologist is interested in seeing how that society is similar to or differs from others. (Davis, n.d.)

Cognitive anthropology involves explaining the unique and meaningful features of a particular culture. Tylor stated that “it is assumed that each people has a unique system of perceiving and organizing material phenomena and the major task of cognitive anthropology is the empirical discovery and understanding of these organizing principles” (Thompson & Roper, 1980, p. 911). The use of the term *intercultural diversity* refers to developing decision models to ensure that all researchers prepare, organize, and record data the same. Researchers often have to study and spend time in the environment before they can accurately evaluate. This need evolves since all researchers have not elicited information the same way in all research, nor have informants always reported or perceived behavior the same in their analysis. Thus there is a problem of reporting data in a uniform manner. “Researchers use quantitative methods of research, such as survey research, secondary analysis, existing statistical analysis and experiments. Qualitative methods include field research, historical comparative research, and natural experiments” (Birx, 2006, pp. 2018–2019).

Sir Francis Galton disputed much of the research of Tylor and other anthropologists. He believed that the experimental design was flawed and not scientific.

When looking back to the period since the 16th century, Europeans had accumulated a considerable body of information on the peoples of Asia, the Americas, and Africa. These reports were unsystematic and unreliable. Throughout the 18th and 19th centuries, information was gathered on various cultures.

In the early twentieth century there was a shift to longer, more intensive field studies of particular cultures. Franz Boas made a long-term study of the native peoples of southern, coastal British Columbia, collecting a huge archive of vernacular texts from key informants. Russian scientists made intensive studies of the Siberian peoples, and European scholars began to publish studies of small societies in the tropical colonies. (Kuper, 1996, p. 23)

The ethnographies produced between 1920 and 1970 were holistic in nature. “From the 1960s, ethnographers increasingly began to develop historical perspectives, drawing on oral traditions as well as archival sources, particularly as more studies were undertaken in peasant societies in Europe and the Near and Far East” (Kuper, p. 24). The development of broadening research techniques has been beneficial for all the scientists, observers, and participants in these studies.

Practical Applications

Cultural anthropology, ethnography, ethnology, and archaeology are all processes to show how studies are used to advance the study of anthropology.

Cultural anthropology involves the description and comparisons made by human groups to the diverse ecosystems

of the earth. Adaptations are seen in the two traditional areas of focus that are referred to as ethnography and ethnology. Ethnography is the descriptive study of one’s culture, subculture, or microculture based on fieldwork, which takes many years to study. It is the genre of writing that presents varying degrees of qualitative and quantitative descriptions of human social phenomena based on fieldwork. Ethnology is the comparative study of culture or a specific attribute of that culture. Ethnology presents the results of a holistic research method founded on the idea that a system’s properties cannot stand alone without some interaction on another. Ethnography requires firsthand research seeking the local people in a village setting to converse and obtain information that cannot be taken only from written reports. It is this method that leads to more in-depth interpretation of data collected. “As projects are compared, our understanding of cause and effect increases. New generalizations about culture change are added to those that anthropology have discovered in traditional and ancient cultures” (Kottak, 2000, p. 358).

The term *applied anthropologist* is used when explaining the hands-on methods of gathering data from various cultures. The applied anthropologists, the forerunners of using fieldwork to answer cultural questions, are part of the following four disciplines: (1) The biological anthropologists are the groups that work in public health, nutrition, genetic counseling, substance abuse, epidemiology, aging, and mental illness. (2) The archaeologist and biological anthropologists are the groups that work alongside each other to determine how physical features play a significant role in determining the time period a human existed. (3) The linguistic anthropologist is the subdiscipline that studies languages of the present and makes inferences about those of the past. Linguistic techniques are useful to ethnographers because they permit rapid learning of unwritten language. Both linguistic and cultural anthropologists are interested in how language links up with other aspects of culture. Some argue that the linguistic categories people use produce distinctive psychological traits in different cultures. (4) The sociocultural anthropologists are the largest group of the disciplines in which social workers, businesses, media researchers, advertising professionals, factory workers, nurses, physicians, and school personnel participate. Each group requires information from the anthropologist to help assess how best to interact with others in their environment.

Practicing and applied anthropology are considered interchangeable yet the discipline of applied anthropology is concerned with producing knowledge that will be useful to others, while practicing work directly involves anthropologists intervening beyond social scientific inquiry, making their knowledge and skills useful and easily accessible. (Birx, 2006, p. 177)

None of these subdisciplines can exist without archaeology, the systematic study of past cultures reorganizing

the remains of a culture and its adaptations to that environment. It is that environment that provides a look into what occurred previously, as well as the language that evolved. In biological anthropology, *Homo sapiens* are studied as beings both in the present and the past. The evolution of our species is taken into account as scientists explain our relationship to other species. Some anthropologists view *Homo sapiens* in a holistic nature seeing the biological and cultural aspects of life being taken into account for every event that has happened during a lifetime. Each event further explains the evolution and adaptation of the human animal. The subdisciplines merge information to establish evidence of human activity before any written account existed.

Comparison (Global/Topical)

There are vast differences among cultures, yet there are similarities as well. In this section, a few cultures will be discussed, which allow researchers to begin analyzing each. The first example is that of the Native American Indian. Tribes have a government affiliation in the United States. Most prefer to be called Native Americans. Many tribes speak their own language, others have lost it, and some are relearning their native language. Tribes had lived in their own environment until the U.S. population grew and they were forced to move to different territories. Scientists would have to be aware of the changes in the tribes due to changing, geographical locations. In this cultural group, the women make up about 50% of the population. They are younger than the national average, undereducated, and have a median income of under \$20,000. The average life expectancy is 74.7 years, and unemployment in this group is 13.4%, more than twice the national average (St. Hill, 2003, p. 29). Some traditional families are reluctant for an infant to be born in the hospital, believing that the hospital is not a safe place. Many students leave school early and only 9% have a bachelor of science (BS) degree or higher compared with the national average of 20.3%. The teen pregnancy rate is the highest among all ethnic groups, with 45% of youth giving birth before the age of 20. Traditionally, young women are considered to be of marriage age by 14 (p. 32). The most frequent causes of death are heart disease and malignant neoplasms. Grieving, burial, and behavioral practices vary by tribe as do burial rituals. Not all tribes are eligible for health coverage (p. 44). Women older than child-bearing age believe that female exams are not needed. Family/relatives share medicines. The cultural view of health and illness is holistic, and health is associated with balancing physical, mental, spiritual, and kinship realms. In order to encourage healthy behavior, the tactics of talking to small groups using spiritualism and holistic behavior would probably get results. The researcher in the Native American population would have to be cognizant of these behaviors and design their research accordingly.

Arab Americans make up another cultural group. Approximately 5,000,000 Arab immigrants and their offspring currently live in the United States. More than half speak a language other than English at home, and 86% speak English as well. More than 50% have some higher education (St. Hill, 2003, p. 45). Higher education is expected, yet boys' education is given more attention. Arab cultures socialize women to be wives and mothers. Male circumcision is an Islamic practice followed throughout the Arab world and in Sudan and Egypt. Between 20% and 30% of Arab women marry by the age of 20, 80% by age 30. Arranged marriages are the norm; divorce is allowed but not expected (p. 50). Major illnesses experienced by the Arab American are hypertension, heart disease, cerebrovascular accidents, cancer, diabetes, renal disease, and anemia (p. 61). Obesity is prevalent in this culture.

Asian Americans make up another large population of people who settled in America:

The Chinese are the largest Asian subpopulation in the United States with more than 2.4 million persons of Chinese descent residing here in 2000. . . . The literacy rate is very high in China and education is compulsory. . . . Between 1970 and 1980, the number of Koreans in the United States increased from approximately 70,000 to 355,000. (St. Hill, 2003, pp. 93, 95, 202)

Getting settled in a new country causes loss of familiar work, caregiving activities, and lack of support in performing these roles. Many ethnic-minority women stand out because of clothes, accents, mannerisms, or responses. Often, they are reminded about their foreignness and lack of belonging, which tends to marginalize them and increase their vulnerability. Marginalized people react differently; their dress, language, religious practices, and food preferences vary from the norm. This group learns to be secretive and disclose personal information only to those they trust and feel safe around. Again, researchers have to take into account all of these factors when designing methods to discover information.

African Americans brought to America as slaves contribute now to the second-largest minority group in the United States. Currently, "54% live in the South, 19% in the Northeast, 19% in the Midwest, and 8% in the West totaling 36.4 million African Americans residing in the United States" (St. Hill, 2003, p. 12). Historically, African Americans in all areas of the United States have adapted to their environments and surroundings to survive. Family members look to other family members for guidance. High blood pressure, heart disease, and HIV/AIDS are dominant diseases, with lupus and breast cancer being prevalent in the female population as well. Due to previous injustices, some African Americans may not trust researchers. A degree of trust and respect would be necessary, as is the case for all groups researchers seek to study.

As several groups have been mentioned above, the area of health care is one that merits attention. For instance, the

way women interact in the health care system provides some insight into how a researcher would approach asking them questions. Existing models of women's health tend to neglect the integration between cultural values and norms that shape their responses and experiences. Various models exist, yet none are totally adequate. Both women and men are influenced by educational background, family, heritage, social class, economic factors, occupation and work, urban/rural origin, length of time in a new environment, and ethnic identity. People employ different cognitive styles, decision-making strategies, and health care providers. People who migrate from the same country share similar historical events, values, and norms based on their heritage. All of these factors are useful to assist researchers as they collect data on various subcultures and groups.

Comparison

Use in Cross-Cultural Disciplines

Whether researchers study individual cultures or evaluate changes in communities, the opportunity to study and analyze various populations is increasingly significant:

The applied anthropologist's effectiveness depends on his being able to obtain data from monitoring the adaptive changes taking place within the target population, and he must be able to model the relationships with the target population as it diverges from the larger community. Time sampling within the project, and between the project and the total community provide the applied anthropologist with the tools for the application of the comparative method to extract objective measures of change in both the project and its environment. (Hackenberg, 1985, pp. 218–219)

A new linkage of physical, biological and social science within the framework of a comprehensive theory of evolution is in the making. Specific hypotheses await the empirical testing at the sociocultural level, and the environment in which applied anthropologists are employed provides the opportunity. (Hackenberg, 1985, p. 222)

Structural changes are the essence of both economic and social development. (Higgins, 1977, pp. 121–122)

The real contradiction in anthropology is not concerning relevance—rather its relevance often serves the interest contrary to the people researchers are studying. Anthropological research in general is systematically shaped and utilized by the dominant interests in our society for ends which many anthropologist would oppose. (Stauder, 1974, p. 48)

Phenomenology is the study [of] independent existence through various participant observation-like methods, of the structures of the life-world, meaning the forms, structures or features that people take as objectively existing in the world as they shape their conduct upon the presumption of their prior independent existence. Phenomenology is the natural perspective for ethnographic research that would probe beneath the locally warranted definitions of a local culture to grasp the active foundations of its everyday reconstruction. (Katz & Csordas, 2003, p. 284)

In the discipline of history, Lepencies (1976) states that “more important than the emergence of new disciplines is the exchange of subdisciplines back and forth between established fields” (p. 287).

In the area of education, focus is given to anthropology and education, anthropology of education, anthropology in education, and the anthropology of education and social problems:

The ethnographer needs to be a sensitive and perspective observer, sympathetic, skeptical, objective, and inordinately curious. He needs to have substantial physical stamina, emotional stability, and personal flexibility. The ethnographer's approach should be holistic, meaning that one must take some view of the total situation, conceptualizing individuals in relationship to aspects of the physical environment, social organization, religion, world view, ideology, and evaluation. (Hill-Burnett, 1979, pp. 8–9)

Research is inductive, so ethnographers must be storytellers, keeping continuous diaries with consistent data collection procedures:

Key skills that are taught and refined in the study of anthropology are germane to the study of education. These include seeking multiple perspectives, rational speculation, dialogue, scientific inquiry, analytical reading, data collection, comparison and contrasting, testing hypotheses and applying theories. Attention is given to research methodology, logic and reasoning, detailed record keeping and clear thinking. Teaching of scientific inquiry therefore is significant when students learn to question circumstances and problems as they arise. Students need to learn that people and other ethnicities and cultures may bring different questions to a situation. (Birx, 2006, pp. 780–781)

John Dewey had a profound and lasting influence on the field of education: “Dewey favored practice over theory, based on his belief that learning best occurs when students are free to generate their own experiments, experiences, questions and creations” (Birx, 2006, p. 784). Emphasis on multiculturalism, hands-on learning, and participation in authentic learning experiences with real world audiences reflect the pedagogical contributions of Dewey. One of his most important works, *Human Nature and Conduct*, was published in 1922. According to Lev Vygotsky, a Russian psychologist,

Human intelligence is not a fixed characteristic, but instead it is a dynamic entity that can be enhanced by social interaction and collaborative work. He also believed that knowledge is not directly transferred from teacher to learner. Rather, through social interaction, the learner constructs his or her own meaning. (Birx, 2006, p. 784)

In the area of linguistics, Zetterberg (2006) has said that emic sentences are those that tell how the world is seen by particular people who live in it. Etic sentences contain additional information and sentences of an observer or

analyst rather than that of a mere participant. Etic observation may contradict truths believed by participants. Claude Lévi-Strauss commented that society was like language with structure.

Communicative actions such as descriptions, evaluations and prescriptions can be an initial phase of research. They can be used by biographers and psychologist, historians, sociologist or anthropologist. By a series of separate logical operations, the units of description, evaluation and prescription thus begin to define units of a society—not only attitudes, valuations, norms, but a host of other terms in the language of social science, such as positions, roles, organizations, networks, media, markets and firms. (Zetterberg, 2006, p. 250)

Thus, language helps to establish and stabilize any group of humans, community, or organization. On the human side, anthropologists were expected to learn the language of the people they studied rather than use interpreters.

In other areas of anthropology, Lévi-Strauss's program became the "normal science" for the discipline referred to as *structural anthropology*. He attempted to bring some order to the accumulated data on kinship relations in his 1949 text, *The Elementary Structures of Kinship*. Lévi-Strauss is remembered for his theory that "human culture is therefore like language in the sense that all human cultures satisfy the same basis needs, like eating or reproducing, but they do so in different ways" (Birx, 2006, p. 156). Structuralism purports that all human social behavior has symbolic meaning—not just at the superficial level of everyday appearance but at the deep level of underlying structure.

Clifford Geertz, the best-known theoretical anthropologist and ethnographer, has led discussions concerning objectivity in research and fieldwork. Geertz's book, *The Interpretation of Cultures*, is widely recognized as a major publication to consult on ethnographic research. "In anthropological discourse, the purpose of any given study is generally presented in the first paragraph, how that study plays itself out and proves or disproves its hypothesis is not" (Stockton, 2002, p. 1114).

An early contributor to the cross-cultural study of psychology was the anthropologist Bronislaw Malinowski, who did research in the South Pacific. Malinowski reached a conclusion that proved significant to other psychologists. His theory demonstrated that individual psychology depends on the sociocultural context in which it occurs. Yet anthropologists perform research in order to better analyze the actions of people in the larger community or society.

Previously, American anthropologists had used the term psychological to describe cultures considered synchronically rather than historically. After Sapir (1917), it became possible to think of cultures and person or dynamic psychologies together. As language differed, so did psychologies. It was Benjamin Lee Whorf who studied Edward

Sapir's theories and further developed these ideas. Sapir in his research was able to advance the goals of anthropology while instilling the connection with sociology and psychology. (Birx, 2006, p. 641)

Birx (2006) commented about economic anthropology, another of the cross-cultural disciplines:

[It] includes the examination of the economic relationships found among pre-capitalist societies (nonmarket economies) which includes band, village and peasant societies. This discipline studies the historical incorporation into the world market economy of state socialist economies of tribal peoples and peasant societies. Formal economics uses individual behaviors as its methodology. Cultural values are important in defining the standard of living. (p. 158)

The social interest of the whole must be used to justify the economy, including the systems of production, distribution, or exchange. All social relations within the economic system reflect a person's moral position within the community. Every step in the production process must meet some social claim to other members of the community. The social claims are the basis of the economic philosophy and the motivations around which people organize their labor. (p. 160)

Marxist and other substantivist anthropologists define economics as providing for the material necessities of life, while formal economics looks at economic choices in how societies and individuals invest their resources. Marxist economics concentrates on production, while formal and substantivist economics look at distribution as central to their studies. This allows a closer look at how anthropologists and economists can draw conclusions about people in different cultures based on respected economic theories:

In all material systems, humans face the practical choice between producing for the self and producing for the other. In the first case, material activities assume a reproductive pattern, and this supports group independence. In the second case, production is set within exchange: humans trade with others to secure needed and desired things. The first form may be termed community economy, the second is market economy. Real economies are complex, shifting combinations of the two, and humans often are pulled in both directions at once. (Kuper, 1996, p. 26)

Ethnographers have discovered that individuals trade within their communities based on their present need. As the need changes based on household, kinship, village, or other situations, the individuals adapts to the model that works for them and their families.

Cross-cultural studies have significant effects on the world of literature and humanities. Although the term *cross-cultural* was mostly used in the 1980s, there are writers that have used this concept in their works of earlier periods. When cross-cultural studies are used, the author is not merely writing about two different cultures. Cross-cultural

studies in literature are better understood when readers have some knowledge of the culture used:

In cross-cultural narratives, some elements that may be used are ethnographic description, travel writing, culture shock, acculturation and social obstacles such as discrimination, racism, prejudice, stereotypes and speech problems. The use of trickery, kindness, luck and hard work are all areas that might be included as the reader seeks to understand various characters in a discourse. (Glimpse Foundation, n.d.)

Future Directions

According to Hill-Burnett (1979), the future includes more global emphasis on research and development, development of a quantitative methodology to complement the qualitative methods. The future must address limits placed on educational process by political economy, dependency, and exploitation. The ethnography of communication provides bilingual and bicultural school programs when videotaping is used as a tool. This process provides a more exact means of collecting and evaluating data.

Great educators that look at all aspects of teaching in a critical manner help our students to understand different perspectives. As we continue to live on this earth, groups of people will combine ideas and principles. Educators will have to be ready to embrace and teach these changes:

An essential part of scientific procedure is the development of precisely defined concepts which together provide an internationally agreed upon frame of reference in terms of which the particular phenomena observed by different investigators may be described. Scientific progress is possible only because all the specialists in a given discipline use units of description that are commonly understood and have precisely defined meaning. (Leach, 1968, p. 339)

With the advent of professional associations to instill guidelines for the cross-cultural studies, researchers will more rapidly reach uniformity in methods of statistical analyses. Associations such as the Society for Cross-Cultural Research (www.sccr.org/description.html) can be consulted. That uniformity promotes acceptance of cultural research worldwide. Naroll, in a quality control study, listed the following six systematic biases. They are “scholarship of the ethnographer, native language familiarity, use of nonnative local resident helpers by ethnographers, the tendency of the ethnographer to make clear commitments, taking of ethnographic census by the ethnographer and ongoing ethnography as contrasted with its opposite, memory ethnography” (Thompson & Roper, 1980, p. 910). Overcoming obstacles such as poor sampling techniques and using multidimensional scales to test related hypotheses advances the future of cross-cultural studies.

Conclusion

A renewed look by societies and anthropologists has taken place. A greater understanding of using scientific methodologies to reach hypotheses and conclusions of cultures has surfaced in the dominant societies. Scientists in most disciplines will inordinately analyze information gathered on poor, indigent, primitive, preliterate, or just different groups of people in a more detailed and exact process.

Anthropological insights can be used to address numerous issues of today. Immigration, migration, education, ethnic relations, racism, and medical problems are better understood as scientists gather information on all cultures and make them accessible. From the earliest anthropologists to the contemporaries of today, the success of understanding and measuring the qualitative and quantitative differences and similarities of cultures all over the world are preeminent. Recognizing this need is paramount and continuous as our society expands.

TWIN STUDIES

GRETA G. BOERS

Duke University

Studying twins offers a unique opportunity to identify and differentiate physical and behavioral characteristics according to their origin. How much of who we are is genetically determined and how much is the result of our environment? By comparing the consistency of *phenotypes*, that is, observable physical and behavioral characteristics, in twins we can hypothesize about their heritability—whether or not a specific characteristic is genetically determined. Based on the assumption that all twins share their environment and that monozygotic twins also share genomes, phenotypes that vary between monozygotic twins must be the result of environmental factors, while those that are consistently the same must be genetic in origin.

Though they must be inextricably linked, there is a difference between research on twins and research that uses the twin studies method. The following chapter will follow both.

Sir Francis Galton: The Twin Study Method

Sir Francis Galton (1822–1911) was the first to articulate the value of twins to the nature-nurture debate. While his cousin, Charles Darwin, culminated his theory of natural selection in the 1850s, Galton was beginning to articulate his related theory of eugenics. By the beginning of the 20th century, eugenics was considered the new liberating science, promising to help control disease and improve the

quality of life. The reasoning was that if a species adapted through the process of natural selection, then it should be possible to control disease and other undesirable characteristics by intentional selection. Breeding in animals and plants had made successful contributions to agriculture; using carefully documented bloodlines among the nobility to identify marriage partners was an accepted cultural practice in Europe, the New World, and many other cultures. Deliberately manipulating reproduction was a recognizable and acceptable idea.

Galton argued that because of their observable similarities, twins were a primary source of data. In his 1876 article, “The History of Twins, as a Criterion of the Relative Powers of Nature and Nurture,” Galton pointed to the unique potential that twins offered to genetic research: “Their history affords means of distinguishing between the effects of tendencies received at birth, and of those that were imposed by the circumstances of their after lives; in other words, between the effects of nature and nurture” (p. 391). He coined the terms *identical* and *fraternal* to describe the degree of similarity between the twins.

Harris Hawthorne Wilder was the first to speculate that identical, fraternal, and conjoined twins originated at different points in the same process. Identical twins were the result of the egg splitting into two parts; fraternal twins were the result of fertilization of two separate eggs. Conjoined twins—unfortunately referred to as “double monsters” during that time—were part of the same process, but in those cases,

the splitting of the egg was incomplete (Wilder, 1904, p. 391). It was not until 1909, when Miguel Fernandez and in a separate study J. Thomas Patterson and H. H. Newman, that scientists were able to observe polyembryology in mammals—specifically armadillos—and to verify this developmental sequence from the point of conception to multiple fetuses to birth (Newman, 1941, pp. 102–103).

Research on Twins: Fetal Development

We now know that *monozygotic*, or identical, twins develop by the division of a single zygote over the first several weeks of pregnancy. *Dizygotic*, or fraternal, twins form at conception by the fertilization of two eggs by two sperm, so their genetic similarity to one another would be like that of any two singleton siblings. The rate of monozygotic twins is consistent, while dizygotic twins varies across ethnicities (Piontelli, 2002, pp. 14, 16). For example, 1 in 11 births in Nigeria are twins, but in Japan, the ratio is 1 for every 250 births (Hall, 2003, p. 735). Twin births are more likely in later pregnancies. Different cultural factors affect women's decisions to start their families later in life, but the trend is consistent across many countries and continents over the last century. In vitro fertilization and other fertility treatments have increased the incidence of twins as well as other multiples in populations where such technologies are used (Piontelli, 2002, p. 14). From 1980 to 2004, the twin birthrate rose by 70% (Martin et al., 2009, p. 2). In the United States in 2006, twins occurred with a frequency of 32 in every 1,000 live births. Almost all of the twins resulting from fertility treatments are dizygotic.

Medical research continues to illuminate the different phases of fetal development in twins and other multiples in order to anticipate attendant risks. In 1995 in the United States, the mortality rate of twins was 32 deaths for every 1,000 births; in the same year, the rate for singletons was 6 deaths for every 1,000 births (Parker, Schoendorf, & Kiely, 2001, p. 14). Approximately 8 out of 10 twin pregnancies are premature, and approximately half of all twins have a low birth weight—a major factor in infant mortality (Martin et al., 2009, pp. 10, 21). Some of these conditions further distinguish situational versus genetic factors, such as vulnerability to specific diseases, sleep-wake patterns in utero, and the complexities of twins and identity such as bonding and loss. Already, in the uterine environment, genetic predispositions and environmental chance begin to interweave.

Four major physiological considerations affect twin *parturition*: the time of division and the way that the amnion, chorion, and placenta are situated. There are four approximate phases over the first weeks of pregnancy that are significant: Days 1 through 4; 4 through 8; 8 through 14; and after the 14th day. The degree of genetic similarity, the particular risk factors, and the further development of the amnion, chorion, and placenta are determined by the day on which the zygote divides. The *amnion* is the inner

sac filled with fluid, which surrounds the fetus, protecting it and allowing movement. The *chorion* is a stronger sac that surrounds the amnion. The *placenta* is embedded in the uterus and is connected to the fetus via the umbilical cord and serves its circulatory system through the exchange of oxygen and carbon dioxide. It also provides nutrition and antibodies to the fetus from the mother. Dizygotic twins always have their own placentas, though sometimes monozygotic twins will share one.

Vanishing-Twin Syndrome

If division takes place during Days 1 through 4, then the two resulting fetuses will each develop its own amnion, chorion, and placenta. In Days 4 through 8, there is a higher likelihood that each twin will have a separate amnion and placenta but share one outer sac, the chorion. In these first two phases, the “vanishing twin” syndrome is possible in which one of the fetuses is absorbed by the mother, the uterus, or its twin. Researchers H. J. Landy and L. G. Keith (1998) estimated that approximately 30% of twin pregnancies are subject to the loss of one of the embryos, something scientists—and parents—weren't aware of until the 1980s when sonography made it possible to see them (pp. 181–182).

Twin-to-Twin Transfusion Syndrome

From Days 4 through 8, the probabilities lean toward two fetuses in one amnion, one chorion, and with one placenta. In Phases 2 through 3, twin-to-twin transfusion syndrome, or *fetofetal transfusion*, becomes a risk for monozygotic twins as the blood flow between the placenta and one twin affects the flow of those substances toward the other. As a result of this uneven flow of blood, oxygen, and nutrients, one twin may become anemic while the other becomes *polycythemic*—with too high a red blood cell count. There's also a danger that the one twin will be surrounded by too much amniotic fluid and the other not enough. The concern with *polyhydramnios*—too much amniotic fluid—is that the fetus has not absorbed enough. With *oligohydramnios*—too little—the fetus's kidneys may be adversely affected. Growth and development of the larger twin may continue to constrict in the available space of the smaller one, causing further developmental risks. Unless diagnosed within the first 15 weeks of pregnancy, mortality from fetofetal transfusion is approximately 80% to 100%. Also, twins who survive are at risk for immune problems. The more closely the twins are situated in one amnion or even one chorion, the more likely they are to be affected by each other's sleep-wake cycle and the subsequent separation after birth. The chance of tangling up in one another's umbilical cords and the developmental effects of constricted movement are also important factors.

Conjoined Twins

After Day 14, an incomplete division is probable—conjoined twins also share the uterine environment

completely. According to Lewis Spitz (2005), 60% of conjoined twins die during pregnancy or at birth; live births of conjoined twins approximate 1 for every 250,000 (p. 814). Most fetal deaths occur during the 1st trimester.

Such twins can be joined at a number of different locations. The most frequent fusions are *thoracopagus*, where the twins are joined at the chest, possibly sharing heart, liver, or intestines. Sharing the heart and cardiovascular system poses the greatest risk, which is why the mortality rate of thoracopagi is also highest. Other major organs can be shared. For example, the famous P. T. Barnum Siamese twins, Chang and Eng, were thoracopagus. After their deaths in 1874, it was discovered that they shared their liver. Though Eng was healthy, Chang's alcoholism contributed to his death. Additional complications occur when the thoracopagus are also *omphalopagus*—that is, joined at the umbilical region. Additional classifications in degree of frequency are *pygopagus*—joined at the surface close to the sacrum and coccyx either side by side or through the posterior. In those cases, the gastrointestinal and/or urinary tracts may be shared. Less frequent are *ischiopagus*, joined at the pelvis, and *craniopagus*, joined at the head.

Each pair of conjoined twins is fused in unique ways, sometimes symmetrically but not always. When the attachment has resulted in unequal fetal development, only one of the twins may survive birth or even the first days and weeks of life. In such cases, emergency separation surgery is required to rescue at least one but hopefully both of the twins. Such instances are not the only difficult decisions: Because the attachments are so unique, medical care, surgery, and survival must be determined individually. Fetal imaging makes early diagnosis possible. The sooner the degree and kind of fusions are determined, the more quickly decisions about abortion, separation, and medical care can be made.

Separation surgery excites the medical community, offering some of the most complicated surgical interventions, because there is relatively little similarity from one case to another. The different kinds of surgical interventions are common. The number of procedures strain the infants' bodies and the interdependence of biological systems that require the planning and performing of the surgery to be so exquisitely careful. In each case, a separate cadre of specialists are required. Each twin will need his or more frequently her (female conjoined twins have a frequency of 3 to 1 over male conjoined twins) own anesthesiologist and monitoring system. Former Surgeon General C. Everett Koop, famous for creating the first intensive-care pediatric-surgery unit, reported that it took 100 hours to plan, 4 hours of preoperative preparation, two surgical teams, 23 operating-room staff, and 10.5 hours of surgery to separate twins Clara and Alta at Children's Hospital of Philadelphia in 1974 (Children's Hospital of Philadelphia, 1974). The separation of Yurelia and Fiorella Rocha-Arias at Stanford University Hospital in 2007 took approximately 200 experts and cost between \$1 and \$2 million.

Separation surgery also excites a range of controversial ethical considerations. Alice Domurat Dreger (2004) argued that separation surgery is not always necessary but is chosen by the parents and doctors because they subscribe to socially defined expectations of normal appearance and identity (pp. 56–60). In contrast, in 2000, the parents of Maltese conjoined twins Jodie and Mary were ordered to submit their daughters to a sacrifice surgery. It was evident to physicians at St. Mary's Hospital in Manchester, England, that Mary was severely deformed and that she would prevent her sister's survival, as well as her own. As Roman Catholics, the parents believed that the death of the twins would be God's will. The High Court argued that Jodie's right to life was a higher consideration.

Theories in Twin Studies: An Overview

To understand the place of twin studies over time and across national and cultural boundaries, it helps to understand the philosophies driving the fashions in research focus and study design as well as the sociopolitical contexts that determined funding, support, and ethical standards of the research itself. What kind of research were twin studies used for? What are the experiences of twin studies' subjects in such research?

The theories that predominantly influenced twin studies during the 20th and the beginning of the 21st centuries are eugenics, phenogenetics, behaviorism, and genomics. A rough survey of their popularity breaks up into three time periods: from 1876, when Galton published his twin study method, to the end of World War I; from the end of World War I to the end of World War II; and from 1948, when B. F. Skinner published his theory of behaviorism, to 1985 when DNA "fingerprinting" made it possible to actually see twins' identical genomes.

Eugenics

Sir Francis Galton (1876) coined the term *eugenics*. It was his belief that scientists could breed a better kind of human, eliminating illness and disease by controlling reproduction. This required determining the heritability of specific characteristics. It would be over 100 years before this could be done by looking at the actual genome. Galton's solution to this mystery was to study the variability or consistency of characteristics in monozygotic and dizygotic twins and make generalizations based on statistical computations.

The eugenicist ambition troubles us today because of the corollary belief that there were inferior human "species" or races, a belief possible at a time when the mutability—the ability to change over generations—of all phenotypes was improperly understood. Human races were not really considered to be different species, but it was believed that they were differentiated by immutable characteristics, some of which were physically visible, such as skin color and hair

texture, while others such as moral propensities were not. The purpose of research was to determine how such characteristics were connected. For those who leaned heavily on nature as the determining influence in human destiny, the obvious step toward a new and “healthy” population was to control its evolution. Nationalism as a matter of collective identity would further magnify these theories in the social and political infrastructures of the early 20th century (Adams, Garland, & Weiss, 2005, p. 233). From today’s vantage, it can be surprising to see how pervasive and acceptable eugenics research, legislation, and mythology were in 20th-century life but then not so surprising that they came to be exploited.

The confusion about genetic versus environmental origins, which drove twin studies, had a long reach from science into politics even in the United States. The base for such research in the United States was the Eugenics Record Office (ERO) at Cold Spring Harbor, established in 1910. Charles B. Davenport created and then directed the ERO; his assistant, Harry H. Laughlin, a passionate leader in the eugenicist movement, initiated the Johnson-Reed Immigration Restriction Act, which was ratified in 1924. This federal legislation set quotas for “inferior” populations to control the number who entered the country, including people who were trying to escape the Holocaust during World War II (Adams et al., 2005, pp. 238–239). Sterilization of the “unfit” was common practice in the early 20th century in many countries, including Sweden, Norway, Canada, Denmark, and Germany. In the United States, the Supreme Court upheld the decision of *Buck v. Bell*, permitting the involuntary sterilization of Cary Buck in 1927. In the 1970s Iowa, North Carolina, and Oregon were still operating sterilization programs: “No revulsion against Nazi sterilization policy seems to have curtailed American sterilization programs” (Reilly, 1987, pp. 161, 167).

Phenogenetics

In Germany, as well as other countries, eugenics became institutionalized to a greater degree—resulting in the concept of *Rassenhygiene* or “racial hygiene,” that is, racial purity. Almost all of the political machinery during the Nazi era was tied up with this mission. The Kaiser Wilhelm Institute was established in Berlin in 1927, partly funded by the Rockefeller Foundation, which also supported the ERO in the United States. Among the many scientists, anthropologists, and researchers who worked there, Otmar Verschuer and Joseph Mengele were particular proponents of the twin study method for their research on heredity. Their object—and the object of most of the Nazi medical and biological scientists—was the opposite of Galton’s original idea. Instead of breeding out negative characteristics of a population through controlled reproduction, they wanted to identify and isolate specific, desirable “Aryan” phenotypes and breed them into the population. Increasing reproduction in the Aryan population

was a major effort of the Nazi regime. Phenogenetic research looked to link specific characteristics in physical appearance, intelligence, and abilities such as musical or mathematical talent to genetic material so that it could be manipulated. Most of this research was done in the concentration camps.

History’s description of Mengele is almost as disturbing for his reputed charm and popularity among the inmates as for his diabolical experiments. Mengele’s research used one twin as a control with the other as subject. His experiments included injecting bacteria, including typhus, into one twin while using the other as a control; injecting chemicals into subjects’ eyes to see if the color of the iris would change; surgically attaching (i.e., conjoining) identical twins to see if and how they would die (Lagnado & Dekel, 1992). Twin survivor Eva Mozez Kor describes entering Auschwitz-Birkenau at 10. She was injected with bacteria that made her so ill that Mengele refused her any medicine because he wanted her to die. Knowing that her twin Miriam would be put to death so that Mengele could compare their corpses, Eva focused on a determination to live (Hercules, Pugh, & Simpson, 2005). The experiments on Miriam Mozez affected the development of her kidneys and eventually caused her death—among the further difficulties of twins surviving Auschwitz-Birkenau was finding out what injections and substances they had been given. Much of the documentation was shoddy or lost. Because Mengele escaped before the doctor’s trial at Nuremberg, twin survivors of Mengele’s experiments finally gave public testimony at a substitute trial in 1985 at Yad Vashem, Israel’s memorial to the Holocaust.

Behaviorism

The tragedy of *entgrenzte Wissenschaft* or “morally transgressive science” continues to be the subject of historical research, anguished confession, and institutional and national reconciliation. Though the German phrase is generally associated with the Nazi era, scientific and moral transgressions continue to damage twin subjects—as with David Reimer, sexually reassigned as a girl, whereas his brother was raised as a boy.

The theory of behaviorism came almost like a backlash against eugenics. B. F. Skinner’s (1962) publication of *Walden Two* heralded a theory that attempted to liberate us from the hardwired-genetic preoccupation of scientists before and during World War II. Skinner was convinced that we developed our identity and much of our physical being in response to the environment; this argued that our development could be controlled by proper conditioning. Among the many mysteries of human experience, sexuality is also developed in a complex interrelationship between nature and nurture.

Its extreme was demonstrated by the tragic experience of David Reimer, a twin whose circumcision damaged his penis and whose parents were guided by Dr. John Money (1975),

a reputable sexologist at Johns Hopkins University. Money's research operated on the principle that gender and sexuality could be programmed. His advice was to have David sexually reassigned and raised as a girl while his brother continued his life as a boy (p. 66). Money's reasoning, like that of many physicians after him, was that the trauma of having a relatively small penis and of not being able to urinate standing up like other boys would be worse than the battery of surgeries, hormone injections, and behavioral modifications of transitioning into a girl. Ethicists like Dreger (2004), above, argue that this is a socially motivated decision based on rigid and unrealistic notions of "normal" genders. The similarity and contrast of the twins' experiences growing up rather proves that genes are fundamental to sexual identity, regardless of training, reinforcement, surgery, hormones, or therapy.

Money lost track of his subject after reporting that his transformation was a success (Colapinto, 1997; Money, 1975), and it was because of Money's reputed success that infant sexual reassignment became accepted practice throughout the 20th century. It was not until Drs. Milton Diamond and Kevin Sigmundson (1997) published their follow-up review that Money's fiasco became public. In the film, *Sex: Unknown* (2001), David Reimer begins to tear up as he says, "The medical community was under the impression that my case was a success story. And I was shocked when I heard that people thought that my case was a success story" (Cohen & Sweigart, 2001, film for television). This is an unusual example of the twin studies method since there are only two subjects—still, it proves the incontrovertible genetic factors that drive our gender identities and sexuality.

Genomics

The technology to "fingerprint" DNA was developed by 1985. Its effect on twin studies can be imagined as accessing the genetic material of subjects greatly amplifies the possibilities in nature-nurture research. How do researchers find twins for their studies? According to the journal *Twin Research and Human Genetics*, there are over 50 twin registries worldwide (Busjahn & Hur, 2006, p. 705). The Danish Twin Registry was established in 1954 and is the oldest national registry. In national twin registries, twins are identified through medical, school, and other available public documentation. In many other countries, for example, the United Kingdom, twins volunteer their participation in the registry.

An example of the kind of documentation now possible is the Biological Psychology Department of the Vrije Universiteit Amsterdam. The department has been maintaining a database of twins and their families, routinely collecting blood and urine samples over time and preserving the DNA in a biobank. Using both the kinship method and the ability to test hypotheses against biological samples from monozygotic and dizygotic twins, the scientists can track the genetic markers for phenotypes with far greater sophistication (Boomsma et al., 2006, p. 853).

Such studies, using registries all over the world, have illuminated the complex interactions of genetic and environmental factors in behavioral patterns, such as schizophrenia (Li, Sundquist, Hemminki, & Sundquist, 2009; Torrey, 1994), attention deficit disorder (Bennett et al., 2006), anxiety and depression (Hicks, DiRago, Iacono, & McGue, 2009; Wray et al., 2009), aggression (Brendgen et al., 2008), perfectionism and eating disorders (Tozzi et al., 2004) as well as drug use and alcoholism (Slutske et al., 2008; Whitfield et al., 2004). A cursory review of the medical literature proves the value of twin studies in determining heritability in a range of conditions including asthma (Thomsen, Ferreira, Kyvik, Fenger, & Backer, 2009), heart disease (Wienke, Holm, Skytthe, & Yashin, 2001; Zdravkovic et al., 2002), fertility (Kohler et al., 2006), osteoporosis (Tse, Macias, Meyer, & Hargens, 2009), obesity (Mustelin, Silventoinen, Pietilaenen, Rissanen, & Kaprio, 2009; Peeters et al., 2007), and immune function (de Craen et al., 2005). Infectious diseases are transmitted by germs in the environment, but susceptibility and the ability to heal also have genetic components (Jepson, 1998, p. 79). Longitudinal studies offer insight into physical and psychological development from infancy onward. As twin registries track the lives of their increasingly older subjects, we can identify and better understand the many factors that affect the health and happiness of the aged (Harvald et al., 2004, pp. 318–335).

Conclusion

In Plato's *Symposium*, several dinner guests are discussing love and its origins. When it is Aristophanes's turn to speak, he tells the story of how we were all originally made up of two heads, four legs, and four arms, each half facing outward. These were beings who created such havoc just trying to move around that Zeus lost his patience and cut them in half. This is why and how we love; each half-being is searching for his or her other, explained Aristophanes. Though Socrates naturally disabused him, Aristophanes's image may explain our fascination with duality, the "glamour" (as Alessandra Piontelli, 2002, described it) that twins so often carry with them as they move through their lives.

The whole of twins research and the twin studies method is centered on these mysteries of similarity and difference and by what magical combination of chance, genetic wiring, and nurturance they occur. By comparing these variations in large populations of twins, we can speculate and then prove whether a particular characteristic is genetic in origin. The twin studies method has untangled the biology and behavior of mental illnesses, such as schizophrenia, as well as pointed to the genes that may contribute to alcoholism, heart disease, or infectious diseases. As new technologies in fertility, cloning, and stem cell research develop, and as siblings become harvestable for

their cells and organs, the ethical conundrums identified in twins research may prompt the right kinds of questions about the experience of others in this new phase of science.

PART VII

TEMPORAL FRAMEWORKS

GEOLOGY AND ANTHROPOLOGY

RHONDA L. QUINN

Rutgers University and New York University

Geology plays a key role in the study of humans, particularly in the subdisciplines of paleoanthropology and archaeology. Anthropologists work closely with geologists and employ geological tools in order to reconstruct aspects of past environmental and ecological contexts from the time of our earliest human ancestors to that of modern peoples.

Extrinsic selective pressures, or those that are derived from a human's surrounding environment, are revealed through the study of the earth sciences. Anthropologists place the human individual, community, and population back into the environment and attempt to understand how humans interacted with that environment. From the origins of hominins, humans' bipedal ancestors, to the ascendancy of modern peoples, anthropologists want to know about temperature, aridity and rainfall, landforms, hydrology, and vegetation cover, among many other factors. From these basic environmental indicators, they surmise the kinds of habitats that may have been available and exploited by humans. Geological tools have also been applied directly to human skeletal and artifactual material or associated sediments in modern and ancient settings to address life-ways and determine age of deposits. One of the subdisciplines of geology, paleontology, is concerned with ancient life. Contexts of early humans also include coeval animals occupying the same territories and habitats or exploited as food sources by humans (see Chapter 41, this volume, "Paleontology and Anthropology").

Some researchers within the two disciplines assert that the relationship between anthropology and geology is a one-way street; that is, anthropologists use geological tools to address questions of the human condition, but anthropology does not offer anything to the study of geology. In that thread, this chapter recognizes the many geological methods as applied to anthropological questions can be observed as indeed one-way. However, implied in this chapter is how anthropology provides relevance to geological data. Certainly, geologists would like to know the history and mechanisms of the earth, but those ideas do not stop there. Geologists also couch that information in the economic, political, (pre)historical, and cultural contexts of humans, all of which are the purview of anthropology and other social sciences.

This chapter is by no means an exhaustive review of geological theory, methods, and applications to the study of humans. Rather it serves as a discussion of some geological tools commonly used to investigate some anthropological questions and suggests further readings.

An Anthropologist's Use of Geological Theory

Largely credited to the work of James Hutton, the theory of uniformitarianism, also known as actualism, holds that observable earth processes, such as erosion and deposition,

occur throughout geological time and are responsible for the landscapes, among other earth forms, present today. That is to say, “the present is the key to the past.” For instance, wind action along a shoreline slowly weathers fine sand grains and transports and deposits the grains in another location. Eventually, a new landform, such as a dune field, is constructed. Uniformitarianism is simplistic in that it evokes the most parsimonious explanations for past geologic phenomena.

Anthropologists using geological methods to reconstruct human environments also follow the theory of uniformitarianism. Archaeological and human paleontological sites are formed by human induced and *natural*, or nonhuman induced, geological processes. Unraveling where the two meet is essential for understanding how each site formed and aids in the interpretation of what the original environment when humans inhabited the site would have looked like. For example, some of the earliest stone tool use has been documented on the shores of Lake Turkana at archaeological sites of Koobi Fora in northern Kenya. These Late Stone Age sites contain fossil hominins, cut-marked fossil fauna, and stone tools, most of which are deposited in ancient river and lake deposits. Early interpretations painted a picture of hominins living along the lake margin, butchering animal carcasses with stone tools. Anthropologists hypothesized about small groups of nomadic hunters and gatherers using home bases nearly 2 million years ago (mya). Actualistic studies of stone tool and fossil transport in fluvial deposits, largely conducted by Glynn Isaac and his students, shed new light on these early human sites. These researchers found that geological processes, such as erosion and deposition, are also responsible for creating accumulations of artifacts and fossils, and therefore, not all of the so-called sites are the result of humans using home bases and discarding artifacts. Isaac went further to compare the “scatter-between-the-patches” and delineated natural background distribution of broken stone pieces from these clusters of human-made stone artifact assemblages.

Uniformitarianism, however, is used not only by anthropologists to frame the geological aspects of human environments. Actualistic studies have been widely used to interpret the human-induced processes. Lewis Binford proposed the application of middle range theory, first developed by Robert Merton, to archaeological problems. Middle range theory explains patterns of material remains preserved in the past with observable processes performed by humans in the present. These studies encompass such subfields as experimental archaeology and ethnoarchaeology. In one of the earliest Paleolithic experimental studies, Francois Bordes began fashioning his own stone tools from the same raw materials used by Pleistocene humans. He reconstructed each blow to rough rock form and made inferences about the thought processes and foresight that went into making such artifacts by human ancestors. Thus, he employed the dictum “the present is the key to the past”

and made analogies from his own toolmaking skills to those of extinct humans. Although Binford disagreed with Bordes’ interpretations of Neanderthal societies based on these experiments and suggested that Bordes look at modern human populations to gain insight into tool function, both anthropologists found explanations in the modern world to make inferences about the past. Zooarchaeologists also use actualistic studies to further interpretations of past human behaviors and lifeways. Robert Blumenschine observed carnivore activity on the savanna grasslands of the Serengeti Plains in order to interpret patterns of Plio-Pleistocene carnivore tooth marks preserved on herbivore skeletal remains at the early human site of Olduvai Gorge in Tanzania. From observable sequences of carnivore carcass access, he refuted models of hunting by early members of genus *Homo* and instead demonstrated the capacity for intense scavenging. In sum, anthropologists have adopted geological theory to frame questions about the context of humans as well as human lifeways.

Geological Methods in Anthropological Contexts

Anthropologists borrow many tools from the earth sciences to use in reconstructing the contexts of humans. Three sub-disciplines presented here are sedimentology, stratigraphy and dating methods, and stable isotope geochemistry. Broadly, these contexts incorporate aspects of time and environment.

Sedimentology

The vast majority of modern and fossil human remains over the past 8 million years of evolutionary time are preserved in sedimentary rocks, and thus, anthropologists working with the rock record study sedimentology to understand past and present human contexts. At outcrops, sedimentologists record information about the characteristics of sediments and sedimentary layers. These characteristics either are formed during the initial formation of the layers or may be secondarily altered after deposition. From this information, depositional environments are inferred, such as those produced by river, lake, wind, or soil processes. Traces of human occupation and activity are found in primary deposits and altered sediments.

Primary Sediments and Sedimentary Structures

Primary data collection of sediments and sedimentary rocks is a hierarchical framework from small to large divisions describing individual grains, layers, members, formations, and groups. For anthropologists studying archaeological or human paleontological sites, the scale of the investigation varies with what context questions are

being addressed. An archaeologist excavating early human sites with evidence of controlled fire, for instance, may be concerned with the sediments of individual hearths in one layer but also with multiple hearths in many layers across landscapes and possibly through time. Characteristics of grains and layers are discussed.

Sediments and sedimentary rocks are formed from the erosion and deposition of other rocks (igneous, metamorphic, or sedimentary) and sediments. The process is a recycling of older materials into new rocks. Characteristics of sedimentary rocks indicate aspects of the recycling history and tell a story of formation. Sedimentologists use characteristics such as grain size, grain composition and mineralogy, and grain angularity and roundness. Grain size and shape are derived from the manner of weathering and transport. For instance, the larger the grain, the stronger the medium in which it was transported. Wind is capable of transporting relatively small grains compared with water. Moreover, fast-moving water can transport larger grains than slow-moving water. Grain shape indicates how long a grain has been in the transport system. A well-rounded grain has likely traveled a longer distance than an angular grain; its roundness reflects how many times it has struck another grain or rolled on a river bottom. Composition and mineralogy indicate source material from which the grain originated.

Comparable grains with similar histories are segregated into mappable units called layers, or strata. Layer characteristics include thickness, color, fabric and structure, and grain sorting. Layer thickness represents a depositional history and indicates a relative amount of time required to build. Fabric is the manner in which grains are orientated and packed within a layer and indicates water or wind flow (current) direction or lack thereof. Grain sorting is a measure of how similar in size each grain is: A well-sorted layer is composed of the same-sized grains; a poorly sorted layer has many different sized grains. Sorting indicates consistency of transport velocity. Sedimentary structures refer to large-scale features and bedforms that reflect aspects of the depositional environments. There are numerous structures, most of which can be classified as bedding, stratification, and bed-plane markings. Bedding and stratification describe the shape of one layer relative to another and include cross-beds deposited at angles from a horizontal plane, parallel beds deposited along a horizontal plane, and massive bedding lacking structure. Ripple marks, or wave-formed sands like those along a near-shore ocean floor, are examples of bedding structures. These examples are forms of sedimentary deposition; however, erosional processes also produce bedforms. Scour marks and channels are missing pieces of sediment, but preservation of these forms indicates the presence of past environments. Bed-plane markings are typically formed on contact surfaces between two layers. As a grain or rock hits the bottom of a river bed, it produces bounce, roll, or skip marks, which are in turn filled by the deposition of the next layer. A mudcrack formed in the sun-dried

surface of an ancient lake bottom is an example of a bed-plane mark. Bed-plane marks are also produced by biologic processes and result in trace fossils, or ichnofossils. These include footprints, tracks, burrows, rhizoliths (root casts), and leaf imprints. Layer color is derived from grain composition and mineralogy or may be the result of diagenesis, or secondary alteration to the sediments after initial deposition. If groundwater bathes a layer of sand permeating into the spaces between each grain, chemical reactions between the water and elements in the grains may occur. Oxidation of iron, for instance, produces a reddish color on the surface of each grain and results in a layer color different from that indicated by grain composition.

Depositional Environments

Descriptions of individual grains and layers are used to infer the past environments in which they were deposited or formed. These environments include the physical, chemical, and biological conditions present during initial sediment deposition as well as those conditions that produce postdepositional (diagenetic) alteration. Sedimentary environments are typically interpreted by a method known as facies analysis. Facies analysis makes use of the relationship between observable environmental processes and their resulting sedimentary responses. Processes can be static or dynamic but typically result in predictable outcomes. Facies are a combination of layers with distinct lithological, structural, and biological properties that represent a defined environment. Facies are usually constructed from known sedimentary environments, thus evoking uniformitarianism, but also can be used to theoretically model environments that cannot be observed or are unknown in the present. Depending on the scale of investigation, facies associations are used to interpret large-scale environments, such as fluvial (river) or lacustrine (lake), deltaic or beach, desert or glacial, or small-scale subenvironments within each environment. For instance, within the fluvial setting, facies are used to distinguish between meandering or braided river systems. Ancient soils, or paleosols, represent another identified facies produced from postdepositional alteration of sediments. Recognizing these facies is critical to determining ancient land surfaces that may have been used by humans.

Stratigraphy and Dating Methods

Stratigraphy describes the relationship between strata and is primarily concerned with providing a temporal framework for events in earth's history. These techniques are essential for understanding the evolution of human ancestors and for examining modern human populations through time. The manner and timing of the formation of sedimentary rocks is explained by a few key stratigraphic principles largely credited to Nicolas Steno in the 17th century. The principle

of original horizontality states that sediments are initially laid down horizontally due to gravity. The principle of superposition describes deposition of layers in an upward sequence and thus represents the relative age of one rock layer to another. For example, the rock layer on top of a succession is relatively younger than the one(s) below it. Applying the principle of lateral continuity, Steno observed that these horizontal layers are continuous across the earth's surface unless disturbed. Sedimentologists and stratigraphers still employ Steno's principles to assign relative ages and to correlate strata. Dating methods are used to assign relative or numerical ages to sedimentary layers or the biotic materials preserved within and are commonly separated into two categories: relative and radiometric (absolute). Several dating methods are presented below that are commonly used in anthropological contexts.

Relative Dating Methods

Relative dating methods largely stem from the principle of superposition and thus do not yield numeric ages. Rather the methods give an "older than" or "younger than" tie point to compare one human archaeological or paleontological site with another. These methods all produce sequences of relative dating information that can be correlated to other locations or records with established numeric ages. As a result, these methods are commonly used in concert with radiometric dating techniques.

Biostratigraphy

Fossils preserved in sedimentary sequences can be used to assign relative ages if the fossil species is geographically widespread (i.e., laterally extensive) and tightly restricted in one or a few sedimentary units (i.e., temporally constrained). A fossil species that meets these criteria is termed an index fossil. One long sedimentary sequence with a fossil succession can be used to develop a stratigraphic chronology of fossil speciations and extinctions; thus, Fossil A is "older than" Fossil B. Fossil A found in other locations is equal to the time horizon preserved in the long sequence.

Dendrochronology

Trees in temperate conditions typically grow by annual increments with early and late forming woods (tree rings). These increments can be counted in cross section and used to estimate how many years the tree lived. As trees respond to varying climatic conditions, the increments wax and wane, and thus, a distinct pattern forms at particular times in the region. Coupled with radiometric methods or historical records, the patterns of numerous trees have been compiled to generate a long (banded) time sequence. Wood used by humans for building materials and preserved at archaeological sites can be analyzed for these tree rings and matched to a particular time.

Paleomagnetism

The present configuration of the earth's magnetic field is *normal* (indicated by a black strip on a rock), where the magnetic north pole is located at the geographic north pole. In earth's history, the magnetic field has collapsed and reformed in the opposite configuration, or *reversed* (white strip), such that the magnetic north pole is located at the geographic south pole. The orientation of the earth's magnetic field, either normal or reversed, is imprinted on those rocks and compact sediments with magnetic minerals at the time of formation. Sequences of rocks and sediments all over the world have been sampled in either discrete intervals (e.g., every meter) or cored continuously and analyzed for magnetic orientation, and they display a record of reversals. The result resembles tree rings as a banded pattern (white and black stripes), which can be matched to long paleomagnetic records of known radiometric ages. The phenomenon of magnetic reversals is global and therefore can be used everywhere an appropriate rock sequence is present.

Tephrochronology

Volcanic eruptions eject ash, pumice, and other products (collectively known as tephra) that can be chemically fingerprinted. The fingerprint is typically unique to a particular eruption of one volcanic edifice and therefore represents a particular time in earth's history. Tephra is characterized by major, minor, and trace (chemical) elemental and oxide abundances. Tephra layers represent synchronous units that can be traced laterally to compare archaeological and paleontological sites across landscapes.

Radiometric Dating Methods

Radiometric dating methods make use of the radioactive decay of chemical elements in various materials (e.g., bone, shell, minerals) to calculate the numeric age of human skeletons directly or to infer the age of humans associated with the measured material. Chemical systems used for dating are specific to time intervals because each chemical element decays at a particular rate. *Half-life* refers to the time required for half of a radiometric element (parent material) to decay to a daughter element.

Radiocarbon

The radioactive isotope of carbon (^{14}C) is found in several different kinds of organic materials (e.g., bone, wood, shell, paleosols) and thus is useful in many anthropological contexts. Living organisms incorporate ^{14}C into their tissues by physiologic processes, such as photosynthesis and respiration, in equilibrium with the atmosphere. When an organism dies, ^{14}C within its tissues is converted to nitrogen (^{14}N). Since ^{14}C decays to ^{14}N at a known constant (half-life: 5,370 years), time since death can be calculated by measuring the amount of ^{14}C remaining

relative to ^{14}N in preserved tissues. Due to the relatively short half-life, radiocarbon methods are applicable to time intervals younger than approximately 50,000 years ago.

Potassium-Argon and Argon-40/Argon-39

Radioactive potassium (^{40}K) decays to argon (^{40}Ar) at a relatively slow rate (half-life: 1.3 billion years), and therefore, the method is typically used to date human fossil contexts older than 100,000 years. This method is restricted to minerals that contain ample amounts of K (e.g., feldspar, sanidine) with negligible ^{40}Ar at the time of formation. Minerals are dated by measuring how much daughter product (^{40}Ar) has been produced by the decay of parent material (^{40}K). A slight variation on the method ($^{40}\text{Ar}/^{39}\text{Ar}$) uses a smaller amount of material and can measure single crystals. Anthropologists employ $^{40}\text{K}/^{40}\text{Ar}$ and $^{40}\text{Ar}/^{39}\text{Ar}$ to date rock and sediment layers associated with fossil materials rather than the fossils directly.

Uranium Series

Various daughter products of ^{235}U and ^{238}U with different decay constants are used to date materials (e.g., coral, enamel, mineral) spanning a few years to 350,000 years old. Uranium decay in equilibrium produces an amount of daughter product equal to that decayed from parent material. If the system is disturbed, the balance between parent and daughter material is offset, and thus, the time since disturbance can be calculated. The method requires that either (1) the measured material formed without prior parent product, or (2) the equilibrium of parent to daughter has been disturbed. With regard to the latter, the initial amount of parent and daughter must be known.

Luminescence

Luminescence refers to light emission by a mineral (e.g., quartz, feldspar) when heated (TL: thermoluminescence) or exposed to light (OSL: optically stimulated luminescence). The dating method requires that a material (e.g., bone, tooth, artifact) has been buried and thus not exposed to light and heat since that individual was alive or since the artifact was used. Burial exposes the material to radioactive elements contained within the sediments, which contributes free electrons to the material's crystal lattice. The amount of light emitted from the material represents burial duration. The method requires known or no residual luminescence from the time before burial and no disturbance since burial.

Stable Isotope Geochemistry

Using stable isotope geochemistry in anthropology rests on the principle that a human's skeleton and preserved soft

tissues represent aspects of the individual's life. In addition, geological materials preserved at an archaeological or human paleontological site (e.g., shell, soil carbonates, animal bone, and teeth) can be used to reconstruct portions of that past human environment.

Stable isotopes do not decay or decay so slowly that the process is undetectable in contrast to radiometric isotopes. Lighter isotopes of a single chemical element, or those with the lowest atomic masses, have higher kinetic energy and are readily incorporated into chemical reactions. The heavier isotopes of the same element, or those with the highest atomic masses, move more slowly and are less likely to be integrated into reactions. These elements behave predictably in nature, and thus, comparing ratios of heavy to light isotopes in different materials can be used to reconstruct environmental conditions. Stable isotopes are analyzed by mass spectrometry. Mass spectrometers have three primary components: ion source, magnet, and ion detector. Once the preparation systems convert the solids to gases, the gases are introduced into the ion source, which removes an electron and creates a positively charged ion. The ions are accelerated and directed along a flight tube toward the magnet. The magnetic field causes the ions to bend to varying degrees based on atomic mass. Detectors at the end of the flight tube count the number of ions of each atomic mass and charge number. These results are compared with a standard and the ratio of heavy to light elements is given in delta notation calculated by the equation $\delta^{18}\text{O}(\text{‰}) = \left(\frac{^{18}\text{O}/^{16}\text{O}_{\text{sample}}}{^{18}\text{O}/^{16}\text{O}_{\text{standard}}} - 1 \right) \times 1,000$, using oxygen as an example and reported in parts per thousand (per mil, ‰). Generally, three stable isotopic systems are employed to answer questions about past human lifeways: oxygen, carbon, and nitrogen, and more recently, trace isotopes, such as strontium.

Oxygen Isotopes

Oxygen, in the form of water, can be ingested and precipitated into tissues such as bone, enamel, and dentin. Oxygen can also be precipitated from water to form invertebrate shell material or carbonate nodules in soils. Oxygen isotopes are all incorporated into the skeletal material of organisms or soil carbonates according to the isotopes' relative abundances in the water source. Due to a greater mass difference, the ratio $^{18}\text{O}/^{16}\text{O}$ is measured and reported as $\delta^{18}\text{O}$ values. The differences in $\delta^{18}\text{O}$ values of water sources result from differential evaporation rates of the two isotopes. The lighter isotope, ^{16}O , is preferentially evaporated from water into the atmosphere resulting in an enrichment of the heavier isotope, ^{18}O , in the water. Water temperature also changes $\delta^{18}\text{O}$ values, and therefore, paleotemperatures can be estimated based on known relationships in biological tissues or soil carbonates formed in equilibrium with water. Oxygen isotope analysis detects systematic variation when individuals obtain water from different sources.

Carbon Isotopes

Carbon occurs in organic and inorganic phases of plant and animal tissue, and as carbonate in soils. In plants, carbon isotopes reflect one of three photosynthetic pathways: C_3 , C_4 , and crassulacean acid metabolism (CAM). C_3 plants use the Calvin-Benson (3-carbon) cycle and consist of trees, shrubs, and moist climate-adapted grasses. C_4 plants use the Hatch-Slack (4-carbon) cycle and include hot and dry climate-adapted grasses and marine vegetation. CAM plants switch from the 3- to 4-carbon cycle due to diurnal requirements and comprise the succulents. C_3 plants prefer the lighter isotope (^{12}C) and therefore have lower $^{13}C/^{12}C$ ratios or $\delta^{13}C$ values. C_4 plants do not discriminate between the two stable isotopes as strictly as C_3 plants, and as a result, have higher $\delta^{13}C$ values. CAM plants in effect display the full range of $\delta^{13}C$ variability. In an individual, carbon isotopic ratios represent the photosynthetic pathway of ingested plant material with additional fractionation, or change in isotopic ratio, by means of metabolic activity as the organism digests the plant material. For instance, an organism that consumes corn or other C_4 plants (e.g., sorghum, sugar cane, and tropical grasses) will have high $\delta^{13}C$ values, whereas one that eats C_3 plants (e.g., legumes, rice, wheat, trees and shrubs) will have low $\delta^{13}C$ values. Carbon isotopic analysis can also distinguish marine and terrestrial floral and faunal dietary sources. Marine sources yield similar ranges of $\delta^{13}C$ values to those of C_4 plants. It is important to note, however, that $\delta^{13}C$ values do not differentiate between an animal consuming plant material directly and a carnivore eating an herbivore that has consumed plant material. For this reason, carbon is a useful tool for reconstructing the ingestion of plant foods but lacks resolution in interpreting protein consumption.

Nitrogen Isotopes

Nitrogen is common in organic systems and provides trophic level information, and by extension, protein consumption. The lighter isotope (^{14}N) is more easily incorporated into metabolic processes, such as ammonia excretion, resulting in enrichment of organism tissue in ^{15}N . At the base of the food pyramid, nitrogen-fixing flora, such as legumes, are typically lower in ^{15}N . These and other primary producers supply herbivores with low starting $\delta^{15}N$ values, resulting in isotopic distinctions between herbivores feeding on legumes versus nonnitrogen fixers. As individuals consume protein, they incorporate the food $\delta^{15}N$ values, resulting in a stepwise function up trophic levels. Additional trophic spaces in marine ecosystems give rise to higher $\delta^{15}N$ values relative to terrestrial and freshwater ecosystems.

Strontium Isotopes

Strontium is a trace element found in numerous lithological and biological systems. Strontium isotopes are

heavy elements and cannot be discriminated by physiological processes. As a result, plants and animals incorporate strontium isotopic ratios ($^{87}Sr/^{86}Sr$) from the bedrock on which they obtain food and water. All isotopes of strontium are stable and do not undergo radioactive decay; however, ^{87}Sr is derived from the radioactive decay of ^{87}Rb . Since the abundance of nonradiogenic ^{86}Sr in a mineral does not change with time, $^{87}Sr/^{86}Sr$ ratios are determined by rock type and age. Old metamorphic rocks contain high ^{87}Rb concentrations and therefore have high $^{87}Sr/^{86}Sr$ ratios. Young volcanic rocks, on the other hand, have little ^{87}Rb and low $^{87}Sr/^{86}Sr$ ratios. Marine limestones reflect the $^{87}Sr/^{86}Sr$ composition of seawater at the time of formation.

Since strontium isotopes are indicators of where an individual obtained food and water, the method can be used to infer mobility and sedentism. In terrestrial ecosystems, $^{87}Sr/^{86}Sr$ ratios reflect the geologic substrate, or bedrock, from the landscape where plants and animals obtain nutrients. Soils and vegetation incorporate $^{87}Sr/^{86}Sr$ ratios from underlying bedrock. Ground and surface waters dissolve and integrate strontium from surrounding substrates, often mixing strontium from various sources. Organisms feeding on vegetation and drinking local water sources record bedrock $^{87}Sr/^{86}Sr$ ratios in oppositionally forming tissues, such as dental enamel and bone. Mammalian teeth are formed at different times in an individual's life, and therefore, several snapshots can be measured isotopically by sampling throughout the dental arcade and, more recently refined, by subsampling growth intervals of individual teeth. Place of origin and movement across bedrocks is then inferred by variable $^{87}Sr/^{86}Sr$ ratios sampled from teeth with different eruption times.

Geological Applications to Anthropological Questions

The geological methods presented above among many others have been used independently or in conjunction to answer critical anthropological questions and have expanded knowledge of the human lineage. As a result, many anthropologists have become experts in the various geological specialties and apply geological tools to modern and fossil human contexts with regularity.

Site Formation and Fossilization Processes

Human archaeological sites, whether they are composed of artifacts, ecofacts, structures, features, or skeletal material, typically involve or are preserved in the rock record. As Waters (1992) articulates, sediments and soils are the *matrix* of the archaeological site. Anthropologists apply principles of sedimentology and stratigraphy to unravel how humans used these sites in the past and how the sites in whole or in part changed through time until discovery. In the context of the site,

sedimentological information and facies associations are intertwined with human activities.

South African Cave Site Formation

From Raymond Dart's first discovery of *Australopithecus africanus* and recognition of its ancestry to humans, anthropologists made inferences of ancient lifeways, hunting capabilities, and history of violence. "Man the Hunter" was the prevailing view garnered from ethnographic studies of modern hunter-gatherer populations, which were constructed as a primitive society and a window into past human behavior. Cultural anthropologists have long since deconstructed these linear models of cultural evolution; however, geological applications by paleoanthropologists also aided in shifting paradigms. *Australopithecus* and other mammalian fossils excavated from cave deposits in South Africa were thought to be the result of interpersonal violence and hunting activities. C. K. Brain conducted detailed analyses of these cave layers using sedimentological and stratigraphic methods. He deciphered the timing of layer accumulations and found connections to surface processes. Brain reinterpreted the cave as a natural sink of bone accumulation rather than a home base used by early hominins. Moreover, based on his observations on modern leopard behavior (i.e., actualistic studies), he found that early humans were not violent hunters at all but just another mammal on the landscape hunted by saber-toothed cats.

Time Averaging of the Human Fossil Record

Similar to archaeological sites, the human fossil record forms by an interaction between geological and biological processes during formation and after deposition. Fossil accumulations represent a mixture of several time scales that culminate to produce a finite sedimentary unit. One fossil skeleton represents one individual with a particular life span, whereas a sedimentary layer full of many fossil skeletons may represent one coeval population, several generations, or more than one species. Paleoanthropologists separate these timescales with sedimentological and stratigraphic methods and actualistic studies of fossilization processes. Kay Behrensmeyer has verified *time averaging* within the human fossil record with modern studies in savanna environments in Amboseli National Park, Kenya. On her "bone-walks" she records the manner in which animal carcasses enter the fossil record and how fossilization processes vary significantly with respect to sedimentary matrices and geomorphological features.

Tempo of Human Evolution

Principles of stratigraphy and various dating methods provide the critical temporal framework for the origins and extinctions of modern humans and ancestral human

species. Early discoveries of primitive and derived human forms in stratigraphic sequence painted a broad-brushed picture of linear and gradual evolution. Over the past two decades, paleoanthropologists have demonstrated a more complicated and branching pattern of human evolution. Below are three examples of how geochronological data informed anthropological interpretation and overturned established paradigms.

Evolution of Early *Homo*

The rise of the human genus *Homo*, represented by fossil material discovered principally by the Leakey family in the Turkana Basin in Kenya and Olduvai Gorge in Tanzania, was long reconstructed as gradual and linear. *Homo habilis*, or handy man, dated to 2.5 million years ago (mya), was placed at the beginning of the human family tree. *H. habilis* possessed a slightly larger brain size compared with members of *Australopithecus*, and moreover, was associated with rudimentary stone tools. *Homo rudolfensis*, discovered on the shores of Lake Turkana (formerly Lake Rudolf), was dated to 1.9 mya and possessed a larger brain than *H. habilis*. In the same location, *Homo erectus* was discovered and dated to 1.8 mya. Corresponding with the model of linear evolution, *H. erectus* indeed showed a larger brain and body size than *H. rudolfensis*. Additional fossil finds led to morphological comparisons that indicated a complex pattern of speciation; however, the linear model persisted until recent years in the scientific community largely due to the handful of dates. Tephrochronological work in the Turkana Basin by Frank Brown and Craig Feibel and $^{40}\text{K}/^{40}\text{Ar}$ measurements by Ian MacDougall in the 1980s and 1990s provided a detailed sedimentological and stratigraphic framework for all paleontological collecting areas. In 2007, Fred Spoor and colleagues reported a new specimen of *Homo erectus* that predated the last appearance of *H. habilis* and *H. rudolfensis* in the region. Based on the established geochronology, early members of genus *Homo* are now interpreted to have lived during overlapping time periods. As a result, these species do not represent an ancestral line of humans, but rather sympatric species competing for resources.

Dispersal of *Homo erectus* From Africa

Anthropologists conceived early dispersal of *Homo erectus* from Africa to Asia as a technological advancement to new resources occurring only after the first appearance of the Acheulean tool kit. Even without numeric dates, researchers claimed that *H. erectus* did not inhabit Asia prior to 1 mya. In 1994, Carl Swisher and colleagues dated volcanic material associated with early *H. erectus* specimens (Mojokerto) by $^{39}\text{Ar}/^{40}\text{Ar}$ and paleomagnetic methods on the island of Java. Previous estimations placed *H. erectus* on Java by 500,000 years

ago; the new date, 1.8 mya, was significantly older and led to a controversy within the anthropological community. Many claimed that *H. erectus* was incapable of dispersing with only the primitive Oldawan tool kit. Others claimed the provenience of the hominin fossils was questionable. The dates remained debated until 2000 when *H. erectus* specimens were discovered in the Republic of Georgia and were dated by many geologists, including Swisher, by $^{39}\text{Ar}/^{40}\text{Ar}$, paleomagnetic, and biostratigraphic methods to be 1.7 million years old. Although some anthropologists remain skeptical about the plausibility of early dispersal, geochronological data provide evidence for an alternative view.

Rise and Longevity of *Homo floresiensis*

The 2003 discovery of the small human specimen on the island of Flores stunned the anthropological community, and researchers are still debating about if the finds represent a new species, *Homo floresiensis*, or a pathological individual. Anthropologists relied on geological tools to determine the context, age, and, possibly more important to the debate of new species or pathology, the longevity of the small-bodied forms. The most complete specimen of the so-called Flores hobbit was initially dated to 13,000 years ago by radiocarbon and luminescence methods. This date was surprising because it meant that these dwarfed individuals were coeval with normal-sized humans inhabiting the region and must have had watercraft/raft technologies. Another mandibular (jawbone) specimen was discovered showing the same unusually small proportions, but it was radiocarbon dated to 18,000 years ago. Overall, several specimens have been recovered and span the interval from 38,000 to 12,000 years ago. The debate over the identity of these dwarfed individuals continues, but because of geochronological evidence, anthropologists must incorporate thousands of years within their explanatory models.

Human Diet and Mobility

Stable isotope-geochemical methods revolutionized studies of human diet and mobility. Prior to these analyses, information about diet and movement was inferred from time averaged and taphonomically altered plant and faunal remains, artifact assemblages, and materials. Geochemical analyses of skeletal material provided an independent test of other methods, but moreover, offered diet and movement information about the individual. Over the last three decades, stable isotope analysis has been rigorously developed and has now become a standard measure of human materials from numerous archaeological and paleontological sites. Here are three examples of geochemical approaches to anthropological questions of diet and mobility.

Introduction of Corn to the New World

Age calculations of North American archaeological sites using radiocarbon methods assumed a constant ^{12}C and ^{13}C abundance in plant tissue; however, due to different photosynthetic pathways, dates on corn yielded systematic errors. Researchers realized that plants with different photosynthetic pathways are distinguished by stable carbon isotopes as discussed in the carbon isotope section above. It wasn't long before anthropologists applied these geochemical findings to questions about the origins of corn cultivation and spread throughout the New World. John Vogel and Nicholas van der Merwe (1977) isotopically analyzed human skeletons from New York State and demonstrated that "you are what you eat." Dale Hutchinson, Lynette Norr, and colleagues have documented the mosaic pattern of corn domestication in southeastern North America integrating skeletal indicators of health, disease, and pathology. These early investigations paved the way for numerous isotopic studies into diet and the rise of agriculture.

Early Hominin Diets and Mobility

Workers from the Light Stable Isotope Laboratory at the University of Cape Town, South Africa, obtained carbon and oxygen isotopic data from several fossil hominin specimens that indicate aspects of early diet and mobility. Matt Sponheimer and Julia Lee-Thorp found that *Australopithecus africanus* and *A. robustus* were encroaching on the more open habitats and may have subsisted on a mixed diet of vegetal matter and animal protein. Lee-Thorp and colleagues interpreted the close isotopic results of carnivore and hominin species indicating hominins as prey, although she demonstrated that saber-toothed cats might not have been the culprits as C. K. Brain initially thought. However, Lee-Thorp cautions that carbon isotopes alone may be insufficient in answering questions about trophic space. Andrew Sillen and colleagues applied strontium isotopes to determine mobility of *A. robustus* across the karst landscape of South Africa. Sillen and later Sponheimer found significant differences between male and female specimens, and those specimens suggest that robust australopithecines (paranthropines) may have had male dispersal patterns similar to that of modern gorillas.

Neanderthal Hunting and Mobility

Groups led by Herve Bocherens and Michael Richards have applied nitrogen, carbon, and strontium isotopic methods to well-preserved Neanderthal specimens from Europe. Although to date few individuals have been analyzed, these studies suggest that Neanderthals consumed high levels of herbivorous prey and may have traveled long distances to obtain dietary resources. Moreover, these dietary interpretations challenge the previous notion that Neanderthals were inefficient foragers and hunters.

Reconstructing Human Environments

Geological methods provide tools for reconstructing the environmental contexts of modern and extinct humans. As discussed above, excavation of archaeological sites involves geological expertise to infer site formation processes; however, geological tools can also be used to infer aspects of the surrounding local, regional, and global contexts with respect to climate, resource distribution, and geomorphology present during the humans' tenure. Two examples are presented that demonstrate how geological data were used to show the influence of the environment on human cultural and morphological change.

Drought and the Collapse of the Maya Civilization

In 1995, David Hodell, Jason Curtis, and Mark Brenner conducted oxygen isotopic analyses and mineralogical studies of lake cores from Central America and Haiti and reconstructed paleoclimate and paleoenvironmental conditions in these regions for the Holocene. The lake sediment records illustrated the gradual shift from cold and dry conditions from the start of the Holocene—coinciding with the last glacial period—to warm and wet conditions reaching a maximum between 7,000 and 4,000 years ago. They also detected a relatively small-scale dry phenomenon from roughly 2,000 to 3,000 years ago previously undetected by deep-sea core operations. At the height of the dry period, Hodell et al. reported a 200-year drought in the Yucatan Peninsula. Radiocarbon analysis of pollen showed that the drought temporally coincided with the collapse of the Maya civilization. Since that time, other researchers have found similar patterns of environmental change and drought. Although archaeologists disagree as to the ultimate cause(s) of societal collapse, the reconstructed context suggests that severe environmental conditions may have been a significant factor.

Grassland Spread and Early Human Evolution

Since Darwin first suggested grasslands played a key role in shaping human evolution, researchers have been drawing temporal associations between environmental change and the rise and extinction of hominins. Darwin explained increased range with living and evolving in open habitats. Paleoanthropologists proposed that hominins were arid-adapted species and took their beginnings in a savanna environment. Several researchers have linked climate to grassland spread to frame hominin adaptations including the rise of bipedality, dietary change, and technological advancements. Although the proposed hypotheses of adaptations involve complex interactions of the environment with behavioral and morphological underpinnings, they all rely on the presence of grasslands.

Evidence for grassland spread was largely determined by carbon and oxygen isotopic geochemistry by Thure Cerling and colleagues. Cerling and others documented a global shift in photosynthetic pathway from C_3 , used by many low- to midlatitude plants including grasses, to C_4 , used mostly by tropical grasses, beginning in the Miocene. Cerling and others isotopically analyzed suites of mammalian enamel and ancient soil carbonates from fossil-bearing sediments, and they reconstructed grassland versus woodland distribution in hominin environs. Evidence to date from many fossil hominin locales illustrates that grassland spread occurred in a mosaic pattern that is both temporally correlated and out of sync with hominin speciation and extinction events. Local and regional tectonic regimes, paleogeography, and paleohydrology, among other factors, rather than climate alone influenced the timing of grassland distribution.

Future Directions

The future likely holds a closer relationship between geology and anthropology, although possibly one where anthropology can be useful to geological pursuits rather than one that is strictly characterized by an anthropologist's use of geological tools. Two new directions are briefly mentioned here: The first illustrates a recent application of geological methods by forensic anthropologists, which has become a new and widespread undergraduate major in the United States. The second direction is how anthropological knowledge and tools may serve geological interests.

Forensic Geology

Geological tools have recently been applied to forensic anthropology and crime scene investigations. When human remains are discovered in sedimentological contexts (e.g., earthen burials), sediments and sedimentary features can prove useful to determine manner and timing of deposition. Recently, stable isotopic methods have been applied to individuate unidentified human remains. Strontium isotopes, in particular, identify a person's place of origin based on geologic bedrock.

Impact of Climate Change on Humans

Departments of earth sciences have become increasingly invested in studying past global climate in order to predict how and when global climate change will affect humans in the future. Geologists are commonly asked to weigh in on political and social decisions about global warming. Anthropology has much to offer geology with respect to perspective, information, and methods in both living and past human groups that can be used to address how climate (and environmental) change will impact humans today.

Conclusion

Methods from the field of geology are critical to advancing understanding of human lifeways and evolution in the past and present. Geology's theory of uniformitarianism has shaped anthropology's use of actualistic studies and the development of archaeology's middle range theory. Sedimentology offers tools to infer site formation and fossilization processes. Stratigraphy and dating methods provide the temporal framework for the human lineage from the earliest members to yesterday's cultures. Over the past three decades, stable isotope geochemistry has been applied to anthropological questions of diet and subsistence, mobility and sedentism, and environmental influences on speciation and extinction.

PALEONTOLOGY AND ANTHROPOLOGY

KRIS “FIRE” KOVAROVIC

University College London

To anyone with a rudimentary understanding of paleontology and anthropology, it may not be readily apparent that these disciplines can be in any way related to one another or useful in informing the other's primary interests. Anthropology, broadly speaking, is concerned with the study of human culture and behavior, with data provided directly by investigations of modern human populations, as well as historical and ethnographic texts and objects. Paleontology, however, is the investigation of the history of fossil flora and fauna and is, as such, allied closely with geological sciences.

Despite what may appear to be two entirely separate and unrelated forms of study, both are united in their multidisciplinary nature, rigorous comparative methodologies, and crucially, an emphasis on context. An object is more meaningful when one grasps the variety of cultural, historical, and geographical contexts of the object itself. Likewise, the context of a fossil discovery can tell us a great deal about how old it is and under what circumstances the organism lived, died, and was deposited. Aside from simply sharing a context-based interpretive framework, where the two disciplines meet, there is a unique branch of biological anthropology known as *paleoanthropology*. Like the straightforward combination of their individual names, this subdiscipline is a straightforward combination of the essence of both paleontology (fossil life-forms over time) and anthropology (human behavior and culture), resulting in the study of the evolution of the

biology, behavior, and culture of humans and our hominin ancestors in the past several million years.

We modern humans, *Homo sapiens*, are primates. We are the only living member of Hominini (the group to which all human ancestors belong), and the only living member of our genus *Homo*, but this was not always the case. Like many of the living, or *extant*, nonhuman primates (e.g., the great apes, Old World monkeys, New World monkeys, etc.), our hominin ancestors frequently lived during the same time periods and sometimes in the same geographical regions as closely related species. The majority of accumulated evidence suggests that our ancestors diverged from chimpanzees between 5 and 7 million years ago (henceforth referred to as mya, and thousands of years ago as kya). The story of how this hominin *clade* (a group of related species that has the same common ancestor) evolved, subdividing into a number of lineages on the human family tree during the past several million years but now represented solely by *H. sapiens*, is what paleoanthropology seeks to understand.

Fossil evidence constitutes a major aspect of our quest to make sense of our complex evolutionary history. Prior to the earliest evidence for stone tools—found in an area of Ethiopia known as Gona and dated from approximately 2.5 to 2.6 mya—our prehistoric ancestors leave us no evidence other than their fossilized remains (Semaw et al., 1997). After this time period, stone artifacts become critically important and comprise yet another major component

of paleoanthropological investigations. Archaeologists who examine the material culture of hominins rely in particular on their stone tools, in the discipline known as *lithics*, and on the remains of other mammals living at the same time. We can glean a great deal about hominin behavior from the differences in lithic industries across time and space, and the marks left by teeth and tools on fossilized bones of other mammals provide evidence of hominin dietary adaptations and the ways in which meat resources were acquired and processed. There are many more sources of evidence included in the paleoanthropological repertoire as well, such as investigations of living primate behavior and molecular studies.

This chapter will focus primarily on the mammalian fossil evidence for hominin evolution. The dental and skeletal features of hominins and nonhominin mammals can tell us a great deal about the evolutionary relationships of the different species as well as how they moved, what they ate, and the types of habitats to which they were best adapted. You will be presented first with background theory in paleontology and ecology focusing on the ways in which fossils can be analyzed and interpreted, and this will be followed by brief summaries of the hominin fossil species known from the major phases in hominin evolution. Emphasis will be placed on Late Miocene through Plio-Pleistocene hominins because at this stage in evolution the fossil evidence is critical as there are fewer archaeological traces compared with more recent stages of evolution where this type of evidence becomes equally important.

Fossils, Depositional Context, and Taphonomic History

Major paleoanthropological fossil finds are rare, and they are often celebrated scientific events. It is not unknown for the discovery of one fossil to radically alter the way in which we understand hominin relationships or the behavior of a particular species. Therefore, it is important to understand what a fossil is, how it is created, and what happens between the death of the organism and its subsequent discovery by field researchers.

A fossil can be simply defined as the remains or traces (such as animal tracks or the imprint of a fern) of a once living organism. In the case of skeletal elements and teeth, which are particularly interesting to paleoanthropologists, they are buried and mineralized in a long process during which minerals present in the sediments replace the hard tissue. It is extremely rare for the remains of soft tissues, such as muscles, skin or hair, to be preserved in the fossil record. For fossilization to occur, skeletal material must be buried quickly. When subjected to a lengthy period of exposure on the land surface, the material may become badly weathered or damaged. Thus, a quick process of deposition, which favors

fossilization, increases the likelihood that an element will survive in a more complete form that ultimately preserves more information for scientists analyzing the material.

Because of this, we can say that the fossil record is biased. If only particular conditions favor the fossilization of bone, then there must be many more bones that are not deposited in such conditions and will never make it into the fossil record. In fact, there are a number of factors that influence a bone's entry into the record; some of these are geological and others biological. Paleoanthropologists must therefore examine the possibility that any one or a combination of these factors influenced the history—and subsequent interpretation—of a particular fossil. The history of a fossil from its deposition to discovery is what is known as *taphonomy*.

As described above, the depositional contexts that favor the preservation of fossils are ones in which sediments accumulate quickly. Lakes, rivers, and seasonal floodplains provide excellent conditions for fossilization; mammals frequently gather at water sources, and if their remains are deposited there, they can be quickly buried by silts that accumulate rapidly as compared with the soils that accumulate on dry land surfaces. Lacustrine (i.e., lake) and riverine deposits are common in the fossil record, but while both are formed through the action of water, they are distinctive depositional contexts that can be identified by their unique signatures in the sedimentary record. There is a wide body of taphonomic literature pertaining to the effects of water movement on the transport and damage of bones in modern environments (e.g., Behrensmeier & Dechant Boaz, 1990), which can be useful analogues when we interpret the depositional context of fossil sites. Bones that have been moved by the flow of water are often abraded, and indeed, we can see this type of damage in a number of assemblages. The speed of the water is also a factor; rapidly moving water will transport bones differentially according to size, moving light bones and those with a large surface area a greater distance than denser elements. Low-energy water contexts, such as lakes, will result in different patterns of accumulation.

Volcanic sediments also preserve fossil remains. Ash is particularly good at preserving the tracks of mammals such as the deposits from 3.7 mya at Laetoli, Tanzania, where hominin footprints were discovered (Leakey & Hay, 1979), and both ash and lava rapidly bury living organisms, capturing a picture of the living community in a fairly short period of time in one geological stratum. In addition, volcanic deposits can not only be traced back to the source volcano but also often be dated with a high degree of precision. The issue of dating is a critical one in paleoanthropology because without sound dates associated with particular fossil finds, it is difficult to interpret the evolutionary relationships of the different species represented in the record. Finally, cave deposits also preserve fossil remains. Bones may accumulate through the activity of carnivores dragging in their prey, mammals simply

falling in and becoming trapped, or even water washing remains inside. The stratigraphy of cave deposits is often quite complicated, and the deposits themselves, often hard, cementlike *breccias*, can be difficult to excavate.

The depositional contexts described above have a significant impact on the fossil assemblage that is eventually uncovered. However, these geological factors are not the only taphonomic forces at work. We must also take into account certain ecological and biological conditions. Consider what the entire mammal community, or *living assemblage*, of an African bushland or European forest would look like. There would be many different species present, and they would represent different body sizes from the smallest of rodents to the largest quadrupedal mammals. They would live in all manner of physical spaces present in their habitat including underground, in the trees, on rocky outcrops, or simply on the land surface. They would also consume a variety of dietary resources from herbs, grasses, leaves, and fruit to insects and other animals.

The relationships of the different species with each other and to their ecological niches will also have an effect on what the *death assemblage*, or the bones of dead organisms in a natural environment, looks like. Carnivorous mammals, reptiles, and birds prey on other animals. As a general rule of thumb, smaller carnivores prey on smaller species, and the remains of their meals look quite different from the remains of the meals of larger carnivores. Small-prey remains might accumulate in dens or other sheltered places as well as being found in the fecal matter of their predators such as in hyena droppings or in regurgitated owl pellets. Larger carnivores, like bears or leopards, may also retreat into caves or trees before consuming their prey. Once the primary, large predator has had its fill of a carcass, other carnivores will often attempt to displace the original predators or wait until the original predators have left the carcass alone so that they may consume the remaining meaty portions of the skeleton. Some carnivores, like hyenas, are specifically adapted to crushing and breaking open bones where marrow may be accessed. Several carnivore species may contribute to the destruction of one carcass, and at some point in the past, hominins entered this process when they left their purely vegetarian-based diet behind them.

In addition to the effects of meat consumption by various predators, if the bones of a dead animal are not transported or buried rapidly, they are subjected to the general effects of exposure, insect activity, damage caused by growing vegetation, or trampling by other mammals. All factors considered, only a small fraction of the living community survives the process of deposition and fossilization, and an even smaller proportion survives without significant breakage or damage. Of course, fossils are only of any use to us when they have been naturally exposed and discovered or intentionally excavated by scientists capable of identifying and analyzing them. These remains, after a long journey from living animal to

deposited bone to fossil specimen, constitute the final *fossil assemblage*, the remit of paleontologists.

Fossil Mammals: A Useful Paleanthropological Tool

The fossil record of interest to paleoanthropologists is not limited to hominins, and in fact, many other families of mammals far outnumber hominin remains. Nonhominin remains are informative: They can tell us about the nature and overall composition of the once-living community, the relationship between hominins and contemporaneous species and the dominant habitat where the community lived, and where hominins were evolving.

There are many ways to examine and interpret the non-hominin mammalian community. In particular, mammals can provide clues as to the characteristics of the habitats where hominins were known to live. It can be as simple as noting the presence or absence of a particular species that is believed to indicate specific conditions. For instance, the presence of a hippopotamus species, such as the extinct *Hippopotamus aethiopicus*, would signify that a permanent water source was in the area in the past. However, these so-called *indicator species* are not always such reliable sources of information. We know that the fossil record can be biased, so in fact, the absence of a particular species in the fossil record does not necessarily mean that it was not present in the past. In addition, we cannot assume that the behavior that we observe in modern mammals is the same behavior that they or their ancestors exhibited in the past.

A much more useful analytical approach to mammalian fauna is an assessment of the *functional morphology* of the skeletal and dental remains, which is an investigation of the relationship between specific morphologies and the functions for which they are best adapted. This approach is neatly grounded in Darwinian evolutionary and ecological theory. Animals have evolved specific adaptations that allow them to efficiently exploit—and thus survive in—their natural habitats. Within any environment there are many niches that the animals can occupy. Living spaces can be under- or aboveground, in the trees, and so on, and this is known as the *spatial niche*. Long bones, such as a femur (upper leg) or humerus (upper arm), will tell us about the kind of environment that an animal was adapted for moving around in or what form of locomotion it used. The *trophic niche* refers to food resources that are exploited. Fossil dentition will tell us primarily about the diet of an individual because there are certain types of teeth that are best for consuming the meaty flesh of prey animals, crushing insects, shearing leaves, and so on.

Recall the earlier examples of an African bushland or European forest. Both habitats provide a diversity of niches. However, the types of niches will be dictated by the specific habitat. Arboreal animals that live in the tree canopy and

those that eat leaves and fruits are abundant in forested habitats where there are plenty of trees. Bushland will support a different array of animals, ones that rely less on trees and more on shrubs, bushes, and grass cover. So by analyzing how an entire fossil community occupied available ecological niches, we can develop a picture of what the overall habitat was like. This is known as an *ecological diversity analysis* (i.e., Andrews, Lord, & Nesbit Evans, 1979), in which each species that is identified at a fossil site is categorized according to its dietary and locomotor adaptations on the basis of its skeletal and dental functional morphologies. This technique has been successfully applied to a number of important sites where hominins were present (Andrews & Humphrey, 1999; Kovarovic, Andrews, & Aiello, 2002; Reed, 1997), and despite taphonomic biases in the fossil record that inevitably result in the differential loss of particular species, it is possible to identify sites that were heavily wooded, those that were more open, and those that possessed sources of water.

One way to address the taphonomic underrepresentation of certain species in a fossil community is to focus on just one family of mammals that might be less biased in the fossil record or where the bias is better understood. For instance, small species may be transported great distances and/or damaged before deposition and, in the past, were often passed over in favor of collection strategies that focused on large-bodied mammals, which not only are abundant in the fossil record but are now well represented in paleontological collections. Primates, suids (pigs and related species), and bovids (antelopes and related species) are all examples of diverse, larger-bodied families that have been subject to functional morphological analyses attempting to reconstruct past habitats. When we consider functional morphologies specifically in relation to the exploitation of particular habitat types, we refer to this as the study of mammalian *ecomorphology*.

A classic example of a well-known ecomorphology is the head of the femur of bovids (Kappelman, 1988). The femur articulates with the pelvis and comprises the hip joint, which is relevant to locomotion. In bovids inhabiting more forested habitats or habitats where a high level of maneuverability is required in order to negotiate obstacles, the head of the bovid femur is round. Bovid living in open habitats must be able to run far and fast to escape predators, and they possess a more cylindrical-shaped femoral head, the biomechanics of which relate to efficient running. Knowing this fact, we can look in the fossil record and analyze the bovid femora that we find at individual sites to determine if the bovid community was better adapted for running in open or closed habitats, thus providing a picture of what the dominant habitat was likely to have been. Analyses of fossil bovid femora have been successful at reconstructing the habitats at the important sites of Olduvai, Tanzania, and Koobi Fora, Kenya, where early hominins are known. Other skeletal elements are also useful in ecomorphological analyses including the metapodials

(Plummer & Bishop, 1994), astragalus (DeGusta & Vrba, 2003), and phalanges (DeGusta & Vrba, 2005); in addition, one can conduct an ecomorphological survey of the entire bovid skeleton rather than rely entirely on one element (Kovarovic & Andrews, 2007).

Fossil mammals are useful in other ways besides habitat reconstruction. In many circumstances, geological strata cannot be absolutely dated; therefore, relative dating techniques must be applied. One approach is to use fossil mammals in constructing a *biochronology* of a region, sometimes called *faunal correlation*. Where particular families of mammals are diverse and abundant and we know the dates of each species's first and last appearance in the fossil record, we can use them as a framework for understanding the time period over which the deposition of a site is likely to have occurred. This is often the first way in which sites are dated, and many families of mammals are considered, especially Suidae (pigs). For example, we know that the fossil species *Kolpochoerus limnetes* evolved at approximately 3 mya and persisted for one million years. *Nyanzachoerus jaegeri*, a species that is part of a different suid lineage, is present in the fossil record from approximately 4.8 to 3.6 mya. Therefore, where we find *K. limnetes* present in a fossil assemblage, we can infer that the site is younger than a site where we find *N. jaegeri*. If an assemblage has more than one pig present, this can help us pinpoint a more specific time period if we know when these species overlapped.

There are, of course, other ways in which mammalian fossils can be informative, including methods such as isotopic studies of tooth enamel that give us an idea of what sort of vegetation an individual was eating and therefore was present in its natural habitat (e.g., Sponheimer & Lee-Thorp, 2003). Skeletal remains also provide us with more direct evidence of human behavior by preserving on their surface the tooth marks left by carnivores and cut-marks left by lithic tools (e.g., Potts & Shipman, 1981). The placement of these two types of marks on the bones can tell us about the order in which the different carnivores—including hominins—were procuring meat-based resources, and that, in turn, tells us about hominin scavenging and hunting strategies and the context of the evolution of meat-eating. The paleoanthropological value of fossil mammals cannot be overestimated. One should also not forget that hominins, as mammals, may be approached using some of the techniques outlined above.

Distinguishing the Hominin Lineage: Early Fossil Evidence From Africa

Prior to the first hominin dispersals out of Africa around 2 mya, our evolutionary history is confined to this continent. The environmental and geological conditions in eastern and southern Africa favored the preservation of fossils, and this is where we find the majority of relevant sites; in

southern Africa, they are primarily cave sites, while in East Africa they are open-air sites, many of which are in the Rift Valley System. The first phase of hominin evolution began in the Late Miocene, a time period that ends approximately 5.2 mya, so to investigate our earliest evolutionary developments, we would look to Late Miocene sediments for evidence of the first species that diverged from the common ancestor with the chimpanzees. Unfortunately, evidence for the earliest stages of these lineages or the probable first hominins is rare. The lack of a good fossil record at this time is compounded by the fact that regardless of the number of fossils available, it is difficult to identify individual species in the past. Zoologists have extra information when they work with populations of modern organisms: Things that do not fossilize, such as fur color, behavior, vocalizations, and DNA, can all be used to distinguish between taxa. Paleoanthropologists have only fossil hominin remains for identifying the different species and determining their evolutionary, or *phylogenetic*, relatedness. They do this through an assessment of shared morphological features, or characters, and the amount of variation displayed within each character that is considered acceptable within a single species.

Features that are understood to define the hominin lineage include bipedal locomotion, smaller canine teeth, and increased brain size, among many others. While these features may be obvious at later stages of evolution, it is not known how they would be represented by the first hominins. There are three recently announced species that are generally considered viable candidates for the earliest hominin. The oldest is *Sahelanthropus tchadensis*, which includes a well-preserved skull, fragments of mandible, and teeth, discovered in Chad (Brunet et al., 2002, 2005). Associated mammalian fossils infer that the region was moist with permanent water sources and heavily wooded, and recent research dates the finds from 6.8 to 7.2 mya (Lebatard et al., 2008). In addition to the early age and habitat, its location in north-central Africa, where hominins are infrequently discovered, makes it a unique species. But is it hominin? It possesses a mix of anatomical features that are considered *primitive* (i.e., apelike) and *derived* (unique evolved characters). Its brain size was small like those of apes, and some aspects of the teeth are also considered primitive; however, the canines are reduced in size, and perhaps more importantly, there is evidence that the species could have been bipedal. Its *foramen magnum*, the hole at the base of the skull through which the spinal column enters, is located directly beneath the skull in a more forward position. This positioning indicates that the head of the individual was placed directly on the top of the body inferring an upright, or bipedal, posture. This is in contrast to apes where the foramen magnum is located toward the back of the skull. The discoverers of *S. tchadensis* and many other researchers propose that this species is an early hominin situated close to the chimp-hominin split.

The next oldest Late Miocene species, *Orrorin tugenensis*, is known from only a handful of postcranial and a few

dental remains discovered in the Tugen Hills in Kenya. The deposits have been absolutely dated to between 6.2 and 5.6 mya, corroborated by mammalian biochronology (Senut & Pickford, 2001). The material is fragmentary, and there is much controversy over its interpretation. The scientists who uncovered the specimens claim that they clearly represent a bipedal hominin (Galik et al., 2004; Senut et al., 2001) but one that is more directly related to the *Homo* lineage as opposed to other species within the genus *Australopithecus* (who you will read about later) that are present in the Pliocene (5.2–1.8 mya). Many critics agree with the overall conclusion regarding its bipedality but disagree with the particular functional morphologies on which they focused their analysis and from which they drew their conclusions regarding its evolutionary relationship to other hominins. A recent and comprehensive analysis shows a reinterpretation of the morphology of the *Orrorin* femora and a conclusion that the species was certainly bipedal but did in fact resemble later Pliocene species and not *Homo* (Richmond & Jungers, 2008).

Straddling the Miocene-Pliocene boundary is the genus *Ardipithecus*. It is considered by many to contain two species separated by approximately 700,000 years. Both are found in the Afar region of Ethiopia, *Ardipithecus kadabba* from 5.7 to 5.2 mya and *Ardipithecus ramidus* from 4.5 to possibly 4 mya. *A. ramidus* was discovered first and *A. kadabba* after that, but it was initially described as a subspecies of *A. ramidus* (Haile-Selassie, 2001; Haile-Selassie, Suwa, & White, 2004; White, Suwa, & Asfaw, 1995; WoldeGabriel et al., 1994). Its discoverers eventually decided that the variation observed in the combined material as well as the time between the two major collections warranted separate species distinctions. *A. kadabba* appears more primitive, with larger, more apelike canines, but both species are, like *Sahelanthropus* and *Orrorin*, a mixture of apelike and hominin-like morphologies. The strongest evidence for the hominin status of *A. ramidus* is the position of its foramen magnum, which is forward placed on the base of the skull. Isotope analyses of fossil nonhominin teeth and the ecological diversity of the mammalian fauna indicate that both species inhabited a mosaic of woodland and open cover, grass-dominated habitats with ample water sources (Levin, Simpson, Quade, Cerling, & Frost, 2008; WoldeGabriel et al., 1994).

Established in Africa: Diversification of the Plio-Pleistocene Hominin Lineages

The number of fossils recovered from African sediments of the Pliocene (5.2–1.8 mya) and Pleistocene (1.8 mya–10,000 years ago) from approximately 4 mya onward can be considered a veritable explosion compared with the Late Miocene material. Some hominin species from this time period are better known than others, and naturally, there are many debates regarding their relationships to one another

and whether or not they have a direct evolutionary relationship to the *Homo* lineage. Although there are numerous species in the Plio-Pleistocene, they can be summarized as (a) *Australopithecus*, a diverse and long-lived genus comprising possibly five species; (b) *Paranthropus*, the so-called robust australopithecus species; and (c) early *Homo*.

The best-known and longest-lived australopithecus is *Australopithecus afarensis*, which is known from remains from East Africa including both the famous “Lucy” skeleton from Hadar, Ethiopia, and the fossilized tracks of footprints at Laetoli, Tanzania, that provide some of the best and earliest direct evidence for bipedal locomotion (Leakey & Hay, 1979). This species emerges at approximately 3.9 mya and is predated only by *Australopithecus anamensis* from the Lake Turkana region of Kenya (Leakey, Feibel, McDougall, & Walker, 1995). The functional morphologies of the *A. anamensis* leg and arm bones and the reduced canine size indicate that it is clearly a hominin and is probably the direct ancestor of *A. afarensis*, which shares a number of anatomical features with it but many derived ones as well, including further reduced canines. *A. afarensis* is an interesting species not just for its longevity but also for its extensive geographic range across East Africa and its variability, especially in body size. This diversity led some paleoanthropologists to suggest that it should be split into two separate species (e.g., Häusler & Schmid, 1995). Although the discussion periodically resurfaces in the scientific literature, most scientists believe it is a single species displaying a large but acceptable amount of morphological variability and *sexual dimorphism*, or variation in size between males and females (e.g., Gordon, Green, & Richmond, 2008).

There are potentially two other East African australopithecus recognized, but less is known of them. *Australopithecus bahrelghazali* was named a separate species on the basis of mandibular material discovered in sediments, which were dated by mammalian faunal correlation to between 3.5 and 3 mya (Brunet et al., 1996). However, referring to this taxon as East African is misleading; the remains are known from Bahrel-Ghazal in Chad. Although its location is exciting because it extends the known hominin geographical range further west at this time period, some people argue that the specimen is not unique enough to warrant its own species designation and it simply represents a geographical variant of the East African *A. afarensis* (e.g., Kimbel, Rak, Johanson, Holloway, & Yuan, 2004). *Australopithecus garhi* from Ethiopia is one of the youngest australopithecus, from approximately 2.5 mya (Asfaw et al., 1999). Cutmarked bovid bones discovered at the same site provide the earliest evidence for hominins making and using stone tools, presumably for the procurement of meat (de Heinzelin et al., 1999).

The final australopithecus species to be considered is not from East Africa but a long-lived species known from South African cave sites, *Australopithecus africanus*. The latest date for this species is 2.4 mya, and there is the possibility that it extends as far back as 4 mya, but as we

mentioned earlier, cave sites are difficult to date and material of this age is scarce (Partridge, Granger, Caffee, & Clarke, 2003). Mammalian biochronologies are constructed based on what is known of East African material where better dates can be secured, and the majority of *A. africanus* sediments fall between 3 and 2.4 mya based on this methodology. Overlapping in time with some of these species is also a different genus of hominin, *Kenyanthropus platyops*, known only from Kenya between 3.5 and 3.2 mya (Leakey et al., 2001). It has an extremely flat face and other derived characteristics that distinguish it from the australopithecus and potentially link it to *Homo*.

Appearing later in time than *Australopithecus* and *Kenyanthropus* but overlapping with some of those species at the end of their evolutionary lifespan are three species commonly referred to as the “robust” australopithecus. They have evolved a very distinct suite of craniodental characteristics, in particular, wide flat faces and molars with large, broad chewing surfaces. On these grounds, most researchers place them in an entirely different genus, *Paranthropus*. Functional morphological interpretations were traditionally seen as indicating a tough vegetarian diet that required the teeth and surrounding facial architecture to withstand significant force from grinding (see Wood & Straight, 2004, for review). However, isotopic studies indicate that they may have also consumed a certain amount of animal matter, and a microwear analysis of several tooth surfaces suggest that the diet might not have been as tough as previously assumed (Sillen & Lee-Thorp, 1993; Ungar, Grine, & Teaford, 2008). The only South African species known is *Paranthropus robustus*, which was found in a number of cave sites dating from between 2 and 1.5 mya. In East Africa, *Paranthropus boisei* persists for a million years between 2.3 and 1.3 mya and is predated only by *Paranthropus aethiopicus*, which is known from a limited number of sites in Tanzania, Kenya, and Ethiopia and is dated from between 2.5 and 2.3 mya. A partial mandible lacking teeth and a tibia from Laetoli, Tanzania, are likely to represent *P. aethiopicus*, pushing their geographical range further south and their date range back slightly further to 2.6 mya (Harrison, 2002). It is not clear how these species are related to each other, but the general consensus is that they were not direct ancestors of *Homo*.

There are possibly four species of early *Homo* in Plio-Pleistocene Africa: *Homo habilis*, *Homo rudolfensis*, *Homo ergaster*, and *Homo erectus*. Species in the *Homo* genus are placed there on the basis of a number of unique features including an increase in brain size and smaller teeth and jaws. The oldest species, *H. habilis* (2.4–1.6 mya), is usually separated from another, *H. rudolfensis*, which possessed a larger brain and dentition, as well as a wider face (Alexeev, 1986). A recent review of the morphological evidence of African *Homo* infers that these two taxa share more features in common with earlier australopithecus than with later *Homo*, prompting a revised taxonomy that places them in the genus *Australopithecus*, which is followed by

some researchers (Wood & Collard, 1999). This system proposes only two species of *Homo* in Africa, *Homo ergaster* and *Homo erectus* emerging at 1.9 mya. Others argue that all of these later African fossils can be lumped under *H. ergaster* and believe that *H. erectus* is a distinct taxon found only in Asia. This later *Homo* material is interpreted as more “modern,” particularly in the further reduction of the dentition and jaw and longer lower limbs adapted for more efficient bipedalism than earlier hominins. *H. ergaster* skulls show only a slight increase in brain size from *H. rudolfensis*, but *H. erectus* brains are most certainly larger.

Plio-Pleistocene hominins inhabited a variety of habitats; at nearly every site there is evidence for grass-dominated areas as well as more wooded areas. This is in contrast to early work in the field that interpreted most sites as representing quite open, arid habitats, suggesting further that bipedalism evolved in response to this type of ecological setting. However, ecomorphological interpretations of certain aspects of the earlier hominin forelimb anatomy, for instance, the long curved finger bones of *Australopithecus*, indicate that they retained the ability to locomote arboreally, which would certainly be advantageous in a habitat providing adequate tree cover where both shelter and food can be sought. Newer interpretations of African paleoenvironments indicate that most sites did in fact possess a significant woodland component and open settings did not arise until approximately 2 mya when we also see more modern forms of bipedalism evolve with *Homo ergaster/erectus* (e.g., Reed, 1997; Spencer, 1997). Despite the diversity of habitats exploited, some distinctions can be drawn regarding hominin habitat preferences. Ecological diversity and ecomorphological analyses indicate that *Australopithecus* is generally associated with habitats that have a considerable amount of woodland present while *Paranthropus* occupied similar areas but also ones with a higher proportion of more open woodland and bushland where wetlands were often, but not always, present (e.g., Kovarovic & Andrews, 2007; Reed, 1997).

In addition to these varying habitat preferences, hominins also evolved different diets, which are indicated by their craniodental adaptations. Perhaps the most significant dietary adaptation to emerge during the Plio-Pleistocene was the evolution of meat eating. The development of the first stone tool industry, the Oldowan, around 2.5 mya, and the first evidence of cutmarked mammal bones in Gona, Ethiopia (Dominguez-Rodrigo, Pickering, Semaw, & Rogers, 2005), infers that a shift to a greater amount of meat consumption evolved around this time (note though that earlier evidence of meat eating may not be visible in the fossil record; in other words, hominins may first have consumed or scavenged meat without the use of stone tools). We mentioned above the isotopic evidence for *Paranthropus robustus* meat consumption, and there is even evidence that this species may have used mammal long bones to forage for

termites (Backwell & D’Errico, 2001). A large body of archaeological and paleoanthropological literature pertains to the first stone tool industry and to using mammal fossils to determine how hominins obtained and processed meat, but this will not be reviewed herein (for informative reviews see Blumenshine & Pobiner, 2006; Plummer & Bishop, 1994). Still, it is important to note again at this point the relevance of fossil mammalian remains in our paleoanthropological investigations.

Moving Abroad: Fossil Evidence of *Homo* in Asia

Determining if the taxonomic distinction between *H. ergaster* and *H. erectus* is indeed correct will be aided in the future by analyses of *Homo ergaster* such as from material from a site called Dmanisi in the Republic of Georgia (Gabunia et al., 2000; Gabunia & Vekua, 1995). The biochronology of mammals found at the site indicates an age of approximately 1.7 to 1.8 mya. This material may provide clues as to which species migrated from Africa and if *H. erectus* evolved in or en route to Asia. Regardless, the material confirms that *Homo* had ventured far from its African home some time toward the end of the Pliocene, expanding into less tropical climates and new environs.

The antiquity of *Homo* in Asia is confirmed by sites in mainland Asia and Indonesia where classic *H. erectus* material is well documented. Many of these sites cannot be absolutely dated, and biochronological dates are offered for most. Some of the oldest dates previously accepted in Asia were from Javanese sites that indicated an approximate age of 1 mya. However, radiometric dates were determined for two critical sites in Java where absolute dating is possible, and they indicate that the *H. erectus* occupation of Asia was well established in the islands by 1.6 to 1.8 mya (Swisher et al., 1994). However, there is some doubt as to the exact location where some of the relevant hominin fossils were found at these sites and if the dates derived from these analyses are indeed from the correct strata. The time frame for *Homo*’s extraordinary migration is not yet clear, but it appears to have started with a rapid exit from Africa shortly after the evolution of *H. ergaster* since the earliest evidence for this species emerges in the fossil record at roughly the same time that *Homo* remains emerge in Asia. Some paleoanthropologists also suggest a scenario in which there were migrations back to Africa and others out again, with some of the African material representing *H. ergaster* and other material representing *H. erectus*.

Classic *Homo erectus* features are not displayed by every known specimen, and there is substantial variation in the Asian sample, as well as between *H. erectus* and *H. ergaster*. However, some of the basic features that define the species include a thick browridge above the eye sockets, thick skull bones, and an angular shape to the top and back of the skull. In addition, more humanlike limb proportions

(i.e., shorter arms in relation to earlier species) are evident in both *H. ergaster* and *H. erectus*; it is particularly obvious in the Nariokotome Boy, a 12-year-old male skeleton found in Kenya (Brown, Harris, Leakey, & Walker, 1985).

Until recently, researchers believed that *H. erectus* persisted in Asia until approximately 30 kya. It was therefore an exciting moment when a team of researchers announced the discovery of the remains of a small hominin, *Homo floresiensis*, at the site of Liang Bua on the Indonesian island of Flores (Brown et al., 2004). The youngest sediments in which the remains were found are only 17,000 years old. This means that hominins existed as an island population long after *H. erectus* had disappeared from the mainland. Analyses of its small skull and other elements, including the wrist bones, indicate that these remains represent an entirely different species of Pleistocene hominin (Tocheri et al., 2007). It retains some primitive traits in relation to modern *Homo sapiens*; this is relevant because some arguments arose claiming that the specimens were modern humans suffering from disease. Although *H. floresiensis*'s exact evolutionary relationships are not agreed on, its unique characteristics clearly distinguish it from other hominin material.

It is likely that *Homo ergaster/erectus* consistently consumed meat (although we still do not understand if they were hunting or scavenging), and the lines of evidence for this are various and come from both African and Asian sites and specimens. A reduction in the size of the molars, which are so helpful in grinding tough-plant foods, indicates a greater reliance on the canines and incisors, which would be good for tearing and biting. The force required for this might have been supported by the more robust nature of the skull. In addition, the Acheulean industry in Africa from 1.6 mya onward, which is characterized by teardrop-shaped hand axes, represents a more advanced form of stone tool. They have been demonstrated to be excellent butchery tools, and in fact, many sites have associated tools and mammalian remains bearing cutmarks (e.g., Schick & Toth, 1993). All lines of evidence in Asia indicate that the climate was colder and more temperate than in Africa, which would affect the seasonal availability of vegetation, inferring that there were times of the year when meat was the most plentiful and likely to be an exploited resource. Finally, there is some evidence for the controlled use of fire in both East and South Africa, as well as in Asia (Bellomo, 1994; Brain & Sillen, 1988). Fire would be useful for processing meat, as well as generally allowing for the colonization of colder climates. It is clear that at this point in evolutionary history *Homo* had developed the technology and know-how to exert a certain amount of control over its environment. Despite this, hominins were still mammals in a diverse landscape of many other well-adapted species. Fossils bearing tooth marks, for instance, the remains of deer at the Zhoukoudian cave site in China where both hyenas and their prey species are found,

remind us that they were not the only carnivore species in the community (Boaz, Ciochon, Qinqi, & Jinyi, 2000).

Recent *Homo* Evolution

The main players on the stage of recent *Homo* evolution used to be restricted to *Homo neanderthalensis* and *Homo sapiens*. However, it is now generally understood that a number of fossils in both Africa and Europe, which were once lumped under the general heading "archaic *Homo sapiens*," can be designated a separate species that is evident by approximately 700 kya, *Homo heidelbergensis*. Other species have been suggested as well, generally with regard to particular geographical populations, but these are contested and not well-known with the exception of *Homo antecessor*. This taxon relates specifically to material from Atapuerca, Spain, where cave sites have preserved large numbers of fossils, with more than 20 hominin individuals attributed to one site alone (e.g., Bermudez de Castro et al., 1997). Researchers there believe that the material may be ancestral to Neanderthals on the basis of shared characteristics, such as a large brain size and the shape of the middle part of the face. The validity of this species will be more generally accepted if fossils that can be definitively assigned to it are discovered outside of Atapuerca, and until then, some prefer to assign these specimens to *H. heidelbergensis* (e.g., Rightmire, 1996).

We may eventually discover that *H. heidelbergensis* merits more than one species distinction as there is considerable variation displayed by the specimens. Generally, they are united by derived features, such as a larger brain size, round cranium, and reduced dentition, that distinguish the species it from *H. ergaster* and *H. erectus*, with which it overlapped in time. This species is widespread across Europe and Africa (where the earliest material is known), with some suggestions that it ranged as far as China by 200 kya (see Stringer, 1993, for a summary of Pleistocene sites and dates). One of the major questions is how *H. heidelbergensis* is related to later Neanderthals and modern humans. It possesses features that seem to indicate a relationship with Neanderthals and is present in Europe before them. This is significant because Neanderthals are only found in Europe, an area of the Middle East known as the Levant, and Central Asia, although we do not know in which region the Neanderthals evolved. *H. heidelbergensis* also overlaps chronologically with the earlier Neanderthal material, so it is possible that Neanderthals evolved from a population of *H. heidelbergensis*, which also persisted as a species. Others believe that *H. heidelbergensis* led only to modern *Homo sapiens* and *H. neanderthalensis* evolved from *H. erectus*. More alternative views exist, often hinging on interpretations of specific fossils, and there is no common viewpoint regarding the relationships of later Pleistocene hominins. It is difficult to interpret the extensive

fossil record of these species. This stage in evolution, in contrast to Miocene and Pliocene evolution, presents us with a much greater amount of fossil material, but regional morphological variations and complicated movements across three continents, coupled with the problematic nature of dating different types of sites, make it difficult to construct a clear framework for evolutionary relatedness.

One of the best-known hominins is, of course, *Homo neanderthalensis*. The wealth of fossil material and great number of sites, in addition to the fact that it was the first hominin material to ever be discovered and identified as different from *Homo sapiens*, means that it looms large in both the popular consciousness and the scientific literature. It has become increasingly clear that they were a distinct and unique species, and advances in genetics will help us understand when they might have diverged from a common ancestor with modern humans. In addition, DNA analysis will also throw more light on the debate regarding the possibility that Neanderthals contributed to the modern human gene pool. Morphologically speaking, they were robust and large brained with many unique features in the skull and dentition including a distinctive projection in the middle of the face, large nasal aperture, and large incisor teeth. Many of their features have been interpreted as representing adaptations to a cold and seasonal climate, which is exactly what reconstructions of their environmental conditions indicate they had to contend with during their evolutionary lifespan. Fossils of large mammals typical of cold Pleistocene habitats are present at their sites, often in association with stone tools and bearing telltale cutmarks of hunting and butchery.

Neanderthals survive until approximately 30 kya, after which point, other than the relict *H. floresiensis* population in Indonesia, *Homo sapiens* is the only remaining hominin (the complicated debate about why Neanderthals did not survive is beyond the scope of this chapter, but see Hall, 2008, for an easy-to-read review). It is likely that *H. sapiens* evolved in Africa, as the oldest material of what is sometimes referred to as “anatomically modern humans” is known from this continent. Cranial remains from Ethiopia and South Africa in particular have been pivotal in discussions about the location, timing, and context of the evolution of *H. sapiens*. The South African material from a site known as Klasies River Mouth was ascribed a date much earlier than people once believed modern humans had evolved from, 120 kya (Deacon & Geleijnse, 1988). Biochronological dating of a modern-looking specimen referred to as the Omo I skull, from Ethiopia, also indicated an age of 120 kya; however, recent radiometric dates for this and another slightly more primitive but still modern skull from the site have proposed an even earlier age of 200 kya (McDougall, Brown, & Fleagle, 2005, 2008). Additional Ethiopian remains from Herto are likely to be from at least 160 kya (White et al., 2003). The likeliest scenario is that *H. sapiens* evolved in Africa and

migrated outward, probably several times. There is extensive evidence for anatomically modern human occupation in the Middle East where Neanderthals are also known, but it is only *H. sapiens* that survived and colonized the world.

And what makes modern humans *modern*? Compared with other hominins, including the ones our species once coexisted with, we have many distinct characteristics although expressed to a variable degree. We lack the robustness of earlier hominins in the thickness and form of our cranial bones, limb bones, and facial features; we possess large brains for our body size, straight limb bones, a projecting chin, and smaller dentition. Simply look around at the people who walk past you every day, and you can see how diverse we are as a species even today, let alone in the late Pleistocene.

Conclusion

Major recent discoveries have significantly expanded our understanding of hominin evolution, and the recovery of new fossils is of primary importance. In the past 15 years, we have established the antiquity of hominins in Late Miocene Africa and Pleistocene Asia; furthermore, we have enhanced our awareness of the diversity and longevity of the different lineages. In particular, we await more evidence of the earliest hominins and fossils found in regions not traditionally associated with the evolutionary narrative, such as northern and central Africa. Defining *Homo ergaster* and *Homo erectus* as separate species and determining the timing of *Homo*'s migration out of Africa will also be critical and feeds into another complex issue that must be resolved: the evolution of later *Homo* and how some of the Pleistocene species (*H. antecessor*, *H. heidelbergensis*) are related to modern humans. We also continue to set hominin evolution in the context of the evolution and migration of other mammals in relation to changing climates and shifting habitat availability and to develop better techniques for assessing how geological and biological processes affect fossil assemblages.

This chapter has focused primarily on the paleontological evidence for hominin evolution, that is, hominin and nonhominin fossils, their geological and environmental contexts, and how paleoanthropologists currently assess the hominin species identified in the fossil record. But this discipline is multidisciplinary in the truest sense; anatomists, geologists, archaeologists, zoologists, geneticists, and primatologists all examine aspects of our evolutionary history from both the biological and cultural perspective. New methods and techniques for approaching the fossil and archaeological record are always under development, and we increasingly rely on modern technologies. The recent announcement of the sequencing of the Neanderthal genome reminds us that what were once unapproachable questions now have

answers within our grasp—and the spirit of discovery in the field, in the lab, and elsewhere is very much a part of this unique science (Green et al., 2008).

PREHISTORIC CULTURES

PAMELA HAYES-BOHANAN

Bridgewater State College

The study of prehistoric culture concerns preliterate societies from their earliest development until the beginnings of the first political structures—the Greek and Roman empires. Neanderthals, *Homo erectus*, and *Homo sapiens* were among some of these early peoples. Of these, only the *Homo sapiens* survived. Some of these peoples coexisted for periods of time. There is not always a clear indication of the time frame when different societies lived, as some developed at faster rates than others. Evidence of humans in Africa is millions of years older than evidence in the Americas. Even today, there are some hunter-gatherer societies that are without written language. The study of these societies is called protohistory.

Anthropologists make determinations about prehistoric cultures based on the best available evidence. Interpretations of artifacts and settlements are open to debate, and as more evidence is found, or uncovered, new interpretations are made.

Out of Africa

Current evidence suggests that the first hominids walked the earth over 5 million years ago. The earliest fossils indicate that there were people in Africa perhaps as long as 5.5 million years ago. These early people were much smaller than modern humans and had a

much smaller brain capacity. They were of the genera *Australopithecus* and *Paranthropus*. These comprised several species that lived in Africa from approximately 5 million to 1.3 million years ago. As the *Australopithecus* and *Paranthropus* moved toward extinction, the first *Homo erectus* began to appear approximately 2.5 million years ago. The first humans to leave Africa were probably the *Homo erectus*. Bones of *Homo erectus* dating 1.5 million years old have been found in Indonesia. Humans continued to evolve and migrate across Asia and Europe, eventually crossing the Bering Strait into Alaska during the last Ice Age and ultimately populating North and South America. Different theories put this at between 13,500 and 20,000 years ago. Some say that this population expansion would have taken place on foot, but new evidence indicates that some of it may have taken place along the western coast of the Americas in boats. Evidence of people in Australia dates to approximately 100,000 years ago. There was no land bridge from Asia to Australia; the migration would have taken place in boats.

More recent theories suggest that hominids may have evolved in Asia separately from those in Africa or even that the migration took place in reverse (Asia to Africa). However, evidence for these theories is sparse. As more paleoanthropological work is done in Asia, more light may be shed on the question. The focus during the late 20th and early 21st century has been on Africa.

There is some debate as to when the very first humans appeared in Europe. Evidence from findings of stone tools can put the very earliest people as far back as 1.5 million years ago. However, the oldest bones discovered come from a cave called Gran Dolina in Northern Spain. These bones are about 800,000 years old. The bones are similar to the *Homo ergaster* found in Africa, but because of facial differences, a new species name was suggested by excavators—*Homo antecessor*. Because of these differences, some suggest that this species evolved from a separate, much later wave of movement out of Africa rather than from those who peopled Asia.

Methodology

Human Paleontology and Archaeology

The study of human fossils involves the recovery and interpretation of remains. These remains are usually bones, wood, and stone. Under certain conditions, however, muscle, tissue, skin, and feces have also been preserved. Cultural adaptations (use of fire, toolmaking, and language) have made the interpretation of these remains more difficult. The earliest humans adapted to the environment biologically and behaviorally. Later humans manipulated their environment. Interpretation is also made difficult by the fact that most fossil records are incomplete. Bones get scattered, and pieces are missing. Skeletons and bones that are missing pieces were historically pieced together with glue and plaster; today, however, computer technology is used to fill in the gaps and to generate images of facial features.

In addition, interpretations are made based on found artifacts and on excavations of settlements and burial sites. Interpretation of the finds can be difficult, as archaeologists cannot always tell if a site has been disturbed by other societies. It is often difficult to study death rituals as grave sites are places where significant wealth can be found and therefore are common targets of looters.

Written History

For the most recent prehistoric societies, anthropologists have some written records; for instance, the Greek and Roman records of the Iron Age reference other pre-literate societies. The conquistadores of what is now Latin America have written records of the people they encountered. And the Europeans who came to Australia in the 17th century have records of the Aborigines. However, researchers must keep in mind that these records are necessarily written by those whose culture was quite different and who would have found the customs of others strange, although they were perfectly normal to those practicing them.

Observation of Modern Societies and Primates

Anthropologists can draw some conclusions by observing preliterate societies today. However, caution must be taken when making these conclusions. Although modern humans (*Homo sapiens sapiens*) have existed for about 40,000 years, today's hunter-gatherer societies are living in a much changed world from that of the original hunter-gatherers. Hunter-gatherers in the 21st century may have contact with those who practice agriculture. They are often living in areas with poor soil, and their hunting practices may be different as the type and range of game available has changed drastically.

Three Ages of Prehistory

The study of prehistoric peoples in Europe, Africa, and Asia is divided into three broad periods, the Stone Age (which is further divided into the Paleolithic, Mesolithic, and Neolithic periods), the Bronze Age, and the Iron Age. The ages are defined by the types of tools used during the period. There are no clear beginning and ending dates for these ages as people in different parts of the world progressed through them at different times.

Stone Age: Paleolithic

The Stone Age is the longest of the three ages, beginning from about 2.5 million years ago and continuing until the beginning of the use of metals for toolmaking (about 5,000 years ago). Tools in the Stone Age were made of stone, bone, and antler.

Lower Paleolithic

The earliest stone tools were formed of flakes and cores, and they appeared about 2.6 million years ago. They were apparently used for hammering, cutting, and smashing. Fossils in East Africa indicate that early hominids of the Pliocene epoch lived in forests and other wooded areas.

Although humans are omnivores, diet was probably primarily vegetarian. Animal protein was probably derived from all types of animals, including birds, fish, amphibians, reptiles, mammals, and insects. Although bones from very large animals (including elephants and rhinoceroses) have been uncovered at some very early archaeological sites, it is unlikely that they were hunted by the early hominids and instead were scavenged. Early humans did not have tools sophisticated enough to kill the animals, and evidence indicates that they would not have hunted any animal larger than themselves. Rotten food was probably routinely eaten—and a taste developed for it—as scavengers ate what they found, and there was no way to keep food fresh.

The earliest fossil specimens of *Homo erectus* date from 1.78 million years ago at Koobi Fori. The range covers most of the African continent, with exceptions in the western and central forest areas. Fossils indicate that some *Homo erectus* were cave dwellers while others lived in open sites. They were the first hominid to leave Africa; early bones were found in Indonesia from about 1.5 million years ago. These bones were given the name *Java man* after the site where the bones were first discovered. At about the same time, tools evolved from course pebble chopping tools and flakes to bifacial hand axes. *Homo erectus* hominids were hunter-gatherers and were well used to fire. They were probably the first to cook food.

There is still debate as to how much speech capacity *Homo erectus* may have had. Some say grunts and basic guttural noises were possible; others say that they could not have lived and hunted cooperatively without a more developed speech.

Social groups were probably small, about 40 to 50 people, with foraging groups 10% of that. Female and male foraging ranges were different. Female ranges would have been less wide. It is unlikely that *Homo erectus* would have foraged more than a day's walk beyond their water source as they would have had no watertight containers with which to carry water for longer hunts. The social organization of the early hominids is still open to debate. Some evidence suggests polygyny, the practice of men having more than one female mate, was observed.

Middle Paleolithic

Several different hominids lived during the earliest part of the Stone Age (approximately 2 million to 10,000 years ago). Some of these peoples coexisted, and there is still debate as to whether some of these human species may have interbred or if some became extinct all together or if one species evolved from another. The Neanderthal (*Homo sapiens neanderthalensis*) is named for the Neander Valley in Germany where many of the remains have been found. Neanderthal remains have also been found in Spain, Britain, Asia, and the Middle East. The Neanderthals' appearance was marked by a short, stocky stature; wide brow; and protruding bun at the base of the skull. These remains date from as long ago as 230,000 years to 10,000 years ago. These hunter-gatherers traveled in small groups (fewer than 30 people) and did not set up permanent settlements. Some lived in caves, although there is also evidence that some of the Neanderthals lived in open sites. The fact that they lived in caves has helped us to study them, as the limestone has preserved their bones well. They appear to have moved frequently over short distances and used whatever materials were on hand rather than taking things with them when they moved. The cooperative hunting they practiced involved big game. Because they used spears rather than bows and arrows, surrounding and herding the game was essential. Thrusting of spears at

close range after driving the game into a bog was probably the common practice; however, this also meant that the hunters were easily put in harm's way, and in fact, skeletal remains often indicate numerous injuries. Very few Neanderthals lived beyond 40 years of age. Neanderthals' diet also included small prey, such as tortoises, shellfish, and lizards. These would have been easy to catch and would require less planning than a big-game hunt and were certainly less dangerous. At many of the Neanderthal sites, there is clearly an indication of taste preference as shown by a preponderance of certain types of animal bones, providing evidence of a hunter-gatherer culture rather than a scavenger culture. Plants were a very small part of the Neanderthal diet.

There is still debate as to whether the Neanderthals practiced any kind of ritual. There is evidence that they buried their dead; however, whether this was part of a ritual or simply an efficient way of disposal is not known. Bodies have been found in most instances placed in rectangular pits in flexed positions and covered with stone slabs and sometimes with "grave goods"—flowers, animal parts, tools, and semiprecious stones. In other cases, bodies were not covered but were found in shelters; however, even these appear to have been placed with some sort of ritual—two bodies placed head-to-head, for example. Grave goods have also been discovered with some but not all of these bodies. Some archaeologists argue, however, that none of these were ritualistic, and can be explained through natural processes.

There is also debate concerning the practice of cannibalism. Cutmarks on some human bones are consistent with those seen on animal bones, indicating flesh removal; bones were broken in a way that would have exposed the marrow. It is not known whether this was a death ritual or if it was a desperate act to get food; indeed, some suggest it does not indicate cannibalism at all and that the cutmarks were ceremonial. There is other evidence that interpersonal violence was not uncommon among the Neanderthals. Skeletal remains show signs of healed wounds; although some appear to be accidental or inflicted by nonhuman predators, others were obviously inflicted intentionally.

Upper Paleolithic

The Upper Paleolithic period marks the transition from the Neanderthals to the "fully modern" human (*Homo sapiens sapiens*). This period was roughly from 45,000 to 30,000 years ago. By 10,000 years ago, all the Neanderthals had disappeared. Humans during the Upper Paleolithic wove clothing and nets, and they began to build huts or other shelters from bones and animal hides or rocks. It is not known whether this indicates that the inhabitants stayed at the shelters year-round or returned to them on a regular basis.

Tools from this period are carved and polished rather than chipped, and show other technological advances.

Blades are long and narrow and have parallel sides; other tools include the eyed needle and the bow and arrow. In addition, we see a profusion of items used as ornaments. Beads and pendants made from bone, ivory tusks, animal teeth, shells, stones, and antlers are in abundance. Art is also in evidence during this period. Carvings of animals and humans have been discovered as well as cave art in the form of painting and carving and fired clay to make figurines.

There is evidence of exchange of goods during this period. Shells and fossils from one area appear to have been transported very long distances (800–1,000 kilometers) to other areas. This exchange can indicate a desire for adornment and/or a social and economic “safety net.”

Stone Age: Mesolithic

The Mesolithic time period (approximately 10,000–7,000 years ago) is marked by the end of the last Ice Age. There were major climactic changes as glaciers melted, and people began to migrate north.

The Mesolithic period also saw the earliest stages of agriculture. Animals such as goats, sheep, cows, pigs, and chickens were first domesticated in Asia and the Near East approximately from 9,000 to 8,000 years ago. Meat was essentially kept fresh by keeping livestock alive until needed.

Tools of the Early Mesolithic were microliths—composite tools inserted into shafts made of replaceable parts. Stone, antler, teeth, and bone were all used in making tools.

Big-game hunting, as well as fishing, was a large part of the subsistence economy of this time period. Shellfish became more important during the late Mesolithic period. This may be due to stabilization of sea levels. Some animals such as beaver, lynx, wildcat, and wolf appeared to have been hunted only for their fur. “Gathering” became more important as legumes, nuts, fruits, and vegetables comprised more of the diet.

Shelter was in the form of caves, rock shelters, and huts. Evidence from these settlements suggests that the Early Mesolithic groups were rather small and somewhat mobile, traveling within a diameter of 80 to 100 kilometers from their settlements. During the later Mesolithic period, groups became more sedentary. There is also evidence of some trade between groups whose settlements were up to 250 kilometers apart.

Art forms began to take on geometric patterns as well as animal and human forms. Beads and other artwork were made from amber, animal teeth, stone, bone, antler, shells, fossils, and red ochre. Jewelry was used during the Late Mesolithic, and tools were decorated with geometric patterns. Pottery and wood were also used during the Late Mesolithic. Hunting and fishing are themes in the petroglyphs found from this time period.

The first real cemetery is dated from this time period. Bodies were placed in a variety of positions (supine, flexed,

and sitting). Grave goods were common. There appears to be a real distinction of gender with men being buried with tools and women with jewelry. There are also indications of segregation by status during this time, with special status given to the wealthy (usually adult males) or shamans. Also, in some areas, there is evidence of a “skull cult” in which skulls are separated from the bodies and buried separately.

Stone Age: Neolithic

The Neolithic ranged from approximately 7,000 to 5,000 years ago. The first farmers practiced mixed farming, using plants and animals. As plants and animals were domesticated, some competition for land between the farmers and the hunter-gatherers would have been expected. It is not known how long these two cultures coexisted or to what extent they cooperated. Some anthropologists believe there may have been an exchange of goods between the two groups (labor for domesticated goods during harvest time). Others believe that as the two groups competed there may have been an increase of warfare. There are several theories as to how farming grew across Europe: Perhaps farmers migrated from the Middle East, or one group of people may have learned about agriculture through trade with others. Slash-and-burn agriculture was probably the method of cultivation. Horses, Bactrian camels, ducks, dogs, and water buffalo were domesticated in Asia during this period. “Aquaculture” (the cultivation of water plants and animals) began in Northern China. In river valleys in China, the importance of fishing is evident in the use of canoes and in tools such as fishhooks, harpoons, spears, and stone net sinkers.

Early Neolithic peoples probably were part of groups larger than those in the previous epochs, perhaps 250 people interconnected through kinship links. These were egalitarian societies. Status was not something that could be inherited but perhaps could be obtained through age, achievement, or talent. It appears, though, that men had a higher status than women. Rituals became important in household and community life.

Exchange of goods across geographic areas was evident as not all raw materials were naturally available in all areas where goods produced from the resources were found. Some of this trade would have been done directly within kin systems and probably involved reciprocity. Trade with strangers, however, may have been more deviant, and included robbery, cheating, and violence.

These early cultivators likely moved frequently, returning to the same place on repeated occasions. People built shelters of wooden posts and mud walls—rather than using already-formed rocks and caves—and lived in villages. Settlements consisted of longhouses and pits. Most longhouses were living spaces, but some appear to have been used for communal or ritual purposes. These buildings were longer than the living spaces and had some structural

differences. Structures were rebuilt on the same spot over generations. Some archaeologists believe that the houses were occupied seasonally; others say that they were lived in year-round and rebuilt when they collapsed. Long-term occupation of specific spots is indicated by the buildup of debris. Some believe that status may have been afforded to those whose family occupied the same spot for a long period of time.

The Neolithic period is marked by the beginning of a pottery culture. Pottery vessels indicate first use of storage for grains and seeds as well as drinking vessels and burials. Pottery was decorated with patterns, using shapes, lines, bands, and whorls. In river valleys where fishing was common, fish designs were used as decorations. Pottery was made from coiling techniques and finished with bone scrapers, stone polishers, and pigment and other decorating techniques using impressions and appliqué. In some areas, kilns were found; in others, it appears pottery was burned on the ground.

In Europe, figurines believed to be part of a ritual or religious icons have been found in what appear to be communal areas. Clay figures of men, women, asexual humans, and human figures with penises and breasts have been discovered as well as animal figurines. The majority of figures, however, are of women. It does appear that goddess worship was part of their religious practices. One theory suggests that there are so many women figures because they represented fertility. This would have been especially important in an agricultural society.

In China, a separate cemetery was part of the village. There was clearly a ritual aspect to the burials. Ornaments, including pottery vessels, beads, and grains were often placed in the graves, with some singular burials standing out as especially elaborate compared with multiple burials. Some burial sites segregated the deceased by gender or age. Placement of bodies was deliberate. They were clearly placed in specific positions and pointed in specific directions. Others appear to be segregated by clan or wealth status; still others did not segregate at all. European burial customs involved burying and cremation. Grave goods were evident, with some of these being gender specific (arrowheads for men, jewelry for women), and as in China, placement of bodies was intentional.

Evidence of violence during this period demonstrates that brutal raids for mates or resources may have taken place. Several sites with mass graves of people who died of similar wounds have been discovered.

Bronze Age

The Bronze Age is marked by the beginning of the use of metals for toolmaking. Ore extraction took place in mines, and alloys (combinations of metals) were developed along with mold forms and other technological developments for an early type of “mass production.” Decorations were added to pieces after they were smoothed, and seams

were removed, providing evidence that aesthetics, in addition to function, was becoming more important.

The Bronze Age began at different times for different societies, as early as 3000 BCE in Greece. But in other parts of Europe, it did not start for another 1,000 years. While some trade of raw and manufactured materials took place in the Mediterranean, farming was still the principal occupation, with subsistence agriculture an essential aspect of the culture. Most settlements were in small villages. Houses were made of wooden posts with daub-and-wattle walls (mud, clay, woven branches) or log cabins. Some houses were small, one-room buildings; others were larger multiroom structures. In some settlements, particularly in the East Mediterranean, there were central palaces, indicating a status given to one family or kin group that was unavailable to others.

Trade of raw materials and of manufactured “commodities,” such as beads, ornaments, pottery, and weapons, is evident. Movement of goods took place not only over land but also by water.

Woodworking continued to be important for building of trackways across wet ground, for making bowls and other containers, and for making farm implements, such as hoes, plows, and rakes. Bone and antler continued to be used for the manufacture of weapons and tools. In the later Bronze Age, elaborate armor and shields were developed for protection during warfare.

Weaving of cloth is evident, and new techniques were developed. Wool and flax were the most commonly used fabrics. Textiles were woven on looms. As the Bronze Age progressed, the weaving became more complex to create patterns; this, in addition to the use of decorations and ornaments on clothes, indicates the desire to express oneself. The ornaments on the pottery became more elaborate during the Bronze Age and included bones, teeth, and jade.

The typical means of disposing of dead bodies was burial or cremation. Urns were used to dispose of ashes. Cemeteries and cremation pits were the norm, and there was often a distinct placement of the bodies when burial was used. Often, there was a difference by sex as to how the head was oriented or on which side (left or right) the body was placed. Grave goods might indicate the occupation of the occupant, such as metallurgical equipment. Men were sometimes buried with swords, perhaps indicating status gained from a warrior society. Women were commonly buried with “ornament sets,” which could have indicated marital status and age. The types of goods placed in the graves as well as the positions and different treatments of the bodies indicate that there was some social status afforded to few that the many did not have.

Iron Age

As iron replaced bronze as the principal material for tools and weapons, new technologies were developed.

The Iron Age ended around the time of Christ with the Roman conquest of Europe. As with other ages, the movement from one manufacturing material to another was a gradual process that developed over hundreds of years. And many of the technologies and industries used in previous times continued to be important. Flint and bronze remained in common use for tools and other purposes, and farming continued to be an essential part of the subsistence economy.

Cereals and domestic animals continued to be an important aspect of the subsistence economy although food production was made more efficient by several technological advances. Iron plowshares allowing for exploitation of richer soils and scythes allowing for more efficient harvesting of hay for feeding animals as well as other tools made farming a more efficient operation, and fewer farmers were needed to feed people. During the Late Iron Age, rotary querns (an early form of mill) made from stone came into widespread use for grinding grains, creating yet another more efficient method for providing more food.

Even as methods for extracting and refining iron came into use, bronze was still commonly used for some tools, jewelry, ornaments, and vessels. Pottery also remained widely used for several purposes: storage containers for grain, seed, and water; tripod cooking utensils; cups and bowls for eating and drinking; and burial urns. The use of the potter's wheel is evident and would have made production of pottery more efficient. Wool, linen, silk (imported from the orient), and animal hair are all evident as textiles and cloths.

Trade between geographically distant areas was a regular feature of the Iron Age. Amber, bronze, precious metals, and salt were among some of the most commonly traded items. A barter system was certainly in place, and by the end of the Iron Age there is clear evidence of the use of coins.

Fortified stone and earth walls; weapons such as lances, spears, shields, and battle axes; and art work depicting soldiers wearing armor all indicate warfare. Lances and shields in graves were common in burials of men who were believed to be warriors.

Complex social and political structures started to form during the Iron Age. Wooden tracks to ease commerce and trade demonstrate political structures beyond subsistence farming. Manufacturing and trade of goods across Europe, the Mediterranean, and the Middle East is evident. Luxury goods at certain burial sites and houses with clay floors at some settlements indicate the emergence of an elite class.

Deposits of metal objects in special locations, such as hot springs, have been interpreted as being offerings to gods or part of another ceremonial practice. This interpretation is made possible by the fact that Greek and Roman societies began using written language, and some of the offerings were inscribed. However, the

practice is evident in many parts of Europe, in both pre-literate and literate societies.

Australia

The Aboriginal culture of Australia dates from approximately 40,000 years ago, although there is evidence of humans in Australia (stone tools and cave art) from as long ago as 100,000 years. Tools were generally made of stone, shell, and bone. The Aborigines were among the first to use stone-ground tools (10,000 years before Europeans) and used the tools for woodworking to make hunting implements, such as spears, clubs, and boomerangs. Designs on these implements as well as on sacred objects were carved or painted, making all objects sacred. Music and dance rituals that called on the *Dreamtime* (the time before the collective memory of the tribe) ancestors gave the implements power.

The Aborigines were organized into tribes, which were governed by elders. Size ranged from several hundred to over 1,000. A variety of factors affected this number such as abundance or scarcity of food. There is evidence of trade between tribes over long distances. Mobility of the tribe may have been based on resources; where there were more, there was less mobility.

Tribes were subdivided into clans based on kinship of genealogy and marriage. A person with whom one could not find a common relative was a stranger, but if a pair had any relative in common, whether through a genealogic line or through marriage, they would be considered kin. Depending on the tribe, a marriage might have been arranged by the families of the man and woman, or the partners may have arranged it themselves. In other cases, camps were raided by others, and the women were taken by force. Polygyny was widely practiced among the Aborigines.

Europeans encountered the Aborigines in the 17th century, which drastically altered the Aborigines' way of life with regard to how land was viewed. Aborigines did not see land as something that could be owned or bought and sold.

Americas

The peopling of the Americas probably begins with the first migration across the Bering Strait, which may have been as long ago as 20,000 years. The migration continued along the west coast of North America and eventually into Central and South America, where evidence shows that the first people arrived approximately 10,000 years ago.

North America

There are not clear divisions of time periods for North American prehistoric cultures, although several attempts

have been made to divide these cultures into time periods based on culture traits, artifacts, and projectile points. The earliest people are usually referred to by the term *Paleo-Indians*; the Clovis and Folsom cultures are two of these very early hunter-gatherer cultures. This period is followed by the Archaic period, the preagricultural cultures of North America. And then came the Woodland cultures, marked by agriculture and ceramics. This final period in some areas of North America did not end until after colonization.

The first people to arrive in North America were likely to have been mammoth and mastodon hunters. Tools found on the continent are dated from about 9,000 to 20,000 years ago and were designed to be used in group hunting to stab a large animal at close range. By 6000 BCE, other game was being hunted such as moose, bison, bear, and caribou.

Paleo-Indians

The Clovis culture hunting tools are identified by fluted points, the first of which were found embedded in some now extinct mammals (bison and mammoth) in New Mexico. It appears that these points were attached to the end of a handle or shaft and used as a knife. Evidence of Clovis culture has been identified throughout North America and into Central and South America. Later Folsom culture tools indicate that these fluted points were used as projectiles. Some Folsom sites appear to have been used as gathering places for communal hunts. Post-Folsom Paleo-Indian sites have been discovered west of the Mississippi. These sites include a variety of point styles, indicating there were several different groups of Paleo-Indians, with differing styles of hunting and diets. Those on the Great Plains appear to have hunted large mammals, whereas those in the foothills and mountains hunted smaller game and ate more plants.

Archaic Indians

As the Pleistocene period ended and the climate began to warm, people of the Holocene period in North America had to adapt to the changes in the environment. Large mammals became extinct, weather became warmer, and lakes in southwestern North America began to dry out. Archaic culture refers to the nonagricultural adaptations prehistoric peoples made in response to these climactic changes.

Drier climates in southwestern North America forced some people to migrate into the mountains; others stayed and adapted by taking advantage of seasonal changes and new flora and fauna. Archaic people of California learned to manage the changing conditions by exploiting a variety of resources, including acorns, plants, fish and other sea food, and large animals. Early Californians also learned to control fires when dry conditions threatened the danger of

chaparral fires and understood that these controlled burns promoted new growth. Plains people hunted bison as well as gathering nuts and berries.

There is a definite correlation between large-scale outbreaks of violence and catastrophic climactic changes. Violence and homicide were not uncommon among hunter-gatherers of North America. Evidence from various parts of the continent shows intentional projectile wounds, scalping, decapitation, and forearm trophy taking. One especially remarkable case involves a site at Saunaktuk (Eskimo Lakes region of the Northwest Territories). Human remains from the massacre show various signs of trauma, including cuts, slashes, and long bone splitting. The latter almost always is an indication of cannibalism. And while it appears that males were usually the victims and perpetrators of violence, most of the victims in this massacre were women and children. The men of the victimized group may have been out on a beluga whale hunt. This case is especially interesting because oral tradition confirms what was found in the excavation site.

Woodland Phase Indians

The Woodland phase is determined by three traits: manufacture of pottery, agriculture, and the appearance of burial mounds.

The gathering of plant foods became more controlled, and people began to select seeds from the best wild plants to sow and harvest themselves. They also began to store food for later use so that migration was less frequent. As populations grew, villages became too big to sustain agricultural productivity. Trade of foods and other goods between distant populations began.

Burial of the dead is clear in several sites. Some burial sites were simple; others, like the Hopewell complex, a large, precisely built burial mound dating from about 2,000 to 1,500 years ago, show an elaborate ritual associated with funerals. Grave goods brought from distant locations and carved into artifacts were buried with the dead.

Mesoamerica

Prehistoric culture in Mesoamerica (Mexico and Central America) is divided into several time periods dating from about 10000 BCE, the earliest evidence of humans in the area, through the time of colonization by Europeans in the 16th century CE. These periods are the Paleo-Indian (10000–3500 BCE); Archaic (3500–1800 BCE); Preclassic (2000 BCE–CE 250); Classic (CE 200–900); Postclassic (CE 900–1519); and Postconquest (up to CE 1697).

Paleo-Indians

It is believed that the first inhabitants of Mesoamerica arrived during the last Ice Age. Tools similar to those

found in North America indicating the Clovis culture have been discovered in Central America as well. There is evidence as far south as Brazil of the peopling of South America from as long ago as 12,000 years. The first people in Central and South America were hunter-gatherers.

Archaic to Preclassic Eras

During the Archaic era, people began to cultivate plant food rather than forage. Agriculture continued to be developed in the Preclassic era through the cultivation of maize, and the first cities began to appear.

The earliest of the preclassic cultures was the Olmec (1200–500 BCE). The name was provided by scholars; it is unknown what the inhabitants actually called themselves. The Olmec Empire was centered in what is now Veracruz, Mexico, on the southern Gulf Coast. This was the first culture to build stone monuments. Most of these monuments appear to be of rulers. Many have been mutilated. It is not known if the mutilation was intentional for ritual purposes or if it was the work of non-Olmec vandals.

Classic

Perhaps the largest and best known of the classic cultures is the Mayan, although evidence from the Preclassic period indicates they had villages as early as 1800 BCE, and there are still over 6 million Mayans in Central America today. The ancient Mayans occupied an area that included eastern Mexico, northern Guatemala and Belize, Honduras, and El Salvador.

City centers were built in rain forests and were therefore sparsely populated. They were used for ceremonial purposes, including human sacrifice. The farmers lived much farther out, as each needed space for crops. Farming would have been difficult in the humid areas. Slash-and-burn agriculture was practiced, and new land would have had to be cultivated every 7 years.

The Mayans were the first in the Americas to develop writing. Their system was based on hieroglyphics and phonetic symbols. There are some records in the form of *codices*, books made of bark, and writings on stones and wood, which provide mythological and historic accounts of these peoples. The Maya also developed a calendar based on a 365-day year with 18 months of 20 days each plus 5 “unnamed” days. They were also the first civilization to develop a mathematical system using zero.

Postclassic

During the Postclassic era, the autonomous villages began to give way to a more hierarchical structure in which some villages were under the control of others during the period from 1200–500 BCE. Along with this hierarchy came palaces for kings and temples for worship of ancestors.

Temples were often built on pyramids in order to be seen from distances. These would necessarily have required intense labor. Empires were formed as different groups began to conquer neighboring towns and provinces. Some of the early empires were the Teotihuacán (CE 400–600), the Toltecs (CE 900–1200), the Mixtec (or Aztec), and the Incas. These last two were still in existence when the Spaniards arrived in the 16th century.

Aztecs of Central Mexico

Aztec legend has it that Huitzilopochtli (their god) came in a vision and told them to find Tenochtitlan, which they would recognize by finding the place where an eagle lived on a cactus with a snake in its mouth. There, they developed their empire by conquering 489 towns. Tenochtitlan was very well developed with a system of paved streets and canals for transportation.

The Aztecs’ hierarchical structure included three levels of nobility: the *tlatoque* (“major nobility”), *teuctlatoque* (“lesser nobility”), and *pipiltin* (“nobles in general”). These levels were achieved through birth. Others (“commoners”) could earn a certain level of nobility (*quauhpipiltin*) through achievement but never to the same status of the pipiltin. Those without status included the *macehualtin* (“commoners”), *mayerque* (“landless peasants”), *tlalmaitl* (“farmhands”), and *tlacotin* (“slaves”).

Human sacrifices were common and believed to be necessary to appease the gods. The people “harvested” for these sacrifices came from wars and battles with neighboring armies, although in some cases a threat of an attack was enough to simply cause the neighboring army to provide captives for sacrifice. Counterattacks were unknown, as the Aztecs believed that the outcome of the battle was decided by the gods. This fatalism would prove to be their downfall when confronted by invaders from Spain.

Inca—Bolivia and Peru

The earliest Incas lived on coastal lowlands and cultivated beans, squash, chili pepper, and cotton. Later, their descendants moved into the lower Andes and eventually into the highlands. As they moved into the foothills, they began cultivating tubers. Moving farther up the mountains, they figured out how to cultivate the land by building soil terraces and upslopes and digging ditches to bring water down the mountain. They domesticated the llama (as a beast of burden), the alpaca and guinea pig (for meat), and the vicuña (for its wool).

Although they had no written records, the Incas created a “record-keeping system” of colored knots and cords called *quipu*. It was used by priests to keep historic and religious records and was also an accounting method, which could be used for adding, subtracting, multiplying, and dividing.

Machu Picchu, located in the Andean mountains, was a sacred city of the Incan empire. Built with huge granite blocks and without cement, how this grand city was constructed is still unknown. Mystery also surrounds the use of this archaeological wonder. For every 10 women's skeletons found there, there is only one man's remains. Some suggest that the city was a refuge for virgins.

The Incas had no royalty until the 15th century when a small group moved into the Cuzco valley of what is now Peru, and rulers Pachauti and his son Tupac began an empire of some 2 million people. There, they developed a system of roads and bridges through the Andes. This society was based on wealth, power, and political stability.

Future Directions

The study of prehistoric cultures has implications in the fields of medicine, agriculture, and engineering. A rather new field of study called evolutionary medicine, or Darwinian medicine, is beginning to emerge. Through the study of diet and activity levels of early societies, health care professionals may gain insight into diseases and obesity that may be connected with a sedentary lifestyle that hunter-gatherer societies did not experience. Questions about how structures such as pyramids, Machu Picchu, and the Olmec sculptures were built and how the materials were transported without modern technology are still unanswered. Early agricultural practices involved mixed farming. Today, most farms are run by agribusinesses that specialize in a single type of crop or livestock. Genetic variability in these products is small and can lead an entire harvest to be wiped out by disease or plague. Some smaller farms are working on preserving genetic diversity by raising heritage breeds of livestock and planting heirloom seeds of crops. Further archaeological work in areas outside of Africa may yield new theories on how and where people evolved.

Conclusion

While contemporary cultures may be studied through direct observation, anthropologists study prehistoric cultures through the things they left behind. Some of these societies had sophisticated rituals for hunting, religion, death, and warfare and in addition built monuments and other structures that defy explanation today. There is much to study and learn from these cultures. Prehistoric peoples span a time period of over 5 million years, and they ultimately populated the earth on six of the seven continents. Despite popular images to the contrary, not all prehistoric people were "cavemen." Some of the first

prehistoric peoples lived in wooded areas or open sites, and later prehistoric people lived in shelters constructed from wood and other materials. The time periods generally associated with the study of prehistoric cultures (Stone Age, Bronze Age, and Iron Age) are specific to Africa, Europe, and Asia. The names of these ages refer to the types of tools used. Tools became more sophisticated as people progressed through these three ages, leading to the development of trade routes as roads were built and agricultural societies replaced the hunter-gatherer societies.

Evidence of humans in Australia is only about 100,000 years old. And people arrived in the Americas only about 20,000 years ago. Only the remains of the modern *Homo sapiens sapiens* have been found in North and South America.

Europeans who arrived in Australia and the Americas during the 15th, 16th, and 17th centuries encountered people who were living in cultures vastly different from their own.

ANCIENT CIVILIZATIONS

TERRY W. EDDINGER

Carolina Evangelical Divinity School

Many ancient civilizations have added to our current knowledge, technology, and understanding of the world. Some provide the foundations of modern ideology. The ones covered in this chapter commenced the movement from the very ancient agrarian society to modern culture. They are all geographically located in the Mediterranean Basin or the Middle East and include Mesopotamia (Sumer, Babylonia, and Assyria), Egypt, the Hittite Empire, Persia, Greece, and Rome. (See Table 43.1, “Ancient Civilizations Timeline,” at end of chapter.)

Mesopotamia

Often called the cradle of civilization, Mesopotamia was the site of the world’s first cities. This urban development involved not only just a large group of people living in close proximity but also a revolution in social organization, in farming, and in technology. This cultural leap was a transition from the primitive settlement to the modern society.

Beginning around 5500 BCE and continuing for the next 2,000 years, people gradually began to move from the mountains into the Mesopotamian plain and settled in cities. In addition to the development of cities, these people developed irrigation, canals, and flood control. They learned how to drain marshes and to turn them into farmland. They also invented the plow, the wheel, and metallurgy

(copper and bronze). During this time, the Sumerians moved to this area and became the dominate people.

Sumer

About 3100 BCE, the Sumerians developed writing. Initially, the writing took the form of pictographs or hieroglyphics, with each symbol representing a word. By 2500 BCE, the language had simplified and developed into cuneiform, that is, wedge-shaped symbols representing syllables of words. For over 3,000 years, various civilizations, such as the Hittites, Assyrians, and Babylonians, adopted and used this system of writing. Most of the early Sumerian texts were records of economic activity, but by 2500 BCE, they expanded to include religious and literary texts as well as historical documents.

As cities emerged, social and political complexity increased significantly and people developed specialized vocations. These developments led to interdependence. Thus, the people became dependent on outside trade and commerce to meet their everyday necessities. Leaders of cities emerged who sought to expand their influence and control into the surrounding villages, and social classes developed among the populations. These communities developed into city-states. Kings (or warlords) expanded their influence to include other city-states through military conquest. They also captured and enslaved people.

The Sumerians invented bronze, a copper and tin alloy. They developed sculpture (high-profile statues), religious imagery, literary styles, and views on kingship, law, and society. They laid the groundwork for various sciences including arithmetic, astronomy, botany, and medicine. Perhaps most notable, the Sumerians developed monumental architecture. Specifically, they developed temples that sat on ziggurat platforms. These temples, dedicated to a patron deity, functioned as more than just places of worship. They also served as banks, libraries of economic records, and trade and political centers. Priests at these temples wielded enough power that they even rivaled the kings.

Around 2350 BCE, Sargon, an Akkadian from central Mesopotamia, overthrew the Sumerian city-states and began the world's first nation-state. The Akkadians adopted much of the Sumerian culture but used the Akkadian language for international business. They developed a national administration, with appointed officials administering, and military garrisons stationed in conquered cities. The Akkadians extracted tribute from subjected people, levied taxes, and expanded trade to as far away as the Indus Valley to the east and Anatolia to the west.

The Akkadian state was short-lived. Around 2150 BCE, the nation collapsed and individual city-states reemerged. Lagash and Ur were two of the more successful city-states. They expanded their control into small empires based on economics rather than military strength. Ur soon became the stronger state and ruled all of Mesopotamia by 2111 BCE. Ur inaugurated a massive building program, its crowning achievement the completed ziggurat dedicated to the moon-god Nanna. They improved transportation on land, on rivers, and on canals; developed law codes; established standardized dry weights and measures; and maintained a strong, centralized government. Influxes of people from the mountains and internal revolts led to the fall of the last Sumerian kingdom (around 2000 BCE).

Babylonia

A new group of Semitic people, the Amorites, moved into Mesopotamia around 1800 BCE, threw off Elamite domination, made the city of Babylon their capital (creating the Old Babylonian Empire), and elevated Babylon to the status of a holy city, a status it would retain throughout ancient history. Hammurabi (1792–1750 BCE), king of Babylon, conquered the Assyrians and claimed to have extended his empire to the Mediterranean Sea. He is most renowned for his law code, which is a valuable source of information on the social structure of this time. His law code, carved on an 8-foot stela of black diorite, was based on an earlier Sumerian code except harsher. Furthermore, Hammurabi is known for his diplomacy and administration. He entertained foreign diplomats. He had advisers and noblemen to oversee his empire. He held court for his subjects, where he heard and acted on their grievances

personally. Also, he maintained control of the military and oversaw public works building programs.

The glory of the kingdom was short-lived. The kings gradually lost their military power and authority. Around 1595 BCE, the Hittites plundered Babylon and returned to their land. Babylon never recovered from this blow and proved too weak to resist new invaders, the Kassites from the Zagros Mountains area.

The Babylonians developed complex mathematics, which included geometry and algebra. They developed a system of symbols representing the values of numbers (such as 100s, 10s, and 1s), knew the value of π (a mathematical constant, 3.1415927, which is the ratio of the circumference of a circle to its diameter), and developed a sexagesimal counting system (based on 60) that has survived until modern times. One Babylonian text has tables that give the square root of numbers to 59 and the cube root of numbers to 32. Also, they invented the abacus, a primitive calculator. The Babylonians applied their mathematics to commerce and large-scale building projects.

Assyria

One of the results of the Amorite invasions around 2000 BCE was the establishment of a dynasty around three Assyrian cities—Nineveh, Arbela, and Ashur. This event marked the beginning of the Old Assyrian period (2000–1363 BCE). Little is known about the Assyrians during this period except that they had trade relations with the Hittites and that Babylon was already a rival kingdom. Assyria began expanding and developing into an empire during Assyria's Middle Kingdom (1363–1000 BCE). They defeated the neighboring Mittani kingdom. They had an ongoing war with Babylonia and at times were able to control Babylon. Also, they fought against tribes to their north and west. The Middle Kingdom ended as Assyrian strength succumbed to the increasing Aramean pressure.

Assyria began to exert its might at the end of the 2nd millennium BCE, beginning the New Kingdom (1000–609 BCE) and what historians call the Assyrian Empire. The empire reached its zenith in the 8th and 7th centuries BCE. Tiglath-pileser III incorporated Syria into his kingdom, as well as set himself up as king of Babylon. His successor, Sargon II, added Palestine. In 663 BCE, Esarhaddon conquered Egypt and expanded Assyrian influence and control to its greatest extent. The Assyrian Empire fell to a Mede and Babylonia coalition through a series of battles. The coalition defeated Nineveh in 612 BCE and Haran in 609 BCE, and it won the final battle fought at Carchemish in 605 BCE.

The last great Assyrian king was Ashurbanipal (669–627 BCE), who had the Babylonian library texts copied and then deposited in Nineveh. The discovery of this library in the 1800s proved to be one of the most important Assyrian archaeological discoveries as the library contained many

texts from earlier civilizations, including a copy of the *Epic of Gilgamesh*, a 3rd-millennium Sumerian story.

Assyria is noted for its practice of exiling captured people. They moved entire populations, including the Israelites, Babylonians, Persians, and Arabians. This policy was not only to control the populations to prevent uprisings but also to maximize skills of certain peoples. For example, some foreign people worked for the Assyrians as scribes, interpreters, artisans, architects, and skilled laborers.

The Assyrians were also known for their proficiency in warfare. They incorporated the war chariot, the use of a cavalry, and iron weapons into their warfare. However, the Assyrian army preferred siege warfare, which they developed to an art. They circled a city, closing off any escape. They shouted at the population, telling them to surrender. After the city weakened from a lack of water and supplies, they attacked the city walls with siege engines and battering rams, contraptions that they had invented. Also, they used psychological warfare. They displayed flayed, defeated warriors; burned people alive; impaled warriors on tall poles in front of a city after a siege; and cut off hands, ears, and noses. These displays served to dissuade others from rebelling.

Babylon experienced a revival under King Nabopolassar (626–605 BCE). He, in a coalition with the Medes, defeated the Assyrians and permanently ended their dominance. Nabopolassar established a short-lived empire (the Neo-Babylonian Empire, or Chaldean Empire) of the once Assyrian-controlled lands. His son Nebuchadnezzar (605–562 BCE) expanded and consolidated the empire. Nebuchadnezzar is renowned for defeating Judah, destroying Jerusalem, and carrying the Jews into exile (586 BCE). After Nebuchadnezzar died, the empire deteriorated under the rule of inept leaders until Cyrus the Persian (also known as Cyrus the Great) captured Babylon in 539 BCE.

Egypt

A cursory look at the monuments of ancient Egypt reveals that this ancient civilization was not only impressive but also important to regional cultural development. The mere mention of ancient Egypt brings to mind Pharaohs, gigantic pyramids, elaborate temple complexes, and hieroglyphics—Egypt's picture language. Not only was ancient Egypt the longest existing ancient civilization, but also it was a unique civilization in that, unlike Mesopotamia, desert and the Mediterranean Sea surrounded its arable land and isolated the Egyptians from other groups of people. Also, Egypt was unique in that life and culture centered on, depended on, and were shaped by the Nile River.

Although people lived in the area from 5500 BCE, historians usually define the kingdom of ancient Egypt as the time between the beginning of the dynastic period around 3100 BCE and the conquest of Alexander the Great in 332 BCE. The dynastic period began with the unification

of Lower and Upper Egypt under one ruler. Little is known about this ruler (usually associated with Menes, or Narmer) or the unification of the two kingdoms due to a lack of written and physical evidence. What is known is that Early Dynastic Egypt (ca. 3100–2640 BCE) was a peaceful kingdom in which the rulers established a standard for the following dynastic periods. They traded as far south as Nubia and into the Levant as far as Syria and had already begun to exploit turquoise mines. During this time, the Egyptians advanced religion, promoted the notion of kingship, centralized governmental administration, developed sophistication in art and architecture, introduced hieroglyphic writing, and initiated the building of pyramids as funerary monuments.

In the Old Kingdom period (ca. 2640–2160 BCE), the Egyptians advanced monumental architecture to levels never seen before and rarely reached afterward. During this period, the pharaohs built the Great Pyramids at Giza, Saqqara, and elsewhere. Such building feats demonstrate that the pharaoh had centralized control of a willing population in addition to having a highly developed bureaucracy needed to undertake such projects. This development also demonstrates that the Egyptians had knowledge of higher mathematics and skill in moving extremely heavy building materials.

Egyptian art became standardized into “Egyptian” form during the Old Kingdom. It became elegant in style, with attention given to linear and rectilinear control and to baselines. The artists paid close attention to natural forms. For example, they drew animals in a common posture as found in the wild so that they looked realistic. Egyptian artists drew humans in an ideal form. They depicted men as being tall, lean, and fit, having broad shoulders and a narrow waist. They depicted women as young, slender, and well shaped, without any excess fat. Artists portrayed both men and women as having an air of self-confidence, balance, and proper proportions.

After a period of war and disunity (First Intermediate period, ca. 2160–2040 BCE), Egypt entered the Middle Kingdom period (ca. 2040–1650 BCE). Provincial lords held much power during much of this period in Egypt. However, the government did regain enough internal stability so that it could reestablish trade with the Levant (Byblos and Ugarit) and Lower Nubia.

During the Second Intermediate period (ca. 1670–1550 BCE), an Asiatic people that Manetho (an Egyptian priest and historian from the 3rd century BCE) called the “Hyksos” ruled Egypt. Eventually, the Thebans ran them out of the country and reunited Egypt. Battle with the Hyksos marked the beginning of a warrior culture in Egypt that led to its rise as a military power that had an organized, standing army. Also, the Egyptians made several innovations in weapons and military technology. They incorporated the chariot as a fighting platform into their ranks as well as the composite bow. This warrior mentality and a predisposition toward expansionism predominated the

New Kingdom period (1550–1070 BCE), a time when ancient Egypt reached the height of its influence, wealth, and power. The pharaohs, particularly Thutmose III, made multiple campaigns into Nubia and into Asia as far as the Euphrates River, amassing the largest empire of ancient Egypt.

Almost all pharaohs of the 18th and 19th dynasties made military campaigns outside of Egypt's traditional borders and then returned home to have their exploits written down and put on public display at temples and at their elaborately built mortuary complexes. The most famous of these campaigns is the battle of Rameses II with the Hittite Empire at Kadesh on the Orontes River. These two chariot armies fought for 2 days before the battle ended in a stalemate. On returning home from the battle, Rameses II had accounts written of the battle, portraying him as the victor, and displayed these accounts at various places throughout his empire. Gifted with a long, 67-year reign, he had more cities, temples, statues, and monuments built than any other pharaoh.

The end of the New Kingdom marked the end of Egypt's empire and her golden years. After the death of Rameses III (1152 BCE), Egypt lost control of the Levant and much of Nubia, due mainly to the invasion of the Sea Peoples and internal struggles. Papyri dating to this time indicate widespread corruption and internal strife. Although a few pharaohs exerted power, none could build an empire. After falling to the Libyans, Nubians, Assyrians, and Persians, Egypt fell finally to Alexander the Great, the Macedonian, in 332 BCE. Egypt did have some glory in the Ptolemaic period (323–30 BCE). Egyptian religions were popular throughout the Hellenistic and Roman worlds, especially mystery religions. Furthermore, the Egyptian coastal city of Alexandria, founded by Alexander, became the learning center of the ancient world during this time, having a library with a vast collection of writings.

One of the more interesting anthropological developments unique to ancient Egypt is the influence of women. Egypt had two women pharaohs for certain: Hatshepsut (18th Dynasty, 1479–1458 BCE) and Cleopatra VII (69–30 BCE). Hatshepsut ruled for 22 years and engaged in warfare in Nubia, the Levant, and Syria. She established trade relations with the land of Punt when she brought back 31 live frankincense trees, the first recorded attempt to transplant a foreign plant. Also, she engaged in a massive building campaign at Karnak and Beni Hasan, with her greatest project being her mortuary temple complex at Deir el-Bahri. Egypt possibly had other women pharaohs; however, the Egyptian records are not clear as to their role or function. These women include Merneith (1st Dynasty), Nimaethap (3rd Dynasty), Ankhnesneferibre II (6th Dynasty), Nitocris (6th Dynasty), Sobekneferu (12th Dynasty), Ahhotep I (17th Dynasty), Nefertiti (18th Dynasty), Meritaten (18th Dynasty), Neferneferuaten (18th Dynasty), and Twosret (19th Dynasty). Whether pharaohs or not, these were women of great influence. Also, Egyptians held the belief

that women carried the royal bloodline. Men had to marry a royal woman, usually the eldest daughter of the previous pharaoh, in order to be pharaoh. Furthermore, ancient Egyptian women had more rights than women in other contemporary cultures. They could own land, inherit from family members, and even go to court to defend their rights.

Ancient Egypt's imprint on humanity continues to be visible today. The Great Pyramids of Giza, Rameses colossal statues, numerous hieroglyphic texts, and Bible stories of the Hebrews' struggle in Egypt are all markers of this past great civilization. Archaeological discoveries, such as Tutankhamun's gold-filled tomb, a plethora of mummies (and the so-called mummy's curse), and ornate temples and buildings, combined with the ancient Egyptian obsession with the dead, have fueled the storyline of many modern novels and movies. Ancient Egyptian art continues to impress upon modern culture and continues to be appreciated for its simplistic yet sophisticated elegance.

The Hittites

The Hittites were an Indo-European people of mysterious origins who peacefully arrived in central Anatolia around the beginning of the 2nd millennium BCE. The Hittite kingdom centered on the city of Nesa and the capital city of Hattusa (located near Boghazköy in modern Turkey). These cities also are significant in that the Hittites called their language "Nesite," named after the city of Nesa, and called their kingdom "the land of Hatti," named after the capital city of Hattusa.

Scholars divide Hittite chronology into two periods: the Old Kingdom (ca. 1750–1500 BCE) and the Hittite Empire, or the New Kingdom (ca. 1430–1180 BCE), with a time of turmoil in between sometimes called the Middle Kingdom. During the Old Kingdom, the Hittites expanded from being colonies of merchants to a kingdom incorporating much of Asia Minor and northern Syria. The most notable event and demonstration of Hittite power came in 1595 BCE when the Hittites under Mursili I took northern Syria, the city-state of Aleppo, and then sacked Babylon, ending the Old Babylonian Kingdom.

After a period of internal struggling for control of the throne, the Hittites once again exerted their power and thus began the New Kingdom. This kingdom expanded to include most of Anatolia and northern Syria. During this time, the Hittites rivaled Egypt in power and influence. In 1274 BCE, these two kingdoms met at Kadesh to fight one of the greatest chariot battles of the ancient world. Although the battle ended in a draw, Rameses II had accounts of the battle describing his great victory written in public places all over Egypt. A few years later, the Egyptians and Hittites made a peace-and-mutual-protection treaty, one of the first of its kind in history. The Hittite Empire ended suddenly around 1180 BCE with the mass migration of the Sea Peoples.

Although nearly forgotten for 3,000 years, the Hittites were one of the most significant civilizations in the ancient Near East. Archaeological excavations in the late 19th and early 20th centuries turned up tens of thousands of texts on clay tablets. Although many of the texts were written in Assyrian or Babylonian cuneiform and could be translated, scholars could not read the Hittite hieroglyphic texts for almost a century after their discovery. Once deciphered, these texts divulged a wealth of information about the Hittite civilization, including laws, treaties, business transactions, correspondences, and religious rites. Also, these texts show that the Hittites excelled at commerce. They traded throughout the ancient Near Eastern world, connecting the Mesopotamian world to Palestine, Egypt, Greece, and the eastern Mediterranean area. The Hittites adopted and modified Sumerian and Old Babylonian culture, including laws, political and economic structures, and ideas, and they passed this culture to their commercial partners. Also, Anatolia was rich in raw ores and metals, which were the Hittites' main items of trade. Particularly, the Hittites developed technology in working with iron thereby leading the transition of this region into the Iron Age. Furthermore, they invented the war chariot and were among the first people to use iron weapons. The combination of the war chariot and iron weapons made them formidable in battle.

Hittite texts also included many laws and treaties. In terms of laws, Hittite laws tended to be fairer than the harsh Babylonian laws, with much fewer capital offenses. The most famous treaty, and the oldest known nonaggression document in history, was one made between Hattusili III and Rameses II of Egypt in 1258 BCE. In this treaty, both sides agreed to cease hostilities against each other and come to the other's aid in the event of external or internal aggression. They sealed the treaty by Rameses II marrying the daughter of Hattusili III; thus, they became in-laws. Such marriage alliances were a common practice in the ancient Near East.

Also, the Hittites are known for their architecture. Hattusa was a heavily fortified, 300-acre city with massive walls, monumental administrative buildings, and grand temples. Recent discoveries show that the Hittites initiated the creation of the underground cities in Cappadocia. Authorities believe that the Hittites began carving underground chambers for storage. The Phrygians expanded these areas into underground cities for protection against the Assyrians.

The Hittites were very accepting of the culture and traditions of other peoples, even their gods and religions. The religious shrine at Yazilikaya, a site located about one kilometer northeast of Hattusa, best demonstrates this incorporation of foreign deities. The Hittites carved this shrine from a natural outcropping of rock that formed two natural chambers. The Hittites carved a parade of Hurrian deities down the side walls of the larger chamber. The two processions of carved figures, one of male and one of female

deities, converge on the back wall. All totaled, they number about 70 figures. Because of their tolerance and incorporation of foreign deities, the Hittites became known as the "kingdom of thousands of gods."

Future research in Hittite studies, particularly of the Hittite texts and continuing archaeological excavations of the main sites, will further illuminate this once lost and remarkable civilization. One of the most exciting areas of current research is the study of the Hittite development of and influence on the Cappadocian underground cities.

Persia

The Persians went from being a group of nomadic tribes to a first-rate empire in the span of a generation. At its height, the empire stretched from the islands of the Aegean Sea and Libya in North Africa in the west, to India in the east, to the Aral Sea and the Jaxartes River in the north, and to the Persian Gulf and Indian Ocean in the south. Cyrus II the Great began expanding Persia, originally located in the Zagros Mountains of what is modern Iran, in 550 BCE by conquering their overlord to the north—Media. This event began the Achaemenid Empire, or Persian Empire, and propelled the Persians on their way to building the largest empire of the ancient world. This empire endured until Alexander the Great of Macedonia defeated Darius III, the last Persian king, in 331 BCE. After Media, Cyrus turned his attention west where he defeated Lydia (in modern Turkey) in 546 BCE, then central Asia, and then Babylon in 539 BCE. Cyrus died in 530 BCE and left the empire to his son Cambyses. Cambyses continued Persian expansion by conquering Egypt in 525 BCE. Darius I the Great usurped the throne after the untimely death of Cambyses in 522 BCE. After stabilizing the empire, Darius instituted many reforms that made Persia great, including improvements in roads, better communications, building programs, the introduction of coinage, and so on. Darius sought to add Greece to the empire, thus beginning the Persian/Greek Wars, but died before he could accomplish this task (486 BCE). Darius's son Xerxes launched a massive land and sea invasion into Greece only to be defeated by a much smaller Greek army and navy. This defeat ended Persian expansionism and marks the height of the Persian Empire. Artaxerxes, Xerxes's son, sued for peace with the Greeks in 449 BCE. Subsequent Persian kings, not being great military generals like Cyrus and Darius I, dealt mostly with internal issues. The Persian Empire fell to the young, ambitious king of Macedonia, Alexander the Great, in 331 BCE.

Politically, the Persians did not follow some of the practices of preceding empires. They allowed exiled peoples to return to their homelands. They encouraged and often paid for the rebuilding of foreign temples. They allowed local rulers to govern their own territories by their own laws. Also, they incorporated foreign armies, usually of defeated foes, into the Persian army; thus, they could amass vast

armies at will. For example, Darius III's army numbered over one million when he battled Alexander the Great.

The Persians also brought innovation to the ancient world. They made paved roads, with small relay stations spaced out about one day's journey, so that people could travel in comfort and safety. However, travel on Persian roads required a travel document—a pass. The Persians had an express postal system along these roads. News from the Aegean Sea, for example, could reach Susa, some 1,200 miles away, in less than 2 weeks. The Persians learned about and adopted the use of minted coins (standardized currency) from the Lydians and spread it throughout the eastern part of the ancient world. Darius I particularly promoted coins, even to the extent of having a denomination of gold coin named after him—the *daric*. Darius used coinage to standardize the payment of tribute from subjugated nations and people groups. Because of the efficient tribute system, the Persian Empire was one of tremendous wealth. The Persians also introduced the first known team sport—polo. It was a fast-paced game with few rules to the extent that fatal injuries were common. They also played a game similar to modern chess.

Studies of the Persian Empire have increased in recent years. Scholars have recognized that the Persian and Greek wars were a defining point for East/West relations. They were not only a clash of militaries but also a clash of cultures, social customs, and worldviews as well. Had Persia won those wars, Europe and the West would look vastly different today. This clash of cultures is still a sticking point as demonstrated by the terror attacks on the United States on September 11, 2001, and subsequent attacks on Western nations.

Greece

The ancient Greeks, especially those of Archaic and Classic Greece, influenced modern Western culture more than any other ancient civilization. Philosophy, democracy, architecture, theater, art (particularly sculpture), literature, and loan words (English words derived from Greek) are just a few contributions the Greeks made to Western culture.

Greece, being a mountainous country with small plains and valleys and a plethora of islands, naturally lent itself to the development of semi-isolated city-states. Furthermore, given the mountainous terrain, the Greeks found the sea to be well suited for communication and travel, and it became their primary means of contact with other cultures.

The Mycenaean Civilization

Often referred to as representing the first civilization of modern Europe, the ancient Greeks were an Indo-European group that moved into the area around 1900 BCE. By 1600 BCE, the Greeks had developed into a warrior society, and they had begun to expand their influence into

the Aegean and Mediterranean seas. They captured Knossos, the palatial capital of the Minoan civilization on Crete. About a century later, the palaces at Knossos lay destroyed; however, the Mycenaean began building palaces on the Greek mainland at sites such as Mycenae, Tiryns, Thebes, Orchomenos, Pylos, and Athens. The Mycenaean constructed megalithic fortifications around these cities with thick walls and massive gate complexes. This period is also known for large *tholos* (cone shaped) tombs and chamber tombs. The Mycenaean mastered hydrology as demonstrated through their building of dams and dikes and their channeling of water via aqueducts into their cities where it collected in underground chambers. Perhaps their greatest hydrological feat was draining the valley area called the Kopais basin—formerly the largest lake in central Greece, a natural, shallow marshy lake measuring about 18-by-11 kilometers—and turning it into farmland. They developed a series of canals leading to a central canal that funneled the water into the northern Euboean Gulf. The Mycenaean heavily fortified a site called Gla, a former island in Lake Kopais, to protect this drainage system. Gla, the largest of Mycenaean sites in land area, had cyclopean walls measuring up to 6.75 meters thick 5 meters high, and stretching over 2.8 kilometers around the site.

Archaeologists have discovered many Mycenaean period texts, written in a script linguists call Linear B. These texts are concerned mostly with business matters including taxation, sale of slaves, distribution of rations, descriptions of textile and furniture production, lists of weapons, estate holdings, and so on. Some of the texts also deal with social matters and politics.

The Mycenaean were a seafaring people. Items discovered in tombs show that they traded at sites all over the Mediterranean Sea area, including Egypt, Phoenicia, Syria, Asia Minor, Crete, Sardinia, Sicily, Spain, and southern Italy.

For unclear reasons, the Mycenaean civilization came to an abrupt end around 1200 BCE. The palatial cities were destroyed, and the people migrated away from these cities to other areas near the Mediterranean Sea or to naturally defensible positions. Political organization changed radically, and writing stopped. This upheaval moved Greece into the Dark Ages (ca. 1100–776 BCE).

Archaic and Classical Greece

The Archaic Age (776–500 BCE) was a time of immense change in Greece. People began to resettle the cities throughout the Greek mainland, which developed into autonomous city-states. They also scattered throughout the Mediterranean world, settling colonies in southern Italy; southern France; on Sicily; on the islands of Rhodes, Cyprus, Lesbos, Crete, and Samos; in Asia Minor; and along the shores of the Black Sea. Although scattered, the Greeks had some commonalities that promoted loyalty. They were of the same race, spoke the same language,

worshipped the same pantheon of gods, held many of the same religious and national myths, and participated in pan-Hellenic cult centers located at Delphi, Delos, and Olympia. Monarchs, members of families of nobility, ruled the city-states at the beginning of the Archaic Age; however, tyrants (Greek *tyrannoi*) ousted the monarchs and were the primary rulers by the end of the age. In conjunction with, and in contrast to, the move toward tyranny was the extension of citizen rights to people outside nobility, usually expressed in the form of city councils.

Athens began developing its democratic form of government in the early 6th century BCE, but it did not reach its fullest form until the 5th century BCE. This city-state was unique in that its citizens could elect political leaders, military generals, and other government officials. They could even vote to banish someone from the city. During this election, the people wrote on a piece of broken pottery, called an *ostrakon*, the name of a person they wanted removed from the city. The person receiving the most votes then had 10 days to permanently leave the city; hence, they were “ostracized.”

In general, Greek city-states flourished during the Archaic Age. They traded extensively with each other and with *barbaroi*, that is, non-Greek-speaking cultures. The Greeks adopted and spread the use of coins, a Lydian invention, which aided in commerce and trade. They also began the tradition of making coins in the shape of flat, round discs with impressions and texts on both sides (heads and tails). Two confederations of city-states dominated this age: the Thessalian League in the north and the Peloponnesian League led by Sparta in the south. The Spartans dominated the Peloponnesian League to the point that they invaded their neighbor, Messenia, and enslaved them (whom they called Helots). Athens did not join either league but rather chose to be independent, eventually creating its own league. Growing tensions between Athens and Sparta tended to dominate national politics late in the Archaic Age. Although related, the Greeks tended to mistrust and fight each other as exemplified by Athens and Sparta’s dubious relationship. However, they tended to join together against a common external foe, as they did against the Persians in the 5th century BCE.

In addition to politics, the Greeks excelled in art, architecture, philosophy, and literature in the Archaic Age. They began to paint pottery with lifelike scenes, depicting both real and mythical events and settings. The two most popular types of pottery painting styles were black figure and red figure where the painters depicted the principle people or characters in either black paint or as the natural red color of the pottery. Both skillfully depicted human and mythic figures in fine detail. This period saw the beginning of monumental sculpture. Sculptors carved humans in life-size or larger than life-size forms in the round. Architecture incorporated symmetrical design and columns using mostly stone for building material. This marks the beginning of “classical architecture,” a style highly influential

up to modern times. Persian and Babylonian thought influenced Greek philosophers living in Miletus, such as Thales, Anaximander, and Anaximenes. They began to ponder the nature of man and the universe as well as mathematical and astronomical principles. Some of the philosophers, like Pythagoras, developed schools and trained followers (students). Although much poetry is attributed to this period, the greatest literary works are the writings of Homer and Hesiod. These works shaped Greek mythology, and scenes described in their literature became common themes in Greek art.

The Classic Age (500–338 BCE) was more a refining of Archaic traditions and customs than a distinct age. War, both external and internal, dominated this period. The Greeks fought the Persians (499–479 BCE) in several key battles—Marathon (in 490 BCE), Thermopylae (480 BCE), Salamis (480 BCE), and the final battle at Plataea (479 BCE). The Persians vastly outnumbered the Greeks in each battle, and the fact that the Greeks won every battle except Thermopylae (which was a psychological victory) is amazing. The Greeks’ surprising victories can be attributed to their using heavily armed infantry who fought as a unit against a lightly armed enemy who fought as individuals, their selection of strategically advantageous locations for battle, their making fewer mistakes than the Persians, and luck. The Spartans, under oligarchic rule, won on land, and the Athenians, under democratic rule, won on sea. These differences in political ideology set the stage for a later clash between these two city-states and their allies. Furthermore, the defeat of the Persians was one of the most defining events of Western civilization, galvanizing a conflict between the East and the West that is still present today. If the Greeks had lost, then the Persians would have taken most of Europe thus radically changing history and the modern world.

Greece enjoyed peace for nearly 50 years after the Persian defeat. Athens grew to be the largest city in the world and created a seafaring empire. Athenians began electing juries to courts and electing and paying magistrates. They even allowed poor people to participate in politics, a move that promoted the fledgling democracy. Sparta continued in its traditional ways. This difference between Athenian and Spartan rule and customs led to growing mistrust and ultimately conflict. In 431 BCE, the Corinthians asked the Spartans for assistance against Athenian oppression. Sparta agreed. This act began the Peloponnesian War (431–404 BCE), a civil war that nearly tore Greece apart and began the decline of the Greek civilization. Sparta came out victorious but even Sparta fell to Thebes in 371 BCE. Greek power continued to wane until Philip II, king of Macedonia, defeated the Greeks at Chaeronea in 338 BCE and incorporated them into the Macedonian kingdom.

The period between the Persian and Peloponnesian Wars were the golden years of ancient Greece and perhaps the time of greatest influence for modern Western culture.

Architecture, literature, and art thrived. The Athenians, under the supervision of the great sculptor Phidias, constructed the famous temple to Athena on the acropolis at Athens, containing a large statue of Athena. The gold plating on the statue of Athena reflected the wealth Athens brought in from its empire. During this time, the great playwrights Aeschylus, Sophocles, and Euripides wrote tragedies while Aristophanes wrote comedies. Herodotus and Thucydides wrote histories, which are significant sources for the modern understanding of ancient events. People listened to great orators, such as Pericles, and a little over a century later, Demosthenes. Socrates, followed by Plato, Xenophon, Aristotle, and Aristophanes, laid the foundation for Western philosophy. In the Hellenistic Age (323–31 BCE), Greece also excelled in discoveries in science and mathematics.

Fortunately, Greek culture did not end with the fall of the Greek city-states. Alexander the Great, Philip II's son, adopted Greek culture and spread it eastward throughout his empire. A few centuries later, the Romans also adopted and spread Greek culture except this time throughout the Mediterranean Basin and into Western Europe.

Rome

The Roman civilization was the last major ancient civilization before Europe and North Africa plunged into the Dark Ages. Modern Western civilization owes much to the Romans, including the influence of the Roman legal system, tactics in warfare, monumental architecture, the spread of Christianity, and the *pax Romana*—the peace of Rome. The Roman civilization was also one of the most enduring civilizations, lasting over 1,200 years.

The city of Rome lay north of the Greek colonies in southern Italy and south of the metal-producing cultures of Central Europe; thus, both cultures influenced it and traded with it. Furthermore, the city was far enough away from the sea to avoid pirates but sat at the first practical crossing of the Tiber River. Being located in the center of the Mediterranean Basin made Rome strategically located to be the capital of a Mediterranean/European empire.

According to tradition, Romulus founded the city of Rome in 753 BCE. However, historians know little about the early history of Rome, except that it was a part of a collection of individual communities in Latium. During its early years, kings ruled Rome and established its political and religious institutions. Rome grew to be a prominent city, partially due to its geographic location, and eventually became the capital of Latium.

In 509 BCE, patrician nobles overtook the government, ousted the king, and began the Roman Republic (509–48 BCE). Under the Republic, the Senate ruled the people and selected magistrates to oversee various administrative functions, including the military. The Senate could

appoint a temporary dictator (for up to 6 months) in times of crisis or war. Roman society also contained groups other than the patricians, including the plebeians, who were free-born commoners. For 200 years after the beginning of the Republic, these social classes struggled for power. In the end, the plebeians won equal rights with the patricians, including the right to vote, hold offices, and make law and the right to intermarry with patricians.

Rome's realm of control and influence spread during the Republic years. In 338 BCE, Rome began to fight with other members of the Latin League and defeated them. Then, the Romans fought the Samnites in the mountains of central Italy, and they had subdued them by 295 BCE. Twenty-five years later, they controlled the entire Italian peninsula, having defeated the Etruscans, the Gauls, and the Greek colonies in southern Italy.

Rome rapidly expanded its land holdings during the three Punic wars (wars against Carthage). During the First Punic War (264–241 BCE), Rome made Sicily, Sardinia, and Corsica their first provinces. They added the eastern and southern sections of Spain during the second war (218–201 BCE, also called the Hannibalic War) and annexed North Africa during the third war (149–146 BCE). These wars left no doubt that Rome was the supreme power in the Mediterranean area. Between the wars, Rome defeated the tribes of southern Gaul and began to spread to the Greek-controlled territories to the east. Contact with the Greeks brought Hellenization to the west (Alexander the Great had spread Hellenistic culture as far as India to the east and Egypt to the south). Rome adopted much of Hellenistic culture, including its religion, art, architecture, literature, and language. The Romans even stole sculptures and objects of art from Greece and took them to Rome. They effectively spread a common culture, the process of Hellenization, into all areas of the ancient Mediterranean world.

A fast-growing population in Rome provided the need for efficiency and promoted the seed of invention. The Romans invented the screw and various kinds of gears, devices they used to make grain mills more productive. They developed aqueducts to bring water from mountains many kilometers away to supply their many fountains and baths with fresh water. They created waterwheels to power olive presses, winepresses, or presses to crush metal ores. Also, they created animal-powered machines similar to the ones powered by water. They developed ceramic technology so that they could mass-produce terra-cotta items, such as fine tableware, roof tiles, and fired bricks. In the late 1st century BCE, they invented glassblowing. The Romans used shipping to move goods cheaply throughout the republic; thus, all kinds of goods flowed throughout the Mediterranean Basin. They built protected ports and lighthouses to aid their maritime interests.

The Roman Republic ended when the Roman system of government (the Roman Senate) could no longer

effectively rule the vast region that Rome controlled. Therefore, powerful men began to serve as tribunes for the people, usually having their own armies and serving over a geographical region within the republic. This led to the Senate's appointment of the First Triumvirate: Julius Caesar, Pompey the Great, and Licinius Crassus in 60 BCE. These men added vast areas to the empire—Caesar added Gaul and Pompey added Syria and Palestine; however, Crassus died in battle fighting the Parthians in southwest Asia. Civil war broke out between Julius Caesar and Pompey when Caesar brought his army south of the Rubicon River and into Rome in 49 BCE. Caesar defeated Pompey in 48 BCE and became sole ruler, thereby ending the Roman Republic. Senators who supported oligarchic rule assassinated Caesar on March 15, 44 BCE, the famous “Ides of March.”

After another period of civil war, Caesar's chosen heir, Octavian Augustus, became the first Roman emperor in 31 BCE. He reorganized the Roman Republic into an empire, consolidating power under the emperor (the principate) and away from the senate although he kept the magistratures in place. Through good administration, he brought organization and efficiency to the empire. He placed the army along the borders of the empire to protect it, and he changed the policy from treating conquered territories as such to treating them as peaceful provinces. He instituted a system of taxation that replaced extortion as a means of collecting revenues. By the end of his 44-year rule (CE 14), Augustus had reorganized Roman politics and laid the foundation for the institution that would govern the Roman world for the next 400 years. Augustus brought peace (*pax Romana*) to the Mediterranean world thereby allowing commerce, literature, and the arts to flourish. During the 1st century CE, Christianity, a new sect out of Judaism, began to spread throughout the empire. Christians tended to maintain their own culture and traditions, and that attracted suspicion. Under Nero (CE 54–68), they became the object of persecution.

Perhaps one of Rome's greatest achievements, and certainly an icon of its strength, was the Roman Colosseum. Vespasian (CE 69–79) began building the colosseum about CE 71, but it was not completed until the reign of Titus (CE 79–81) in CE 80. This elliptical structure measured 189 meters long, 156 meters wide, and 48 meters high and had a seating capacity of around 50,000. The colosseum floor covered underground rooms and tunnels where performers and animals remained until elevators and pulleys raised them up. The colosseum hosted a variety of shows, including battles with gladiators. The colosseum is a major tourist attraction in modern times.

The Roman Empire reached its largest extent under the emperor Trajan (CE 99–117). Trajan conquered Arabia, Mesopotamia, and Dacia. A few years later, Hadrian (CE 117–138) had to evacuate Mesopotamia thus starting the shrinking of the empire. Trajan's reign began a “golden age” for the empire that lasted until the

death of the “philosopher emperor” Marcus Aurelius (CE 161–180). The empire enjoyed good rule, relative peace, and cooperation between the senate and the emperor. During this time, many people became Roman citizens. Architecture flourished such as the building of Hadrian's Wall across Britain. The Romans invented concrete at this time. Concrete allowed for the construction of structures that spanned wide spaces. Literature also flourished, as exemplified by Tacitus's writing of history and Juvenal's writing of satire.

The 3rd century CE saw the beginning of great change. Caracalla (CE 211–217) granted Roman citizenship to all people within the empire. This move shifted the tensions between citizens and noncitizens to a struggle between the upper and lower classes. Internal struggles and foreign invasion began tearing the empire apart. The Roman emperors blamed the Christians for the empire's plight and began widespread persecutions. Although persecutions had been carried out sporadically and locally before, Decius (CE 250) and Valerian (CE 257) carried out general, empirewide persecutions of the Christians. Interestingly, Christianity became a tolerated religion under Constantine I the Great (CE 306–337) and made the official religion of the empire under Theodosius I (CE 379–395).

Diocletian (CE 284–305) realized that the empire was too large for one person to control. He created the tetrarchy in CE 285 thereby dividing the empire in half into the West and East. In CE 324, Constantine I established the city of Constantinople as the Eastern capital. Afterward, the East (Byzantine) Empire prospered while the West disintegrated. The city of Rome finally fell to Germanic tribes in CE 476 thus ending the Roman Empire. The East (Byzantine) Empire continued to exist and thrive until the Ottoman Turks captured Constantinople in CE 1453 and ended the empire.

The Roman civilization set the foundation for Western culture. It introduced and spread the Latin language, provided a legal system that many modern Western governments would emulate, and spread or produced many inventions that aided in mass production. Also, the Roman Empire saw the development and expansion of Christianity. Interestingly, the church was the means that provided continuity of culture into Europe's Medieval Age.

Conclusion

Modern Western civilization owes much to the civilizations of the Mediterranean Basin and the Middle East. They provided the foundation for art, architecture, science, mathematics, literature, religion, philosophy, law, and technology. One can hardly walk in a modern, Western city and not see evidence of this influence in architecture or hear it in the words people speak. Even the names of the stars and planets have links to these ancient cultures.

HISTORY AND ANTHROPOLOGY

MICHAEL J. FRANCISCONI

University of Montana Western

History is both a structured and a dynamic process. The history of history begins with the proposition that it is the telling of history that is important. Objectivity is a specific interpretation that is related to a specific subjective reference point. The social facts a historian deals with are related to dominant but changing social forces that appear dissimilar to people with different points of reference. These social facts and forces are defined in terms of historical trends that are interpreted differently by different historians of the same time period. Historical trends then presuppose that a transformation is happening with these social facts. Changes in the social life of a nation are reflected in the changes in the class structure, and ultimately changes in the productive techniques and social environment.

Human knowledge as expressed by individual psychology develops collectively through growing up and interacting in a social setting in concert with a changing social environment. Even the language that a people speaks is learned through communication within social groupings. The world as we experience it is created out of the way we see our lives and think about our personal active participation in the events of our lives. This, in turn, is at every point a social creation.

We are products of our social upbringing. Our thoughts and ideas are the invention of a specific set of social, cultural, and historical conditions. We learn through the exchange of ideas in the social setting we participate in.

Each culture within its own historical setting develops a unique worldview. Every culture develops along its own path, with its own thought patterns that are created out of a shared but changing worldview and narration. This is reflected in the way a people responds to events in their world.

Within each society and each ethnic group in that society, different classes often develop different, and sometimes competing, belief arrangements and points of view. Even within classes, different genders and generations develop competing convictions and perspectives. This is true even if people are employing the same symbols and unifying ideologies. These distinctive occurrences in the collective beliefs and attitudes are built on historical paradigms. New sets of assumptions that constitute a way of viewing reality for the community are forged from what is left over from past worldviews, creating an acknowledged understanding that becomes recognized as real. This change develops continuously because life is always changing. Altered circumstances that are lived in the present stand in contrast with past interpretations of life. Because people are active within their social environment, their environment reflects that activity. People interact consciously with their environment. While reacting to their immediate needs, they often create outcomes that have long-term effects. This is in part the nature of social evolution. The result is largely the consequences of our collective actions that are, in fact, unpredicted. This leads to a need for a people to come up with new strategies to come to terms with the changes brought

about in the societal ecosystem. History at this point is the story of important modifications.

History reflects recurrent adjustment to a continuously changing environment. There is constant engagement between communities, between individuals within communities, and between people within their larger environment. This alteration also coaxes a persistent reinterpretation of the conventional cardinal philosophy. This is the essence of the enduring human condition.

To understand these changes by using both diachronic anthropology and historical sociology, we begin by observing just how situational truth is. It is not enough to describe a social fact objectively. The historical sociologists/anthropologists need to also look at the cultural understanding of the fact in the context of the larger society. This includes the careful examination of the motives, values, and interpretations of the participating actors in their lived social drama. In the social sciences, objective explanations are in fact trite, dispassionate accounts, and without cultural understandings, they are basically dull.

Because changes in people's attitudes reflect changes in their existential reality, a people's beliefs and point of view are part of any scientific study of society. The actual experience of existence is filtered through a shared worldview that is culturally and historically specific. Each cultural-historical epoch has its own unusual and salient worldview. The historical artifacts of socially created worldviews are the tense interaction between differing worldviews of the historian and the subject matter being studied. The actual threat of domestic communism during the post-World War II era is going to be told differently by historians who came of age in the turmoil of the 1960s and those who came of age in the post-Cold War era, 30 years later. The second set of historians does not have the same sense of moral indignation leveled against the U.S. government's antisubversive programs.

Along similar lines, particular sociological theories are set in specific historical settings. Established social theories correspond to the position and point of view of the individual who initially set up the theory. The devotees inhabit a distinctive point in the tiered social structure. Each theory, then, has a legitimate perspective given the social site of the researcher.

Any serious study of anthropology or sociology would require that at some point students carefully read the classics while examining the historical context in which they were written. Because the contemporary code of beliefs and philosophies is created out of elements of past theories, the classics remain important to any dynamic study of sociology. Through anthropology, we can better understand the historical and social-cultural context that gives rise to any theory.

For example, the idea that a society is like an integrated organism requires that the writer be living in a modern industrial nation-state. British structural functionalism is set in the early 20th century and is intellectually reflective of the British Empire. The incorporated essence of this

society bears a resemblance to an organism. This analogy is derived from the structure of a society in which different institutions, like different organ systems of a living individual, tend to specialize in function. Functionalism reflects the development of a modern industrial society following the French Revolution in Europe. In these societies, because of an integrated market economy, the society moves in the direction of a more centralized and efficient economic and political amalgamation.

A modern industrial society cooks up a multitude of theories developed to explain the same or similar phenomena. The anthropologist or sociologist or historian is a product of this environment. The opposing theories represent conflicting social positions in the same society.

19th-Century Evolutionary Thought

Evolutionary thought began to take root during the 18th-century European Enlightenment. By the second half of the 19th century, evolutionary anthropologists were developing evolutionary thought even before Charles Darwin published *On the Origin of Species* (1859). Biblical scholars looked on non-European societies as being an erosion of a basic humanity that monotheism, and specifically Christianity, had generated. The evolutionist developed an alternative view by hypothesizing that nonwhites (i.e., non-Europeans) were a more primitive type of human subspecies. Monotheism was superior to either polytheism or animism. Science was superior to religion and rationalism superior to mysticism. Consequently, European civilization was at the apex of evolutionary development. All other cultures were somewhere along the evolutionary trajectory from early apelike hominids to modern Europeans.

In reaction to universal evolution, Franz Boas became a founding spirit of historical particularism, which claimed that the universal or unilinear evolution, in which Europe was the apex, was teleological and therefore not scientific. British structural functionalism also became antievolutionary in how it saw the separate parts of a society interact to form a cooperating whole as being the focus of their studies; this synchronic theory characterizes the most important goal of any cultural element as being the harmony of the society as a whole. In doing so, history is not the core in these studies. However, history could not be ignored. Change is a constant in all social settings. Therefore, societies must be studied in their historical context. Cultural evolution reemerges as a fact of life.

Diachronic Anthropology

Historical sociology as a part of diachronic anthropology demonstrates the continuous development of groups, classes, nations, and social institutions in which one set of social organizations replaces earlier examples. In doing this, we learn how each small part interacts with

the others in order to establish ever-larger units until we define a global economy.

In the study of the mixture of discrete elements, we learn that these parts come together to provide an interrelated whole. The world is made up of a combination of millions of local communities that are always in a process of transformation. Because of the increasing tempo of change following World War II and the degree of external intrusion in local affairs, process theory developed as a sharp criticism of functionalism by a younger anthropologist hostile to colonialism.

Cultural motifs form themes that condition the evolution of future national designs. A modern way of looking at the world would not have been possible before the advent of the Industrial and Liberal Revolutions. The modern mind-set develops a way of looking at things along the lines of a concept that holds that both the past and the future are real units of time and that this linear time frame is real and related to an ever-changing present. This liberal worldview is a noticeable departure from the previous age in which people saw truth as both absolute and unchanging.

Capitalism, liberal government, industrial technology, and scientific development mutually feed one another. Liberal society began being defined during the Enlightenment of the 18th century, and with Adam Smith's *Wealth of Nations and the Market Economy*, its rough outline was delineated. Along the same lines, feudal privilege and the power of religion was being challenged. Science developed in this environment. Modern rational philosophy was the expression of a revolutionary, capitalist bourgeoisie in its ascent to power. Empiricism and science became the practical expression of the empowered capitalist class. The growing capitalist economy required the quantitative analysis of market possibilities, production expenses, and technological innovation.

With a market economy, production grows in importance, replacing local subsistence economy. The new market economy was founded on an exchange of values and prices that defined the relationship among production units and thus among individuals. Previously, production and production units were embedded in social obligations. Thus, the expansion of market relations within a society changed the established social relations.

Because liberalism became the dominant worldview, the political changes that followed were revolutionary. Natural law and human nature became the cornerstones of the new philosophy. National identity creates a general spirit of the time and outlook, going beyond local distinctiveness and native uniqueness. "The rights of man" and resistance against tyranny replaced theocratic absolutes. Through revolution in Europe and America and colonialism everywhere else, liberal ideas spread throughout most of the world. As the liberal bourgeois society spread, it destroyed much of the time-honored social organization in traditional society. The ideas of John Locke, Jean Rousseau,

Adam Smith, and others helped to define much of the liberal thought, which gained a definition.

Conservative Philosophy

The reaction to the spread of liberal society was the expansion and fruition of conservative philosophy. Conservatism came into existence with the advent of liberal capitalism. Because there is a specific connection between beliefs, attitudes, values, and the social circumstances of a particular group, it can be seen that the conservative ideology appeals to those most threatened by the spread of capitalism. By putting an end to the ancient order, a call for its return is likely to follow.

Because of the rise of liberal society and its corresponding worldview, conservative philosophy would be characterized by its way of following and countering an opposition to liberalism. Conservative philosophy was born after and not before liberal philosophy. Because it was a reaction against capitalism, it was a dream of a return either to feudalism in Europe or to a traditional society everywhere else. Because science, empiricism, rationalism, and modern technology coevolved with capitalism, conservatives find a lot to fight against. Because this progressive market economy undermines the ancient order and the saga of heroes—to free both people and resources for production for profit—those who did better under a traditional society will oppose both free enterprise and science. To the conservative, liberalism, capitalism, and modernism were seen as the destruction of all that was decent in life to the conservative thinker.

The conservative movement was a romantic attempt to reestablish traditional communities that existed before capitalism. The capitalist and the working class are a product of capitalism, and both stand to gain nothing by a return to the antique civilization. Thus, both the capitalist and the working class are very much underrepresented in the ranks of the conservative thinker.

Those elements utterly damaged by the development of bourgeois-capitalist society are the small-property owners, such as small farmers, peasants, urban small-business owners, independent artisans, and the self-employed. These factions join forces with the natural leaders of the conservative movement, the large-landed aristocracy with ties to their feudal or traditional past.

With the robust formation of a romantic-conservative movement, a milieu is set up in which some intellectuals, who feel alienated from both bourgeois liberalism and the socialism of the revolutionary working class, can find a home within the setting of the romantic folklore, that is, a vision of what the traditional society was like before the Enlightenment of the 18th century, the Industrial Revolution of the 19th century, and the modern global capitalism of the 20th century. Community is defended against society. The spiritual is seen as preferable to science. Family and

kinship are understood as favored over contracts and professional qualifications. The conservatives such as Friedrich Wilhelm Joseph von Schelling or Joseph de Maistre believed that society must be governed by divinely inspired internal principles that are embedded in deep traditional roots, which are culturally embedded and long established within deep historical roots.

The Radical Left as an Intellectual Tradition

With the advancement of the market economy and the Industrial Revolution, a new industrial working class is formed from the disrupted elements of the previous society. These detached fragments come together to form a distinct organic class unique to capitalism. Wage labor is the minimum requirement for the further development of industrial capital. The working class has lost its connection to traditional society and can now be fashioned into an original class within capitalism. Because the very nature of wage labor is creating a surplus for the capitalist, the defining characteristic of the proletariat is exploitation. It is only the natural workers who develop an alternative perspective in opposition to liberal philosophy. Socialism stands in marked opposition to both liberals and conservatives. Because of shared common experiences, socialism can be neither liberal nor conservative.

Anthropology of Advocacy

Along similar lines, many anthropologists see their roles not only as researchers but also as advocates for the people they study. In 1968, anthropologist Helga Kleivan formed the International Work Group for Indigenous Affairs as a human rights support organization to help indigenous peoples define their rights, maintain control over their lands, and maintain their independent existence. Science has served capitalism well by creating this worldview of objectivity in which truth is independent of ethics. Now, these anthropologists claim that they must offer whatever assistance they can to help the surviving indigenous peoples to resist becoming the victims of someone else's progress.

Rise of Fascism

Fascism is the effect of failed liberalism and the excessive remains of conservatism that has come to nothing. As fascism goes, it absorbs disempowered liberals and disenfranchised socialists. Fascism is both activist and irrational. Militant engagement and the intuitive sentiments are glorified over reason and caution. Leadership is virtually made sacred. Elite theory states that history is made by elites, and everyone else simply follows. The acting without regard to science or reason, placing the act of conquest above ethical principles, negates the need for careful analysis or an interpretation of history.

Fascists believe that history at the simplest level, while an intellectually coherent and understandable method of knowledge, disappears. Fascism is the irrational exaltation of the deed, and the antihistorical myth takes priority over history as the imaginative symbols provide the edifice for the simple rendition of a future golden age based on a newly created folklore of the past that is envisioned by the leader. History becomes a lie, and the myth is a creative fiction become real in the hearts of the masses. Only the leader has the vision, and the rest of the population is only glad for the prophet to lead them out of the wilderness.

In the beginning, Fascism was anticapitalist and antisocialist. While destroying socialism by its strong hostility to equality, democracy, and all socialist ideology, it borrows from the people's socialism in order to make the claim that it speaks to the masses. While being anticapitalist, fascism can never come to power without making peace with the very largesse of capitalists who not only support but also finance it in the quest for power.

Fascism makes an extremely patriotic use of platitudes, catch phrases, flags, symbols, songs, and strong emotions to rally crowds of people into the frenzy of a unifying mania of patriotism. Xenophobia and a passionate love of one's "country" rally large groups of people against the treat of a common foe, that is, anyone or anything that is different. Because of a perceived need for national security, basic civil liberties and human rights are seen as a luxury that needs to be suspended for the greater need for security. The military, our protector, is given top priority in government funding until social programs must be cut to pay for the swollen military budgets. Life in the military is glorified, while human rights and peace activists are vilified. Sexism is commonplace. Opposition to abortion is a high priority, as is homophobia and antigay legislation. Religion is central to fascism. Government backing for the dominant religion receives support from many in the church hierarchies. The industrial and business upper crust support the government leaders, creating a mutually beneficial business-to-government relationship and strengthening the position of the power elite. In spite of a popular appeal, ordinary working people are treated like expendable resources. Workers in their labor unions are severely suppressed. There is encouragement of an open hostility to higher education. Intellectuals are dismissed as irrelevant. Professors who are competent are sometimes censored or fired for taking a political stand. Openness in the arts is blatantly harassed either in the public media or by the government, which refuses to fund the arts. Either the mass media are directly controlled or their range of opinions are limited through a control of funding.

Elite Theory

Elite theory is based on the idea that a small, powerful ruling elite rules all societies. Politics is but the tool by which this elite maintains control. Leaders govern because

the masses are too weak to rule themselves. Vilfredo Pareto (1848–1923) claimed that the ruling elite was in fact an association of superior individuals having the will to power. Because of this, history is the “circulation of elites.” As one group of elites becomes weak, it is replaced by another group of elites in a violent revolution. Gaetano Mosca (1858–1941) added that the superiority of the political elite was based on the fact that the elites have the virtues needed to rule. Often proponents of this theory looked on fascism as a necessary corrective force.

Conflict Approach

The conflicts among classes, ethnic groups, and classes within ethnic groups reflect larger social contradictions. The long-lasting results are the deployment of reciprocally contradictory explanations for social reality in capitalist societies. Sociology gives us the tools to study the complex interactions of a whole society within a global context. Anthropology adds a cross-cultural and historical component within which to better understand the relational connections among social interactions. But there is more than one kind of sociology, and social or cultural anthropology is often found in a separate department at a college or university. Competing groups use the sociological method in mutually antagonistic ways.

Critical historical sociology is the basis of scientific socialism. What is largely a cultural subconsciousness of competing groups within a larger society is exposed through historical sociology. This is why Marxism defines the rest of sociology as either a debate with the ghost of Marx or an attempt at trying to disprove or defend or reform Marxism.

Historical studies are embedded in a rigorous theory that can be used to examine the data. Radical social scientists use the critical methods in the demanding engagement of social activism. This is analyzed in the context of power relationships to determine the possibilities of collective vigorous action as a means of achieving radical political and economic change. By becoming aware of one's social, cultural, political, and economic situation, the activists become aware of the real conditions. From this awareness, one can begin to see the possibilities in terms of strategies to strengthen one's class or group's position in society.

Intellectuals exist in all classes, and many, for personal reasons, transcend class lines by strongly identifying with another class. Because many intellectuals identify so closely with a class other than the one of their origin, they bring fresh insights into their adoptive class. Communication among intellectuals of antagonistic classes is easy. This allows for the intellectual in each of the major classes to develop counterarguments to any and all criticisms of the intellectuals' theories. This creates a cross-fertilization of ideas. Intellectuals are strongly influenced by their opponents. Departmental divisions and specializations at the university only weaken this trend.

At one level, a group of intellectuals representing themselves as professionals structurally becomes its own class, both in and for itself. With the increasing specialization and growth of bureaucracy since the end of the 19th century, the modern nation-state saw the rise of a new class to challenge the capitalists for dominance. Not the industrial working class but the professional class is next in line to be the ruling class.

With increasing specialization, the expanding bureaus or departments are staffed with educated professionals. The importance of the expert means that democracy is continuously being undermined. Both capital and labor become increasingly dependent on the expert, and the professionals progressively take on more responsibility for all aspects of life. The overall working class is kept permanently disempowered. At the top levels of the major universities and research institutes, a small group of professionals form a power block that can be seen as a real threat to the most powerful capitalists. Because of the capitalists' dependence on these intelligentsia, there is a monopoly of expert knowledge.

With experts in a class of their own, the two power blocks, capitalists versus professionals, begin to compete for dominance in the larger capitalist society. The prize is control over the economy and politics. A small elite versus a not-quite-as-small elite means the serious rivalry between capital and expertise, suggesting that the majority of the population is left out of the preponderance of decisions affecting their lives. Add to this a highly industrialized military, and the total domination of society by these twin oligarchies is complete. Most people, because of the quality of their education, are kept ignorant of the process that allows a small group of autocrats to dominate their lives.

The anxiety of the powerless is intensified because of their inability to gain any substantive insight into their lives. Personal shrewdness replaces political understanding. Because rebellion becomes undirected, the repressed assert themselves through irrational outbursts. Leaders of the nation count on this and manipulate the influence of management in order to control the population. Either crime for the individual or fascism for the many allows people to avoid the worst aspects of this perfidious class structure. Crime and fascism is preferred to revolution.

For the proletarian intellectual, the challenge is to gain an understanding of these social facts in order to direct social change by influencing people to take the actions that will strengthen their choices. If a proletarian mental laborer and cultural worker carefully examine the current social situation and its historical background, the iron cage can be unlocked. The essential major thinking is the hopeful knowledge of objective opportunity making it likely to coordinate tangible circumstances and capability. Since each of the competing factions within society use their own sociological theories and have a drastically different understanding and analysis of what is going on, it is important to understand that the opposing theories are of the

social environment and must be carefully studied. The more complete the study, the more likely the activist will come up with a successful program.

If a psychological explanation fails to take into account changing goals, values, and beliefs that are socially defined, we will know nothing about how changing social and cultural circumstances mold the personality. Every judgment includes values of good and evil, beauty and unattractiveness, or just better or worse. All knowing or learning is a group project. Individual knowledge is born in this group process, and each person influences that process. This is what we study in our struggles with the opposition. Combined achievement of conflicting groups establishes daily habits while defining the struggle.

Different cultures have their own evolutionary trajectories. Individuals experience similar events differently, and the significance of events is viewed differently by different classes. Elites and the dispossessed live in different universes. Each segment within the larger group has unique standards and deciphers the ordinary contents and knowledge of daily life and life experiences differently. Unless an individual has a real break with the past, his or her experiences generally confirm what is already believed to be true. Only when the external world comes in direct conflict with established beliefs does conversion become likely.

While knowing is interpreted through the living experiences of a personal biography, it is set in a social and historical context. Social position and life situations influence the particular character of this world and the encounters of real people. Through the active creation of their technology, their material culture, and the process of survival, people reproduce and change their social relations, resulting in a particular way of thinking and responding to their environment.

Meaning is related to the general ideas that bring together a combination of culturally unique processes and purposes for a historically explicit episode. When a person fails to understand the long-term consequences of an immediate action, it can be viewed as an example of false consciousness. Because knowledge is set in a historical context, it is not relative because some statements are incorrect. Knowledge is dependent on historical and social relationships to be correct. However, values and goals of the observer are as important as the subject in any study. The interaction between theory and the social setting points to a relation between various elements in the social setting.

Ideology, Revolution, and Reaction

Science has grown with the advent of the university's independence from the church. Science by the mid-19th century was closely allied with industry, finance capital, and the rising power of the nation-state. During the prior 200 years, science had to fight against the feudal theocratic monopoly of political domination over the rest of

society. With the establishment of the liberal state, science as an intellectual movement became the new symbol of hope or official creed. The romantic-conservative reaction fought a pitched battle, retreating into idealistic reconsideration of a venerated fable of history. It established a historical tradition creating an antirational folklore of the way things should remain. However, socialists, both utopian and scientific, would steal science in support of a revolutionary transformation of society and its eventual management. This world-shattering overhaul and ultimate organization would develop but not replace science.

Science is a method of studying events and objects around us and produces a history of ideas developed using an evolving scientific method. What is chosen to be researched is entrenched in the history that the researcher is part of. These research priorities are in turn affected by and effect our living concepts of nature. The ever-changing result is that discoveries are embedded in political, social, and economic historical forces. Social science follows a similar path.

In point of fact, the economic base only sets the limits of what is possible, as the environmental and technological bases set the limits for the economy. The economy in turn is limited by the possibilities of the rest of the sociocultural environment. All parts of the social and cultural whole have a profound effect on each of the other parts of the historically changing whole. Science is no exception. The history of science is the investigation of associations. Now, although the arrow of causality goes both ways, it more often than not travels from existence to consciousness. This complicates social science research, making the break between science and philosophy less clear.

The philosophy of social science, like science itself, is set inside a moving history that reflects a set of values or reflects a point of view that is overloaded with cultural biases. Theory is necessary to understand anything, and theory reflects both ideologies and their underlying world-views. These basic culturally derived assumptions saturate our scientific thinking. This in turn establishes what we consider to be facts. This becomes the foundation of our scientific theories, and an established theory sets up research priorities and delineates adequate scientific discoveries.

Historical sociologists such as Weber, Mannheim, and Merton (and their current counterparts) find a way of rooting the history of science in society without risking tenure or promotion in the academic world by believing that they are objective scholars. Theory and practice are forever separated in their cowardice. While attempting neutrality, these scholars studied in detail the historical and social context of the development of science while avoiding the moral context of scientific research. These brilliant intellectuals carried on excellent scholarship. They even studied the close relationship between technology, economic class, and a global economy within the evolution of science, but what is lacking is the ethical consequences of scientific research. Much has been done in

the way of research into the class origins of scientists. The culture of scientific communities, patronage of individual research projects, commercial and political investments in grants to researchers, scientific accountability and to whom have been carried out in detail without asking the difficult question of ethical responsibility. The honors given to top scientists along with accolades, the ethos of laboratory analysis, and scientific lack of responsibility to the powerless, poor, and dispossessed is left unstudied.

Where Is Science Now?

Chronological storytelling would have us believe that scientific insight develops progressively in the path of a superior gathering of more and more factual knowledge. This myth is at the present time generally ridiculed as a history that is overly simple and highly subjective of a romanticized fantasy of fulfillment (Mannheim, 1936, p. 205). This fairy tale is founded on the illusion of a universal scientific method, similar to the economic fable of marginal utility. This literary fiction would have us believe a body of scientific knowledge is allegedly expanded by generalizing from the gathering of information from meticulous observations and experiments rather than to the articulation of universal laws presented as fact.

There are convincing points of view that there are many acceptable methods in any research. We need to subject all research to rigorous assessments because it is possible to chip away at the complete scheme of a single scientific method by arguing that human action cannot be comprehended as a simple process of following general rules applicable to any research project. It may be that working scientists are not constrained by any of the rules of method that are universally applicable.

Conclusion

The conflicting total worldview of an entire class in contemporary society is molded by the existential condition of history. This existential moment of choice is the focus of the external manifestation of a way of life. Each particular mind-set identifies itself as the psychology of an individual. What lies behind a personal set of beliefs is born out of that person's social and historical location. Ultimately, the total social and cultural origin of the psychology lies in a changing historical setting.

All philosophy or science or religion is a social product that is created out of a very real living history shared differently by different groups. Each person is the product of a specific social environment. Because different classes experience life differently, they develop conflicting interests and opposing values. The oppressed want change that will end their oppression. The oppressed look to the future with their utopian dreams. The liberal looks to preserve the

current social inequality by allowing only those reforms that will safeguard the status quo. The romantic looks longingly at the existing conditions of the past in the hope of reestablishing those golden days of yesteryear.

The predominant patterns that are socially arranged provide the raw resources for shared culture. Thinking, accepted wisdom, reasoning, imagining, judgment, conclusions, opinions, and beliefs can be radically transformed through ever-changing social conditions. However, the new patterns of thought are formed out of the obsolete and altered outlines of previous thought.

In every historical period, knowing is given birth from genuine existing phenomena. All elements of meaning in a given situation are interconnected causally and have reference to each part and to the whole. When a shared, collective set of circumstances changes, the arrangement of norms, customs, and values ceases to be in harmony with real life and a rupture arises with reference to traditional beliefs.

A crisis arises within the traditional philosophy of wisdom and its corresponding historical perspective. This forms a new reciprocal interrelated framework of thought. People themselves change as does basic human nature, both of which are culturally distinct. People are always adapting and regenerating through the awareness of a new body of knowledge and are consequently generating innovative factions. There are new compositions of groupings of intellectual categories, leading to changes in patterns of social stratification in the larger society and ever-changing debates between antagonistic segments of society and their differing views of that society.

Competing social theories are always being redefined and reinforced to offset potential criticism. The theories once articulated directly inform the participants of what needs to be done. Then, they act in ways that change the social environment and the corresponding political culture.

The statement of any scholar may be true or false, valid or invalid, but it is so only in the context of a specific social, cultural, and historical context. Because of continuously changing social environments, categorical forms of knowledge are always changing. What is right in any one period of time will be wrong in another. Validity is determined within the context in which categories themselves are changing. Consequently, theory must continuously be updated to be valid.

PART VIII

THEORIES IN ANTHROPOLOGY

THEORETICAL ANTHROPOLOGY

MICHAEL J. FRANCISCONI

University of Montana Western

To understand the history of anthropology, it must be remembered that anthropology occurred as a response to twin events. First, it became apparent that Europeans were not alone on earth; and second, their initial theological view of humanity could not answer all questions about the “other.” This questioning accelerated during a period of time we call the Enlightenment, from around 1689 to 1789.

In the 1500s, the European awareness of the “other” greatly expanded. Travelers told of distant, radically different and exotic peoples. The first question was whether these surprising, remote, and alien peoples were, in fact, people. People had souls and could become Christian, from the European viewpoint. Europeans wondered if they were indeed people, then how could they have been created so bizarrely. Peoples outside of Europe were seen as degenerate forms of humanity. As scholars began using science to question the Bible, new explanations were sought and anthropology slowly began to take form.

Enlightenment

The Enlightenment was a European movement that became a commemoration of science and reason over blind faith. It reflected the growing rebellion of 18th-century intellectuals. All major institutions and official values were subjected to serious and critical examination.

John Locke (1632–1714) was possibly the earliest architect of this development. He shaped the idea that knowledge was actually intellectual perception, or perceptive intuition, and the foundation of learning. Locke, as an empiricist, announced that there were no innate ideas. The mind at birth was a *tabula rasa*, or clean slate. Soon after birth, experiences are drawn through the senses. These experiences are rationalized through reflection. Learning is then gained from thinking and from the development of the memory. Substance becomes our facility to recognize and comprehend those traits that come together along the lines of cause and effect. One collection of thought soon produces another clump of thoughts and changes the tendency of how one forms ideas. The way we rationalize the world changes with experience and reflection. Consequently, all knowledge comes from experience as revealed through our senses.

Real knowledge is always limited. Knowledge begins with simple ideas that cannot be broken down into simpler components. This basic knowledge comes directly through our senses. From these simple ideas, we can construct more complex ideas made from compounds of simple ideas. Upon doing this, we can compare two or more complex ideas to see which one best suggests the essence of the basics. From this, we create abstractions that recognize the characteristics that objects have in common. This is called *conceptualism* and is often falsely confused in the creation of the human imagination with reality.

Primary qualities come directly from our experience of the world around us. Secondary qualities are not through direct experience of the external world, but our attempt to sort information in order to make sense of our experiences. These secondary qualities are not true reflections of the world, but are at best a partial distortion of that reality. Our mind then interprets what it experiences. Through careful observation and reflection about what we observe, comparing one set of results with other careful observations, we come closer to the truth of the external world. Thus, we observe the world around us and systematically analyze our findings, getting closer to reality. We begin to understand the world without reference to the Bible.

The authority of the writings of Locke spread to France, where it effected an entire movement. Voltaire (1694–1778) became a member of the freethinking community, where he assumed the role of comedian, exposing the charade of the religious and political world around him. For this, he was imprisoned in the Bastille for a year in 1717. Teaching a deist philosophy, he believed God created the universe, including the world, according to rational laws discoverable through observation and reason. Afterwards, the universe and human society operated alone, according to these principles. God had no influence.

Voltaire came under the influence of Locke and later moved to England. There, he learned about English literature and theater. He advocated that the meaning of life was not achieving heaven through faith and repentance, as Christianity had taught. For Voltaire, humans could secure happiness only by progress in the sciences and arts, and as a part of the celebration of life on earth. His major passions included religious tolerance, material prosperity for all people, respect for the rights of all people, and the elimination of torture and ineffectual punishments. Ironically, Voltaire believed Europeans were superior to Africans and would always need to lead the rest of the world.

Paul-Henri Dietrich (1723–1789) exemplifies the thought being expressed during the 18th century. In his book, *The System of Nature*, under the name J. B. Mirabaud, he sarcastically ridiculed the religion of the time. He openly promoted an atheistic and skeptical worldview that was both deterministic and materialist. He saw religion as being false and detrimental. Humans were biological machines like any other animal. Humanity could thus be studied as a branch of biology.

Étienne Bonnot de Condillac (1632–1704) called attention to the importance of language in logical reasoning, while stressing specialized language as particularly designed for scientific investigations. The language of science was based upon a functional understanding of mathematics. Knowledge expanded through systematic, empirical investigations. Throughout history, observations of our “sense perception” were the ultimate underpinning for practical human knowledge in any society. Each of the human senses operates independently and brings information that cannot be

accessed by any other source. The mind of a person brings this information together and this knowledge has an effect on the sense perceptions in the future. From this, we study history as human development molded through both education and the environment.

Charles-Louis de Secondat (1789–1755) examined society through the use of ideal types. There were three basic types of society: the republic (which was further divided between democracy and aristocracy), monarchy, and despotism. The virtue of a republic was civic integrity, the virtue of monarchy was honor, and the virtue of despotism was fear. Each type of society was organized in a specific way in which all institutions and elements were reflective of the type of state in existence. The ideal types were broad similarities that categorize different societies into these distinctive groupings because of shared characteristics. Typologies made science possible. In addition, he believed that there were savages who were hunters and made up dispersed bands that could not be united into a larger clan, while barbarians were small nations of herders who could be united into a larger united group. Thus, thought began to arise about the connection between the political economy of a people and its subsistence patterns.

These ideal types are continuously developing and changing. The histories of specific societies are related to particular causes. Not only are other social elements reflective of the type of state, but also political traditions are consistent with the distinctiveness of other elements of society. The critical fundamentals of the type of society are size, territory, and population. Climate and geography are contributing factors.

Jean-Jacques Rousseau (1712–1778) believed that the enduring fulfillment and liberty of people rested on a lucid knowledge of natural laws. Through ignorance, people create social orders in conflict with basic human nature. Humans have two conditions: the first is natural and the second is social. The “natural man” is a situation in which a person lives outside society and its influence. If it is decided that a particular social order is inappropriate to freedom, work can be done to change society. This is learned by conceptually removing all the qualities of social derivation until only the “natural foundation” remains. The natural foundation is human nature. The “state of nature” is the essential psychological makeup of the personality. This fiction promotes the understanding of what sort of society would allow individuals the maximum freedom to maximize their full potential.

To understand human needs, it is first necessary to conceive what a person uninfluenced by society would be like. All traits must be removed that have any social or cultural starting point until all that is left is the essential human nature, centered upon unaffected underpinnings. In an imaginary state of nature, there would be a balance between the basic needs and resources at the disposal of the person in a natural state. These uncomplicated and modest needs are for food, rest, protection from the weather, and a mate.

Harmony and satisfaction are easily achieved. Theft, brutality, and supremacy are not a part of human nature. Without society, humans are uninterested in the needs of the community. People can feel sympathy for other people because the imagination is part of human nature.

Society originated with families. The individual was no longer isolated, because numbers of people and complicated relationships required people to work together. As more families lived closer together, natural equality within the community slowly eroded. With the advent of agriculture, division of labor encouraged an inequality between families to develop. The prosperous would be called upon to lend assistance to the unfortunate. In return, the poor had to submit to the dominance of the wealthy. Resentment toward this injustice would threaten the security and safety of every member of society. Governments were created to protect property, the source of all wealth. Without a government, pandemonium, belligerence, and obliteration awaited everyone.

Society, made up of individuals, was also perfectible. It was morally wrong and against natural law for the lucky minority to be avaricious with irrelevant embellishments, while the hungry, overworked masses lived in constant unremitting need for the meager requirements and rudiments of life. Through the general will, liberty would require a new measure of excellence. Free and equal individuals would voluntarily form this contract. In small communities, democracy would work. In the larger society, a benevolent and educated aristocracy would coordinate the smaller democracies.

The Enlightenment began to look at history as an evolutionary process. "Primitives" were no longer considered to be degenerate forms of humanity fallen from grace. When Europeans looked at other cultures, they now saw their own past. While Europe held the most enlightened and most advanced of all people, one form of racism replaced another. Yet now science at least was being developed and offered a hope of someday understanding other peoples.

Romantic Conservatism

The Enlightenment unfolded and provoked the pervasive confidence in the prospect of humanizing the human condition through political progress, as well as freedom of and from religion. The revolution shaped a new Europe based upon the point of reference of rationalist philosophy and political beliefs. The difficult position of modern conservatism was one of looking backward to a romanticized past. In the face of constant rationalist innovation, conservatives were often forced to adopt a merely defensive role, so that the political initiative lay always in the other camp.

The main relevance of the Romantic conservatism movement was an aversion to the 18th-century rationalism of the Enlightenment. This included a love of nature and revival of

the value of the aristocratic "Middle Ages." The French Revolution and Napoleonic Wars had a profound impact on antimodern and conservative intellectual thought of the day. This brought about a strengthening of idealist philosophy.

Romantic conservatism viewed society as a natural synchroization with divinely inspired internal principles that embraced deep traditional roots that are historical and time honored. Society itself is always ethically greater than the individual. It is society that creates individuals and God who created society. Social relationships and institutions create society, and the individual is but an abstraction created by what is real—the social community. All parts of society are mutually dependent and intimately interconnected. Civilization, customs, beliefs, way of life, organizations, and institutions are, in actual existence, intertwined in a web of associations. Challenges to these traditional bonds threaten the moral fabric of society. Human needs are fixed, eternal, and divinely created. Social institutions are created by God to meet these needs.

This was one of the universals for all of humanity, with Christianity serving as the most positive reflection of this truth. Anything that allowed an individual to stray from God's plan could not be tolerated. Society, made up of smaller groups like the family and village, was brought together to complete God's plan. These smaller groups consisted of people who gained the support needed to live. Revolution, civil liberties, democracy, and individualism led to the moral disintegration of society. Only by uniting all of Europe, and ultimately the world, under a single Catholic faith could God's will be done. Under this doctrine, humans needed ritual, ceremony, and worship rather than rationalism and science. Status and hierarchy, controlled by the church and sovereign, were necessary for society to survive.

Friedrich Wilhelm Joseph von Schelling taught that human desire for power and carnal lust is more powerful than the rational or the good. This was Adam's fall from grace. When God became human in the person of Christ, this deception of man was overturned. This creates two possibilities and the result is freedom of choice. God is self-defined by self-conscious projections toward the peoples of the world.

Nature and the human mind formed a shared correspondence. According to Schelling (as cited by O'Meara, 1977), nature is the unconscious mind, and mind is unconscious nature. Through art, nature—the unconscious—is united with the spiritual or conscious. Through art, it can be shown that the *absolute* communicates openly as the harmony of the subjective and the objective. Freedom of humanity allows for good, as well as evil, and the irrational was at least as real as the rational.

Friedrich von Schlegel, another character of significance, integrated a unique notion of Romanticism with imaginings of medieval Christianity. As a Romantic, his philosophy was the result of the most straightforward interpretation of the major convictions of the character of the

church in the Middle Ages. His ideas were a reaction against the scientific rationalization of the study of nature. Schegel emphasized a devotion to vigorous feelings as a source of aesthetic experience, and thus creativity. By introducing new emphasis on such emotions, humans were seen as basically emotional and irrational, and that was a good thing if humans accepted the authority of the crown and the throne. Conservative Roman Catholic legitimism is a common strand in the romantic generation that dominated the conservative thought of the 1820s.

Joseph de Maistre was a most important champion for legitimism. He took a position opposing the principles of the French Revolution, democracy, and separation of church and state. He approved a united monarchical and ecclesiastical authority. Most of all, Maistre was counterrevolutionary and opposed the secularization of society. Traditional authority was a necessary precondition to security and the threat of liberal concerns for civil liberties. Traditional elites were central to the smooth, everyday sanctuary of a healthy society. Maistre created a depiction of humans as being fundamentally weak and emotional creatures born in original sin and given to a life of indulgence, chaos, and wickedness. This state could only be overturned if jointly controlled by the throne of the sovereign and the ecclesiastical altar, and if surrounded by a tough political structure restrained by a fixed monarch, priests, and the ubiquitous intimidation of the executioner. In fact, Maistre is most remembered for disapproving of the Enlightenment and social revolutions of the 18th century for having undermined the supremacy of traditional religion. The reestablishment of the rule of time-honored elites was essential to reestablish order. He granted reverence to the public executioner who was the primary guardian of a divine and sacredly endorsed social hierarchy. Maistre promoted the need for the dominion of Christianity, the unconditional leadership of both the monarch and the papacy, and the institutionalization of public executions as not only necessary, but also God's will.

Louis Gabriel Ambroise taught that God gave language to humanity and the meaning contained within the use of words is divinely predetermined by revelation. In the end, society must be founded upon the laws of God or it will suffer the consequences. The individual learns the will of God only by living in the community of God led by the church. Knowledge or culture could be learned only by tradition, ritual, the declaration of religious dogma, and revelation. In this doctrine, God stands outside of time and nature, and God is the author of the universe. God also governs humanity as part of this creation. The liberal revolution was God's punishment for rationalism, science, and other liberal ideas.

The Romantic reaction led to a reintroduction of the book of Genesis as the only history of our ancient past. Only Christianity carried the key to progress and happiness. Non-Europeans, then, were sinners fallen from grace.

Reaction to the Reaction

Hegel and History

For Hegel (1807/1967), reason was integral to the very process of historical development. What is rational is real and what is real is rational. Reason is an indwelling core of the universe, remaining within the historical recounting of the universe. History is the continual unfolding of reason as it evolves toward the absolute. According to Hegel, reason objectifies itself in every single creation through the blending of inborn contradictions. Each new fusion produces a new thesis with a new set of contradictions, which resolves itself with new amalgamation with its own inconsistencies. Each new idea then has its own reality, which is the thesis. This has a limited time frame within history, and the innate contradictions destabilize any consistency. Born out of this conflict is a new thesis and the process continues in a new historical setting. Within each thesis is its own antithesis, and the antithesis has its own set of contradictions.

Hegel's concern was based on the idea of *essence of being*, which states that something is negated in the process of creating something new, which leads to the *sum of essence*—the end of the previous historical setting. The new essence is only an appearance of being as revealed by the absolute. Each new conclusion is only temporary and fleeting. This development, Hegel asserted, is completely conditional on a specific historical setting. History is only a specific manifestation of an approximation of being. The resulting contradiction is the negation of the negation of the essence of being, leading to the actuality of a more advanced harmony. This brings together essence or “real meaning” with “existence.” At each stage in this process, Philosophy is moving closer to the absolute.

Hegel's assertion that human history follows the same pattern as one epic replaces another, right after the one before it, results in the continual unfolding of the world spirit. History, and not a specific social structure, becomes real. This is important for anthropology and sociology because this leads to a historical, instead of a functional, study of culture.

Young Hegelians, or the Next Generation

Bruno Bauer (1809–1882) was a leader of the left-Hegelian movement, developing a republican interpretation of Hegel, which combined ethical and aesthetic motifs. His theory of infinite self-consciousness, derived from Hegel's (1807/1967) account of subjective spirit, stressed rational autonomy and historical progress. Investigating the textual sources of Christianity, Bauer described religion as a form of alienation, which, because of the deficiencies of earthly life, projected irrational, transcendent powers over the self, while sanctioning particularistic sectarian and material interests. After the defeats of 1848, Bauer repudiated Hegel. He predicted a general crisis of European civilization,

caused by the exhaustion of philosophy and the failure of liberal and revolutionary politics. New prospects of liberation would, he believed, issue from the crisis. His late writings examined the emergence of Russia as a world power, opening an era of global imperialism and war.

In the early 1840s, Bruno Bauer wrote this salient examination on both the gospel of John and the synoptic gospels, which were seen by him as self-aware expressions of a community responsive to the spirit of the time at a particular stage of development. Thus, the works of Hegel were defined as atheistic, radical, and revolutionary.

Feuerbach sets the tone by outlining humans as having the capacity for reason, determination, and love. These are central to our human willpower and the human condition. We create God out of our own imagination and thus become alienated from who we really are. Feuerbach understood the Christian mysteries to be no more than symbols of the human alienation of creative resources unconditionally redefined as divine attributes, thereby crippling the individual through faith. To regain our freedom and human essence, we need to become aware that humans created God and not the other way around. We become powerless and passive in the presence of our creation, God, and rely on figments of the imagination to give us strength to accept what we can change.

The political repression in Europe was not only intense, but also mounting, as radicals had every intention of carrying the liberal revolutions to the next level in opposition to both the liberals, who made peace with the authorities, and the romantic conservatives. Arnold Rue made the accusation that introspective reason was to downgrade philosophy to the acquiescence of obtainable circumstances, thereby strengthening the status quo.

One group of young Hegelians believed that objective detachment, or value-free social science, in philosophy was necessary to understand existing conditions. This group included Max Stirner and the Bauer brothers. Another group believed that theory was, at its core, advocacy and active political engagement. Most noted in this second group was Karl Marx.

The historical materialism that Marx established took a position against the idealism of even the materialist philosophers. Marx addressed the principle that the basis comprising the relations of production, both the forces and relations of production, coordinate the superstructures. The superstructures would include not only political, legal, organizational, and cultural institutions, but also religion, philosophy, and ideology. The various parts are interrelated and historically specific. The movement that exists between the various functions among these areas of configuration, contained by the entirety of any historical era, need to prevail over the contradictions inherent in the society in question. Action of the individual players could be progressive, by easing the transition to the next epic in history, or reactionary by trying to slow down this change. This materialism was intended to be

linked to the continuous polemical interaction and intersecting challenging issues, widespread, for the duration of the succeeding history of any social movement.

Utopian Socialists: The Other Rebellion

In 1817, Robert Owen outlined what he saw as a design for a new society. He believed that people were a product of both their social circumstances and what they learned. In poverty, and without any hope, people are educated to survive at any cost. Humanitarian virtues were undermined with the concerns of immediate survival. This was the fault of a society that was structured in a way that benefited the wealthy and powerful.

The dominant theme of powerful individuals in a society is motivated by the wealth and power of the few. The indisputable source of prosperity is the labor of the poor. The poor, as Owen saw them, were denied any real options in life and were reduced to misery and wretchedness. Both the powerful and the powerless were corrupted by this arrangement. Because the ones bound in servitude are denied freedom, the threat of insurgence in these lowest classes also reduces the freedom of those who have control over the lives of others.

For Owen, happiness of the individual reaches its summit in the happiness of everyone in the community. By expanding the joy of everyone, even the rich find their own personal contentment increased. Owen used ethical arguments to explain his economic theory.

Children are born with many possibilities, are taught either to be selfish or generous, and are capable of either. Children learn from which they are exposed. The human nature with which we are born is molded through learning. The values and goals we embrace as adults are reflections of our early childhood education. Education begins within hours of birth, as the infant becomes aware of its surroundings. By teaching the child about other people existing in its world, the child learns to have concern for others. Owen saw this as the beginning of the development of an ethical code. When a child is raised in an environment in which these other people intend injury to the child or its kin, the moral programming is impeded in its instruction.

Owen contended that a person's happiness is closely tied to the satisfaction of every other person in the individual's homeland. Contentment is attached to well-being, confidence, heartiness, and serenity; it is the only real prospect for peace. For Owen, this is not speculation, but has been proven repeatedly through practice where given a chance. If properly educated to teach compassion and set up a social enterprise, where empathy is rewarded, then kindness and understanding become a pleasure. Education in the right surroundings becomes a part of everyday life and is enjoyable in its own right.

Because people are a product of their social background, Owen asserted that they become what life has taught them to become. Most laws are irrational, for they punish ignorance.

Reeducation is more sensible than retribution. Reeducation is but the first step. The criminal is also a victim—a victim of a scandalously immoderate society. Dispossessed people gain knowledge of survival by learning criminal activities. Owen viewed law enforcement and criminal courts as founded upon a desire for vengeance and not upon an attempt at solving the problem of criminal behavior. Harming others for personal gain is criminal when practiced by the down-and-out. It is good business routine when put into practice by the select few and the advantaged. Owen calls on society to actively create a community in which goodness is rewarded. Then it is possible to teach children virtue. When integrity becomes the norm, then decency is easily achieved.

Because the desire for happiness is the chief motive of the decisions all people make, the failure to achieve universal happiness is behind global evil. This colossal disappointment is the result of not observing that only when the powerless are empowered can national security mean anything. Only when the poor and the disposed reclaim what is rightfully theirs, Owen asserted, can the privileged and the wealthy reclaim their abandoned joy. Through changing how people are educated, and allowing working people control over their workplace and communities, crime will disappear within a generation because the social causes of crime will disappear.

Claude-Henri de Saint-Simon (1760–1825) believed that human thought evolved from the theology of paganism to the metaphysics of Christianity and now was to be replaced by science. The study of society must be based upon the same scientific principles as the rest of the sciences. Science would replace religion and scientists would become the new natural elite, replacing both the clergy and the nobility. Science and industry would replace the church as the origin of social values. There were three classes seen by de Saint-Simon in this new society. The first were the elites made up of scientists, artists, and “men” with a liberal education. The next class was the property owners: the former elite in the old order. This was the class of conservatism and could be counted on to oppose the new elite. The last class was the vast majority of everyone else. The lower class could be expected to support the new elite, rallying around the cry for equality. Yet the new elite must never relax control over the mob. What was needed was a shared social ethic that puts the needs of society above the special interests of a single class. This social ethic becomes obvious through science and positive philosophy; objective principles lead the leaders. Laws are natural, discovered through both scientific observation and rational analysis.

Marx and Sociology

Marx and his many followers united the inspiration of the young Hegelian and utopian socialist. Marx claimed there are real regularities in nature and society that are independent

of our consciousness (Marx & Engels, 1970). This reality changes, and this change has patterned consistencies that can be observed and understood. Tensions within the very structure of this reality form the basis of this change. These changes add up until the structure itself is something other than the original organization. A new entity is then formed with its own tensions or contradictions.

When studying a society, Marx instructed, the research should begin with a people’s interaction with nature (Marx & Engels, 1970). Humans, through their labor, produce the means of their own survival. The environment—natural and social—in which people provide the basis for their own survival becomes central to the analysis of a society.

Through the means of production, which includes technology, environment, population pressure, and work relationships, people are able to take from nature what they need to survive; this in turn creates what is possible for the various parts of the *superstructure*. Any study of the historical change of a people must assume economic factors will be of first importance. The economic primacy is not absolute, however, because each of the various parts of a society has its own continual influence on the social whole.

Researchers who study noncapitalist societies become aware that major differences do exist between individual noncapitalist societies. One major difference noticed by social scientists is the degree of complexity in social structures between one society and another. It is argued that the differing degrees of complexity of the social relations are directly related to different productive levels, including how efficiently a technology can utilize a particular environment to support the people of that social structure.

With changes in the organization of labor, there are corresponding changes in the relationship to property. With the increasing complexity of technology and social organization, changing societies move through diverse variations to a more restrictive control over property, and eventually, with a state society, develop restrictions on access to property, based upon membership in different economic classes.

A social system is a dynamic interaction among people, as well as a dynamic interaction between people and nature. The production for human subsistence is the foundation upon which society ultimately stands. From the creation of the specific methods of production in an economic system, people in turn establish their corresponding set of ideas. People are the creators of their social ideology. People are continually changed by the evolution of their productive forces and by the relationships associated with these productive forces. People constantly change nature, and thus they change themselves in the process.

In Marxist thought, the study of history begins with the material or objective organization of people living their everyday lives. This is set into motion by means of a people’s relationship with nature, as expressed in their social and cultural life. Through these relationships, humans produce their own *means of subsistence*. Each generation inherits and reproduces this means of subsistence, and then

changes it to fit their changed needs. This historically and culturally specific setting shapes individual human nature. This means that how people are organized and interact is determined by production.

Production molds all other social relations. This includes the relations of one nation to another, as well as the internal social structure of a single nation. With every new change in the forces of production, there exists corresponding change in the relations of production. These changes lead to changes in the division of labor. With changes in the division of labor, there are changes in the property relations of the nation. Ultimately, this brings ideological changes as well.

Marxism identifies the first historical act as the production to satisfy material life. Following the first historical act is the production of those new needs that are the practical result of satisfying the needs of material life. People reproduce themselves, their families, and their culture daily. These acts of production and reproduction are prearranged by the historical past of a people, but this very activity changes both the people and their culture. With these changes, the needs of a people are changed; old needs are redefined or eliminated and new needs are created. With these ever-changing needs, the development of human life is both social and natural. Humans are both the animal creations of nature and the social creations of society. With this, each society creates its own social organization based upon its own historical *mode of production*. The nature of society is based upon the mode of production and consciousness. People's relations to nature mold their relations with each other. Peoples' relations with one another affect their relations to nature.

Social Evolution in the 19th Century

At the same time the young Hegelians and the utopian socialists were struggling to find a way out of the quagmire of Romantic reaction following the waves of revolutions, a new evolutionary view of humanity challenged the biblical account of human history. Jean-Baptiste de Lamarck (1744–1829), among others, began to advocate an evolutionary model of characteristics acquired from adapting to changes in the environment. What was seen as true for biological heredity would also explain cultural change. Many of these early writers speculated about why there were so many differences among human cultures. Biblical scholars looked upon non-Europeans and non-Christian peoples as being the result of degeneration, both physically and culturally, from the white race brought about by their separation from God's plan.

The evolutionists challenged this religious view by speculating that nonwhites were a more primitive variety of humans. Science was superior to religion. Monotheism was superior to either polytheism or animism. European civilization was at the apex of evolutionary development.

All other cultures were somewhere along the evolutionary trajectory from early apelike hominids to modern Europeans. Humans started their history as savages, and savages could still be found in the 19th century. Some of these savage groups had advanced to the next stage called barbarism, and barbarians could still be found in the 19th century. Civilization eventually replaced barbarism.

Sir Edward Burnett Tylor (1832–1917) maintained that all peoples evolved from simple to complex societies. Change of course happened at vastly different rates, thus the survival of savages and barbarians. Simple primitives were similar to stages the civilized Europeans had already passed through.

Lewis Henry Morgan became a defender of the land rights of the Iroquois of western New York; his interest in primitive peoples led to the publication of *Ancient Society* in 1877. He also divided peoples into savages, barbarians, and civilization. Dividing savages and barbarians each into low, middle, and high stages of development further refined this model of evolution. Marriage, family, religion, and political organization reflected the stage of technological development. Morgan speculated that the family evolved through the six stages of savagery and barbarism until the family of civilization emerged. The first was the promiscuous horde without any sexual prohibitions or real families. Middle savagery was marked by a group of brothers who were married to a group of sisters. Brother-sister mating was still permitted but not mother-son or father-daughter. Third stage brothers and sisters were not allowed to mate but group marriages were still practiced. Lower barbarism was described by loosely paired male and female couples who could end relationships easily or have sex with other partners. This was followed by male-dominated polygamy. The last stage was one of monogamous families, in which one wife and one husband were married and were comparatively of the same rank.

The problem with Morgan's conclusions was that recent studies failed to support his views on families among other societies. For example, in general, no society permitted group marriage or tolerated brother-sister mating.

Following Morgan, Herbert Spencer (1820–1903) believed that human nature was an ever changing and evolutionary process. This progress followed universal laws of development. Societies that did not adapt to changes in the environment died out. Savages stood in the way of progress and should be eliminated. It was Spencer, not Darwin, who coined the expression, "survival of the fittest."

For Spencer, humans gradually specialize, beginning with biological evolution, toward self-sufficiency and individuation, reflected in liberal capitalism. This innate tendency was revealed in the natural quality of rational self-interest. Those societies and individuals who make the most of this principle survive; those who are slow in learning this truth become extinct. Ethically, individualism was "most important," and individual growth was "egoistic." Society and all associations with others were largely made

up of instrumental and contractual agreements between individuals. Government should then protect the equality of freedom, and not interfere with a policy of *laissez-faire* in economic matters. Equality in control over economic resources or in the distribution of rewards undermined efficiency and was therefore wrong.

Evolutionary theory was trapped in a European mind-set of development from simple to complex, from primitive to the advanced. A return to the view of the racial and cultural superiority of Europe, held by scholars of the 18th century, carried with it the same pitfalls of distortions and the same limitations of bad science.

Historical Particularism

In an earnest response to the judgmental mind-set and assessment of 19th-century social evolution, a school of thought called historical particularism came into being. Universal evolution was seen as unscientific because any theory that places “European civilization” as the apex of social evolution was in fact theological and thus began with a preconceived conclusion and then arranged the data to support the subjective and predetermined deduction. With this as its basis, Franz Boas (1963) and his followers in American anthropology went to live with people whom they studied for fairly long periods of time. Through their observations, they collected considerable quantities of actual cultural data. They developed a research method called ethnographic studies in the field. Based on meticulous data, researchers described a specific culture. They were not interested in broad-spectrum theories (e.g., evolution) that relate to all societies and cultures.

Whereas Boas focused on individuals in his research, and deemed such information as a vital source in his cultural investigations, Alfred Kroeber (as cited by Boas, 1948) alleged a society changes consistent with its own internal laws. This cultural feature was the superorganic, where individuals played only a minor role in cultures. Culture could only be explained by bearing this objective force of the superorganic in mind.

Rebirth of Evolutionary Theory in Anthropology

Cultural Ecology and Cultural Materialism

What became apparent was that anthropologists were working with diverse historical settings and needed a way to reflect that. Borrowing from Marx, the concepts of production, human needs, population pressure, and change help us understand social ecosystems. The various human communities found in social and ecological associations are both historically and culturally diverse. To aid in this understanding, Julian Steward (1976) coined the term

cultural ecology. This was an extension of his theory of multilineal evolution—a search for regularities in cultural change. Cultural laws are then defined as a way to explain these changes, by searching for outlines of historical change that follow patterns of an interaction between the parts of a society and the larger environment. Cultural traditions have distinctive elements that can be studied in context. Similarities and differences between cultures are meaningful and change in meaningful ways. The evolution of recurrent forms, processes, and functions in different societies have similar explanations. Each society has its own specific historical movement through time.

Cultural ecology studies the adaptation of a unique culture adapted historically in a distinctive environment. Using this explanation, Steward (1976) appraised a creative process of cultural change. Steward focused on recurrent themes that are understandable by limited circumstances and distinct situations. This helps to establish specific means of identifying and classifying cultural types. *Cultural type* is an ideal heuristic tool designed for the study of cross-cultural parallels and regularities. This analytical instrument allows assembling regularities in cultures with vastly different histories. This type of classification is based upon selected features. With this, it is important to pick out distinctive configurations of causally interdependent features of cultures under study. The researcher chooses specific physiognomies that have similar functional interrelationship with one another.

For example, economic patterns are important because they are more directly related to other social, cultural, and political configurations. Universal evolutionary stages are much too broad to tell us anything concrete about any particular culture. The changes from one stage to another are based upon particular historical and cultural ecological arrangements unique for each society. Exceptionalism, then, is the norm. Global trends and external influences interact with a locally specific environment, giving each society a unique evolutionary trajectory.

Cultural ecology looks at cultural features in relation to specific environmental circumstances, with unique behavioral patterns that relate to cultural adjustments to distinctive environmental concerns.

Cultures are made up of interrelated parts. The *cultural core* is grouped around subsistence activities and economic relationships. Secondary features are more closely related to historical contingencies, and less directly related to the environment. Cultural ecology focuses upon attributes immersed in the social-subsistence activity within the specific environment in a culturally directed fashion. Changes are, in part, alterations in technology and productive arrangements as a result of the changing environment. Whether these technological innovations are accepted or not depends upon environmental constraints and cultural requirements. Therefore, population pressure and its relative stability are important. Also, internal division of labor, regional specialization, environmental tension, and economic surplus create

the cultural conditions in which technological innovation becomes attractive, leading to other cultural changes. These social adaptations have profound effects upon the kinship, politics, and social relations of a group.

Culture, according to Steward (1976), is a means of adaptation to environmental needs. Also, social relations reflect technological and environmental concerns. These social relations organize specific patterns of behavior and their supportive values. A holistic approach to cultural studies is then required to see the interrelationship of the parts.

The researcher begins with the study of the relationship between technologies of a people and how they exploit their environment for their survival. To use these technologies within an environmental setting, certain behavior patterns are established. The interaction between labor (behavior patterns) and the connection between technology and the environment has a reciprocal relationship with other aspects of culture, including ideology.

Leslie A. White (1969) looked at culture as a superorganic entity that was understandable in cultural terms. The three parts of a culture are the technological, the social, and the ideological. All three parts interact, but the technological is the more powerful factor in determining the formation of the other two. Thus, cultural evolution has all three parts playing important roles: The technological influences the sociological to the greater degree, and the sociological in the end shapes the ideological. Culture becomes the sum of all human activity and learned behavior. It is what defines history. Through technology, humans try to solve the problem of survival. To this end, the problem arises of how to capture energy from the environment and use this energy to meet human needs. Those societies that capture more of this energy and use it most efficiently are in a more advantaged position relative to other societies. This is the direction of cultural evolution. What decides a culture's progress is its capability of harnessing and controlling energy. White's law of evolution claims that a society becomes more advanced as the amount of energy harnessed per capita, per year, is increased, or as the efficiency of putting the energy to work is increased. This is cultural evolution.

Marvin Harris (1968, 1974, 1977, 1980, 1998) expanded upon cultural ecology, and called his approach *cultural materialism*. Human communities are fused with nature through work, and work is structured through social organization. This, Harris has asserted, is the basis of the industry of all societies. Social science must reflect this if it is to understand the deeper underlying connections between specific social actions and global trends. Industry, commerce, production, exchange, and distribution establish the social structure, which in turn gives birth to the ideological possibilities of any culture. Along these lines, socioeconomic classes are determined by the interaction between technology and social organization in a particular environment. The needs of every society and the individuals in that society must be met; this in turn creates its own ideological

support. With the development of capitalist society, for example, science develops to meet the needs of its economic requirements. Even more important, science is established as the integrating principle of modern industrial capitalism. This is possible because the principle ideas of any class society are that of the ruling class. Workers are subject to those ideas, while the dominant ideology reflects the dominant material relations of the society. In this, Marxism, cultural ecology, and cultural materialism have similar thoughts on the subject.

The complex relationships among the material base of technology, the environment, population pressure, and the ideological superstructure are a constant factor in studying social change. The social consciousness, while being the product of real material relations of society, in turn has an impact on those social relations. This feedback loop is central to understanding the historical dynamics of society. Social consciousness becomes the collective reflection of social relations. Through social consciousness, people become aware of and act upon nature and society. Even though forms of social consciousness reflect a specific social existence, this social whole is not a static or passive relationship. The ideological superstructure is different in each community and changes as the economic relations of society are changed. The ideology of a society reflects the social conditions of its existence. The superstructure and structure are ultimately molded and limited by the infrastructure. The infrastructure sets the limits of what is possible for both the structure and superstructure.

The interaction between social organization (structure) and the use of a technology within an environment (infrastructure) can be used to understand many particulars about the total culture. The evolution from band-level society to tribal-level society, tribal to chiefdom, and chiefdom to state-level society has to take into consideration changes in the organization of labor, including the growing division of labor, and, ultimately, changes in the technology used by a people. With changes in the organization of labor, there are corresponding changes in the relationship to property. With the increasing complexity of technology and social organization, societies move through these various stages to a more restrictive control over property, and eventually, with a state society, restrictions develop on access to property, based upon membership in economic classes.

Marxism, cultural ecology, and cultural materialism all agree that a social system is a dynamic interaction between people, as well as a dynamic interaction between people and nature. The production for human subsistence is the foundation upon which society ultimately stands. In producing what people need to live, people also produce their corresponding set of ideas. People are the creators of their ideology, because people are continually changed by the evolution of their productive forces; they are always changing their relationships associated with these productive forces. People continuously change nature and thus continually change themselves in the process.

Cultural Core

Cultural core is the central idea of cultural ecology. Current scholars in the field add the use of symbolic and ceremonial behavior to economic subsistence as an active part of the cultural core. The result of cultural beliefs and practices leads to long-term sustainability of natural resources. The symbolic ideology becomes as important as economics in the cultural core. Through cultural decisions, people readapt to a changing environment. This opens the door for a critical anthropology; the anthropologist can act as an advocate for groups threatened by corporate agricultural concerns. This humanistic approach does not negate anthropology as a social science. Instead, the new anthropology has a new activist approach by recognizing that different agents may have competing interests in resource management. Any historical analysis of important issues must then include indigenous knowledge to maintain not only long-term sustainability, but also to protect the rights of those most vulnerable.

Eric Robert Wolf

Eric Robert Wolf (1982, 1999) spent his professional career describing and expounding on peasant society, state formation, development of capitalism, and colonial expansion. He worked with the Marxist concept of modes of production as a conceptual tool to study the historical and materialist consideration of people in a cultural and ecological context adapting to a changing environment. Modes of production were looked at in a cultural ecological setting, as a specific adaptation to a particular social and physical environment. Interconnecting relations with other cultures in different environmental settings was a modification of this adaptation.

In the mode of production theory, Wolf, in *Europe and the People Without History* (1982), classified historical cultures into three basic modes of production: kin-ordered, tributary, and capitalist. Kin-ordered relates to band and tribal societies or stateless societies. In tributary modes of production, the direct producers possess the means of production. The elite expropriate the surplus product by political or other types of noneconomic means. Wolf stated that all precapitalist states were tributary. Asiatic is an example of a strong (centralized) tributary state, while feudal is a weaker (decentralized) one; these two replace one another over time. Europe, from the 16th through the 18th century, was not capitalist but a mercantile tributary (centralized) state, with capitalism emerging in England in the late 18th century. Labor was enlisted under capitalism through the buying of labor power, leaving the workers with nothing left to sell but this labor power. Liberal political revolution, the industrial revolution, and free trade came together in England partly because of its unique history and geography. England then became the homeland of capitalism, which divided the world to meet the interests of the British capitalist.

Through comparative studies, Wolf (1982, 1999) examined peoples of Latin America and the Caribbean who combined Marx's concept of modes of production with Steward's (1976) cultural ecological adaptations. This developed a working model of world markets and imperialism with a history of colonialism and U.S. economic domination of the region.

In *Envisioning Power: Ideologies of Dominance and Crisis* (1999), Wolf investigated the history of ideas, power, and culture and how they interact. He argued that power is important in shaping cultural evolution. Ideology incorporates power, but ideas reflect cultural input. Actual power and belief about power converge through culture. Societies face tensions posed by ecological, social, political, economic, or emotional crises, and use conceptual answers drawing on commonly unique, historically rooted, cultural understandings. In case studies of Kwakiutl Indians of the Northwest Pacific Coast, the Aztecs of pre-Hispanic Mexico, and national socialist Germany, Wolf analyzes how the ruling ideology, together with power, sanctions the significant relationships that govern social labor.

Conclusion

Anthropology is concerned with the study of humanity, putting together and testing hypotheses (provisional explanations of observed occurrences). From this procedure, theories slowly develop. In doing this, anthropologists ask how human life within society is possible. Humans are both animals and socially defined beings that are both creative and created.

Theory is a working model that organizes concepts of the empirical world in a systematic way, to help guide further research and analyze the findings. All theory is based upon empirical and variable facts. The strength of a theory is the skill with which it arranges information that can explain complex information in a manageable form. It must contain empirical statements that can be tested, and explain a complex interaction of observable phenomena. Theory is not a guess; a guess is a hypothesis. Theory is a factual statement.

From the *American Heritage Dictionary*, theory is defined as follows:

A systematically organized body of knowledge applicable in a relatively wide variety of circumstances, especially a system of assumptions, accepted principles, and rules of procedure devised to analyze, predict, or otherwise explain the nature or behavior of a specified set of phenomena. (p. 1861)

As such, we carefully study myth as a source of data and not the conclusion of our studies.

Myth is a nonrational and sacred, or intact folk explanation, for the origins or creation of natural, supernatural, or cultural phenomena. These explanations are a matter of

faith and not subjected to scientific or empirical inquiry. To end with a myth and begin with a myth is teleology, which happens when we begin with a conclusion and arrange evidence to support this conclusion. Teleology can be defined as explaining phenomena by final causes, or being directed toward an end shaped by a preexisting purpose. Science, then, is anti-teleological.

Social science is that application of the scientific method used to study people and society. It is the systematic pursuit of knowledge by recognizing a problem, formulating a question in a way that can be stated in a hypothesis and empirically verified or rejected.

Anthropology takes an approach that is holistic and evolutionary (i.e., historical). In this, anthropology is similar to sociology. Anthropology is global and comparative. Cultural anthropologists compare one culture to another in order to examine similarities and differences, and explain them.

In this chapter, culture is the sum of all shared knowledge, learned behavior, patterns of attitudes, and perceptions of a people. Humans adapt to their ever-changing environment through culture. While adapting to their environment, both social and natural, they change their environment; thus people are constantly readapting and changing their culture while doing so.

Culture and society stand as interconnected, grouped jointly into a single whole. Society is the social organization of any defined group that interacts through patterned communal association of individuals.

IDEOLOGY AND ANTHROPOLOGY

KATHLEEN NADEAU

California State University, San Bernardino

This chapter looks at hermeneutic and Marxist theories of ideology in anthropology that link the concept to underlying social processes and material conditions that work to sustain relations of power and dominance in a given society. It employs the example of religion as an aspect of ideology for illustrative purposes. *Religion* as used here does not refer to some supernatural or theological category at a universal level. Rather, it is looked at as an aspect of ideology in all of its historic and synchronic connections to an already existing society to provide the knowledge needed to constructively understand it. The chapter is arranged accordingly. Karl Marx's approach to the study of ideology is first introduced. Next, Louis Althusser's concept of ideology as social praxis and as part of a particular social and economic formation is given. Then a review of relevant theories on religion as an aspect of ideology in hermeneutics and anthropology is made. Included in this review are the works of three anthropologists (Talal Asad, Stephan Feuchtwang, and Abdul el-Zein) who are deemed to be exceptional. They are the only anthropologists, as research to date has shown, who have successfully combined concepts from hermeneutics, cultural Marxism, and Althusserian structuralism in their investigations of religion. This is followed by a discussion of recent trends and future directions of research pertaining to the study of ideology and society.

Introduction

The French word *ideologie* was first used in Western academic discourses in the year 1796 by Pierre Jean George Cabanis and Destutt de Tracy who used the term to refer to the science of ideas in contradistinction to ancient mysteries. Then onward, the word was employed in epistemology and linguistics until the 19th century, when Marx and Engels used it in a new way in *The German Ideology* (1847/1972). Tom Bottomore (1983) explained this as a reaction to two divergent lines of philosophical thought in their exegesis, namely, that of Feurbach and Hegel, respectively. Unlike Feuerbach and Hegel who did not link religion to an actually existing society, however, Marx and Engels took the unprecedented step of referring religious inversions and metaphysical distortions back to their material and social conditions. In other words, they explicitly looked at the relationship between misplaced forms of consciousness and the material conditions of human society. They argued that most problems confronting humans are not caused by mistaken ideas but by social contradictions. That is, subjective forms of objective realities are intricately interconnected. So, distorted notions and false consciousness can be a problem and cause of human suffering but they are, in turn, caused by material conditions. Bottomore (1983) stated, "It is this relationship (between thought and material social reality) that the concept of ideology expresses by

referring to a distortion of thought which stems from, and conceals, social contradictions” (p. 219). Ever since, the word *ideology* has been used primarily by creative Marxist scholars with a critical and negative connotation referring to distortions of thought that conceal, in obscurity, the social contradictions in which they are founded.

Marx, in his early work, criticized Hegel and Feuerbach’s thesis that thought determined the course of social change in history. Like Vico before him, Marx argued that we make our own history. Robert Murphy (1971) explained that Marx turned the theoretical perspective of Hegel and Feuerbach right side by proposing, “History was not the history of the mind but the history of humankind and its institutions, begotten by labor upon nature” (p. 98). In other words, thought is not divorced from society. Rather, it works its way through human institutions and changes them, as it is changed, in the process. Marx put it this way:

The chief defect of all materialism up to now, is that the object, reality, what we apprehend through our senses, is understood only in the form of the object of contemplation; but not as sensuous human activity, as practice; not subjectively. (Marx & Engels, 1970, p. 197)

Marx sought to demonstrate that human beings misrepresented their social practices and material conditions of existence, while thinking about them. He developed his concept of ideology on the basis of such mistaken, symbolic notions in the human mind. Marx analogized:

Consciousness can never be anything other than conscious existence, and the existence of humans is their actual life-processes. If in all ideology, humans and their circumstances appear upside down, as in a camera obscura, this phenomena arises just as much from their historical life-processes as the inversions of objects on the retina does from their physical life-process. (Marx & Engels, 1970, p. 14)

In other words, men and women interpret their human practices and circumstances in society in their thoughts, and these thoughts inform and drive social action. Hence, in a class society, Marx used the term ideology to explain how the ruling classes were able to rationalize their position of dominance and persuade the other classes to serve them. However, Murphy (1971) stipulated that this is not the only source of inverted ideas and illusions. Ideology also comes from the limited and restricted character of human relationships with nature and other humans (p. 99).

Marx first alluded to the concept of ideology in his critique of religion and of Hegel’s conception of the state. While Hegel argued that it was the idea of the political state that manifested itself in the empirical world as an absolute universe that determined reality, Marx countered that ideas were inverted to conceal the real character of society. He also challenged Feuerbach’s interpretation of religion. Although he agreed with Feuerbach that religion was a human invention and that the idea of God as our creator was really an inversion, Marx argued against

Feuerbach’s conclusion that religion was therefore an illusion. Rather, Marx (1974) showed that religion served to disguise irrationalities of the system of production, and he predicted its demise once men and women enter into rational relations with one another.

From this perspective, religion acts as an opiate of the people by concealing social contradictions that bring about suffering in the world: It serves as a palliative for unintelligible life circumstances and natural calamities. It provides a solution outside the realm of the present moment to account for the contradictions in the life experiences of people, individually, and as a group. Yet, it is important to remember that Marx analyzed religion in the context of the times in which he lived. Alternatively, as is illustrated by the emergence of liberation theology in the late 20th century, religion can be used to encourage people to face their problems through direct, nonviolent means. Participants in this movement seek solutions to their problems through Bible study, prayer, and reflection. But, they also confront their social, economic, and political problems head on by using tactics such as collective planning, decision making, and pressure techniques in negotiations with employers, landlords, development agents, and government officials.

These strategies inherent in the movement of liberation theology, however, are in keeping with Marx’s basic tenet that as long as men and women do not actively work to solve perplexing problems in a practical manner, they will imagine solutions in the form of ideological distortions that conceal those contradictions. In so doing, such ideological forms of consciousness will be passed down from one generation to the next, and they will continue to further the interests of the dominant classes. For Marx, the conscious act of bringing social contradictions into the light of human awareness through debate and criticism, however, is not enough to resolve them. It is only through sustained collective action that men and women can effect real, concrete change.

Bottomore (1983) explained that Marx, later, in *Capital* (1867/1974), added a final element to his concept of ideology. Through his analysis of capitalist social relations he concludes that the relationship between “inverted consciousness and inverted reality is mediated by a level of appearance that is constitutive of reality itself” (p. 220). This level of appearance is the economic infrastructure of a society that determines, in the last instance, its logic and motion. For example, in a society dominated by capitalism, the level of appearance is competition and the market. That is, it is through the sphere of circulation and exchange that the economic and political ideologies of the ruling classes in Western European and North American capitalist societies are generated. However, Marx did not mean by this that all societies are departmentalized into separate functioning parts whereby the economy becomes obviously visible, as it is the case in capitalist societies.

Under European and North American capitalism, the unity of society and economy is achieved through bureaucratic channels whereby society becomes differentiated

into discretely functional and separate institutions such as the family, education, religion, politics, and business. Hence, relations of production are enacted in the economy and one can easily see how the economic instance becomes the basis upon which other spheres of social life are made possible. But, in precapitalist societies, relations of production and corresponding forces of production governing distribution and exchange are often carried out through interpersonal relations embodied in social organizations, such as the family or religious system. In other words, in precapitalist societies, the economy is not readily seen. As in capitalist societies, however, ideology works to conceal the underlying contradictions of social life in these societies by focusing on the way in which economic relations appear on the surface as will be illustrated and discussed again later in this chapter.

In summary, Marx used the word *ideology* to refer to a double inversion in consciousness and reality. Ideology works to conceal the hidden reasons why economic relations appear on the surface in different ways in diverse societies and cultures. For example, if in precapitalist societies kinship or religion dominates social life, then productive and redistributive networks are founded in kinship and religious systems (Godelier, 1978). That is to say, the external form that the relations and forces of production take are—themselves—constituted by the sphere of circulation and exchange, which perpetuates ideological forms. Economic, political, legal, educational, familial, and religious ideologies are all interconnected in various ways and reproduced within a total social and economic formation, and these ideologies cannot be studied apart from the particular society in which they are situated. Marx's conceptualization of ideology provides a wide range of opportunities for further sophisticated inquiry, and it is to a discussion of Louis Althusser's formulation that we now turn.

Louis Althusser: Concept of Ideology

Ted Benton (1991), in his article titled "Louis Althusser: An Appreciation," suggested that a full appreciation of Althusser, who passed away in 1990, has yet to be realized. Althusser challenged dogmatic tendencies in Marxist theory. He opposed the use of Marxist dictates by communist parties and bureaucratic arms of state in communist and socialistic societies of his day. While doing so, he demonstrated that the alleged incorporation of Marx's ideas in the politics of communism in what was then the Soviet Union and Maoist China, for example, had no real basis in the writings of Marx. Althusser chided his iconoclastic and dogmatic communist colleagues for not promoting an environment that was conducive to the development of a creative Marxist social science. He specifically blamed the ideological and repressive state apparatuses of the Soviet Union, including the Eastern European block, for initiating the repression of creative scientific Marxism.

Without going back any further, we can say that this crisis was blocked and sealed up for us in the forms of Stalinist-state dogmatism, which doomed all who tried to approach the problem to condemnation and political isolation. Today—and this is a novelty of considerable importance—the forms of this blockage are breaking up, and elements of crisis are—even in their dispersion—becoming visible to the popular masses (Althusser, 1990; Benton 1991).

Indeed, Althusser was ahead of his time. He predicted the breakup of the Soviet Union, end of the Cold War, and reunification of East and West Germany more than 10 years before the actual events occurred.

Benton (1991) explained that for Althusser, the Marxism crisis in the late 20th century could only be rescued by subjecting Marx's work to rigorous criticism. This is because leaders of anti-imperialist revolutions had used his ideas and work as politics, rather than as an impetus for developing new and innovative courses of action that went beyond Marx's own thought. This post-Marxian stance is well supported in the work of Peter Worsley (1984) and Eric Wolf (1982), in that, they too argued that the early Soviet leaders dogmatically misconstrued Marx's concept of mode of production as forming the revolutionary core of their theory. In so doing, party leaders set a precedent for what Worsley called "a deformed socialism" (p. 337). Althusser explained that Marx was not in a position to realize that his ideas would become twisted and stagnated in the communist party's state apparatuses. Although he credits Lenin, the founder of the Soviet Party, for turning Marx's dialectic into a revolutionary method by analyzing current situations, he opposes Lenin's successors for blindly applying Marx's formulation to preexisting content (Althusser, 1990, p. 179–180). That is, subsequent party leaders had wrongly given determinant primacy to political ideas over people, rather than to the relationship between them. This began a long line of misconceptions of ideology in theories influenced by Marx that were credibly challenged by the French Marxist anthropologists (Godelier, Meillassoux, and Terray) under the influence of Althusser.

Bottomore (1983) explained that one of the reasons why early students of Marx misconstrued the term ideology was because they did not have access to Marx's *The German Ideology* until it was first published in 1920. These students (e.g., Lenin, Antonio Gramsci, Georg Lukacs) defined the term in two ways: to refer, first, to the social consciousness, or the ideological superstructure, of a society and, second, to the political ideas of particular classes. Althusser's (1990) point was that both conceptions of ideology ran the danger of being misused to refer to ideology as a separate abstraction that could exist in isolation from a living society (p. 170). Instead, he provided the following alternative definition of ideology.

Ideology is the lived relation between humans and their world, or a reflected form of this unconscious relation (e.g., a philosophy, etc.). It is distinguished from a science not by its falsity, for it can be coherent and logical (e.g., theology), but by the fact that the practico-social

predominates over the theoretical, and over knowledge. Historically, it precedes the science produced by making an epistemological break with it, but it survives alongside science as an essential element of every social formation including a socialist and even a communist society (Althusser, 1990, p. 252).

Althusser (1990) is exceptional because he argued that a preceding theory is needed before sociocultural transformation—of a domain in which a Marxist theoretical practice does not yet exist—can occur. In the study of other cultures and societies outside of Marx's *Capital*, the Marxist theoretical practice of epistemology, for the most part, remains to be constituted. Marxist anthropologists of other societies are not lacking, but Althusser explained that they do not have the revolutionary practice of *Capital* behind them. In other words, their practice needed to be set on a correct theoretical basis that was grounded and constructed in the context of real social life. He insisted that the theory of dialectical materialism was an apt method for this task. As Althusser (1990) argued,

A real understanding of materialism reveals that the researcher's labor is not a labor of the universal, but a labor on a pre-existing universal, a labor whose aim and achievement is precisely to refuse this universal the abstractions or temptations of philosophy (ideology), and to bring it back to its condition by force; to the condition of a scientifically specified universality. (p. 183)

That is, the use of dialectical materialism is not a matter of applying its formula to preexisting content. Rather, the method clarifies goals as it guides the researcher's analysis of a particular subject in all of its specificities. Although Althusser's methodological distinction between science and technology is controversial, Bottomore (1983) pointed out that, at least, he distinguished them. Moreover, since the anthropologist of precapitalist societies and cultures is essentially moving through uncharted territory in dialectical materialism, the primary research instrument is still the anthropologist, not theory.

Althusser (1990) explained that Marx's theory was not fully developed in his youthful work. Then, Marx was concerned mainly with questions of alienation and self-realization in the newly industrializing world. Although Marx criticized Hegel's ideas, his split from Hegel's thought was not complete. Marx chided Hegel for being guilty of the fallacy of abstraction. He argued that the egocentric individualism existing in the bureaucratic arms of European society obviated the Hegelian notion that the bureaucracy of the modern state was a universal class whose purpose was to realize the universal interest (Jessop, 1982, p. 4). However, Marx's basic proposition that humanity was the author of its own history and destiny was still very similar to Hegel's fundamental thesis that the world created itself according to some universal spirit (Bottomore, 1983).

Later, however, Marx (1964, 1982) radically broke away from Hegelian epistemology to develop a science of dialectical materialism. The mature Marx was interested in the

theory of social formations and their histories in all of their conceptual and structural variations. From this time forward, Marx never again viewed history as a series of stages unfolding along some unilinear pathway. Instead, he saw history everywhere as variable and subject to tireless investigation. Althusser (1977) was one of the first Marxist thinkers who emphasized the importance of this epistemological break with Hegel's thought in the development of Marx's ideas. Even Carl Boggs (1984) in his review of Gramsci's two revolutions in Marxism (scientific and revolutionary) does not mention Marx's key shift from Hegelian thought as Althusser does in his work. Neither does Jay (1984), in his exegesis on the concept of totality in Marxist theories, adequately differentiate Althusser's concept of the social whole from that of his predecessors Gramsci and Lukacs. This is because Jay concentrates only on Althusser's aversion to collective notions of the social whole, which is an aversion, shared by Gramsci and Lukacs, rather than on the detailed differences in their respective theories of social change. However, Althusser argued that Gramsci and Lukacs were Hegelian Marxists precisely because they aimed to recenter humanity as the megasubject in their theories. In contrast, Althusser's theory emphasized that the social whole was actually decentered, even under the ruling class of communism. Althusser was more focused upon the use of Marx's theory as an impetus to research new possibilities for social change than to use it as some sort of political weapon to be placed in the hands of a class, or coalition of classes, to forge another society along communist lines.

In other words, Marx's concept of the social whole departed in a revolutionary way from Hegel's concept of totality. Hegel's dialectic was dependent on the presupposition of a simple original unity that unfolded within itself by virtue of its own negativity in order to realize its original unity in some ever more concrete totality. However, Marx developed a very different thesis of the social whole. Althusser (1977) explained how Marx insisted that the simple can only exist within a complex structure of dominance. According to Marx, the structure of a given society is made up of two levels: the infrastructure or economic base and the superstructure or political, legal, and ideological aspects. He used the metaphor of an edifice to show how the economic base in the last instance determines the superstructure of a society. Althusser does not reject this metaphor; rather he argues that the classical metaphor of an edifice merely represents Marx's descriptive theory and should not be misconstrued. As Marx (as cited in Althusser, 1977) explained,

The concrete totality as a totality of thought, as a thought concretum, is in fact a product of thought and conception; but in no sense a product of the concept of thinking and engendering itself outside or over institutions or conceptions, but on the contrary, a product of the elaboration of intuitions and conceptions into concepts. (p. 182)

Thus, Althusser cautions to look beyond descriptive theories and rethink them anew in terms of the particularities and

specificities of different cultures and societies. Once this is done, it becomes clear that Marx's model is not reductionist in regards to the relationship between the economic base and superstructure. That is, ideology cannot be thought of in abstraction to its positive and negative connotations and relationships to a dominant mode of production in relation to other modes of production in an actual social formation.

Althusser (1977) defined a social and economic formation as a decentered totality made up of the forces and relations of production, the economy, superstructure, state, and ideology. He refers to ideology as the imaginary relationship that people have to their real conditions of existence. In other words, ideology is inscribed through human practices, and its existence is material. Even when a person's ideas do not exist in those practices, they give credence to other ideas that correspond to those actions. In Althusser's words, "ideology has no history" (1977, p. 150) because particular ideologies express class and regional positions that always pertain to particular histories. That is, in contemporary societies, ideology is realized as a result of a continuous and bitter struggle between classes with the ideology of the ruling class exercising its hegemony in and over the repressive and ideological apparatuses of state.

Many anthropologists and social theorists (e.g., Baudrillard, 1975; Sahlins, 1972; Ulin, 1984) are critical of the Althusserian perspective for being functionalist and outdated. They fault him for being too rigid in his theory of a social formation as having an economic base and political, cultural, and ideological superstructure. However, Althusser's theory is anything but economistic and iconoclastic. He does not eliminate men and women from his theory and, aptly, defends himself from such accusations in his *Essays in Self Criticism* (1976). Moreover, he paved the way for the emergence of postmodern cultural Marxism. Was it not Althusser who showed how culture might be seen in institutional terms? Did not the culture theories of his critics arise in debate with him?

Later in this chapter, the work of several anthropologists of religion who have significantly advanced Althusser's theory of ideology (Asad, 1983; el-Zein, 1977; Feuchtwang, 1984) will be reviewed. Before doing so, a discussion of the theoretical work of Ulin (1984) is provided because he brought together late 20th-century Marxist and interpretive ideas in anthropology. His scheme provides a way to transcend the ideology of positivism in anthropology, which is an important first step to study ideological variation in diverse cultures.

Hermeneutics and Ideology

Robert Ulin (1984) explained how hermeneutical approaches to the study of historically remote texts are equivalent to the anthropological method of fieldwork in that an anthropologist also seeks to make the customs and beliefs of distant peoples intelligible (p. 92). Both the anthropologist and the

textual scholar seek to understand what is essentially foreign to them. Although anthropologists can enter into dialog while questioning their subjects, deciphering the meaning of cultural products, behaviors, rituals, and codes resembles the process of interpreting an alien text. This complementary relationship between the hermeneutical problem and anthropological problem rests upon the disguised nature of appearances—they are not always as they seem and need interpretation to understand them.

The interpretivists—Hans-George Gadamer (1975, 1979), Paul Ricoeur (1979, 1986), and Jurgen Habermas (1971)—contend that the old, positivist notion that the social scientist should remain neutral and free of bias in the field is neither practical nor possible. Anthropologists should be aware that their traditions, including academic ones, filter into dialogs with subjects of study. By recognizing the inexplicable nature of their own traditions, anthropologists can better come to grips with the traditions of their subjects. Gadamer (1975, 1979) suggested that anthropologists can only come to know their subjects through language. That is, it is only through language that human existence can be made intelligible. However, Ricoeur (1979, 1986) stipulated that only a small part of human existence is reflected in language.

Roger Keesing (1979) also pointed out that it is fallacious to make a dichotomous distinction between linguistic knowledge and cultural knowledge. Linguistic knowledge includes more than knowledge of linguistic rules; it also includes knowledge about the culture of its speakers. That is, to communicate competently in a conventional sense, the people involved need to understand social rules, apperception of contexts, and of what is not—and need not—be said. At the same time that Ricoeur and Keesing challenge Gadamer, they also call into question Clifford Geertz's (1973) thesis that symbols exist in the mind of the actor to provide an individual with strategies for possible courses of action. They suggest that Geertz's theory ends by dividing thought and action.

According to Ricoeur (1979), symbols find their origin in some prelinguistic bios, rather than in culture or convention. He refers to *bios* as energy or desire in Freudian terms, and to the sacred in religious language. Ulin (1984) further explained that Ricoeur seeks to transcend a positivist tradition that divides nature from culture by rethinking them dialectically (pp. 105–109). Gadamer (1975), likewise, criticized Western positivism, which has developed an absolute notion of the science of reason. Ricoeur slightly diverges from Gadamer's view, however, in that he argues that symbols are not merely cultural constructions arrived at through intersubjective consensus, rather they unite individuals to cosmic space. His method of looking at metaphors from this double view can be distinguished from Gadamer's theory of the meeting of horizons through discourse. Like Gadamer, however, Ricoeur contends that it makes no sense for the social sciences to follow the methods of the natural sciences, for it is in the science of semiotics that human activity becomes objectified in the

external world. In contrast, the anthropologist Maurice Bloch (1977) arrived at a somewhat different conclusion than that of Gadamer or Ricoeur. He considers that it is within the relation between nature and culture that new conceptions are developed since they cannot come from a social structure defined as a shared system of meaningful categories. That is, it is not in language-like processes that human activity becomes externalized. Bloch (1991) brought forth an alternative theory of connectivism to show how new ideas result from a process of associating visual and mental images with a rapidity far greater than a mere sentence-logic model would allow.

Despite individual differences and shortcomings, Ulin (1984) found hermeneutic theories to be liberating because they offer alternative views of humankind. They can be used as a kind of guide to policy because they provide a wide range of possibilities for the future. However, he suggests that interpretive anthropology is lacking something that creative Marxism has to offer (p. 104). For example, the theories of Ricoeur and Gadamer do not account for how underlying historical processes within a social system are produced. Ulin explains that neither one of them accounts for how power relationships can confine human interaction and behavior, which is a point of contention also made by Habermas (1971, pp. 105, 108). Jay (1984) explained that Habermas improved upon theories of Ricoeur and Gadamer by integrating hermeneutics and critical theory. For example, in *Knowledge and Human Interest* (1971), Habermas expanded interpretive descriptions of the whole to include room for a study of oppressive dimensions. He challenged positivism in Western Marxism and the Frankfurt school's weak notion of Hegelian reason. Habermas borrowed techniques from psychoanalysis to develop a socioanalysis that could uncover meanings in communication processes found in situations of dominance and exploitation. He synthesized ideas from many of the social sciences in his call for a dialogic enlightenment of society. However, Habermas's theory is shortsighted because he concentrates only on the intersubjective realm of human experience and communication. Jay (1984) explained that by making the goal of speech perfect communication, Habermas's theory runs the risk of becoming an abstract philosophical anthropology divorced from its concrete basis in a given society (p. 497).

Ulin (1984) amended the hermeneutic theories of Gadamer, Ricoeur, and Habermas by way of what he called a materialist dialectic of social being. He develops his approach by criticizing and revising Althusserian structuralism to include concepts from cultural Marxism and interpretivist anthropology. In his scheme, the reproduction of inequalities in communicative action take place within the repressive and ideological apparatus of state. Ulin's model is sophisticated theoretically, and supplements Althusser's work. Many of Ulin's ideas are repeated in the following discussion of the works of Asad, Feuchtwang, and el-Zein. As mentioned in the introduction, their works are selected for consideration because they have successfully brought together a combination of

concepts from hermeneutics, cultural Marxism, and Althusserian structuralism in their perspectives.

Religion as an Aspect of Ideology

Talal Asad, in his 1983 essay "Anthropological Conceptions of Religion: Reflections on Geertz," took Geertz to task for misdefining religion. He suggests that Geertz is guilty of the fallacy of equating religion to culture. Culture, which can take the form of religion, stated Geertz (1973) is "an historically transmitted pattern of meanings embodied in symbols, a system of inherited conceptions expressed in symbolic forms by means of which men and women communicate, perpetuate, and develop knowledge about their attitudes toward life" (p. 89). Asad critiques this view of religion as culture (system of shared meanings) for being one sided in considering only how people communicate and develop their attitudes toward life, rather than looking at how the conditions of life also affect human experiences (p. 239).

In place of Geertz's paradigm, Asad (1983) offered an alternative approach for the study of power and religion to account for the ways in which religion is conceived, reproduced, and transformed as a result of historical processes. He exemplifies his mode of inquiry by focusing on the history of Christianity, selecting Christianity for study because he claims that Geertz conveniently ignored this in his theoretical discourse on religion. Asad suggests that Geertz's omission of a discussion of Christianity is symptomatic of a general tendency in anthropology to view Christianity as irrelevant, or marginal, to the study of other religions (p. 238). However, to Geertz's credit, he did allude to Christianity upon occasion (see Geertz, 1973, pp. 110, 125). Also, since writing his exegesis on religion, Geertz (1980) has changed his views and become less positivistic and more antiscience.

Asad (1983) criticized Geertz for looking at religion in terms of modernization theory. Geertz's scheme for looking at religious experiences of non-Christians resembles that of unicultural development theories of the 1960s. He seems to exhibit an ethnocentric prejudice when he concludes that the degree of the articulation of the religious experience is less in modern societies. He presents a picture of religion as if it were some amorphous whole that is destined to be surpassed eventually by modern science (see Geertz, 1973, p. 125). However, this part of his theory is an easy straw man to knock down because it derives from now defunct modernization theory. Asad's analytical critique is most interesting when he explores an alternative way of looking at religion (p. 237). He wants to explain how power constitutes the conditions that formulate religious ideology. He raises the important question of how certain symbols become established and how they are changed. Asad's point is that the dominant symbols and classifications accepted in society are part of the ideology of the leading classes, or leading fraction

of a class in a classless society such as a hunter-gatherer society. That is, according to Cricks (1982), dominant symbols are “constructions which are imposed and pass as knowledge only because the symbolic imposition is accepted as an act of power” (p. 303).

Asad (1983) focused on the history of Western Christianity because it provides a rich store of documented sources from which to formulate questions to study other religions. His basic argument is that the many varied denominations and assemblies that Christianity takes today are quite different from the form it took in medieval times. In those days, power was defined differently and it had different results. Religiosity worked its way through different human institutions and notions of self that constructed, legitimated, and distributed different categories of knowledge. One of the effects of this variable distribution of power is that religion is a result—not a cause—of the historical processes that shape, perpetuate, and transform it. Thus, there can be no universal definition of religion. In other words, religion needs to be investigated in all of its historical specificity.

Asad (1983) indicated that there were no real attempts to systematize a universal definition of religion until the 17th century, precisely, because the attempt was an expression of the repressive and ideological conceptions of certain relations of power and knowledge. Religion then came to be abstracted from its context and universalized with subtle and explicit force. However, in actuality, the definition of religion was a mere referent to established rules and practices that were developed to screen, oversee, and authorize certain relations of power and knowledge from a singular papal source.

Asad's thesis is supported by el-Zein in his 1977 essay “Beyond Ideology and Theology: The Search for the Anthropology of Islam.” In it, he reviewed five different studies of Islam, by Geertz, Crapanzano, Gilsenan, Burjra, and Eickelman, respectively. Here, we look exclusively at el-Zein's review of Geertz's *Islam Observed* (1968). However, it is noteworthy that Asad faulted all five case studies for beginning from the point of a singular definition of Islam as if it were some abstract category of meaning that existed at a universal level. He argued contrarily that there is no such unity of religious meaning in the category of Islam as expressed locally in context. From this perspective, religion—whether Islam, Christianity, Buddhism, or Hinduism—cannot be viewed as an amorphous, theological, or ideal category divorced from its relationship to a particular society and culture.

Supporting Asad's contention that Geertz mistakenly begins from the false premise of an overriding notion of religious experience and meaning within an Islamic tradition, el-Zein (1977) simultaneously focused on the variability in the context of religious experience acted out in daily life. Geertz mistakes religion as referring to a system of shared symbols and meanings, which synthesizes a worldview and ethos. Worldview and ethos are then seen as constitutive of the essential reality of nature, self, and society.

They are transmitted from one generation to the next through the agency of powerful, sacred symbols.

As el-Zein (1977) explained, for Geertz, religion is not static, and religious symbols react to the constant ebb and flow of history (p. 230). He defines history as a perpetual process of the sedimentation and change of meaning. There are certain restrictions placed on the continuum of meaning in history that are learned during the formative stages of human growth and development. Religion reflects an underlying tension, namely, between humans striving to create new symbols and meanings and their intention to solidify meanings in symbolic forms. The power of religious beliefs can lessen in the face of change, or it can be increased to abnegate change. Religion is a form of culture that can be understood by a so-called higher-order culture: science. In other words, Geertz reifies both culture and science. He reduces the Indonesian and Moroccan social formations in his study to two different versions of the culture of Islam (orthodox and folk). Islam can be understood in all of its variations through a process of thick description that Geertz refers to as science, but the type of science that Geertz refers to is the spirit of positivism or scientism. That is, through thick description, an anthropologist holds his own cultural biases in abeyance in order to look at the whole process of human experience to explain religion in context. Therein, the researcher discovers the intricacies of human expression and makes them intelligible to others. However, Geertz's reduction of religion to mere reflections and local variations of a universal category of religious meaning is not a satisfactory explanation for the diverse expressions of Islam.

Instead of assuming Islam to be a set of positive terms from which to begin to study it locally, el-Zein (1977) proposed an alternative way to study religion. He recommends that scholars conduct their research by first thinking of religion as a result of articulations of structural relations. This approach to the study of religion is a variation on Marx's second-level scheme. It would allow the researcher to start from an indigenous framework of Islam to investigate the relations that produce its meaning. There would be no separate, analytical category of Islam, and no autonomous entities (e.g., religion, economics, history) from which to start with; rather, researchers would begin their studies from a hermeneutic perspective. He forwards a viable premise that anthropologists and their partners of study inevitably share in an underlying logic rooted in both culture and nature. The anthropologist's job is to uncover this logic in the different contents of specific religions in various cultures and social formations. There are no strict standards of truth against which to study religious expressions in other societies and cultures. Instead, objectivity is grounded in the dialogic mode of both the anthropologist and her local partners of study. However, there is more to religion than making logical sense of religious content. The researcher also needs to account for the subjective realm of religion in connection to its concrete material conditions and structural relations in a given social and economic formation.

Feuchtwang, in his 1984 “Investigating Religion,” provided a useful model for the empirical study of religion as ideology at the concrete level. Following Althusser, he refers to ideology as part of a specific social practice and part of a particular social formation (p. 68). As Althusser (1971) put it, “Ideology represents an imaginary relationship of individuals to their real conditions of existence” (p. 162). That is, it is through ideology that individuals are constituted as subjects, and they are called into action in relation to a cluster of relationships in the concrete society of which they are part. Feuchtwang critiques the work of several 20th-century anthropologists (Dumont, 1970; Firth, 1964; Spiro, 1966; Worsley, 1970). He chides Firth for being guilty of the flaw of functionalism, even though Firth aimed to improve upon earlier functionalist theories (p. 64). That is, not only does Firth continue to look at religion as an institution alongside other institutions, in terms of its fit in relation to a Western conception of a departmentalized society, but Firth also commits the double fallacy of assuming that a postulate of suprahuman action is a universal text.

Likewise, Spiro (1966) is faulted for incorrectly defining religion as “an institution consisting of culturally patterned interaction with culturally postulated human beings” (p. 96). Spiro begins his definition from the basis of the projected existence of supernatural beings and defines religion as consisting of subjective ways in which different cultures and their peoples enter into relation with them. Spiro mistakenly takes the reality of supernatural beings as a given in his definition, rather than as a postulate that needs to be explained. He tries to be obviously logical, but this leads him to oversimplify the world into distinctly separate variables of analysis. Spiro reduces religion to an institution that functions to fulfill a universal, psychological need to explain what seems to be unexplainable, but he does not do this psychoanalytically. Furthermore, as indicated by Feuchtwang (1984), some people need no such explanations (p. 63).

Worsley (1970) was taken to task by Feuchtwang (1984) for using categorical distinctions from Western science to define religion—distinctions that may not be in the minds of the individual believers. Mary Douglas (1978), however, cautioned that the question of whether, or not, anthropological categories can be valid if they imply meanings not implied by their actors and actresses remains a subject of controversy in anthropology. Worsley, to his credit, confronted many of the problems inherent in earlier functionalist theories of religion by looking at what religion means to believers in local contexts, and at its indigenous effects. Feuchtwang’s point is that Worsley’s proposal to look at the believer’s subjective ideas about the existence of the supernatural realm, and at how that supernatural realm, in turn, influences their behaviors, is an empirically untestable proposition. It is not that Worsley refers to religion as the belief in the realm of the superhuman powers and spirits. Rather, he borrows Western notions such as the *nonempirical* and *technical domain* to distinguish the supernatural

realm from the earth-bound world of human experiences and meanings (pp. 310, 311).

In contrast, Dumont (1970) is criticized for reasons pertaining to method, not theory. Dumont does not make the same kinds of mistakes in his study as Firth and Spiro by employing some universal category of religion. Rather, Dumont begins his investigation of religion from the ground of an ideology specific to a given society. However, he commits some of the same misnomers in his methodology that Firth and Worsley do in their theories. Dumont divides for analysis the ideological (conscious ideal) aspect of society from its nonideological (social) part. Although he can be credited for seeking to understand the relation between ideology and its exterior expressions, locally and contextually, he falls short due to the determinant primacy he gives to ideology over society. Feuchtwang (1984) stated, “No sooner is the contemplating subject separated out as part of the independent variable or social life, then social reality becomes an appearance to this subject, not a system of a social formation” (p. 67). That is, Dumont proposes that the order of India comes from ideology, rather than from the human combination of relationships that make up the Indian social formation. In other words, Dumont takes a literal interpretation of the religions of India, without considering that ideology often takes on a life of its own in the minds of theologians that has no connection to infrastructural phenomena.

Instead of looking at religion in terms of subjective idealism, Feuchtwang (1984) argued, “The peculiar property of ideological practice is the formation of subjectivity” (p. 81). That is, the researcher of religion in other societies and cultures needs to look at religious ideas not only as thought, but behavior. Ideas and thought are inscribed in practice, and help to shape as they are shaped by what has been produced before, and this process unfolds in relation to the existing relations of production.

Feuchtwang (1984) called for a Marxist theory of social practice to research religion because it is a theory from which all other forms in a society are derived. Such an analytical technique can differentiate between different social formations. That is, practices are repeatable and so too are societies in all of their detailed variations. Since Marxist analysis neither seeks nor starts from the basis of some universal categories existing at a supreme level, it can explore different social and economic systems to produce knowledge needed to understand them in a constructive manner. He defines religion as ideology and its set of shared symbols and meanings. That is, religion as a form of ideology is always attached to the category of the subject. Men and women think and act in relation to their circumstances as they define them, and it is by means of ideology that they are culturally constructed as individuals or some other subject. Feuchtwang elaborates on his concept of religion as ideology by way of the following example of ritual toasting behavior from Taiwan (p. 72).

Ritual feasting is a common means through which collective decisions and bargaining are made in contemporary Taiwan. The feast serves to ritually bind members in association and seal their agreements. An association becomes formally recognized by means of a toasting ritual, but a person drinks only when they recognize in another a common identity of name, ancestral village, work, school, or military service. In Taiwan, they usually toast one another before an incense burner that they believe acts as a medium to a patron deity (e.g., an ancestral craft, scholar, or heroic military god). There is a given deity who represents the unity of the association and before whom partners are sworn in solidarity.

The ritual of toasting between humans and their gods in Taiwan finds its counterpart in the guilds of late Imperial China. Feuchtwang (1984) explained that the present religious ideology of ceremonial feasts reflects some of the ideology of the dominant division of class in late Imperial China, which defined the conditions of hierarchy for the rest of society (p. 69). An ideology, at another level, represented their moral order of heaven as emperor and its consortium of landlords, military generals, and government literati over a purgatory of disarrayed spirits. The religious ideology and its ceremonies are the obverse side of real positions within the hierarchical and geographical array of the Chinese imperial empire. Even though contemporary Taiwanese ritual feasts are related to other ideologies such as capital, Feuchtwang finds their underlying logic is continuous with a Chinese past.

Late-imperial China was an agricultural society, which formed a pyramid-like social structure with a large peasantry at its base and the gentry at its peak. Peasant farmers needed to maintain the minimum unit of land necessary for their own reproduction, while gentries concerned themselves with owning enough land to support their livelihoods from the rent they collected. Although the social organization of the peasantry was contiguous with the boundaries of their particular village, the associations of the gentry cut across many villages and cities. Villages were linked together by exchange networks in an extensive and periodic system and through commercial centers for accumulating and processing surplus products. Merchants organized the market, while the imperial bureaucracy controlled large tax monopolies. Landlords organized public works.

The reproduction of the collaborating elites, unlike the peasantries, did not depend on the reproduction of the basic agricultural unit of production. Rather, it depended on the reproduction of the political order. Elites constituted themselves into extended families and lineage organizations—to ensure the survival of their next generation—needed to withstand threats from partitioning inheritance rules and competitive succession into office. They strategized through such means as affinal networking, extended-family budgeting, and setting up trusts that were excluded from laws of partition. Since small farms, once they reached

a stage in the domestic cycle of the stem family, were divided between sons it was unlikely that small farmers could ever move up the hierarchy. However, they could join a lineage association to increase their family's opportunities over the long run. By means of a lineage association, a small farmer could send his son to school, and even hope to see his child sponsored under its auspices. These kinds of opportunities for the advancement of small farmers reinforced their acceptance of the descent organization and its ideology (Feuchtwang, 1984, p. 75).

It was in the lineage organization that the forms of feast ceremonies connected to a common ancestor were formed. These feasts were used by the powerful for their nonideological projects (infrastructural development, trade, and political mobilization) in explicitly ideological ways (marriage customs, ancestor worship, filial piety). The lower class aspired to the ideology of the leading class, largely, by modifying it. Otherwise, they could not afford the high costs of dowries and feasts to promote their alliances and lines of descent. Even though the living conditions for the masses, during Imperial times, did not change substantially as a result of their participation in the lineage associations of the elite, they were sustained ideologically due to their hope for upward mobility.

In short, Feuchtwang (1984), Asad (1983), and el-Zein (1977) all recommended that researchers begin their studies from the viewpoint of the underlying conditions and assumptions that allow subjective expressions of religion. Their approach challenges many of the categorical assumptions born of Western science. Like many of the traditional units of study in anthropology such as ethnicity, kinship, and the individual, supernatural categories that exist at some superhuman level are not universally given. Rather, their definitive existence needs to be determined through analysis of the historical and structural context of the subject of study and in relation to a particular social formation.

Conclusion

Interpretive anthropologists and cultural Marxists continue to argue for a materialist and dialectical approach to the study of ideology into the 21st century. The concept of ideology is not an abstract category of meaning that exists at some universal level. Rather, it is grounded, contextually and structurally, in the contemporary globalized world in which we live. For example, religion as an aspect of ideology needs to be examined in its historic and synchronic relations to an already existing social and economic formation to provide the knowledge needed to understand it constructively. Otherwise, students of ideology run the risk of losing contact with their subjects of study by creating theories that have no concrete relation to them. Or, they risk identifying with their subjects of study to the point of misconstruing their indigenous

beliefs and philosophies in terms of an abstract theory. Finally, a lasting insight from anthropology for the study of ideology is to begin from the point of view of the defining social subjects themselves who are the makers of their own history. Ideology cannot be defined definitively because human communities are constantly changing and adjusting to their changing circumstances in a global world.

ENLIGHTENMENT AND SECULARISM

JAMES PLEGER BONANNO

State University of New York at Binghamton

In the broadest sense of the word, *enlightenment* refers to the development and dissemination of the arts and sciences. Enlightenment entails secularism to a great extent in the Western intellectual tradition, though the two terms are not interchangeable. The entailment of secular ideas distinguishes the European Enlightenment from that of other traditions of the same name, namely the Buddhist Enlightenment of a much earlier period. However, enlightenment can also be described as transcendence, and in this regard, the Western Enlightenment is much less distant from its Buddhist counterpart. Indeed, transcendence is a key component of both enlightenment and secularism. This chapter describes the key components of enlightenment and secularism, and the relationship between the two concepts, as they have developed in the Western intellectual tradition, and as they continue to develop in our time.

In 1784, the German philosopher Immanuel Kant (1724–1804) accepted the challenge of defining the elusive concept of enlightenment in an essay titled, “What Is Enlightenment?” Already a renowned figure of the 18th-century Age of Enlightenment, which will be discussed ahead, Kant responded to the question with the following opening, provocative for its age:

Enlightenment is man’s emergence from his self imposed nonage. Nonage is the inability to use one’s understanding without another’s guidance. This nonage is self imposed if its cause lies not in lack of understanding but in indecision and

lack of courage to use one’s mind without another’s guidance. Saper Aude! Dare to Know! Have the courage to use your own understanding is therefore the motto of the Enlightenment. (as cited in Durant & Durant, 1967, p. 540)

Kant’s insistence on the importance of using one’s own mind without another’s guidance is a central theme of enlightenment. The implications are perhaps greatest for humankind’s relationship with religious establishment. Individual thought and reasoning are closely linked to skeptical inquiry, and the application of skeptical inquiry is the basis of secular thought. In light of the implications, the challenge posed to religious orthodoxy is considerable. The conflict between free thought and religious orthodoxy has been, and in many respects continues to be, an enduring theme of history.

Concisely defined, *secularism* is the affirmation that government institutions and religious institutions and beliefs exist in separate spheres, if not in practice then in theory. Although the term is of relatively recent origin, the concept was not unknown to the ancients. George Jacob Holyoake (1817–1906), British author and philosopher, is credited with coining the term *secularism* in 1846. Holyoake described secularism as the kind of knowledge that relates to the “conduct” and “welfare” of this lifetime. Secular knowledge is that which can be tested and understood through human reasoning. Secularism thus places emphasis on rational thought. The connection to science and scientific methodology is implicit.

Insofar as state and society are concerned, secularism entails the neutrality of government on matters concerning religion. The debate on the meaning of this, and on the question of degree, has been prominent throughout the history of Western societies and persists worldwide today. In the United States, the debate over the separation of church and state has perhaps never been more pronounced than at present. The implications are particularly significant in the realm of scientific and medical research, and government support thereof. To recognize the importance of these debates, their implications, and their future direction, it is necessary to turn first to their origins and development. The following pages provide a rather concise sketch of enlightenment and secularism from some of the earliest speculations on humankind to the present debates.

Speculations on Humankind

There is little doubt that human beings in societies across the globe have speculated on the nature of humankind. Such speculations can be the simplest of questions and yet can have the most complex answers, if they can be answered at all. The struggle to comprehend the unknown has given rise to numerous creation myths, many of which have long perished while others endure. While a reliance on supernatural explanations for understanding the universe persists, the development of science over time has unquestionably diminished popular faith in myths. Inherent in the emergence of scientific methodology is the application of skeptical inquiry. In this regard, the scientific revolution was not without its forerunners.

The period of secular philosophical achievement in the world of ancient Greece spanned more than five centuries, from the materialist philosopher, Thales, to the atheistic philosopher, Carneades (214–129 BCE). The earliest documented secular thinkers of the Western intellectual tradition were pre-Socratic materialists and skeptics (Sophists). The most notable include the mathematician Pythagoras (582–507 BCE), perhaps an early forerunner of Newton, who conceived a mathematically based universe absent the Homeric gods. The philosopher Protagoras (490–420 BCE) opened his treatise *On the Gods* with a candid denial of humankind's capacity to know whether or not gods exist. This subversive language led to perhaps the first recorded incident of a public book burning. Socrates (469–399 BCE) placed emphasis on inquiry and doubt with his famous Socratic method, intended to challenge traditional assumptions. Plato (427/428–348 BCE) and Aristotle (384–322 BCE) expanded on these notions and developed their own metaphysical approaches to understanding the universe. Aristotle in particular championed scientific inquiry and the possibility of an infinite universe. Ancient Greece was hardly lacking in religious orthodoxy, and polytheistic belief was pervasive throughout the Mediterranean world, yet a culture of speculation clearly prevailed, without

which, it is safe to say, modern science and enlightenment would not have become possible.

The Romans triumphed more in the art of war than in the science of enlightenment. Notwithstanding, significant contributors made their mark, drawing on the intellectual traditions of Athens and Alexandria. Rome's "golden age" of intellectual achievement during the 1st century BCE witnessed several notable enlightened thinkers. The orator Cicero (106–43 BCE) published works expounding the importance of skepticism and inquiry in determining truth. His contemporary, Lucretius (99–55 BCE), promoted Epicureanism in his *On the Nature of Things*, an epic poem that encourages the use of logic over superstition and appeals to humankind to overcome the fear of death. Indeed, humankind's so-called fear of death has been a recurring theme prevalent among enlightened thinkers throughout time, often articulated as a source of popular belief in religion. The hope of an afterlife existence can be said to undercut the anxiety over the termination of existence in the present.

The conversion of the Roman Emperor Constantine in 312 CE signaled the legitimization of Christianity, already pervasive throughout the Mediterranean world, as the official religion of the Roman Empire. The tendency toward religious homogeneity and the consolidation of papal authority after the fall of Rome in 476 effectively stifled the types of free thought so prevalent in Greek and early Roman civilization. The tendency toward monastic lifestyle and a Manichaean worldview furthered this trend at the expense of enlightenment. Although secularism was a concept nearly extinct in practice during the period known as the Middle Ages, the characterization of the period as a continuous "dark ages" has been contested by modern scholars. Several "renaissances" flowered in Europe before the scientific revolution, such as the Carolingian Renaissance at the time of Charlemagne, but these were generally limited in scope and not secular in nature. The Italian Renaissance beginning in Florence in the late 14th century began to witness the enduring revival of Greco-Roman ideas. A climate of interest in the arts and sciences, and the humanistic speculations on humankind inherent in such interest, was certainly more favorable to ideas of scientific inquiry.

The Scientific Revolution(s)

In 1543, Nicholas Copernicus (1473–1543) published *De Revolutionibus Orbium Coelestium (Concerning the Revolutions of the Celestial Spheres)*, challenging the existing notions of the universe and of humankind's position in it. In this major work, the Polish astronomer challenged the Ptolemaic theory of the solar system, hitherto accepted as accurate, proposing alternatively his own heliocentric model. Copernicus maintained that the sun is at the center of the universe and that the earth rotates on an axis and

revolves around the sun. The Copernican revolution generally marks the advent of the scientific revolution because of the tremendous implications of heliocentrism. In replacing the earth with the sun as the center of the universe, Copernicus revolutionized humankind's understanding of science and religion. Indeed, the Copernican revolution marks the beginning of the disagreements between science and religion that would quickly become a persistent theme of history thereafter. The science-versus-religion debates have increasingly developed as a struggle between conflicting worldviews, of enlightenment versus orthodoxy.

The notion of an infinite universe, with untold number of planets, moons, and even suns was met with disdain by religious authorities, both Catholic and Protestant. The reformer Martin Luther (1483–1546) dismissed heliocentrism and chided its supporters. The Roman Inquisition sought to make an example of the Italian philosopher Giordano Bruno, a well-known supporter of heliocentrism who also elaborated on its precepts, by condemning him to death on the charge of heresy. Bruno was burned at the stake in 1600. The Italian astronomer Galileo Galilei (1564–1642) and his contemporary Johannes Kepler (1571–1630) further developed the laws of heliocentrism, planetary motion, and optics. Galileo twice defended himself before the Roman Inquisition, the latter occasion recanting his speculations. In spite of this dubious recant, Galileo's research helped to bring the new laws of astronomy and physics to a much wider audience than ever before. Speculations on the configuration of the universe and the role of humankind increasingly became a source of debate during the 17th century.

The application of a scientific method to investigate problems and acquire knowledge did not originate in the 17th century. The ancient Egyptians and Greeks both applied methodology to investigate phenomena. The Muslim scientist, Alhazen (965–1039), developed a scientific method that emphasized the testing of hypothesis using experimentation. Francis Bacon (1561–1626) therefore drew upon the work of predecessors when he developed his own system of logic, the Baconian method. His most notable work in this regard, *Novum Organum* (1620), is in fact a direct reference to Aristotle's syllogism, as the title suggests.

Mathematical principles were employed by the French philosopher Rene Descartes (1596–1650) in his development of a "method of doubt" based on deductive reasoning. In *Discourse on the Method*, Descartes arrives at the famous maxim, "I think, therefore I am" (*cogito ergo sum*), concluding that the process of doubting in and of itself proves existence. Descartes nonetheless maintained deeply held religious beliefs, discounting any inherent contradiction. Fellow rationalist Baruch Spinoza (1632–1677) proposed a more pantheistic interpretation of God, rejecting all supernatural phenomena such as miracles and demons. Like many freethinkers of his day, Spinoza sought refuge in the Dutch republic, where such views were tolerated to a greater extent than in the adjacent nations. All of Spinoza's published work

was placed on the Roman Catholic Church's *Index Librorum Prohibitorum* (List of Prohibited Books).

The long development of scientific methodology is an important part of humankind's pursuit of enlightenment. The transition from trust in supernatural phenomena and mysticism to the application of a scientific method for understanding the universe is a central theme of enlightenment. Indeed, it was only a matter of time before religious beliefs would undergo the scrutiny of scientific inquiry. Early scientists, or natural philosophers, attempted to fuse science and religion, minimizing fundamental disagreements. In the Age of Enlightenment, even this synthesis would be challenged. The contributions of Francis Bacon, Thomas Hobbes (1588–1629), Rene Descartes, Baruch Spinoza, Pierre Bayle (1647–1706), and a host of others set the stage for modern secular and enlightened thought, even as they maintained religious beliefs, and certainly disagreed widely.

The Age of Enlightenment

The skeptical inquiry that emerged as a dominant theme of the scientific revolution was soon applied to other spheres, especially political and social. This development coincided with the emergence of a public sphere in Europe. A gradual development in the truest sense, the rise of a public sphere entailed the dissemination of the written word, and the proliferation of venues at which ideas could be discussed. This process can be traced at least back to the development of the printing press by Johannes Gutenberg around 1440. Necessity gave rise to invention with growing literacy rates and increased demand for the written word during the Renaissance and Reformation. The proliferation of venues for discussion of ideas included coffeehouses, freemasonic lodges, debating societies and salons, to name a few. The circulation of pamphlets, journals, letters, and later, newspapers all contributed to the level of discussion and certainly to the exchange of ideas. Historians debate the question of how "public" the public sphere was by the Age of Enlightenment. It can safely be said that the level of discussion and the number of participants had never been greater. The notion of a public opinion, virtually unknown during the Middle Ages, became something increasingly important for the arts and for politics.

These developments are of profound importance to the spread of enlightenment and secularism. The emergence of a public sphere meant that critical ideas would reach a broader audience. The transfer of a monopoly on enlightenment among a select number of elites, to a broader enlightened society, was for the first time possible. The idea of human progress, of the progression of humankind to a better existence, gained many adherents. In the 18th-century Enlightenment, science, and especially medical science, came to be seen as the greatest hope for humankind. Critics of the Enlightenment denounced what they considered to

be a naive or excessive faith in the human capacity for progress. Enlightenment thinkers, for their part, disagreed widely on a variety of matters, but maintained in common a confidence in human reason as the most reliable means to understanding the natural world.

It is no wonder then that Enlightenment thinkers viewed the English physicist Isaac Newton (1643–1727) as the culminating synthesis of the scientific revolution, and a key transitional figure to the Enlightenment. Enlightenment philosophers embraced the philosophical notion of determinism, the Newtonian conception of the universe whereby fixed, “natural laws” could be applied to describe phenomena. In his *Principia Mathematica*, Newton formulated laws of motion that put to rest doubts about heliocentrism. Newton contributed immensely to the field of mathematics in order to demonstrate his laws. Enlightenment thinkers applied the concept of natural laws to other fields of human knowledge, including economics and politics. The transition of philosophy from cosmology to agnosticism thus took an important step.

Though there is no consensus on the precise beginning of the Age of Enlightenment, scholars generally look to England’s “glorious revolution” in 1688 as an approximate starting date. This development preserved parliamentary democracy in England and circumscribed the powers of the monarchy. Enlightenment principles were concurrently advanced by key early-Enlightenment figures. Notable among them was the English empiricist philosopher John Locke (1632–1704). Locke’s influence on epistemology and political philosophy was enormous. His ideas on liberty, toleration, and the social contract can be seen in both the Declaration of Independence and the Constitution of the United States. Indeed, these principles remained a central theme of the Age of Enlightenment, emerging from theory to practice in the American and French Revolutions at the end of the 18th century.

The secular tone of Enlightenment philosophy increased as the geographic center shifted from London and Amsterdam to Paris. The former cities were known for their comparatively tolerant atmosphere, and thus the premier destination for freethinkers in exile. Paris, however, was the center of an absolutist-monarchical regime, where freethinkers could be sent to the infamous Bastille-fortress prison for publishing works critical of throne and altar. Though critical books were frequently banned in France and printing presses closed down, the Bourbon regime could not prevent the large number of publications from being smuggled into the country and disseminating. These works included a variety of subjects produced on a wide range of medium. The tone of Enlightenment work was largely anticlerical, especially in societies such as France in which clerical officials were ubiquitous. The monarchy too bore the brunt of much critique. The marriage of church and state, and the concept of “divine right” of kings to rule, came under heavy scrutiny by those who promoted the concept of natural, unalienable rights.

The public intellectuals who produced much of the provocative literature of the age called themselves *philosophes*. Unlike traditional philosophers, for whom theory is predominant, the philosophes were public intellectuals who sought progressive change through the application of theory. They used satires, plays, novels, poems, operas, and many other venues to express criticism of superstition, dogma, and tyranny, in their different forms. Though the term *philosophe* is French, these public intellectuals of the “Republic of Letters” lived and wrote throughout Europe and later, the early United States. They included figures from Pierre Bayle to Thomas Jefferson (1743–1826), the latter an example of the movement of Enlightenment philosophy across the Atlantic. An incomplete list of the most prominent and influential philosophes would also include the Baron de Montesquieu (1689–1755), Francois-Marie Arouet, better known as Voltaire (1694–1778), Julien de la Mettrie (1709–1751), Denis Diderot (1713–1784), Jean-Jacques Rousseau (1712–1778), David Hume (1711–1776), Benjamin Franklin (1706–1790), Thomas Paine (1737–1809), Immanuel Kant (1724–1804), and Mary Wollstonecraft (1759–1797). Many of these thinkers contributed to Diderot’s *Encyclopedie* (1750–1765), which contains numerous Enlightenment topics.

While certainly many Enlightenment thinkers were theist, atheist, or agnostic, the 18th-century Age of Reason is also well-known for the triumph of deism. Deists believe in the existence of a deity (from which the word derives) but maintain that this belief is purely based upon reason and observation rather than faith. Deists uphold natural law as opposed to divine revelation or supernatural explanations for the universe. Given the contributions of the aforementioned thinkers, who built upon one another, it is easy to see how and why deism emerged when it did. Inherent in deism is a pronounced skepticism of religion, especially in dogmatic forms. Strongly influenced by Newtonian physics, deists believe in the God of nature who designed the universe as a great machine set in motion according to natural laws. Often referred to as “the grand architect” or “divine watchmaker,” the deistic God created the universe, but does not intervene thereafter. This interpretation renders all supernatural events such as prayer, miracles, and prophecies as illusory and holy books such as the Bible and Koran as human-made. In spite of its 18th-century prominence, the word *deism* fell out of popular usage by the beginning of the 19th century. The concept, of course, has endured and evolved in a variety of forms.

The Evolutionary Framework

By the dawn of the 19th century, secular and enlightened thought had made considerable advances. Humankind’s desire to investigate and examine the natural world proved to be the underlying impetus for the spread and development of enlightenment. The intellectual culture of skeptical inquiry

that emerged during the 17th-century scientific revolution, and developed during the 18th-century Enlightenment, affected nearly every field of human thought. Belief in supernatural explanations diminished as humankind developed a greater understanding of the universe. Of course, new questions emerged and old ones remain unanswered. However, more people came to accept the idea that science was the best means to understanding our world. Though literal interpretation of religion was increasingly undermined by science, the origins of life remained a mystery. As such, even Enlightenment thinkers, often highly critical of religious orthodoxy, could not conceive of a universe without a creator. It would take the application of skeptical inquiry to the fields of biology and geology in particular, and the emergence of anthropology, to piece together the origin of species.

The idea that species evolved over time was not unknown to the ancient Greeks. Philosophers and naturalists in different civilizations have suggested evolutionary ideas in relation to organisms long before the emergence of specialized scientific fields. Scientists in the 18th century, or natural philosophers as they were then called, began to formulate biological mechanisms for how evolution of species might occur. Pierre Maupertuis (1698–1759), Erasmus Darwin (1731–1802), and the Comte de Buffon (1707–1788) all made important contributions. The French naturalist Jean-Baptist de Lamarck (1744–1829) developed the idea of inheritance of acquired characteristics, also known as *Lamarckism*. This hypothesis purports that physiological traits or characteristics may be transmitted to offspring. Lamarck maintained that organisms adapt to their environment over the course of their existence, developing characteristics that are passed on. While the basic concept of Lamarck's proposal is today largely refuted, his ideas nevertheless influenced the most important figure in the field of evolutionary biology, Charles Darwin (1809–1882).

That Darwin's ideas built upon the work of predecessors in no way diminishes the revolutionary nature of his contribution. This is equally true of Newton and Copernicus before him. As with Newton and Copernicus, Darwin's ideas had vast implications for humankind. Also like his revolutionary predecessors, Darwin formulated his theory carefully over many years before publication. The famous voyage of the HMS *Beagle* between 1831 and 1836 was followed by more than two decades of thoughtful examination. In *On the Origin of Species* (1859), Darwin proposed his theory of evolution by natural selection and the notion of common descent of species. The book provides an overwhelming mass of supportive evidence, much of it accumulated during the *Beagle* voyage, but also collected from colleagues in the various related fields of science. Darwin's proposal was indeed startling: The diversity and differentiation of species was not the result of the 6-day creation of a powerful deity, as had been taught and largely accepted for centuries, but rather is attributed to the gradual, organic process of natural selection. Very succinctly put, this process entails the

passing of genetic traits (characteristics) beneficial to survival from parent to offspring, over many successive generations, causing the emergence of new species. Adaptation to environment is, of course, an essential component of natural selection. Charles Darwin's theory of evolution by means of natural selection quickly became known simply as *Darwinism*.

In 1871, Darwin published *The Descent of Man, and Selection in Relation to Sex*. In this work, he elaborated on what *Origin of Species* had already implied regarding the origins of humankind. Human beings were certainly no exception to evolution and in fact, argued Darwin, are the most developed product of natural selection. The consequences of the Darwinian revolution are a comprehensive rethinking of the nature of humankind and of our relationship to the natural world. Humankind's understanding of religion was also thoroughly affected. Evolution and the principle of common descent demolished the scientific plausibility of creation and design for the universe. Even the existence of a deity was put into serious question and for many, marginalized almost entirely as a possibility. Indeed a multitude of philosophical, theological, and historical debates emerge from Darwinism. The belief that human activities should be based on evidence and verification absent the influence of religion was greatly boosted by evolutionary theory. Today, the evolutionary synthesis is uncontested among credible scientists of all related fields. However, evolution remains an active source of debate in many societies due to the fundamental contradictions between religious interpretation and scientific investigation. The sections ahead provide greater detail on these important debates and the new conceptualization of humankind.

The Emergence of Anthropology

The origins of anthropology can be found in antiquarianism, colonialism, and to some extent, travel narratives primarily between the 15th and 19th centuries. The field crystallized following the development of scientific methodology, evolutionary biology, and later, a holistic approach to understanding culture. Early forerunners include the Greek historian Herodotus (484–425 BCE), the Venetian traveler Marco Polo (1254–1324), and the Muslim scholar Ibn Khaldun (1332–1406). However, these prominent figures were not anthropologists in the modern sense because they did not inquire on the nature of the observed, merely recording observations. Like all of the social sciences, the necessary ingredient in the formation of anthropology was the development of a systematic approach. It is not an accident that anthropology emerged out of the Enlightenment.

Antiquarianism broadly refers to the prescientific interest in ancient civilizations. Often this took the form of hobby for affluent gentlemen, or artifact hunting in the pursuit of

profit. The subfield of archaeology especially is rooted in the 18th-century interest in antiquity—Greece, Rome, and Egypt. Early archaeologists focused on the Mediterranean world, and prior to the mid-19th century, often searched for ruins associated with biblical events. The gradual inclusion of methodology and systematic approaches to conducting research soon transformed the field.

Colonialism is not entirely distinct from antiquarianism, and was for at least four centuries the primary means by which Westerners came into contact with other civilizations. European colonists, explorers, Jesuits, and naturalists often transcribed their observations, which were, of course, generally based upon their own perspective rather than that of the observed. It was for many years through these accounts that most Europeans understood non-Western cultures. These early observations naturally gave rise to many assumptions, questions, and preconceived notions about the “other.” Traditional assumptions could also be challenged through comparative analysis, such as the notion of Christian universalism. Taxonomy and the invention of racial categories flourished in the 19th century alongside notions of “inferiority” and “superiority.” In the 20th century came the practice of observers actually immersing themselves within another culture in order to attempt an objective understanding of the observed.

Anthropology is very much an interdisciplinary study, emerging from the synthesis of knowledge gained in multiple fields that developed in conjunction. These include social sciences and natural sciences. In the case of the latter, developments in the fields of physics, geology, and biology, and their many subfields have collectively dealt a mighty blow to religion. It is an understatement to say that the emergence of evolutionary biology, and the theory of natural selection in particular, fundamentally transformed anthropology. It would not be possible to understand the origins of humankind, or what it means to be human, without evolution. Indeed, much of science would simply make minimal sense absent this fundamental theory. Anthropologists have pieced together much of our distant past through research and excavation work during the last 150 years. Distant hominid ancestors have been unearthed and dated using a variety of means. While many questions certainly remain, today we have a reasonably good understanding of the course of human evolution.

The Controversy of Science Versus Religion

The relationship between science and religion has been uneasy throughout much of history. Revolutionary scientific developments such as the Copernican, Newtonian, and Darwinian revolutions all significantly strained the relationship. The source of this unease has been the reliance on opposing methodologies to understanding the universe, and the fundamental contradictions that have emerged in the cumulative knowledge of science over time. Religion

in the Western sense rests upon what has been revealed to humankind by or through a deity. The term *religion* itself is problematic. Some “religions” practiced throughout the world are absent a deity or divine revelation. In that case, they may be referred to as philosophies or “codes of living.” Religions that have become defunct or extinct in terms of popular practice may today be referred to as mythologies. The major revealed religions—Judaism, Christianity, and Islam—are fundamentally based upon sacred texts that increasingly came into question by scientific inquiry. Religious orthodoxy has been in a position of defense in the West at least since Copernicus, as we have seen. Historically, this relationship between science and religion may therefore be characterized as one of advance of the former and retreat of the latter.

Sacred texts such as the Bible and the Koran have long come under intense scrutiny with the advance of scientific knowledge. Literal interpretation in particular has become impossible if one is to accept the results achieved by scientific research. Consequently, many believers have sought compromise between two seemingly opposed worldviews. Philosophers and theologians in the 17th and 18th centuries wrote texts arguing for allegorical meaning. Enlightenment thinkers such as Voltaire and Diderot questioned the authenticity of sacred books. The emergence of deism as a substitute religion can be seen as an outcome of this skepticism of divine revelation, yet reluctance to abandon the notion of a prime mover. While few 18th-century thinkers were willing to take the bumpy road from deism to atheism, in the 19th century this was much less the case.

Darwin’s publication of *On the Origin of Species* in 1859 added tremendous fuel to a conflagration. The theory of evolution by means of natural selection presented a major crisis between science and religion, as it undermined the Judeo-Christian-Islamic story of creation. Darwin’s assertion of the antiquity of humankind also suggested that the earth is significantly older than previously believed. This substantiated the findings of the geologist Charles Lyell (1797–1875), who argued in his voluminous *Principles of Geology* (1830) that the earth is much older than the 6,000 years calculated by the Christian theologian, Archbishop James Ussher. Lyell was a proponent of *uniformitarianism*, the theory that slow, gradual natural processes have shaped the earth (and other planets) over the course of time. In the 20th century, British geologist Arthur Holmes (1890–1965) built upon these principles with the publication of *The Age of the Earth* (1913) in which he used radioactivity to estimate the age of the earth as at least 1.6 billion years. Today, evidence from radiometric dating suggests that the earth is approximately 4.57 billion years old. Geologists have organized this immense span of time into a detailed geologic time scale. A vast span of time would be necessary for the theory of plate tectonics and continental drift, among many other geological propositions.

During the 150 years subsequent to the debut of natural selection, numerous advances in knowledge have been

made that authenticate evolution and the antiquity of the earth. Important contributions have been made in the fields of genetics, chemistry, paleontology, geology, molecular biology, physics, and of course, anthropology, to name a few. New fields and numerous subfields have also emerged. The contributions made in these fields converge in support of Darwin's theory. Perhaps the most notable, albeit unknown to Darwin at the time, was the research in genetics by the Augustinian cleric Gregor Mendel (1822–1884). Mendel's work was rediscovered in 1900, after his death. Mendelian genetics were soon embraced by scientists and have become an integral component of the modern synthesis of evolutionary biology. Consequent to these developments, many people of religious faith have sought to find synthesis between religion and science. Many Christians, Muslims, Jews, and Hindus have modified their interpretations to accommodate scientific findings. The Roman Catholic Church, perhaps mindful of the embarrassment caused by the treatment of Galileo and Bruno, has acknowledged that evolution may indeed be accurate, without explicitly endorsing or opposing the notion.

Despite numerous advances in knowledge of the arts and sciences, and particularly in the natural sciences, the theory of evolution has many detractors. The “Scopes trial” (*State v. Scopes*) in Tennessee in 1925 highlighted the division in American culture over the issue of evolution. The trial helped to create a lasting impression in the United States of the rift between two opposing approaches to finding truth. While many people of religious faith have found compromise, often by opting for nonliteral interpretation of sacred text, fundamentalists among Christianity, Islam, and Judaism, as well as other faiths, remain a potent and vocal force in the modern world. In the United States, many critics of evolution embrace the concept of intelligent design (ID). The basic premise of this concept is that organisms are simply too complex to have evolved, and therefore must have been designed by a god. Scientists, court rulings, and even some theologians have dismissed ID as pseudoscience and a religiously based critique of evolution. The concept is nonetheless popular in many Islamic countries, as well as in regions of the United States.

The Triumph of Scientific Naturalism

The 20th century witnessed a remarkable increase in the secularization of the human world. As has been heavily implied, this pattern has occurred in conjunction with the spread of enlightenment, or the progression and dissemination of the arts and sciences. Humankind's greater understanding of the natural world has affected popular belief in supernatural phenomena at an inverse relationship. The pace of revolutions in scientific knowledge has increased to the point that, today, we may speak of a concurrence of multiple scientific revolutions developing

simultaneously. Notably, the ongoing DNA revolution, the use of stem cell research, genetic engineering, transhumanism, evolution, space exploration, and of course, the computer and Internet revolution, all attest to the triumph of scientific naturalism and of humankind's ability to use nature for the cause of improvement. Of course, use of the term “improvement” in this regard is not without controversy. The question of ethics as it relates to scientific research is a persistent source of debate. The purpose of scientific research and of the ongoing revolutions noted in this chapter is to increase humankind's knowledge and awareness of the universe we live in, and insofar as is possible, to improve the human condition.

The field of genetics has seen a revolution on multiple fronts. In 1953, geneticists James Watson and Francis Crick identified the double-helix model of DNA structure. This solved the mystery of how genetic instructions are passed on from parent to offspring. Knowledge of the structure of DNA propelled research in drug development, human identity and brain activity, medical uses such as organ transplantation, stem cell research, and especially in evolution by natural selection. In the case of the latter, no longer is it necessary to research human evolution purely through identification of the fossil record, but also through identification of genetic lineage traced using the DNA of living peoples. Recently conducted DNA analysis shows humans and chimpanzees to be 99.4% identical. This has raised questions about our genus classification, suggesting that perhaps humans and chimpanzees should both be classified in the genus *Homo*. It is now through multiple facets of scientific research that we are able to recognize our distant ancestors and discover what it means to be human.

While it took many years for the popular acceptance of the heliocentric model of the universe and planetary motion, among many other great scientific revelations, in time these truths were universally recognized. Evolution indeed has functioned in a similar manner in terms of gradual popular acceptance. The overwhelming convergence of data in support of evolution by natural selection has made reasonable dismissal of the concept difficult. Resistance predominantly persists in geographic and cultural zones less affected by secular humanism. Religious fundamentalism often incorporates the concept of *denialism* in regard to scientific findings. Politics too can be affected by fundamentalist religious views and by the pressure from populations resistant to perceived assaults upon traditional orthodoxy. Scientists, for their part, maintain that good science knows no agenda—political, ideological, or otherwise. The purpose of scientific research is the pursuit of truth and the improvement of the human condition. To that end, research in evolutionary biology is ongoing. Broad acceptance of evolution and a growing acknowledgment of a cosmic perspective, including support of the cosmological model of the big bang theory, are much more pervasive today than at any other time in our past.

The Secularization of the Human World

In 1846, British writer George Holyoake (1817–1906) coined the term *secularism*. As we have seen, the concept of free thought was nothing new by this time; nevertheless, religion remained a potent force in government and society even in Great Britain. Holyoake, himself subject to persecution for blasphemy, set upon defining and articulating the concept that had already crystallized in theory more than in practice. In his 1896 publication titled *English Secularism*, Holyoake described the concept as such:

Secularism is a code of duty pertaining to this life, founded on considerations purely human, and intended mainly for those who find theology indefinite or inadequate, unreliable or unbelievable. Its essential principles are three: (1) The improvement of this life by material means. (2) That science is the available Providence of man. (3) That it is good to do good. Whether there be other good or not, the good of the present life is good, and it is good to seek that good. (p. 36)

Holyoake's definition is broad, incorporating nontheists of many different stripes. For many, secularism simply entails the promotion of social organization and justice separate from the sphere of religious belief. Secularism is therefore not intended to be an assault on or dismissal of religion. Others are actively critical of religious influence in government and society, and may therefore deem it appropriate to challenge such influence. At the heart of secularism is the view that tolerance and skeptical inquiry should be the underlying principles inherent in a free society.

The neutrality of the state on matters pertaining to religious belief is a question of central concern for many theists and secularists alike. So important was the issue for the authors of the Constitution of the United States that it is addressed in the First Amendment. Largely influenced by the Enlightenment discourse of the 18th century, the authors sought to emphasize the neutrality of the government—prohibiting Congress from either making laws promoting or prohibiting religion and the exercise thereof. Interpretation of this clause has been a source of disagreement between secularists and religious fundamentalists since its inception. Contemporaneously in France, revolutionary events began to unfold that would make the issue of secularism a theme of central concern to the present. France and Turkey are two examples of nations with an official separation of church (religion) and state. Many other nations worldwide officially or unofficially have a secular-based relationship between church and state to varying degree. Critics often argue that secularism is discrimination against religion, or even a form of religion itself. Proponents associate secularism with enlightenment and the principles of freedom and tolerance. They note that the most progressive and prosperous nations in the world are typically secular, suggesting an evident link. Conversely, secularists maintain that theocratic societies enjoy less freedom and prosperity.

The worldwide trend during the course of the last century has been one of increased secularization.

Prominent variants of free thought include agnosticism, atheism, and deism, the latter described previously. Though often portrayed as a middle ground between theism and atheism, agnosticism is rather a philosophical position than a belief system. It entails that metaphysical and particularly supernatural claims can be neither proven nor disproven, and are therefore ultimately unknown to humankind. British biologist Thomas H. Huxley (1825–1895) first used the term *agnosticism* in the 1860s. Huxley (1896) described agnosticism thusly:

Agnosticism, in fact, is not a creed, but a method, the essence of which lies in the rigorous application of a single principle. . . . Positively the principle may be expressed: In matters of the intellect, follow your reason as far as it will take you, without regard to any other consideration. And negatively: In matters of the intellect, do not pretend that conclusions are certain which are not demonstrated or demonstrable. (p. 246)

Many people worldwide have articulated *agnosticism* before the term itself was coined. Prominent, self-described agnostics include the American orator Robert Ingersoll (1833–1899), British philosopher Bertrand Russell (1872–1970), and German-born physicist Albert Einstein (1879–1955). Today, a substantial number of people worldwide identify as agnostic, particularly in the world's most progressive societies such as Sweden, Denmark, and Japan.

Atheism is the position that deities do not exist, and hence religion in all of its manifestations is spurious. Skepticism is a central component, as atheists tend to doubt supernatural claims for which empirical support is wanting. Prior to the 18th century, the term *atheist* had a markedly negative connotation. It was loosely applied to those guilty of alleged heresy or blasphemy rather than explicit atheism. It was during the Age of Enlightenment that it became relatively more common for a person to identify as atheist. Denis Diderot and Paul Baron d'Holbach were two notable examples. The French Revolution of 1789 to 1799 had a profound influence in Germany, where philosophical discourse during the 19th century was dominated by secular thought. The German philosopher Ludwig Feuerbach (1804–1872) described God in *The Essence of Christianity* as a mythical creation of humankind upon which human qualities are projected. As such, the narrative that God created man in his image is replaced by that of man created God in *his* image. Other influential thinkers of the 19th century who expounded atheism include Ernst Haeckel (1834–1919), author of *The Riddle of the Universe* (1899); Arthur Schopenhauer (1788–1860); Friedrich Nietzsche (1844–1900), author of several books critiquing religion; Karl Marx (1818–1883), who famously referred to religion as an “opium of the people”; and Sigmund Freud (1856–1939), who called religion a “mass delusion.”

The 20th century has undoubtedly witnessed a continuation in the trend of expressive free thought. Secular humanism, existentialism, nihilism, communism, structuralism, and psychoanalysis are but a few examples of the 20th-century philosophical discourse associated with secularism. Many 20th-century thinkers have written on the subject of free thought—certainly more than in any previous century. More significant is the extent to which this philosophical discourse has influenced societies around the world. The transformation of ideas in conjunction with rapid advances in technology has rendered the world of 2000 considerably more secular than that of 1900. Religious institutions once known for staunch opposition to scientific advancement have today, in the face of widespread secularization, modified their dogma to accommodate social changes. Resistance to do so and tension between orthodoxy and moderation has spurred violence at the dawn of the 21st century. Such responses can be seen as a reaction against universal secularization and modernization.

Future Directions

While secularism has spread worldwide at a spectacular rate over the course of the last century, its appearance in each nation has been uniquely dependent on the local social, cultural, political, and geopolitical conditions. Secularism developed quite differently in France, Germany, the United States, and Russia, for example. It is likely that this unique development, contingent on local circumstances, will continue to be the case. In addition, societies must cope with the globalization and mass society of the 21st century. The most noticeable feature of globalization is the spread and pervasive use of the Internet worldwide. A conduit for the exchange of information and ideas on this scale has the potential to usher in a second Enlightenment. The 18th-century Age of Enlightenment became possible because of the rise of a public sphere, in which new ideas could be discussed and debated, eventually eroding the monopoly on information hitherto held by throne and altar. Public access to information was the central indispensable component of the first Enlightenment. Today, in the 21st century, global access to information is unprecedented. The exchange of ideas on such a scale has the potential to challenge religious orthodoxy, traditional assumptions, and inherited beliefs. Those interested in preserving status quo are likely not unaware of this revolutionary potential.

A resurgence of religious fundamentalism and anti-democratic movements worldwide at the beginning of the 21st century has been met with a no less determined movement for secular humanism. Organizations advancing the cause of secularism and enlightenment are active worldwide. In Amherst, New York, the Center for Inquiry and the Council for Secular Humanism are two such examples. Both organizations promote the ideals of free

inquiry, separation of church and state, freedom and democracy, moral education, religious skepticism, the advancement of science and technology, understanding of evolution, and of course, the human capacity for reason. These ideals are today spreading worldwide to an unprecedented degree. The many aforementioned thinkers and writers have, over time, contributed to the ascendancy of reason. Science and technology have fundamentally transformed social institutions in Europe, the United States, and in many other nations. It yet remains to be seen whether the principles of secular humanism will be universally embraced.

MARXIST ANTHROPOLOGY

KATHLEEN NADEAU

California State University, San Bernardino

This chapter looks at the contribution of French Marxist anthropology and modes of production theory to the development of economic anthropology. Mode of production theory represents an alternative approach to earlier substantivist and formalist frameworks for the study of economy and society. By the late 1970s, most economic anthropologists agreed that the expanding world's capitalist system had a deteriorating effect on pre-capitalist societies and cultures. What they did not agree on was the question as to how these societies were transformed and changed. Substantivists argued that spread of capitalism disrupted traditional values, agricultural practices, and the social relations of production by forming both new classes and outside alliances that undermined the preexisting system at the expense of the commonweal. In contrast, formalists contended that the capitalist market improved individual well-being by rewarding farmers who adopted new behaviors and farming techniques to maximize yields and profits. This chapter is arranged accordingly. The mode of production concept is introduced. This is followed by a discussion on the substantivist and formalist controversy in the development of economic anthropology. The mode of production concept that countered this debate is then elaborated upon.

Mode of production (MP) as a theoretical framework for the study of socioeconomic systems was never fully developed by Karl Marx, who alluded to the concept here and there in his works. He introduced the idea in *Capital*,

A Contribution to a Critique of Political Economy, and *Pre-Capitalist Economic Formations*. It was from these texts that later scholars, especially Althusser and Balibar in their *Reading Capital* (1979), derived and developed the term for use in social analysis. Marx's work continues to be inspirational for the study of globalization and socio-economic and cultural change in the 21st century. Earlier scholars, like Maurice Godelier (1972) and Eric Wolf (1982), to take two of the better-known examples, referred back to him in constructing their MP concept. This chapter concerns the work of those scholars whose interpretations of Marx's theory are deemed most congenial to current anthropology.

Definition of the Mode of Production Concept

The concept of mode of production has never been definitively defined in Marxist social anthropology from which it derives. During the late 20th century, there were heated debates over this very issue, such as occurred between world system theorists (e.g., Wallerstein, 1974) and MP scholars (such as the French Marxists Godelier, 1972; Meillassoux, 1979; and Terray, 1972). World system theorists contended that global capitalism would inevitably eclipse traditional societies and cultures. MP theorists countered that, while capitalism could lead to the greater polarization between

classes, it also could encourage more divisiveness and stratification within a preexisting class society, as insiders hedged and shifted between capitalist and precapitalist relations in a transitional economy. Marx used the concept of MP interchangeably to refer to both a social formation and an economic system. For example, MP has been used to categorize the evolution of different societies and cultures, from primitive communist to ancient, Asiatic, feudal, capitalist, socialist, and advanced societies, even though a society and MP are two very different concepts.

A society-and-culture is a particular social formation that is made up of several particular and overlapping modes of production. This confusing of the concepts of a society versus an MP formed the basis of an archaic, now defunct, evolutionary scheme through which world history was viewed by Marxists as a kind of evolutionary ladder upon which each historical epoch was marked as being dominated by a particular MP that evolved into a new type through revolution. Yet, Marx (1982) clearly stated, "Events that are strikingly analogous, but taking place in different historical milieu, lead to totally disparate results" (p. 110). Eric Hobsbawm (1964) also defended Marx from those who would use his theory as if it existed outside of history at some superstructural level: "The general theory of historical materialism requires only that there should be a succession of modes of production, though not necessarily any particular modes, and not in any particular predetermined order" (p. 19).

Evolutionary theories of MP have been well criticized by the French Marxist anthropologists and other scholars (e.g., Bloch, 1984; Lukacs, 1968) for being dogmatic and nonscientific. Peter Worsley (1984) argued that they lacked a concept of culture. Louis Althusser and Etienne Balibar (1979) stressed that the MP concept had to be looked at as coming out of a particular MP. They explained, "To think the concept of production is to think the concept of the unity of its material and social conditions" (p. 101). Marx's concept was taken to a new level, by creative and nondogmatic Marxists anthropologists in the late 20th century, to refer to societies, past and present, where several different types of MP could be going on at the same time, usually with one being dominant. The concept of MP came to be used as a tool for social analysis, rather than as a way of delineating certain evolutionary stages. The MP concept came to be contingently defined as that complex of social relations that link human beings together in any production process, and the means of production (tools, technology, knowledge, and skills) around which work is organized to ensure the material survival and reproduction of a particular group.

The MP is constructed of two main components: the means of production and social relations of production. Marx theorized that the MP gave rise to social relations. In other words, the economic base of a society gave rise to its superstructure (political, cultural, and ideological aspects). But, cultural Marxist anthropologists of the late

20th century argued that Marx's MP theory was too deterministic and dogmatic in regards to the relationship of the economic base to the superstructure. They argued for an open-minded and bottom-up approach for the study of other societies and cultures. Godelier (1972), among other cultural materialists, substantially illustrated that, in precapitalist and semicapitalist societies, the economy is frequently embedded in kinship, religion, and politics. While this MP controversy has yet to be settled, most scholars of this school agree that the general logic of social life is grounded in material conditions. That is, the analysis of consumption and distribution begins, as Althusser and Balibar (1979) explained, "at the true site of the determination of the economic: production" (p. 265). The MP approach takes production as its logical starting point; although, in an ongoing economy, all three processes are occurring simultaneously.

The Substantivist and Formalist Debate

The substantivist and formalist debate arose in the early 1960s in response to the question of the place of the economy in society. Economic anthropology, by then, had only recently come into its own as a subfield of sociocultural anthropology. Anthropologists were interested in finding an appropriate methodology for the study of nonindustrialized societies. Their interest came to the forefront after World War II, when there was a widespread interest among nations in theories of economic development. This interest in modernization led to numerous "development" projects in the non-Western world. However, these projects usually failed, because they were implemented without consulting the findings of anthropologists and, perhaps even more importantly, the local people themselves. This debacle advanced a disagreement over the applicability of formal neoclassical economic theory for the study of noncapitalist societies and cultures. The dispute climaxed into what has become known as the substantivist-formalist controversy.

The formalist school (e.g., Eder, 1982; Herskovits, 1968; Schneider, 1989) proposed that neoclassical economic theory was appropriate for the study of human economic behavior cross-culturally. Implicit in this theory was the idea that all humans sought to maximize their individual behavior for their own self-profit. Formalists held that theories of human rationalism, developed for the study of human behavior in Western capitalist societies, could be modified and applied for the study of human behavior elsewhere. In contrast, the substantivists (e.g., Dalton, 1968, 1969; Polanyi, 1957; Sahlins, 1972) argued that "Homo-economus" or the idea that humans "naturally" strove to maximize their behavior for personal profit was a product of a particular society being dominated by the capitalist MP. They defined the economy as the way people make their living from nature and the relationships

between them; and contended that economic systems were not operating in the same way in different societies and cultures and therefore required new methods in order to study them. The substantivists realized that formal economic theory could be useful for the study of some societies. However, it was not a universal theory applicable for the study of all societies and cultures everywhere across the historical horizons.

Contemporary anthropologists still use both formalist and substantivist methods for the study of economic phenomena. However, the substantivist-formalist debate has subsided. From the perspective of MP theorists, both views are incomplete theoretically because they offer only partial explanations for human behavior. On the one hand, formalists attempt to make “institutional rationalism” derived from capitalist societies fit precapitalist societies while neglecting to consider their moral fabrics. Methodological individualism can be criticized for overlooking the dialectical relationship between human beings and their society. In other words, the formalists overlook the idea that people make their decisions in relation to outside social influences. On the other hand, substantivists seek to universalize an alternate theory for the study of tribal and peasant economies while dodging the issue that each society has its own unique culture, which eludes generalization.

Substantivist theory also is problematic because it separates out and sets apart the economy for analysis but then falls back on functionalism to explain it. Both formal and substantivist theories have something to offer, for example, that humans usually act rationally in accordance with their particular social and cultural circumstances, and formal economic theory can be employed to measure economic data in varied settings. The two approaches, whether used separately or in combination, will result in only a partial understanding of a society, because they focus mainly on the acquisition, distribution, and exchange of goods, rather than the entire production process that includes the way goods are produced, utilized, and exchanged, so argue the MP scholars.

Advantage of MP

The study of the economy includes more than the study of the circulation of goods. The economic field encompasses four related processes: production, distribution, exchange, and consumption. It makes good economic sense to begin from the point of view of production, because production precedes distribution and distribution comes before exchange. As Althusser and Balibar (1979) stated, “It is production that governs consumption and distribution, not the reverses” (p. 168). Prior to the rise of the MP school, most economic anthropologists attended, almost exclusively, to the study of the distribution and exchange of goods. In contrast, the MP perspective offered an advantage because it began from the point of origin where goods were being produced, and then looked at the entire production

process. The MP approach lessened the importance of the substantivist-formalist controversy, because it considered the economy as a whole by looking first at production, and then at how goods were being used and transferred. The MP approach, because it was a tool for social analysis rather than a theory, appeared to be more promising than the substantivist or formalist theories.

Anthropologists and the MP School

By the 1980s, there were a number of anthropologists (e.g., the French Marxists mentioned earlier and Joel Kahn, 1981; June Nash, 1979; Carol Smith, 1984; Anne Laura Stoler, 1985; Eric Wolf, 1982) who constructively used the concept of MP for the study of different cultures and societies. Firth (1984) and Roseberry (1988) divided these scholars into two different schools of thought, according to whether they were interested in theoretical issues or classic issues of revolutionary change. However, this categorization gave the impression that the French Marxists were armchair anthropologists above matters of class and social change. However, many of them had built their academic careers around their political beliefs. They were interested in matters of causality in MPs, which included considerations of culture, human agency, and class. The French Marxists used real-world examples to illustrate that, in precapitalist societies, relations of production were enacted through kinship, religion, or politics, rather than through the economic sphere, as is the case in capitalist societies.

The MP school of anthropology was given great impetus by the French Marxist anthropologists (e.g., Godelier, 1972; Meillassoux, 1972; Terray, 1972) who used the concept to go beyond the prevailing substantivist and formalist paradigms to study the economy. They were influenced more by the substantivists than the formalists, since the substantivists contended that the economy was a product of history. However, they considered the substantivist framework to be inadequate, because it overlooked the production process. Initially, the French Marxists were concerned to distinguish themselves from other Marxists who adhered to mechanistic models of MP. Godelier (1972) explained that they were developing a theory “as distinct from the Marxism normally practiced, a Marxism which can very quickly become vulgar materialism” (p. 62). Like Lévi-Strauss, they were interested in issues of structural causality in modes of production.

According to Godelier (1972), when Marx proposed that the economic infrastructure of a society determined the superstructure, he did not mean by this that all societies are divided into separate functioning parts, wherein the economy becomes visible as it does in a capitalist society like the United States or the European Union. In the United States, for example, the unity of society and economy is achieved through bureaucratic means, which allows the society to become differentiated into discrete

and functional institutions (the economy, education, family, politics, and religion, etc.). In this way, relations of production are enacted through the economy, and one can see how the economic instance becomes the basis upon which all other domains of social life are made possible. However, in precapitalist, semicapitalist, or noncapitalist societies, relations of production, and the corresponding forces of production that govern distribution and exchange, are carried out through interpersonal relationships embedded in noneconomic social organizations. In precapitalist societies, the economic instance is not apparent. It becomes, then, the work of the anthropologist to uncover the MP in precapitalist societies, even as they may be in articulation with and under the influence of capitalism.

In hunting and gathering societies (e.g., Australian Aborigines or Kalahari bushmen), the infrastructure and superstructure are enacted simultaneously through kinship relations. In these societies, it is infeasible to study the economy apart from kinship, as if it were a separate domain. Hunters and gatherers in primitive communist societies often control human access to the production process by regulating marriages, which provide a social framework for political and ritual activities. Godelier (1972) explained that kinship relations also function as a symbolic code for expressing relations between humans and nature. It is the kinsmen and women who perform the relations of production in correspondence to the level of development of the related forces of production. However, the notion of kinship in these societies does not stop at the level of the family; rather, it extends through a whole constellation of bands that form a single tribe organized into a system of subsections in relation to the natural environment, in order to ensure their survival.

Transition Debates

During the 1980s, MP theorists (e.g., Carmen Deere, Sidney Mintz, James Scott, and Eric Wolf) entered into another hotly contested dispute over the direction of social change in peasant societies. They argued over whether or not precapitalist traditions would inevitably be transformed into capitalist class relations once capitalism set in, or if peasant MPs were the effects of capitalism itself. This controversy stems back to the Lenin-Luxemburg dispute and the Lenin-Chayanov disagreement. They disagreed concerning whether the peasantry became stratified through its relation with capitalism, or if it was already a class as a whole in relation to other classes in a wider social formation. Ledesma (1982) explained that, from this perspective, the peasantry might be better off if it were a class unto itself, because stratification can lead to the marginalization of some segments of the peasantry. Marginalization gives rise to unemployment, which probably did not exist in precapitalist societies prior to their being dominated by the capitalist MP. Marginalization also

begins a process of the incomplete reproduction of peasant family households through semi-proletarianization, indebtedness, and outmigration. These conditions in the peasantry gave rise to another serious contestation over whether peasant households can still be measured in terms of farm output, rather than in terms of total input from a multiplicity of sources both on and off the farm.

The transition debates, much like the earlier substantivist-formalist controversy, were long and contracted. World-system theorists (e.g., Braudel, 1984; Frank, 1967; Wallerstein, 1974) contended that the precapitalist MP was subsumed into the capitalist mode; hence, relations between them are capitalistic. But the French Marxist anthropologists, especially Meillassoux (1979), argued that Marx studied precapitalist societies only in so far as they pertained to capitalist societies. Elsewhere in his works, notably his reference to the Asiatic MP, Marx suggested a tendency in precapitalist MPs to resist capitalism. Furthermore, contended Meillassoux, the world-system view reduces the relationship between capitalism and precapitalist MP to a one-way process that pays little attention to local interactions. The French Marxist anthropologists agreed that the relationship between global capitalism and precapitalist MP can lead to capitalist relations of production, but that this is not always necessarily so. There is widespread resistance to capitalism, and some rebellions challenge capitalism by calling for its replacement by a completely different MP altogether. Also, the capitalist mode has sometimes encouraged the continuation of precapitalist modes when it is profitable to do so.

Articulation of MP Debates

MP theorists (e.g., the French Marxists anthropologists Joel Kahn, Eric Wolf, and Harold Wolpe) held that precapitalist MPs are not underdeveloped forms of the capitalist MP, as liberal economic theorists portended. They are completely different economic systems that require different concepts and theories to study them. Precapitalist societies have to be differentiated and set apart from capitalist societies because, even if they are changed as a result of capitalism, they can only be understood in terms of the characteristics internal to the MP dominant before capitalism arrived. Meillassoux (1979) argued that capitalism both undermines and perpetuates preexisting MPs in order to ensure itself a labor supply. Wolpe (1980) explained, "The capitalist sector benefits from the means of subsistence produced in the non-capitalist MP to the extent that it is relieved of paying a portion of the necessary means of subsistence by way of indirect wages" (p. 248).

MP theorists, from the 1970s to the early 1990s, critiqued world-system theory, the development of underdevelopment theory, and modernization theory on the basis that there is not only one capitalist system through which, logically, all the others can be explained, but there are also

various coexisting MP with laws internal to themselves. In other words, Mandel (1976) explained that the world capitalist system often gets embedded and transformed through preestablished cultural constructions of inequality. That is, an MP often gets transformed through the formation of class alliances between the dominant classes in each production mode. With the influx of capitalism, the bourgeoisie frequently becomes interested in bonding with the precapitalist, dominant class because it has the power to exact labor. Capitalism, far from replacing other MPs, often dominates and exists side by side with them. As Wolpe (1980) explained, "It is one thing to argue that pre-capitalist relations of production may be transformed into capitalist relations quite another to assume that this is a necessary and inevitable effect of the capitalist mode" (p. 41).

Another debate arose over the question of whether simple commodity production (SCP) is an MP. Carol Smith (1984) and Jacques Chevalier (1983) view petty commodity production as an incipient form of capitalist production, rather than an MP. From their perspective, SCP exists within the logic of capitalism, although they are contentious as to whether or not it is bound to be fully subsumed by capitalism. In contrast, Kahn (1981) analyzed SCP as a separate MP in terms of its own logic articulated together with a few other modes, usually the capitalist MP and subsistence MP. Chevalier (1983) found this way of looking at SCP problematic, because it took a one-sided view of the capitalist MP as being more progressive and dominant, with all other modes being variable. Smith (1984) explained that simple commodity producers might subsume their labor under capital, even in the absence of monetization, because they have to commodify their goods for exchange in a market in order to reproduce their means of subsistence. However, the French Marxist anthropologists interjected that this is not always necessarily so. MP scholars, who analyze SCP as a separate mode, do not necessarily view the influx of capitalism as an overarching structure. They look at it as a subject for investigation, one to be constructed out of the particular social and historical societies in which it is situated.

Concept of Class in Precapitalist MP

Under capitalism, classes are economic groups that account for economic distinctions, but in precapitalist MPs, the relationships between classes are determined by means other than economic bonds. In precapitalist societies, for example, surplus is not extracted from the direct producers by economic means. Mandel (1976) explained that Marx was not seeking universal laws of economic organization in his study of class formation under the emergent capitalist MP of his time: "Indeed, one of his essential themes is that no such laws exist" (p. 12). Marx did not try, as he did for capitalism, to find out the internal

laws governing precapitalist societies and cultures. Instead, he dealt with other societies and cultures only in so far as they bore a relation to the development and origins of capitalism. More generally, however, Marx (1974) intended his concept of class for the study of other societies: "The specific economic form, in which unpaid surplus labor is pumped out of direct producers, determines the relationship of rulers and ruled, as it grows directly out of production, itself, and, in turn, reacts upon its determining element" (p. 791).

The French Marxist anthropologists explained that a concept of class is integral to a concept of an MP, but one must begin a definition of class, not from an MP but in the context of the society and a larger world in which it is situated. This is because, within any society, more than one MP occurs together and one of these modes is usually more dominant. Terray (1972) stipulated that whether an MP is in a dominant or subordinate position is different than what it would be in a pure state. In other words, stated Althusser and Balibar (1979), "The relations of production cannot be thought in their concept, while abstracting them from their superstructural conditions of existence" (p. 177). That is, the classes cannot be divorced from the societies and histories in which they are grounded.

According to Terray (1972), a concept of class can be defined as a "totalizing entity": In it economic, political, and ideological forces of society converge to determine an MP. One needs to account for both the superstructure and infrastructure, because class is a product of these combined structures. The French Marxist anthropologists contended that for each MP, it is essential to construct the concept of class that is contingent upon it. Therefore, a concept of class applicable for the study of all societies and cultures at some universal level does not exist. But, a more basic definition can be given as follows: Classes are social entities formed on the basis of their differing relationship to the means of production, where ownership relations are focally instrumental but not the exclusive determinants of social position.

To grasp the difference between MP, cross-culturally, and the relations of production, contextually, one should proceed by way of class analysis. The concept of class is the motive force undergirding Marx's MP theory. For Marx (1974), usually but not always, there is a discrepancy between two opposing classes: master-servant, aristocrat-serf, and the wealthy-poor. This inequality between classes causes them to struggle for their elevation, thereby causing their own transformation into new social relations that sometimes cause a new MP to emerge. Hence, a discussion of two or more MPs concerns a discussion of classes or groups that need to be accounted for in any theory of articulation. So, late 20th-century MP theorists also reflected and wrote on the totality of classes, their connected class-consciousness, and the relations between classes in particular societies and cultures around the world.

Concept of Ideology and MP

Kahn (1981) provided a framework for a general theory of the formation of ideology in order to look at class alliances and the struggles between classes as they articulate to develop MPs. His model is worth discussing here, because it provides an example for dealing with the complex issue of classes as they are articulated within different MPs in particular societies. He proposed that, in the past, researchers have used concepts, such as vertical alliances, ethnicity, and patronage politics as models for the study of economic systems in peasant societies that were actually concepts of ideology. He defined peasant ideology as *anti-modern* or *antiquarian systems of meaning* that existed in relation to *capitalist rationality*. These aspects of ideology articulate with the capitalist ideology when the peasant modes of subsistence and SCP enter into relation with the capitalist MP. From this perspective, a general approach to the study of ideology is a first step to the study of peasant economic behavior. That is, peasant behavior is not determined mechanically by the infrastructure of the society, because ideological systems are a product of their own internal properties and are outside socioeconomic and political constraints.

Patron-client relationships, vertical alliances, and ethnicity are kinds of “folk models” based on the appearance of social reality experienced through social interactions. Patron clientage is developed through the perception of structural relations of exploitation and political dominance. Kahn (1981) explained that patron clientage becomes a model for human behavior but, at the same time, the social structure is being built up by all the interactions between inferiors and superiors based on their differential access to valuable resources that define their place in the class structure. He stressed that, where patron clientage has become part of the local ideology, it is based on an assumed coincidence between interaction and both economic and political relationships. However, it is important to remember that social and economic structure need not coincide with the folk models or with appearances. Social change moves by way of its own internal ideological volition, not from external structural changes.

Finally, Kahn’s (1981) model for the incorporation of ideological aspects in the study of the articulation of MPs met the challenge of disentangling the relationship between changing class relations and the persistence or disappearance of traditional relations in precapitalist societies, because it considered visible social structure and perceived empirical models of behavior. It began from the premise that a concept of class and contingent class-consciousness is integral to an MP approach. It is a significant rendition of the MP concept that provided a way to avoid some of the pitfalls of generalizing from preconceived models that do not fully account for the ongoing processes of continuity and change.

Future Directions

Research trends in the study of economy and society since the 1970s and 1980s have moved the discipline forward. Evolutionary frameworks, made to measure the level of development of precapitalist societies against the backdrop of development taking place in advanced capitalist societies, have been largely discredited. Early anthropologists looked at MP in terms of a techno-economic base upon which all other aspects of the superstructure of a society are derived. Cultures could then be categorized based on their level of technological development. Post–World War II development specialists used this model, and made theories of world economic change consist of the transfer of technology from richer to poorer countries. These schemes usually did not work, because they failed to account for the social relations of production.

Later anthropologists examined the distribution and exchange of goods from the point where they were produced. Production assumed a key role because, through it, all other aspects of the economy were actualized. Prior to the introduction of the Marxian concepts in economic anthropology, analysis of the economy in noncapitalist-oriented societies was made in terms of substantivist or formalist theories. These theories provided an inadequate definition of the economy. The formalist theory, by focusing only on the formal aspects of the economy, excluded those characteristics of the society that may be more important to the local people; by omitting such characteristics, they could project concepts from their own social-economic system onto those who held no such views. On the other hand, the substantivist theory, by largely limiting itself to the study of the circulation of goods, is only able to obtain an incomplete understanding of a given society.

Marxist analysis became most useful in the late 20th century for the study of the articulation of MPs as they interacted with capitalism. Although this approach went down with the fall of the Soviet Union in 1991—which gave rise to a new school of postmodern scholars influenced by the work of Marcus and Fisher (1986), who critiqued Marxist theory for being outdated—it has since come back into ascendance. Marxist studies are being revisited for the light they bring to bear on contemporary issues of global and local change. Kahn (1981), in his earlier study of SCP in West Sumatra, was able to show how blacksmiths organized their productive relations indigenously and how these were influenced by the market economy, which determined the price range of local goods, since these goods could not compete with factory goods. Meillassoux (1979) looked at how peasant villages often act as a social security system for capitalist enterprises established in less wealthy countries, where underpaid laborers with no social security benefits go home to retire or work on family farms during the off-seasons. The concept of MP in such cases helps to illuminate the nature of globalization and development, and

raises the question of who benefits from such economic development. It could be used to find problematic areas in the articulation of two or more MP in places undergoing transition (e.g., 21st-century China, or, in the future, post-war Iraq) that could be targeted for change beneficial to the direct producers.

Finally, MP studies have paved the way for a hybrid cultural perspective that has contributed significantly to ethnographic practice, because it avoids some of the pitfalls of generalizing from preconceived models that do not fully account for ongoing processes of continuity and change. Studies of MP are equal to the task of looking at social, cultural, ideological, and economic changes occurring in real-life communities, with their own unique cultural configurations resulting from interactions taking place both locally and beyond. What they argue for is the importance of looking at social relationships against the backdrop of the MPs that oriented them.

AGENCY AND PRACTICE THEORY

ANGELA KRISTIN VANDENBROEK

University of Southern Mississippi

In 1984, Sherry Ortner predicted that practice would be the key symbol of anthropology in the 1980s. Research on practice, agency, structure, and power actually filled not only the 1980s, but also the 1990s and extended into the 2000s as well. Issues of inequality, oppression, and resistance have been a staple of anthropological literature and have influenced its many theories, both before and after the 1980s. However, time, from the 1980s up to and including today, has seen a steady strengthening and thickening of agency-related theories.

The critiques of feminism, postcolonialism, and race and ethnicity studies brought to light the many problems with earlier constructions of agency. Two main lessons were taken from these critiques. First, agency is not interchangeable with the notions of freedom, the human spirit, or autonomy. Second, notions of agency as purely resistance impoverished the complexity of agency and often allowed for ethnocentric slippages into complex situations of actual resistance.

Theoretical perspectives to explain agency are diverse. In this chapter, they are divided into theories of agency and theories of practice. However, in reality, the divide is blurry and the exchange of knowledge and inspiration crosses the border frequently. Yet, there are commonalities in practice theory that separate it from other theoretical models and thus its distinction here. There are also explorations into agency that are not explored here because they are beyond the scope of this entry, particularly those studies

in psychological anthropology. This chapter presents the three most widely cited and most common threads in the anthropological discussion of agency: poststructuralism, language, and practice.

Lessons From Anthropological Critiques

Perhaps the easiest place to begin a discussion of agency is at its definition. However, as has been noted by many of the prominent theorists of agency theory, this is not an easy task. Like other troublesome anthropological terms, such as culture and identity, agency lies at the intersection of what many have taken to be self-evident, and what others have found highly problematic in real ethnographic experience. However, ethnographic experience has brought into focus some aspects of what agency is not, a quality that indicates humanness or only acts of pure resistance.

Agency as Humanness

A frequent misuse of the term *agency* is as a quality of humanness. Often associated with action theorists, a group whose aim is to differentiate action from events, this form of agency is seen as synonymous with free will or the ability to act intentionally versus being a passive receiver of an event. Donald Davidson's essay "Agency" (1971) describes the difference with an example of his morning routine. He pours

himself coffee and accidentally trips on a rug, spilling that coffee. Pouring coffee, Davidson argues, is an action; he intentionally and knowingly made the choice to pour the coffee. Tripping and spilling the coffee, however, was an event that happened to him, rather than an intentional action. On this level, agency seems to be an easily distinguishable behavior that could be easily transported to anthropological theory. However, this simple definition fails to connect the social nature of agency and the impacts of culture on human actions with the internal will of individuals.

To further problematize this understanding of agency, poststructuralists such as Bronwyn Davies (1991) found that humanist discourses that equate agency to humanness also tend to equate agency with “freedom, autonomy, rationality and moral authority” (p. 42). The interchangeability of these terms allows for groups—such as children, women, the insane, the oppressed, and others—to be described as being incapable of having agency and thus less than fully human. Even for those individuals or groups that are classically seen as having agency, such as adult sane men, agency is only seen as legitimate in so long as the actor’s agency conforms to the dominant discourses that determine what is rational and moral.

Intentionality, the degree to which an action and its outcomes are intentional, has been important to action theory, as well as practice and agency theory, for differentiating between actions that are agentic and those that are everyday practices or events. However, some theorists, such as John Comaroff and Jean Comaroff (1992), have called out the overemphasis or obsession with intentions as representing colonialist ethnocentric biases. They found that by imagining agency to be like the actions of a Western hero, who can overcome all obstacles of his cultural context simply through sheer will, social scientists transport Western ideals of resistance and glory into contexts where they are not. This not only distorts the reality of anthropological subjects, but also creates a false impression of the strength of power structures and the abilities of actors to resist and overcome them. In some popular discourses, similar ideas have led to the argument that the dominated remain dominated out of a lack of will rather than out of a lack of power. Comaroff and Comaroff further problematized intentionality by demonstrating how placing focus on the intentions of individuals distorts the complex and unpredictable relationship between actors’ intentions and the social outcomes of that agency. They argue that social outcomes frequently are unintended consequences of agency, rather than the carefully planned, intended consequences of heroic actors.

Agency as Resistance

Rebellion in the face of oppression is a romantic ideal of agency that has been invoked by anthropologists and other social scientists in increasing frequency, particularly as the discipline’s focus on power and inequality

becomes more intense. Even those theorists such as Lila Abu-Lughod (1990), who in her influential article “The Romance of Resistance” denounced this glorification of resistance in ethnography, has admitted to falling prey to the idea in her earlier works. The narrative of the dominating structure being overthrown by the downtrodden underdog, while romantic, fails to portray the lived reality of resistance. One difficulty of equating agency with this form of heroic resistance is that it upholds Western ideals of individualism and transplants them to non-Western contexts. As has been pointed out by Laura Ahearn (2001c) and Comaroff and Comaroff (1992; among others), even in Western contexts, resistance rarely takes this idealistic form.

Resistance is often messy and contradictory, and is played out in a wide variety of forms from foot-dragging to revolution. Abu-Lughod (1990) pointed to her ethnography among the Awlad Ali Bedouins as an example of resistance forms that do not fit the romanticized model. She observed irreverence toward men imbedded in the joking of women, minor defiances of traditional modesty and sexuality hidden in poetry, and subservient acts of women to block unwanted arranged marriages. However, Abu-Lughod argued that casting a light of romanticized resistance over these acts fell short of the reality for the women she observed. The actions were not representative of Western-feminist politics of resistance against male domination. Yet, women were creating power for themselves within the framework of male power in their lives. The contradictory behavior of upholding structures of male power on the one hand, while undermining it on the other, is also incompatible with traditional views of resistance.

To avoid the Western and ethnocentric view of resistance, Abu-Lughod (1990) suggested that anthropologists should study resistance as a diagnostic of power, rather than as a phenomenon indicating human freedom. This analytical switch allows ethnographers to view the various types of resistance in a context of their complex relationship with power structures without privileging one over the other.

Agency Theories

Many schools of thought within anthropology have explored agency. This section explores just two of these. Yet Davies’s (1991) article “The Concept of Agency” and Ahearn’s (2001c) article “Language and Agency” are excellent examples, because both propose new directions for theory, and both thoroughly document prior understandings and known issues that have arisen in agency theory. Both poststructuralism and feminism developed as a response to earlier theoretical models and common trends, as well as assumptions in anthropology. Davies explored how these earlier understandings of agency have influenced anthropological understandings of women’s agency, and then proposed a new model that would take the lessons already

learned in feminism and poststructuralism to overcome these biases. Ahearn, coming from a linguistic background, made a persuasive argument for the importance of language studies for agency, as she found that current theories of agency were insufficient to bridge the gap between social reproduction and social transformation.

Feminist Poststructuralism

In 1991, Davies, a poststructuralist and feminist, wrote the widely cited article “The Concept of Agency.” This article is an outline of the differences between humanist and poststructuralist theories, as well as an outline of Davies’s argument for poststructural understandings of power and agency in light of her feminist background. Davies argued that while humanist theories emphasized the individual as having a complete and independent identity with the capacity for agency, poststructuralism viewed individuals as having multiple identities with each being constituted by the subjective positions of the individual in discourses. Agency, as understood by humanists, is thus illusionary since the individual is forced into “choices” that reflect what is accepted as rational and desirable by the discourses that constitute the individual’s identity.

Davies (1991) disputed the humanist theories primarily because she found that rather than representing the reality of power structure and human agency, humanist theories upheld racist and masculinist power structures. She also argued that humanist theories pit the individual against the collective and force the individual into struggling against the collective in order to obtain an individual identity. Poststructuralism views the individual as constituted by many discourses, with the heroic individualism of humanism as simply one. The model of the essential and continuous self that most individuals view themselves in, Davies argues, is the result of regular positioning in a set of discourses, the use of life-history story lines to string together an individual’s existence into a cohesive whole, the internalization in the body and the desires associated with it, and features such as the male/female dualism that Davies argues are consistent through all discourses.

To escape the power of strong discourses and the male/female dualism, Davies (1991) argued that individuals must recognize the ways they are constituted through discourses and then act as authors to disrupt, contradict, and rewrite the discourses that constitute them. These acts of “authority” represent agency in the poststructuralist model. However, she was quick to point out that while agency exists in the poststructural framework, it is impossible for an individual to escape the discourses that constitute the self. An individual can only recognize the multiplicity of discourses involved in the constitution of the self and resist, subvert, and induce change within those discourses. Thus, agency, in this framework, is the ability to author and have a voice within the discourses one is involved in.

Agency in Language

Ahearn (2001c), in her “Language and Agency” review, argued for greater use of linguistic knowledge in the study of agency. Because agency and culture are so closely intertwined, a study of agency necessarily requires an understanding of the ways it is represented in language. Linguistics, she argued, could build the bridge between social reproduction and social transformation—a bridge, which she argues, practice theory has not yet built.

Grammatical agency, Ahearn (2001c) explained, is created through the grammatical structure of a language. While grammatical agency can overlap with social agency, grammatical agency is different in that it reflects how a language represents the different roles taken by linguistics subjects. Ahearn argued that an understanding of grammatical agency can give insights into social agency. For example, in a 1992 study, LaFrance found that participating English speakers had a bias against women. He observed that when speaking about women, the participants were more likely to make women’s agency “disappear” by structuring their sentences grammatically so that women took more passive roles as subjects. Men were more likely to be portrayed grammatically in more aggressive subject roles.

Linguistic anthropology, more so than other forms of linguistic studies, focuses on language as social action. This means looking at how people use language to reproduce and transform culture. Ahearn (2001c) loosely defined agency as the “socioculturally mediated capacity to act” (p. 112). She found that the study of language as social action, with an understanding of the ways in which language constructs social understandings of the subject, creates important knowledge for anthropological understandings of agency, particularly in the areas of language and gender, literacy studies, and dialogic approaches.

Practice Theories

Practice theory originated in the late 1970s and early 1980s as a response to earlier structural theories and the argument over the privileging of human action over cultural forces, or the privileging of structure over human action. Practice theory aimed to explain the ways that culture was created, sustained, and changed. The early theorists had various emphases on aspects of this aim; however, the overall goal remained. Pierre Bourdieu, a French sociologist, achieved much with his *Outline of a Theory of Practice* (1995) that inspired and became the basis for much of practice theory. Bourdieu focused on both the way that culture was perpetuated over time and the systems of control that influenced human action. Marshall Sahlins’s thin yet rich book, *Historical Metaphors and Mythical Realities: Structure in the Early History of the Sandwich*

Islands Kingdom (1981) focused on how cultural history influenced the actions of people and successfully created a mode for cultural transformation. Anthony Giddens's (1976, 1979, 1981) contribution to practice theory came from his background in sociology and what he lacked in ethnographic experience, he made up for in his observations of the nature of structure and its relationship to human agency and agency's dependence on structure.

Since the early formations of practice theory, anthropology as a discipline has explored new understandings of culture and undergone intensive internal critiques from postmodern influences. From these observations, Ortner (2006) found that three main influences contributed to the growth of practice theory: the "historic turn," the "reinterpretation of culture," and the "power shift." The historic turn, she explained, was a turn from synchronic studies to diachronic explorations into history. Of the three founding fathers of practice theory, only Sahlins (1981) had a truly historical perspective of practice. Ortner (2006) argued that the historic turn made clear the importance of understanding history's impact on practice and that historical perspectives must be included in any true theory of practice. The reinterpretation of culture from a simplistic and essentialist bounded category—from early anthropology to a complex system yet to be fully understood—also impacted practice theory. The power shift, which occurred parallel to the development of practice theory, was propelled by three works identified by Ortner: Raymond Williams's *Marxism and Literature* (1977), Michel Foucault's *History of Sexuality, Part I* (1978), and James Scott's *Weapons of the Weak* (1985). This shift was the result of several critical studies in anthropology including feminism, postcolonialism, and studies of race and ethnicity.

Two recent approaches to practice theory, and the most influential, are William Sewell's (1992) article "A Theory of Structure: Duality, Agency, and Transformation" and several works by Ortner (1984, 1989, 1996, 2001, 2006). Sewell, a diverse social scientist, created a widely cited theory practice, worked from the foundations of Bourdieu (1995), and particularly Giddens (1976, 1979, 1981). Ortner, over a 20-year period, contributed an array of works concerning agency and practice theory, resulting in serious games theory. Together, Ortner and Sewell represent the more recent trends in practice theory and general anthropological theory.

Three Early Theorists

Pierre Bourdieu

Pierre Bourdieu (1995) wrote an *Outline of a Theory of Practice* amid growing unease among social scientists about earlier structural theories, particularly the work of Lévi-Strauss (1969). Postmodernists, particularly from the field of literary criticism, began to question the Western assumption that objective reality existed in a way that

individuals experienced reality similarly or that social scientists could observe it. In an *Outline of a Theory of Practice*, Bourdieu added to and propelled this argument by suggesting that much of observed reality is subjective and that human agents largely control culture, as they create, maintain, and alter taxonomies through practice.

Field, as defined by Bourdieu (1995), is the objective social domain where relationships of inequality take place and where agents, informed by subjective *habitus*, negotiate that inequality. *Habitus*, originally introduced by Marcel Mauss and adapted by Bourdieu, is the internal subjective reality of the individual that is built for them through their encounters with the field or objective reality. *Habitus* contains both the variable array of options available to the agent, as well as the limits to their actions. He described the quasiperfect arrangement of the objective structures of the natural world and the subjective structures of culture as *doxa*, the state where the objective and subjective are fit so well that agents do not question the arbitrariness of it, but rather accept it as self-evident or natural, creating limits on the actions of agents.

However, not all human action functions as *doxa*; subjective reality does not always have a near-perfect fit with the objective field. Bourdieu (1995) argued that dominated agents question *doxa*; he called this process *heterodoxy*. Dominated agents, under Bourdieu's theory, have the capacity for and an invested interest in resisting *doxa* and thus their dominated status. Powerful agents must then defend it; he called this process *orthodoxy*.

Practice, as laid out by Bourdieu (1995), is thus the processes of agents asserting their power by creating, maintaining, or altering symbolic taxonomies. These are enforced by making them appear as part of the natural order that makes up culture. Bourdieu overcame many of the troubles postmodernity had revealed about earlier social theory by providing a framework to observe agency and structure immersed in power and inequality, and by sidestepping the assumption of objectivism.

Marshall Sahlins

Marshall Sahlins's (1981) *Historical Metaphors and Mythical Realities: Structure in the Early History of the Sandwich Islands Kingdom* was influenced by many of the same postmodern sentiments concerning earlier structural theory that influenced Bourdieu (1995) and Giddens (1976, 1979, 1981). Sahlins, however, was particularly concerned with the lack of a diachronic perspective in structural theory. Ferdinand de Saussure and other structuralists, Sahlins argued, had written structural theory in ways that placed structure in binary opposition with history. Sahlins, through his historical ethnography of Hawaiian interactions with the British, aimed to dispel the idea that structure exists outside of history.

Sahlins (1981) argued that agency reflected one's cultural history and cultural knowledge. He presented a

picture of agents filling and acting in their cultural categories until change is brought about by the clash of power struggles, such as between the Hawaiian leaders and the British captains. Each action, Sahlins argued, put structures at risk. Sahlins's work, however, lacked the tragic sense of the inequality inherent in structure that later practice and agency theorists emphasized.

Anthony Giddens via Ivan Karp

Giddens, a British sociologist, wrote in the late 1970s and early 1980s three works on agency and structure that helped shape the work of later practice theorists, such as Ortner (2001, 2006) and Ivan Karp (1986). His works are: *New Rules of Sociological Method* (1976), *Central Problems in Social Theory* (1979), and "A Contemporary Critique of Historical Materialism" (1981, in *Power, Property and the State*). Giddens's achievements in his theory of structuration, while not positioned within anthropology, were nonetheless influential on anthropological theory. However, Karp has noted that anthropologists must take responsibility for relating Giddens's theories to anthropological work, since Giddens's work often "runs aground" in areas of anthropology as he has little appreciation for the fieldwork methods of anthropology. Karp's 1986 review of Giddens's work successfully accomplished this, and thus this discussion of Giddens's contribution to practice theory in anthropology will not be separated from it. Giddens's works make two major contributions to practice theory: the nature of actors and agents, and the process of structuration.

Karp (1986) described actors as individuals involved in action that is governed by rules, while describing agents as individuals engaged in actions of power, where the individual is able to "bring about effects." Giddens's agents were knowledgeable participants in structuration with goals, unlike those agents of Bourdieu (1995) and Sahlins (1981) who were generally ignorant of their position and fulfilled their cultural roles without reflection. This understanding of agents helped to overcome some of the critiques of Bourdieu and Sahlins that accused practice theory of placing too much emphasis on structure over human agency.

Giddens's (1976, 1979) theory of structuration, outlined in *New Rules of Sociological Method* and fleshed out in *Central Problems in Social Theory*, attempted to overcome the divide between structure and agency. Giddens argued that structure, rather than being separate from or in contrast to agency, is constantly created through collective agency and agency takes inspiration and resources from structure for further action. Thus, structuration is the process of agents creating structures that are then used for further agency. Because of this relationship to agency, Giddens argued that structures are virtual, existing in a constant state of becoming rather than being. In this model, power is the ability of agents to bring about change

through agency. Karp (1986) explained that Giddens's work overcame a number of "two-headed monsters" in practice theory, thereby paving the way for other theorists, such as Ortner (1995) and Sewell (1992), who were both influenced by his theories.

Recent Approaches

William Sewell

William Sewell's influential article, "A Theory of Structure: Duality, Agency, and Transformation" (1992), built upon the foundations of practice theory laid out by Giddens and Bourdieu by incorporating the critiques of earlier practice theory, as well as the larger shifts in social theory since the 1970s. He presented five axioms for the future of practice theory: (1) the multiplicity of structures, (2) the transposability of schemas, (3) the unpredictability of resource accumulation, (4) the polysemy of resources, and (5) the intersection of structures. Sewell's arguments create a picture of structure and agency existing as a dynamic dialogue situated within power structures and historical context.

The foundation of Sewell's (1992) theory of structure comes from Giddens, the forefather of practice theory. Giddens (1976, 1979, 1981) argued that structures were dual, meaning that structures both form the practices of society and are formed by those practices. Giddens also postulated that structures were made of rules and resources. Sewell, however, found that this central terminology was insufficiently defined. The term *rules*, he argued, was ambiguous and he, instead, elected for the use of the term *schemas*. Schemas are virtual, generalizable procedures, meaning that these procedures can be observed in a range of situations and contexts, and they cannot be reduced to a single practice, location, or moment. For example, schemas can be etiquette rules, social norms, metaphors, or dichotomies. As defined by Giddens, resources were split into two categories: resources of allocation and resources of authorization. Sewell adopted this portion of Giddens's theory. However, he felt that the concepts would be better understood using ordinary English: nonhuman resources and human resources. Nonhuman resources are objects of both natural origins, such as oil or diamonds, and manufactured origins, such as clothing or money. However, objects only qualify as resources when they have the potential to be used to create or maintain power. Human resources are those that come from within individuals or groups, such as physical strength, emotional connections, or knowledge. Thus, a basic understanding of Sewell's theory of structure could be described as a cycle of schemas creating resources that then reinforce schemas.

Sewell (1992) found that Bourdieu's (1995) habitus fit well with his theory of structure. However, Bourdieu's habitus failed to provide a mechanism for change within the habitus system, which requires schemas and resources

to enforce one another so strongly that structures can only be changed from external forces, such as the example of Captain Cook from Sahlins's (1981) work in Hawaii. To overcome this, Sewell argues that a more flexible and less totalized theory of structure must be created. For this, he argues five axioms for the theory of structure.

According to Sewell's (1992) theory, structures vary widely within and between institutions such as religion, kinship, or class. While some structures may be homologous, as the structures imagined by Bourdieu (1995), Sewell argues that the multiplicity of structures allows for a diversity of schemas and resources that can be accessed and used by knowledgeable actors. Agency, as defined by Sewell, is the ability to creatively apply schemas in new situations and contexts. This is made possible through understanding that schemas are transposable to an infinite number of contexts, and that other actors cannot always predict this transposability. Resources are subject to a wide array of impacts, both from the environment and from human interaction. Sewell argues that it is not possible for actors to accurately predict resource accumulation, and thus successful validation of a schema is also unpredictable. In this lies the potential for change, defined by Sewell (1992) as follows:

If the enactment of schemas creates unpredictable quantities and qualities of resources, and if the reproduction of schemas depends on their continuing validation by resources, this implies that schemas will in fact be differentially validated when they are put into action and therefore will potentially be subject to modification. (p. 18)

Since Sewell argues that agency is the ability to creatively apply schemas in new contexts and that resources are the embodiment of schemas, it is necessary to understand resources as polysemous (i.e., that they are able to carry multiple meanings). This allows actors to reinterpret and mobilize resources to enact schemas in new ways. To further add to the potential for change from within the structural system, structures overlap in social life, which creates the ability to easily transport, reinterpret, and enact resources and schema. These five axioms transform Giddens (1976, 1979, 1981) and Bourdieu's (1995) theories of structure in order to create space for internal change and a more specified view for ethnographers seeking to observe structure and agency.

Sherry Ortner

In 1984, with her article "Theory in Anthropology Since the Sixties," Sherry Ortner began 20 years of practice-theory publications. She explored the meanings of history, practice, and agency in her 1989 book *High Religion: A Cultural and Political History of Sherpa Buddhism*. She approached the problems with resistance studies in her 1995 article, "Resistance and the Problem of Ethnographic Refusal." In 1996, she presented serious games in *Making Gender*. She defended Comaroff and Comaroff's (1992) work and

explored different kinds of agency in her 2001 article, "Specifying Agency: The Comaroffs and Their Critics." Finally, in 2006, Ortner published *Anthropology and Social Theory*, which outlined and examined her previous works in practice theory, as well as aimed to summarize her arguments about practice theory, structure, agency, and serious games. "Theory in Anthropology Since the Sixties" contained first an outline of the general trends of anthropological theory during the 1960s and 1970s, and then her observations of the growing trend toward understanding social action. Practice theory, she stated, would be the key symbol in 1980s anthropology.

In *High Religion*, Ortner (1989) aimed to describe the components of practice theory: practice, agency, actors, and history. She defined practice as social interactions that involve inequality. She defined structures as being far less rigid than her predecessor, Bourdieu (1995), and instead aligned herself with Giddens's (1976, 1979, 1981) flexible, integrated idea of structure. Finally, she defined actors as individuals that partake in practice. However, Ortner also argued that past definitions of actors placed too much emphasis on intentionality and aspirations of power, including some of her prior work. Therefore, she introduced the idea that actors are influenced by structure and power relationships, but not exclusively. History, both individual and social, she argued, played a large role in the behaviors of actors. In this work, she also argued for the usefulness of both the political-economy approach, which focused on externalized forces of change, and the ethnographic-history approach, which focused on internal forces of change. However, the most lasting lesson to be taken from *High Religion* is the role of history in practice theory. As cultural transformation is a slow process, Ortner argued that history is the only location that the process can be fully observed, including the complete relationship between practice and structure.

In her article "Resistance and the Problem of the Ethnographic Refusal," Ortner (1995) tackled several issues surrounding resistance theory and its ethnographical use. She argued for a combination of the objective and subjective viewpoints for understanding individual agency, as well as the importance of understanding internal and external political influences on actors. She explains as follows:

In short, one can only appreciate the ways in which resistance can be more than opposition, can be truly creative and transformative, if one appreciates the multiplicity of projects in which social beings are always engaged, and the multiplicity of ways in which those projects feed on as well as collide with one another. (p. 191)

In *Making Gender*, Ortner (1996) fleshed out her ideas on serious games; this theory meant to use the tools learned in practice theory and yet move beyond them to include issues of power and inequality. Serious games theory looks at the ways actors reconfigure their world through their goals and projects. The term "games" was

chosen to represent the intentions, plans, and desires of actors to avoid the overemphasis of conscious intentions imbedded in “projects,” and the scripted and fictitious implications of “dramas,” “stories,” and “narratives.” Serious games, Ortner explained, were meant to embody the notions that social life is constructed with cultural rules and goals, that games are flexible and multiple, and that agency comes from actors who play the games. Ortner stressed that serious games, while at first glance appear to focus on the particular, hold the ultimate goal of understanding larger transformations and forces in social life.

In 2001, Ortner attempted to further “specify agency.” In her article of the same name, she distinguished between two types of agency: agency of power and agency of intention. Agency of power is the objective agency that allows individuals to influence their world and act on their own behalf. Agency of power, then, can be either domination or resistance. She broadly outlined resistance as everything from “outright rebellion” to the “complex and ambivalent acceptance of dominant categories and practices that are always changed at the very moment they are adopted” (p. 78). She defined agency of intentions as being centered more on the subjective individual’s projects and desires. Separating the two forms of agency allowed Ortner to demonstrate that both objective and subjective understandings of agency are relevant and present. She was quick to explain, however, that agency of power and agency of intentions are often inseparable in reality and are for heuristic purposes only.

Ortner’s most recent book, *Anthropology and Social Theory* (2006), draws together her endeavors in practice, agency, and serious games theory. The book encompasses some of her earlier work and some new work, and it also covers a wide array of topics (from the history of practice theory, to class, to subjectivity, and to media). However, the overall theme is a development of Ortner’s serious games theory and the further exploration of agency within it. In her concluding chapter, she identifies three questions for defining agency: (1) Does agency inherently involve intentions? (2) Can agency be simultaneously culturally constructed and universal? (3) What is the relationship between agency and power?

To the first question, Ortner (2006) drew on the work of Sewell (1992) and argued that his “hard” attitude toward intentions aligned well with her understanding of serious games. This hard definition of agency included the idea that agency requires a level of intentions that may not always be conscious or leading to definite goals, but are active and motivated in social interactions. She explained that intentions are the things that separate agency practices (involving desire, creativity, and will) from everyday routine practices. She argued as well that when imbuing agency with intentionality, it was also important to take heed of the warnings expressed by theorists such as Comaroff and Comaroff (1992). They expressed worry concerning the overemphasis of intentions in agency,

which they found to be ethnocentric, individualistic, and lacking in an understanding of the complex relationship between intentions and outcomes. To further soften the “hard” definition of agency, Ortner expressed that agency with intentions and routine practices existed on a continuum, rather than in bounded categories.

Ortner (2006) argued that theorists, such as Alessandro Duranti, Sewell, and Ahearn, generally accepted the universality of agency. Duranti (2004) observed that all languages represent agency in their grammatical structure. Ortner explained that while agency is universal, its frequency and intensity is also shaped through cultural constructions, history, and power.

Ortner (2006) argued that power is intrinsically linked to agency, as it explains the inequality in the system. She found that there were three levels of power in agency. First, the basic level that all agency is power. However, this level is insufficient to explain more complex agency and thus she made the distinction between “agency of power” and “agency of projects.” The former is the agency involved in the domination and resistance dialectic. The latter she illustrated as the agency of “intention and desire” that involves more personal projects and goals.

Future Directions

Agency and practice theories have come far and have overcome many hurdles that have been placed in the tracks of anthropologists. However, there are yet many unanswered questions about the nature of agency and social life. Further studies in agency must explore the influences of power on human action and the structures of society. While theorists have made significant headway on this subject, it is far from complete. Also, larger questions in anthropology—such as the effects of globalization, the nature of identity, and the usefulness of concepts such as relativism—will likely have great impact on the study of agency and practice, which lies at the heart of many of these questions. As anthropologists explore new locations of fieldwork at home and abroad, and dive into deeper understandings of their own subjectivity, ethnographic experience will bring to light new questions on the topic.

Conclusion

Agency, the term that some theorists, such as Ortner and Ahearn, have indicated as one of the most abused terms in anthropology, has a complex history and today has multiple complex definitions and further complex methodologies for finding and understanding it. The critical theories of the last few decades have punctured where the concept was the weakest with holes. These holes formed where biases of ethnocentrism lay hidden in the discourses of agency and its sometimes partner, sometimes nemesis,

structure. Structure, in its most radical forms, obliterated agency, painting human action as little more than another system of control.

Yet, through the careful and thoughtful work of agency and practice theorists, agency blossomed into functional and balanced theories. Old biases were understood, and significant progress has been made to avoid them, by defining agency in ways that avoid making agency a quality of humanness or a heroic and romanticized resistance. The newer understandings of identity and power led post-structuralists to reimagine the workings of agency as positioning in discourses. Linguists, through studies of grammar and language as social action, have found compelling evidence for the way agency is played out and represented in language. Practice theorists creatively found new understandings of how agency and structure work together to create, maintain, and transform social life. In the 21st century, new directions in the field of anthropology will continue to push agency and practice theory from these foundations and into other realms as anthropologists continue to expand the collective ethnographic knowledge associated with human action.

OPEN AND CLOSED SOCIETIES

JOACHIM KLOSE

Commissioner of the Konrad Adenauer Foundation for the Free State of Saxony

Karl Raimund Popper first suggested the distinction between open and closed societies in his social philosophical work *The Open Society and Its Enemies* (1945/1993). He aimed to formulate a plea for rationality and freedom—one against all kinds of totalitarianism. Popper wrote as follows:

Neither the war nor any other contemporary event was explicitly mentioned in this book; but it was an attempt to understand those events and their background, and some of the issues which were likely to arise after the war was won. (1945/1993, Vol. 1, p. 6)

His considerations are, to a large degree, shaped by the examination of national socialism, as well as Stalinist totalitarianism.

Above all, Popper (1945/1993) radically opposed historicism and broke with the tradition of speculative historical philosophy. *Historicism* means looking at historical events from a metaperspective: The truly important actors on the stage of history are not individuals, but rather the larger nations and their important leaders, or the big classes and big ideas. Understanding the laws of historical developments in order to predict future developments and advise policy decisions is the goal (Vol. 1, p. 31). The simplest and oldest form is theistic historicism: the teaching of the chosen people. Other forms include naturalistic, spiritual, and economic historicism. In each case, there are

specific historical laws that need to be identified and upon which predictions about the future of mankind can be based. According to Popper's convictions, progress and improvement of the living standard are not achieved by collectives, which are empowered by a higher principle, but exclusively by self-reliant and erring subjects. Popper's "critical rationalism" assumes that one may only justify those opinions and values that (at least tentatively) withstand critical examination. Rationality is fallible. Theories, or empirical-scientific systems, still need to be able to be disproven and thus should not be immune to critique; this is not possible in a "closed society," in which dogmas and traditions determine social interaction. In such systems, changes do not occur due to acceptance of critiques, but rather due to new taboos.

Popper considered Plato, Hegel, and Marx to exemplify prophets of such social orders. As an opponent, he pleaded for the model of an "open society," in which the individual finds his place in society through independent decisions. The shape of the open society results from critical discussions about the correct norms and values. "Critical rationalism" is the only reasonable way to make a gradual improvement of society possible. The plea for the "open society" thus not only results from moral decisions, but also from the way Popper sees himself, based on theoretical scientific principles. His demand that theories can be criticized and corrected implies the right to freedom of expression and the reversibility of political

decisions. Thus, “critical rationalism” can be looked upon as the epistemology of a democratic-liberal, dynamic-pluralistic social order.

By linking skepticism with the legacy of Age of Enlightenment, Popper (1945/1993) built a bridge between Anglo-Saxon empiricism and the continental philosophy of conscience. The maxim “liberty, equality, fraternity” guides him. Only liberty enables human beings to bear responsibility; hence, liberty must be defended (Vol. 1, p. 163). Equality results from critical rationalism, while fraternity, in the Christian sense, is the foundation of rationalism in the occidental civilization (Vol. 2, p. 300).

Starting Points

Augustine’s *City of God*

Augustine’s teaching of two worlds divides humanity into two camps: a large camp of sin (*civitas terrena*) and a small flock granted divine grace (*civitas dei*). Neither links to state structures or earthly commonwealths. Real societies exist in a mixed form (*corpus mixtus*), which will only be separated at the time of the Last Judgment. The *civitas terrena* as *communio malorum* is shaped by hollow peace, pride, egoism, and imperiousness. Its objective is earthly peace, whereas the *civitas dei* distinguishes itself as *communio sanctorum* through peace of heart, humbleness, doxology, piety as the highest wisdom, and coexistence. It aspires to heavenly peace. As justice and real peace are only possible in the eschatological theocracy, Augustine concludes they can be neither the basis nor the goal of a state. This can be seen in the selection of politicians; they are chosen not based on individual suitability or performance, but through opaque decisions. Mundane communities are unjust, resting upon a solely pragmatic consensus about their goals. To demand more would mean proposing unrealistic moral claims. In this sense, a state’s ability to act is limited. Its tasks are defence, the preservation of earthly peace, and the protection of the *civitas dei*.

In Augustine’s opinion, politics can improve living conditions gradually at best. Human suffering is basically insurmountable. To make the world a better place, the political order does not need to be altered; rather, the people need to be perfected. The rules for an ideal society are known from Christian Revelation. Incidentally, human beings are themselves incapable of acquiring discernment, as only divine Revelation can guide the way to verity; hence, the political process as a means to find consensus and solutions is redundant.

John Locke’s Two Treatises of Government

Locke (1689/1992), a representative of British empiricism, held the view that all knowledge and ideas are rooted in sensory perception. For Locke, there are only two sources

of experience: (1) sensation, referring to outer, material things; and (2) reflection, arising from internal operations of the mind. The conception of rationality takes a dominant position in Locke’s work; however, as it is limited, rationality is supplemented by faith (“natural religion”).

The starting point for the theory of the state is natural rights, which safeguard life and freedom. The natural state guarantees absolute freedom out of natural principles—self-determination and self-sustainment—as well as the state of equality. The social contract leading to the foundation of a state is a collective decision by a group of individuals to cede their rights to protect their immaterial (life, liberty) and material possessions (property) more effectively against both internal and external attacks. Signing the contract is voluntary and leads to the following outcomes: the election of the ruler, decision making according to the majority principle, the creation of legislative and executive institutions, and the right to resistance and tolerance.

Locke’s (1689/1992) revolutionary idea is that of ensuring the freedom of individuals, who seem to surrender their freedom, but in fact have contractually institutionalized it. What has thus far only been inscribed in the “heart” and “soul” of the people is now a contract. Freedom becomes the decisive criteria of the state’s actions and possesses a normative character for the individuals. Each individual possesses the right to resist, and the power transferred to the ruler by society may be confiscated if the ruler abuses his authority. Despite the honest transfer of power, Locke remains fundamentally skeptical toward the rulers: Security of the individual through the state must be met with security of the individual against the state. Therefore, the state is not given the right to meddle in its citizens’ spiritual affairs.

John Stuart Mill

For Mill (1859/1991a), freedom is the strongest desire of human nature. Plurality facilitates both moral freedom and rationality, and promotes creativity. Freedom is a fundamental precondition for social and intellectual progress. Any intervention intended to force individuals into certain behaviors is illegitimate and must be avoided. Any government should only be judged by how their individuals can practice and develop their skills.

The democratic society is a community whose individuals can freely deploy and apply their skills. Democracy is, above all, justified by the possibility for self-development and individuality. It safeguards individual perfection and is founded upon the principle to limit the freedom of the individual only for the purpose of self-protection or the protection of other members. When democracy is jeopardized due to the suppression of individual differences, minority opinions, and minority cultures, it needs institutions that build strong, resilient characters. An outstanding role is therefore given to education policy, since it provides the preconditions

for elites and education, as well as the basis for the acquisition of personal freedom.

Intellectual elites are needed to counter the “tyranny of the majority” and “collective mediocrity.” The representative democracy possesses a class-based suffrage supported by the acquired education. For Mill, only educated personalities are eligible and would wield multiple votes. Democracy lives off the assumption that all citizens are interested in political participation and the shaping of society. Thus, society does not have the right to oppress the individual’s opinion. If an opinion is correct, then discussions enable the accepting of these positions as “secured” truths. If wrong, then one can gain a better and deeper understanding of the truth through falsifiability. As a result of the free competition among ideas, incorrect ideas are eliminated and errors corrected. There are no fixed truths, but in a forum of competing opinions, “No light that could be thrown on the matter from any side is shut out” (Mill, 1867/1991b). Ideas and actions must face critical assessment in the marketplace of ideas. Still, they only have temporary validity, as the debate is unfinished. Thus, individuality is not only a precondition for personal happiness, but also for others’ happiness. Sameness and uniformity threaten with decline or stagnation, thus impeding both scientific and social capacity for innovation.

While Mill is a utilitarian and aims at the maximization of happiness, Popper’s objective is the minimization of suffering.

Society and Community

The terms *open system* and *open society* were first used by Helmuth Plessner (1924/2001) and Henri Bergson (1932), respectively. Bergson distinguishes, in his philosophy of the organic life (*The Two Sources of Morality and Religion*, 1932) between closed and open societies. The “social instinct” is always targeted at the former for the purpose of the traditional community, but mankind must soar to the level of an open society (global society) in order to continue the creative *élan vital*. Plessner approaches the differentiation between open and closed society anthropologically, placing it in an area of tension between society and community. Hence, he borrows F. Tönnies’s (1991) conception and W. Wundt’s (2007) psychology of people, which differentiates between state and tribe. Three considerations about the open society precede Plessner’s reflections: (1) an ethnic-historical one, which traces back to Wundt’s differentiation between state and tribe; (2) a sociological one, which Tönnies has shaped with the terms *society* and *community*; and (3) an ethical one, which results from the demand to abandon the closed society in favor of an open one. Plessner distinguishes the closed society between a community of familiarity and a community of rationality, nationalism, and communism, respectively. He states, “Today the dictatorship is marching, either Bolshevik or fascist” (p. 43). Its power is legitimized

by the *ethos* of the community. In his book *The Limits of Community* (1924/2001), he socioethically examined the individual positions he himself faced by the constraints of the community, that is, the attachment by blood (tribe) or matter (things of the world), and the freedom of the community (i.e., the mode of social affairs). Plessner (1924/2001) explained further:

This open system of intercourse is segregated into individual, peculiar spheres, depending on the requirements of specific value classes, for law, the customs and education, the state, the economy, and the “intercourse” in a more narrow sense. (p. 93)

Existentially, human beings are placed in an area of tension between society and community. Due to their eccentric position, they have to balance the roles (function) they take in society—their “masks,” their intrinsic existence, and their position in the community. This balance is equally a game between “diplomacy” and “tact,” and it is shaped by “prestige” and “ceremony.” Plessner (1924/2001) elaborated as follows:

All public positions rest on the principle of mutuality. Everyone gives one another as much scope as he would claim for himself; only out of the conflict of individual measures can the enlargement of one scope result—at the expense of another one. In every instant, the opponents are in control of themselves due to this just mode of playing, until the logic of these matters has decided. The harshness of the principles of life is thereby not alleviated, only the danger of a violent outburst at the expense of human dignity is eliminated. (p. 101)

Plessner’s theory of masks as a social theory of “limits” is also found in Niklas Luhmann’s (2002) theory of social systems.

Community and Nation

The concept of community arose in the second half of the 20th century from the critique of modern civil society. Until the 18th century, the term *community* was a synonym for *society*. Only as a result of the clash between the economically founded civil society and authentic, inner social stratification did the term gain lasting coinage and become a politically charged term for utopian solidarity and conservative, revolutionary ideals. In the romantic perception of a political system, the term assumed an emotional meaning, contrasting with a contractually and individually founded society. Tönnies (1991) distinguished community as an internally connected organism from society, based on exchange and contract. The historical process of modernity is the transition from community to society, from collective to individuality. The opposing movement is shaped by collectivization (Max Weber), in which action is based on subjectively felt togetherness. The concept of community culminates in the national

community, marked by an anti-individualistic, normative-political holism. The term community becomes a rallying cry in the sense of an action group against the civil order in Germany in the 1920s. It was later borrowed ideologically by the national socialists (1933–1945), as well as by the socialists (1945–1989). All socialist utopias aim for the abolition of the civil-capitalist society.

The principle of nation-states is developed parallel to the concept of community. The stages of development include Wilson's principle of national self-determination, the resistance to Napoleon's invasion, Rousseau's concept of the general will, Herder's vision of a natural national border, Fichte's "identity through language," and Hegel's belief in authority. Hegel's philosophy and Ernst Haeckel's Darwinism are the foundation of Friedrich Nietzsche's teaching of the *Übermensch* (overbeing), which directly led to the national socialist racial doctrine. As Popper (1945/1993) explained,

The biological superiority of the blood of the chosen race explains the course of history, past, present and future; it is nothing but the struggle of races for mastery. In the case of Marx's philosophy of history, the law is economic; all history has to be interpreted as a struggle of classes for economic supremacy. (Vol. 1, pp. 9–10)

From this, Plessner (1924/1991) further added,

As Nietzsche was a conscious opponent of society because of aristocratism, so does Marx appear hostile toward society due to the mobilization of the instinct of the masses. The individualist resolves society in favour of the big individual, whereas the socialist resolves it in favour of the community. (p. 34)

For Popper (1945/1993), the source and trigger of modern historicisms is above all the German idealism, particularly the historical philosophy of Hegel; the Marxist extreme left wing, as well as both the conservative center and the fascist right, founded their political philosophies upon it (Vol. 2, p. 39). Hegel is equally a link between Plato and modern forms of totalitarian ideas. Still, Popper interprets Plato one-sidedly, as he reads him only in a personal, rather than an institutional, context. Especially in the *Politikos*, the dialogue that serves as the link between *Politei* and *Nomoi*, Plato makes relative his one-sided, person-oriented view: *Politei* describes the theoretically perfect state, whereas his later works deal with the best practical approach to the ideal state. Essential are the institutionalization of the issuance of laws, the participation of various groups, and the abidance of the laws by everyone. Nevertheless, the rule of law is not sufficient to prevent the abuse of power. Therefore, Plato resorts to an older device—the mixed constitution. It combines—institutionally—monocratic, oligocratic, and democratic elements into the polity's political foundation. To prevent the abuse of power and protect the freedom of the citizens, various societal forces are engaged. In *Nomoi*, Plato fundamentally readjusts his

thinking toward an institution-oriented political theory, which has not been considered by Popper.

For Plato, the Spartans developed the best domestic solution to the problem of power abuse with their mixed institutions. Hence, Plato sees the political system of Sparta as an example for all other states. Plato compares the "real constitution" of Sparta with Persia and Athens: The unmixed Persian monarchy imposed too heavy limits on the freedom of the people, while the unmixed Athenian democracy left its citizens too much freedom. For Plato, the right mixture between democracy and monarchy is crucial.

Athens or Sparta

Sparta was considered to be the second most powerful polity—behind Athens—of the Greek states. The cities embodied two different social systems and constitutional models: military state and democracy. Sparta's political stability and military clout were idealized by contemporaries and attributed to the public education system. Xenophon praised its military virtue at the beginning of the 4th century, and Plato believed the Spartan education and discipline enabled humans to lead better lives. Eventually, in the 4th century, Aristotle elevated Sparta to the model of a "mixed constitution"—possessing monarchic, as well as aristocratic and democratic, elements (kings, *gerousia*, people's assembly). In this form, it later became exemplary for the Romans. Even today, Sparta is considered the epitome of a statutorily, strictly regulated, and exclusively military-oriented state. The "equality" of the Spartan citizens, expressed by the term *hómoioi* (equal), has fascinated thinkers in both antiquity and modernity.

The notion of a strict regulation of all areas of life and its focus on the state has been expressed by the 20th-century name "Spartan commonwealth." This includes the commitment to common values and the state-sponsored education of young men to obedience and conscientiousness. Hence, Sparta epitomizes a myth that should be constantly questioned. How does Popper characterize Sparta and Athens? Which characteristics do the closed and the open society have?

Social Life

Citizens of an open society have a critical attitude toward their social customs. The norms determining everyday life and its institutions are accepted as the work of man (self-determined, worldly, man-made), whereas the closed society is attributed a different genesis. Its norms and institutions are perceived as given by nature (heteronomous, extramundane, God-given). While they can be criticized and changed in an open society, in a closed society, they are static and preserved emphatically. This leads to powerlessness and determinism. Constructive and creative dealings with norms and values do not occur; rather, the system

of values upon which all actions are based is consciously or unconsciously taken over by an authoritative source. The norm-giving entity possesses the monopoly of sense. While the notion of what is desirable is determined by the value of humanity (liberty, equality, fraternity) in an open society, the “highest good” is dictated by a higher entity in a closed society.

Autonomy of Action and Social Differentiation

The character of social customs and the attitude toward societal institutions have consequences on human actions. While absolute autonomy of action prevails in the open society, it is limited in the closed one, as there are no alternatives to the existing rules of (social) life. The only freedom of the individual is to harmonize one’s actions with the effective rules or to fail. In an open society, the individual is free to act in accordance with the predominant rules or not. Thus, one can gain experience and learn from mistakes. This offers great personal scope and leads to individual independence. Nevertheless, individuals are also held responsible for the consequences of their actions and have to be able to defend ethically relevant decisions by using critical arguments. This is not demanded from an individual in a closed society, as long as one complies with the rules.

Popper (1945/1993) marked the closed society as a “semi-organic unit,” upon which the organic or the biological theory of the state can be applied (Vol. 1, p. 173). Its members regard their allocated social position as sacrosanct. Hence, the closed society allows social development to take place only incrementally, guaranteeing stability and order. In the open society, individuals are not bonded by biological-organic relationships. Competition for social positions is one of its most important features; its low social differentiation allows its members high mobility through competition. The structures of differentiation are unstable and versatile. Thus, the open society has an active social dynamic.

Position of the Individual

In the open society, the individual is, while emphasizing independence and freedom, the origin of thoughts and actions and, thus, the origins of the society’s development. The distinction “private-public” guarantees the liberty of personality development and self-fulfilment. In the closed society, the collective has priority over the individual. The individual defines himself exclusively through the collective and realizes his potential as part of the whole by functional association and subordination to the collective. The individual is primarily understood in a social status, rather than as a personal identity.

Tasks of the Commonwealth

No ideal of the state exists in the open society. The social engineering of individual planning rejects the goal

of maximizing happiness and, instead, attempts to resolve the most urgent evils through gradual improvements. In contrast, the notion of an ideal state exists in the closed society. “Common good” means “happiness for all.” It dominates the collective aim in life, and a central-planning mechanism promises collective happiness. As everything that is foreign is perceived as destabilizing, one must be isolated from all foreign influences.

While it is the task of the state to protect the freedom of its citizens and to guarantee their best possible development in the open society, it is the task of the individual to maintain and bolster the stability of the state. The closed society is characterized by appropriation, subordination, coercion, and dictatorship; the open society is characterized by emancipation, maturity, independence, and equality. The consensus in the closed society is forced; a harmony of interests and determinism prevail. The open society is marked by a plurality of interests, voluntariness, and progress.

According to its different concepts, open and closed societies differ particularly in their methods of exercising power. While Plato asked in *Politeia*, “Who should govern?” and replied with his principle of “the rule of the wise men,” Popper (1924/1993) posed the question, “How can political power be controlled?” His response is the principle of democracy. The exercise of power is thus bound to policy and prejudice. Democracy controls the abuse of power institutionally, removes personal monopolies, and facilitates the peaceful dismissal of a government. Governance in a closed society is personal. The elite possess the monopoly of power; the leader, autocracy, and dictatorship are in command.

The principle of critical rationalism shapes the open society. The objective is to approach truth. Existing knowledge must be malleable, and critique is institutionalized, facilitating creative progress, tolerance, and openness. In the closed society, the scientific task of the commonwealth is to pass on reliable knowledge. Its objective is security, certainty, and conveying a binding worldview. In contrast to the open society, knowledge is protected against falsifiability. Hence, a monopoly on knowledge and interpretation prevails, and contradictions are avoided. As a result, dogmatism, ideology, and fixedness shape the closed society.

Summary

To which degree do human beings enjoy freedom in these two societies? In the open society, voluntariness shapes their situation. Various alternatives are at their disposal, and social reality is experienced as a reflection of the human will (convention). In the closed society, their lives are completely determined. They have no alternatives for development. Social reality is shaped by the reflection of practical constraints or “higher” powers (historicism).

In the open society, the individual is at the fore. One possesses a high degree of personal freedom and equal

opportunities. Individual development is shaped by high social mobility and plurality. In the closed society, full attention is paid to the collective. The individual is “unfree”; equality of opportunities does not exist, and social immobility, enforced conformity, and uniformity dominate.

Scientific findings have a tentative character in the open society. They should be falsifiable. Errors are part of the system, and open critique is demanded. Critical rationalism promotes tolerance, openness, and a dynamic development. In the closed society, scientific findings are infallible. Dogmatics, fixedness, and ideology prevail.

The structure of the open society is characterized by (1) the nonviolent dismissal of a government, (2) the freedom of thought and communication, (3) the autonomy and responsibility of the individual, (4) the transfer of rationalism to the society, and (5) the rejection of historicism. The closed society is shaped by determinism, collectivism, and definitiveness.

If open societies do tend to revert time and again to communities, then whether general criteria exist as indicators of transitions from open to closed societies should be examined. What differentiates the closed society from classical theories of totalitarianism? Moreover, attention must be given to anthropological aspects to explicate what impedes the transition from the closed to the open society.

Totalitarianism

When comparing the mentioned structural characteristics of modern closed societies (socialism, national socialism) to classical theories of totalitarianism, it is striking to see that Popper (1945/1993) did not mention any instruments of repression. Eric Voegelin (1993), who interpreted fascism and communism from a socioreligious framework, also argued only according to the principle of the history of ideas: Voegelin understands fascism and communism as political “religions” vying to create the ideal society in the material world. He opines that the belief in immanent promises has been catalyzed by secularization as promoted by enlightenment. For Popper, religion does not define a society—religiously justified social orders more frequently characterize closed societies—and enlightenment has not paved the way for totalitarian tendencies, but has opposed them. Hannah Arendt (1955) interpreted totalitarianism as something historically new that could only evolve against the backdrop of the societal upheavals of the 20th century (the decline of nation-states and rise of mass societies). She finds the correlation between ideology and terror particularly remarkable.

For Arendt, ideology includes the citation of “historical laws” in Stalinism, and the “laws of nature” in national socialism. She associates the actions of the secret police and the erection of the camps with terror. Popper is silent on the repressive implementation of totalitarian ideology. Yet, he and Arendt share common ground on totalitarian

ideology, particularly regarding the theory of history. However, Popper did not consider the mentioned societal model only as a phenomenon of the 20th century. Carl J. Friedrich’s (1957) concept of ruling power and structure is regarded as the most well-known classical societal model. Totalitarianism means an ideology, a party, a terrorist secret police, a monopoly on information, a monopoly on arms, and a centrally managed economy. As Friedrich is strongly oriented toward the instruments of totalitarian rule, there is little common ground with Popper’s understanding, which is more focused on totalitarian thinking. After all, the historian Ernst Nolte (1987) described bolshevism and national socialism as two structurally similar systems of government. Bolshevism not only preceded national socialism chronologically, but also caused its creation as a defense mechanism. Nolte does not reflect on the ideological roots of totalitarianism; as a result, there is also little common ground with Popper’s approach.

Compared with 20th-century-style totalitarianism, Popper (1945/1993) saw a totalitarian social order in Sparta’s social system. His bisection is perhaps too harsh as he contrasts the closed, totalitarian society with an open, democratic society. He does not sufficiently consider the structural peculiarities of totalitarianism as they reside in the scale of the rule, the systematic use of terror, the deliberate manipulation of the masses, and the pseudodemocratic mobilization of the masses. But Popper is most interested in the evolution of the closed society, in terms of the history of ideas, more than in the description of the instruments of power.

The transition from the closed to the open society is even today unfinished. Open societies must be vigilantly defended as they are permanently in danger of devolving. The political and spiritual profiteers of a hierarchic and homogenous social order are not the only supporters of the closed society. A dynamic and pluralist social order poses a challenge to the majority of the nongoverning population as well, a challenge that must be coped with incessantly. While it is difficult to build open societies, it is relatively simple to destroy them. Whether looking at Mussolini’s Italy in the 1920s, Stalin’s Russia and Hitler’s Germany in the 1930s, the German Democratic Republic (GDR) in the 1950s, Czechoslovakia in the 1960s, Chile in 1973, or Latin American dictatorships and communist China in the late 1980s and early 1990s, ignoring all regional and political differences, a list of 10 coinciding aspects for the toppling of a liberal democracy or the flattening of democratic tendencies emerges. Their product is a totalitarian “fascist” system. The *Colombia Encyclopedia* defines fascism as follows:

[a] philosophy of government that glorifies the state and nation and assigns to the state control over every aspect of national life. . . . Its essentially vague and emotional nature facilitates the development of unique national varieties, whose leaders often deny indignantly that they are fascists at all. (as cited by Wolf, 2007, p. 21)

Two criteria unite various definitions of fascism: It refers to a military system that is opposed to democracy and attempts to destroy it ideologically and practically; and, fascism deploys terror against citizens to achieve this goal. Therefore, fascism implies a violent dictatorship instead of a liberal-democratic development of a society. Wolf (2007) explained as follows:

All dictators: invoke an external threat; develop a paramilitary force; create a secret prison system; surveil ordinary citizens; arbitrarily detain and release them; harass citizens' groups; target writers, entertainers, and other key individuals for dissenting; intimidate the press; recast dissent as "treason" and criticism as "espionage"; and eventually subvert the rule of law. (p. 21)

Transition From a Closed to an Open Society

What is the allure of totalitarian ideologies and social systems? Why is the transition from a closed to an open society so painful? The transition itself triggers irritation and disorientation. Popper (1945/1993) explained as follows:

The strain of civilization was beginning to be felt. This strain, this uneasiness, is a consequence of the breakdown of the closed society. . . . It is the strain created by the effort which life in an open and partially abstract society continually demands from us—by the endeavour to be rational, to forgo at least some of our emotional social needs, to look after ourselves, and to accept responsibilities. We must . . . bear this strain as the price to be paid for every increase in knowledge, in reasonableness, in co-operation and in mutual help, and consequently in our chances of survival, and in the size of the population. It is the price we have to pay for being human. (Vol. 1, p. 176)

Popper further described the longing for a guarded and well-regulated life, without facing the challenges of a complex world and the burden of independent actions, as follows:

This dream of unity and beauty and perfection, this aestheticism and holism and collectivism, is the product as well as the symptom of the lost group spirit of tribalism. It is the expression of, and an ardent appeal to, the sentiments of those who suffer from the strain of civilization. (Vol. 1, p. 199)

All aspects described by Popper can be observed among the East German population in the transitional process from dictatorship to open society after 1989. East Germany has been shaped by a long experience with dictatorships. It experienced both German dictatorships (1933–1945 national socialism, 1945–1989 socialism) and had to walk the difficult road to freedom after the peaceful revolution of 1989. In this process, it was an advantage that

the GDR was integrated into West Germany, as it was an economically powerful and successful democracy. What were the challenges and how were they met?

The Totality of the Totalitarian State

How dependent was the individual on the totalitarian state? Did all citizens support the dictatorship? How was the dictatorship enforced? The former GDR had 16 million inhabitants, of which 1.5 million were members of the ruling party, the socialist unity party. About 20% of the population, equivalent to 3 million citizens, actively supported the system and enjoyed more benefits compared to the general population. The overwhelming majority had a passive attitude toward the system; they looked for a niche and lived in a parallel world. How did one behave toward the political organizations and how could one escape the ideology? If one didn't want to risk life and physical health or accept grave disadvantages, one had to compromise. The question posed after the collapse of the system was not if one had made compromises, but rather what the line of compromises looked like, and whether someone had agreed to minimal compromises, or even resisted or rushed ahead, in obedience and support for the system.

The system confronted every individual over and over with decision-making situations, which must be regarded as "ideological examinations." In the case of a positive response, career advancement was guaranteed; if one diverged from the rulers' expectations, then one was set back, criticized, summoned to educational talks, observed, or eliminated. The "ideological barriers" started rather harmlessly with the membership in a youth organization, but they were marked by significant consequences, if military service, party membership, or collaboration with the secret police were concerned. Often the decision was due to the advantages, such as university admission or job selection. It was suggested to individuals that the system's generosity depended on his behavior, for the system as a whole could never be questioned.

Fear of the secret police only played a secondary role in the population's consciousness of everyday life. Further, it only affected those not responding positively to the "ideological barriers" for conscientious reasons, such as conscientious objectors or the political opposition, who in turn became a burden for the secret police. The state party—with its indoctrination, ideology, and militant atheism—was omnipresent and, thus, difficult to resist.

What effect did the accommodating political behaviour have on the organization of democracy after the peaceful revolution of 1989? The schizophrenic education in GDR times (private world of experience vs. political compliance) has resulted in many citizens' lacking of identification with the political system. There are no political milieus, and there is a large distance between political player and low political commitment. Less than

0.5% of the total population of Saxony are members of a political party.

Creativity of Deprivation

It is striking that characteristics of the negative system are perceived retrospectively as positive. Alongside the initially unequal economic situations after World War II, the GDR economy was not set up as a free-market economy, but rather as a planned economy following the Soviet model. This led to shortages right from the beginning, for which it became increasingly difficult to compensate in the time leading up to the economic collapse.

Deprivation led to a constant preoccupation with the provision of material necessities. Experience from economic crises shows that in crisis situations, people continue to live in residences and to eat. The question is: Under which circumstances? In the event of a permanent economic crisis, a shadow economy begins to emerge, shaped by a particular creativity and ingenuity to manage crises and alleviate deprivation. On the other hand, people lived systematically at the expense of the environment and ultimately of the economy itself; thus, the quality of living conditions was reduced to a critical level. In addition, due to the constant preoccupation with the material basis, a deep-rooted and distinctive materialism came into existence. In this regard, open and closed societies mimic each other.

Deprivation possesses the potential to produce motivation and creativity and leads to an intense exchange, and vivid communication; its loss is perceived as a deficit of the open society. Since books were not openly available due to small printings and censorship, they were even more intensively read, exchanged, and discussed. Some books were only available once; that opportunity had to be seized. Thus, reading occurred more systematically and intensively than in an open society. The ban on Western rock music had similar effects. Records were a communication medium. The lack of telephones led to more intense and unannounced visits. Hence, spaces of exchange and friendship were created and their loss after the peaceful revolution was experienced painfully.

Situations of deprivation are meaningful, for they motivate actions that are perceived as useful. Then again, a certain pressure to act is required in order to become creative. Although deprivation causes creativity, how much deprivation is necessary to be creative? What is it that prevents the individual from continuing the positive experiences of the dictatorship in an open society?

The Abundance of Time

The individual experience of time differs significantly between dictatorships and open societies. On the one hand, career opportunities are limited due to the power structure. Therefore, there is seemingly no professional

telos to which one could aspire. The futurity of personal developments collapses back upon a long-lasting uniformity, making the future predictable and hinting at a relative security and stability. As career advancement largely depended on destiny and creative self-fulfilment was only possible to an extent, the heteronomously imposed work time was not considered time spent “living” but as a period of service and, thus, reduced to a minimum. Hence, life was structured by clearly defined rhythms, and a maximum of freely configurable time was available. But this free time was needed to compensate for the scarcity in society. The individual was constantly “organizing.” This led to a paradox known from the psychology of time perception: Unfilled time shaped by boredom is perceived at the time as “stretched” but, in retrospect, as having passed quickly. In contrast, the filled time of the present is experienced as very short but, retrospectively, as long lasting. It is similar when one acts over a period of time: The individual was in a permanent mood of disquietude, seeking to compensate shortages. In retrospect, the elapsed time of restlessness is perceived as filled, in contrast to the open society, where this coming to terms with the present is not needed. Self-motivation for creativity and personal responsibility is required.

Another aspect of time perception deals with the loss of the past and, thus, historic roots. Due to the ideological transfer of knowledge fixed in the history of the working-class movement, the wider historical context had been concealed from GDR citizens. The loss of the historical consciousness caused a detachment from the flow of time; the individual did not regard himself within the tradition or responsibility of the past. As its dangers are unknown, a responsible concept for the future is difficult.

Loss of Power and Empowerment

Societies are shaped by power structures. “Whenever people communicate with one another, the possibility exists that they orient themselves on mutual disadvantages and are thus affected. Power is a cultural universal of human existence” (Luhmann, 2003, p. 90). Thereby, it is not only a matter of the political-representative power of the system, but also of the power to interpret reality (endowment with meaning, ideology), the education system, and the distribution of resources. Their function provides means to sanction and threaten, which can be used as the foundation of power. The transitional process from a closed to an open society is accompanied by a reorganization of power in the entire society. Hence, the transformational process meant a loss of power for the majority of the East German population. This concerns not only the societal elites, exchanged in the wake of the transformation, but also the common man. In an economy of scarcity, those who own the goods or those who participate in the distribution of goods ultimately possess power. A saleswoman possessed the power to distribute, just as the possession of

a car produced jealousy. The loss of power, as a result of the transformational process, led to a narcissistic mortification causing the transfiguration of the past, which cannot be compensated by any following social system.

Furthermore, some social areas lost their influence. The churches, shelter of the opposition and structural counterweight to the dictatorship's monopoly on teleology, must now hold their own in the market of opportunities.

All power transfers are accompanied by injustices and power struggles. Only from the perspective of the loss of power can one explain why—despite material prosperity—a large part of the East German population is unsatisfied with the open society. This applies to the older generations to a greater degree than to the younger ones. The actual power of organizations substantially depends on the influence on careers and the filling of jobs (Luhmann, 2003, p. 104) Due to the change of elites, the typically more strenuous evaluation of East German biographies, and the social attachment of the new elites to their areas of origin, the East German population has been excluded from political and social responsibility over a longer period of time. This still has an impact, even 20 years after the peaceful revolution.

It is remarkable that due to the minimal willingness to compromise by many GDR citizens, who (accordingly) kept their distance from the state, filling the power vacuum seemed impossible after the peaceful revolution, although these citizens would have been capable of filling it. "Power" in the dictatorship was not understood as responsibility but almost exclusively for its abuse. Thus, there was also a responsibility that consequently abstained from power. This had the unsatisfying consequence that those who exerted power in the dictatorship were again pushing pack into social positions after 1989. This fact is one of the reasons for the GDR opposition's reluctance to get involved in party politics. Even mere membership in a political party in a dictatorship brings one close to the political power and is suspicious. This aspect is amplified when one becomes aware that membership in the state party constituted a commitment to atheism and demanded secession from the church. Former GDR citizens do not primarily interpret parties as lobby groups, but rather as groups of identity and power. The GDR citizens' distance from power is frequently misinterpreted as an inadequate adaptability and a lack of support for democracy.

Loss of Sense and Utopia

One of the seductive powers of socialism was its pseudoreligious system to explain the world. Its is based on the assumption that human beings are themselves capable of creating a society in which they can lead a "good life." But the political utopias refer to a rationality dictated to every individual *a priori*. They are fictions of intramundane societies condensed to ideals or deterrents. Above all,

they criticize the existing institutions and political conditions by contrasting them with a rational and comprehensible alternative. Their profane epiphanies consist primarily of concealed religious longing:

They transferred everything, what until then had been embodied by "God" and the "afterlife," into this world and substituted it with words like "reason," "history," "society" or "providence," but naturally not without equipping them with a spiritual—or, rather, metapolitical—content. (Fest, 1993, p. 52)

The two German dictatorships caused the churches to be greatly repressed in East Germany. While about 95% of the population had been members of a church in 1944, membership declined to only 29% by 1989; 80% of the population of East Germany's cities confesses to atheism. This decline of religion is a globally unique phenomenon that only affects East Germany and the Czech Republic.

How does a postreligious society deal with its religiosity? If humans are able to abstract and if causal and transcendental experiences are part of being a human being, then one must ask what they believe in when they don't believe anymore. As socialists and national socialists apostrophized a "new" man, their collapse meant the triumph of anthropology over the historical philosophy of men, as they have always been and will be above all ideals. But at the same time, it becomes apparent that the need of faith or promises to ease the inconsistencies of life is part of the *condition humaine*. With the collapse of the political system, the utopia breaks down as well. The promise of redemption, to which socialism stuck until the end, caused the collapse of their vision of the future to be perceived as a metaphysical loss. What is the substitute that will take its place? Interest in the churches has not gone up, contrary to hopes.

Comparisons of the populations of East and West Germany have shown that the majority of West Germans defend freedom instead of equality, while the ratio is reversed in the East. The utopia of a just society, in which everyone is equal, is followed by the demand for real equality at the expense of freedom. Equality destroys variety and, hence, beauty. This aspect is one of the most fatal consequences of the East German uniformity: The society suffered under "good taste" and beauty in a striking manner. If beauty has not always had a purpose, but rather suggested a dimension that exceeds the mere existence of reality, one encounters the religious dimension. Maybe it is the loss of beauty in the East German society that is the cause of its radical rejection of religiosity. The theologian Hans Urs von Balthasar professed that beauty is a disinterested entity that, once lost, gives the impression of never having existed in the first place. The loss of the socialist utopia has led to a loss of meaning, and the residuum of the demands for equality to suffering under the injustices of the world and material envy. The consequences can hardly be compensated for an open society.

Limits of an Open Society

It was Popper's (1945/1993) desire to show why a functioning democracy is a desirable state, as well as what the open society is not. Thus, he provided a guiding principle that needs to be amended. He has, for instance, not shown what the functionality of a democracy depends on. Otherwise, one might be left with the impression that once democratic institutions are set up, little can go wrong.

According to Luhmann (2002, 2003), the present society is composed of various systemic and communicational cycles, and these function according to their own logic, develop their own language, and are shaped by a specific rationality. Social subsystems include the legal, educational, scientific, and religious systems. Remarkably, there is no connecting, inclusive band around all systems, apart from a generalized communication. In this functionally diversified society, all problems of the open society become apparent.

On the one hand, the open society is marked by disenchantment with politics and a lack of participation. The subsystems tend to become independent and to estrange themselves from the everyday life of the citizens due to their specific rationality. Politics can only set up a framework for the subsystems—not the systems themselves. Hence, politics only possess limited influence on the development of society, although suggesting rational predictability and controllability.

On the other hand, there is no rationality that would be suited as a binding corrective. In Popper's (1945/1993) work, reason and rationality only appear singularly, but they have multiplied in the functional, diversified society. From the perspective of which rationality should criticism be passed? What might be politically reasonable could be economically questionable. Different rationalities criticize one another, for they are based on different premises. There is no binding or absolute rationality, as democracy has just denounced the idea of the absolute.

Moreover, there is no central ombudsman for complaints and criticism. Not only individuals, but also the subsystems are gaining freedom and autonomy in the open society. Yet, while people can be held to account, they cannot be directly addressed in the case of the subsystems.

In addition, the process of the open society does not answer all questions and does not describe the end of history. New anxieties and challenges will always emerge. Something that adds sense to these options—deep structures—is missing. Open societies tend to resolve this gap, which may result in national socialism or religious fundamentalism as apparent ways to give life meaning. Since it is impossible for open societies to revert due to the gained knowledge, they are at risk of veering toward national socialism. Furthermore, open societies depend on the support for their institutions and the belief in their values, as they convey neither a unifying force nor any sense of identification.

Conclusion

An open society requires consistent activity and creativity on the part of its citizens, and the desire to conquer and fill in areas of freedom. But there are also times when people feel comfortable, when they do not try out new ideas, or cannot carry them to their extreme. Instead, they accept and try to adapt. This apparently leads to a retreat to the private domain or the preoccupation with the closer living environment, respectively. The trust in democracy and freedom does not seem to suffice as a motivation to engage oneself in public affairs. The open society had no other perspective than the preservation of its openness. The loss of a motivating vision for the future leads to erosion. Ernst-Wolfgang Böckenförde professes that the open society is living on preconditions that it cannot create itself. It is the great—and probably inherent—flaw of open societies: They do not convey a palpable meaning of life that justifies the suffering and fears of the people. Liberal structures, division of powers, and a market economy, as well as laws safeguarding freedom, are the only mechanisms on which the open society is founded. They are the instruments that guarantee an orderly social coexistence, but not the matter itself.

Democratic institutions are means to facilitate freedom. They must be joined by a codex of predefined convictions, a consciousness about forms and institutions, reason and foresight, reliability, courage, tolerance, and adherence to the law. The conveyance of this codex is one of society's tasks. The individual's task remains to practice the perception of reality without simply accepting it, acting responsibly, and sharpening one's sense for permanent dangers.

CULTURE AND PERSONALITY

GERALD SULLIVAN

Collin College

Perhaps, as George Stocking (1986) has contended, *culture and personality* was but a temporally delimited version of psychological anthropology, with psychological anthropology being the most “historied” of anthropological endeavors. If so, then the appropriate questions one might ask in the current era would concern the legacy of culture and personality or, perhaps less charitably, its relevance. But culture and personality is also perhaps, at least within the discipline, American anthropology’s most mythologized undertaking. If this is so, then culture and personality is likely also central to more argument within American anthropology about anthropology—its purposes, failures, limits, internal disciplinary relations, and so forth—than other anthropological undertakings.

In part, such centrality arises out of the confusing breadth of culture and personality. The major figures discussed in this chapter—Edward Sapir, Ruth Benedict, Margaret Mead, Gregory Bateson, and, but only in passing, A. Irving Hallowell—brought to their work interests in language, culture, personality, and biology. Their work concerned itself with the psychological reality of symbols, hence with living with and within myth.

Sapir (1917, 1949, 1994) played a crucial role in calling anthropology’s attention to the centrality of people in social relations. But individual people living real lives in psychologically real worlds are curiously absent from his work. It follows that so, too, are those symbols or myths that people make psychologically real, both individually

and collectively. Many of his most important essays—“Culture: Genuine and Spurious,” “The Emergence of the Concept of Personality in a Study of Cultures,” “The Psychological Reality of Phonemes, Why Cultural Anthropology Needs the Psychiatrist”—were gathered together and republished posthumously (Sapir, 1949).

Benedict (1922, 1934, 1946), in particular, suggested a notion of cultural selection, inverting thereby earlier ideas of diffusion and culture circles. She and Mead (1928, 1930, 1935) remain widely associated with the idea of pattern or configuration. From the notion of configuration, they derived similar but differing visions of how individuals might be at odds with the pattern of an anticipated or well-formed life locally understood; this they called *deviance*. From this notion of pattern, they also derived ideas about damaged or incoherent societies. Furthermore, Benedict developed a theory on the relativity of significance within and between patterns, which was not a theory of moral relativism per se; her books on race and racism, as well as her late-life project of an anthropology “beyond relativity, beyond pattern” attest to this (Benedict, 1942; Young, 2005).

Mead, along with Bateson (1942), taking her lessons from Sapir and from the psychology of the era, concerned herself with innate dispositions, the accidents of life, and variable cultural forms. To this work, Bateson brought his talents as a photographer and his interests in interactive processes.

Hallowell did not publish much pertinent to culture and personality during its heyday. He did, however, publish

a singular and in some respects curious overview of the sub-discipline in A. L. Kroeber's *Anthropology Today* (1953). Kroeber's volume also contains an overview of national character studies by Mead. Benedict and Mead, especially, attained great stature outside the discipline of anthropology; their position within the discipline was more tenuous. Yet, to varying degrees, they have receded from view, other than perhaps as caricatures, objects of scandal, straw people, or the obsessions of specialists. They have, for many, become icons for this or that position, rather than people engaged with intellectual and scientific projects; hence, they are easily and unfortunately often misrepresented.

A Lattice of Interests and Scholars

Daniel Segal and Sylvia Yanagisako (2005) have recently argued that the distinctly American notion of a four-field anthropology has lost much of its utility. According to their account, anthropology is the last of the great, composite 19th-century disciplines. The other disciplines, such as political economy or natural history, have broken up into smaller, more professionalized units of scholarly endeavor organized around university departments and funding-agency areas of interest. Anthropology, at least the American four-field anthropology, remained intact, partly for reasons of bureaucratic convenience, within universities and partly because of a general, if not always happy and often ambivalent, commitment to a concept of holism.

From this general perspective, the history of anthropology becomes largely a tale of somewhat conditional compromises within the academy set against and responsive to sets of changing circumstances, both in allied disciplines and in the world outside the academy per se.

When, in the 1890s, Franz Boas brought together in uneasy harmony several subdisciplines under the general rubric of anthropology, none of those subdisciplines were particularly well developed. Ferdinand de Saussure had yet to give his famous course on general linguistics; Sapir's book *Language* would come out in 1921 and his essay proclaiming the psychological reality of phonemes for speakers in 1933. The sorts of fieldwork techniques epitomized in the idea of ethnographer as field note had yet to be devised; Mead proved particularly methodologically innovative and has left us voluminous notes among her papers, but she did not start working in the field until 1925. Equally, in the 1890s, archaeologists were only beginning to devise the sorts of methods for recording assemblages in situ upon which all subsequent methodological and theoretical development has relied. William Bateson did not publish his discussions of Gregor Mendel's genetic work until 1902, by which time Boas had already established the department at Columbia University and Kroeber had completed his, by today's standards, very short doctoral dissertation. Theodosius Dobzhansky and Julian Huxley would not publish their studies, bringing Darwin's theory of evolution and

Mendelian genetics together, until 1937 and 1942 respectively. Gregory Bateson (hereinafter Bateson), William's son, introduced Mead to Mendelian genetics in 1933; Bateson and Mead read Charles Darwin's *The Expression of the Emotions in Man and Animals* while in Bali, most likely in 1936. Our current sense of evolution as changes in genetic frequency within reproductive populations, of genomes and the like, are even more recent.

In one sense, then, anthropology as Boas proposed it in the 1890s could only have been a work in progress. His interest, and subsequently that of several of his students and their associates in matters connecting psychology and social life, was likewise a work in progress. Anthropology's internal, subdisciplinary stresses could only emerge as problems, methods, and techniques became refined. Those same stresses could only be exacerbated as the volumes of research increased, as an emphasis upon recent scholarship became more pervasive, as knowledge of pertinent literatures diverged, and as various forms of reductionism—biological, cultural, linguistic—either appeared, came to be feared, or were used by some for other unfortunate purposes. Nor should we forget human qualities, vanity, envy, and resentment being among them.

In perhaps the most interesting contribution to Segal and Yanagisako's volume, Ian Hodder (2005) suggested that we think of disciplines and subdisciplines less and more about a lattice of shared interests bringing scholars together for some projects but not others. It would be ironic, then, that perhaps the most mythologized, if not also the most historied, of American anthropology's endeavors, culture and personality, was just such a lattice of interests and scholars working in a variety of disciplines, notably but not exclusively psychology and anthropology.

Few read the psychology of that era anymore, hence many have lost any understanding of how deeply that psychology—culture and personality—engaged biological notions. Given Segal and Yanagisako's (2005) desire to establish a cultural anthropology dedicated to the study of the operations and consequences of power separable from, or at least not reducible to, biology per se, this earlier engagement with biology poses its own ironies. As many—Derek Freeman, Steven Pinker, and Melvin Konner, each in his own way—have used Mead in particular as a poster child for a rigid cultural determinism indifferent to biological notions or biological processes, Mead and Bateson's specific and very explicit engagements with the psychology and biology of her day multiply the ironies.

Mead and Bateson, working within a lattice of interest and scholars, developed but did not explicitly publish an articulate research paradigm joining ethnographic, psychological, and biological observations and processes; this was their squares hypothesis (on the squares see subsequent section; see also Sullivan, 2004, 2005, 2008). The squares hypothesis was in ways consonant with the holism that Segal and Yanagisako (2005) criticize, yet not hostile to the studies of the operations of power Segal and Yanagisako

advocate. Taken in conjunction with Benedict's late life project of an anthropology "beyond relativity, beyond pattern," a worthy predecessor Segal and Yanagisako were likely unaware of, a reexamination of the premises of what we call culture and personality may revivify interest in a set of lattices consonant with much of the last, great, composite 19th-century discipline. From time to time, anthropologists have returned, in one guise or another, to this particular set of interests in matters ethnographic, psychological, and biological and the associated processes; culture and personality, particularly as developed by Bateson and Mead, has its successors, even if those successors rarely acknowledge or perhaps even know this to be the case (e.g., see Csordas, 1994; Hinton, 1999; Hirschfeld, 2002).

Segal and Yanagisako's (2005) suggestion that American four-field anthropology grew set against and responsive to the internal imperialist expansion of the United States and its consequences deserves close attention. Hallowell (1965) made a similar point in his discussion of the history of anthropology as a particularly and necessarily anthropological problem.

Much, but surely not all, of the work associated with the rubric of culture and personality was undertaken outside the United States and its empire, albeit within other empires. Benedict (1934), however, found consequences of the American empire for the original indigenous peoples of North America embedded in culture and personality's founding notions; people(s) seek coherence, but ways of life may rupture. Regna Darnell (2001) called attention to Benedict's sort of observation, referring not only to what Darnell called the invisible genealogies, which comprise Americanist anthropology, but also anthropology's particular need for a useable past.

But for whom is that useable past useful? For what purposes and to what ends is such a past useful? Of such questions, perhaps Segal and Yanagisako (2005) would approve.

An Original, Dysfunctional Politics

Some of the early arguments surrounding culture and personality were personal, petty, and maliciously destructive.

In 1925, Mead and Sapir had a brief affair that must have moved them both very deeply; Mead said as much later in her letters to Benedict. At the time of this affair, Mead was married to Luther Cressman. She was also preparing to undertake fieldwork in Samoa. Sapir, meanwhile, wanted Mead to leave her husband. Sapir also lobbied Boas, behind Mead's back, in an attempt to keep her from journeying to the Pacific. Sapir's arguments concerned Mead's frailties, but his intent was to keep her close and to secure her as his bride and stepmother for his children. Mead learned of Sapir's approaches to Boas, perhaps through Benedict.

Relations quickly soured between Mead and Sapir. Mead would burn Sapir's letters on a Samoan beach; it is

unclear what happened to Sapir's copies of Mead's letters. Sapir would contend that Mead was an incompetent in his 1929 review of Boas's book *Anthropology and Modern Life* and imply she was immoral in a thinly veiled description, in his article, on the so-called "new woman."

American anthropological circles at the time were small. Sapir was perhaps the leading intellectual light among Boas's first generation of students. Well-known and respected—his eminence earned him positions at Chicago and Yale—he was a formidable enemy. Mead, however, had earned Boas's support, and tangible support at that; Boas found Mead a job, with salary, at the American Museum of Natural History. By contrast, Benedict worked at Columbia's anthropology department, but without pay, until her marriage crumbled sufficiently for her to need a salary. Cole (2003) pointed out that Columbia awarded 20 doctorates in anthropology to men and 19 to women between 1920 and 1940. The other female Boasians were mostly underemployed if not also itinerant.

Benedict—Mead's friend, mentor, and sometimes lover—either could not or chose not to avoid this dispute. Benedict was present soon after Mead arrived in France from Samoa obviously enamored of Reo Fortune, but despite her own disappointments, Benedict sided with Mead, hence perforce against Sapir. Benedict and Mead's conversations on their voyage back from France gave rise to what is usually referred to as culture and personality, or sometimes as the configurationist school, but their work was part of a much larger body of interdisciplinary work (on Benedict, Mead, the *gestalt* psychologists, and the notion of configuration, see Sullivan, 2009).

Darnell (1986) has contended that there was a Sapirian alternative to Mead and Benedict. If so, then during the 1920s, 1930s, and even the 1940s when Mead and Benedict brought out at least one important dissertation, a series of major books, and many articles, that alternative brought forth a sparse literature, mostly by Sapir, from which real people living real lives in real worlds are largely, if not entirely, absent. Sapir's students, younger colleagues, and their students champion his legacy; Darnell belongs to this camp, having studied with Hallowell.

In 1941, Hallowell, Leslie Spier, and Stanley Newman organized a memorial volume for Sapir. In that volume, Clyde Kluckhohn defended Benedict against Sapir's criticism. The organizers of the volume thought Mead irrelevant to Sapir's legacy. They did not think of her as close to him personally. Mead went undefended. Sapir's students and younger colleagues came to dominate the positions teaching psychological anthropology.

Benedict taught for many years at Columbia; of her students, one, Victor Barnouw, made contributions to psychological anthropology; others, notably Sidney Mintz and Eric R. Wolf, seem to have developed aspects of Benedict's late-life project of an anthropology of freedom and power beyond relativity, beyond pattern. Abraham Maslow, a leading American humanistic psychologist perhaps best

known for his theory of a hierarchy of needs, worked with and thought highly of Benedict.

Mead's position at the American Museum of Natural History meant that she had few students of her own prior to the late 1950s. She did employ a considerable number of young anthropologists over the years at the museum. But her legacy derives from her methodological innovations, her books, and the articles she published with Rhoda Metreaux in *Redbook*.

To his students and younger colleagues, Sapir (1994) contended that Benedict's, and by implication Mead's, work was mischievous in that psychology can only come about in the interactions between people. Concerning Mead, this criticism is simply misplaced. Given Sapir's (1949) contention that phonemes are psychologically real for speakers of languages, and his contention that a culture appears to take on the characteristics of the organization of a personality the more one studies that culture, Sapir's (1994) criticism of Benedict on these grounds seems odd at best.

At least within the academy, the Sapirians largely won the day, reproducing themselves and their positions. Sapir's original contribution, however, should not be over- or underestimated.

Edward Sapir

In 1917, Kroeber published his essay on culture as the superorganic in the *American Anthropologist*. Kroeber drew responses from A. A. Goldenweiser and Edward Sapir. Of these responses, Sapir's has had the deepest resonances. Sapir's question was simple: Do we need the superorganic? His answer was equally simple: No.

But the consequences of that answer were not so simple. If culture is not superorganic, then culture, to put matters one way, and social facts, to put matters in another but similar way, must somehow arise in the interactions of individual human beings. That is, culture and social facts must be somehow psychological. Concomitantly, social processes must all proceed through the activities of people.

From 1917 until his death in 1939, Sapir continued to expand upon this initial observation. Effectively, his 1994 criticism of Benedict and, via Benedict, Mead was an extension of his earlier criticism of Kroeber.

Elaborating on J. O. Dorsey's comment, "Two Crows denies it," Sapir (1994) noted that any understanding of a given culture differed depending upon whom one asked about that culture, its institutions, and practices. Thus, the particular version of culture a person expounded would be psychologically real for him or her, but not necessarily for his or her neighbors. There was no psychology of culture as such; ordinary people, regardless of the society in which they lived, would be generally psychologically similar even as they viewed matters differently from one another. Put slightly differently, Sapir held a comparatively weak conception of culture and its powers as psychological stimulus; the individual had to give culture meaning. According

to Mead (1959), Benedict held that Sapir desired to prove that culture does not matter.

Sapir widely read the psychology of his day, writing reviews of significant works by W. H. R. Rivers and C. J. Jung, for example. In 1925, before their relations became frayed, Mead introduced Sapir to Kurt Koffka's (1924) book, *The Growth of the Mind*. Not long thereafter, Sapir made the acquaintance of the American psychiatrist, Harry Stack Sullivan; they became close friends. Sullivan's work with schizophrenics grew out of a sense of crucial points in human lives, especially male lives, when difficulties in relations with others could push a person into mental disease; for Sullivan, perhaps the most significant of these difficulties was a fear that others might think one experienced homosexual desire. On the other hand, successfully navigating these crucial periods of life yielded a sort of mental health. Sapir and Sullivan, along with the political scientist Harold Lasswell, collaborated, developing a broad, multidisciplinary, institutional, and intellectual framework for studying the interrelations of personality and culture. This framework can best be seen in the 1933 Hanover conference and in Sapir's course on the psychology of cultures.

In what must be something of an irony, Mead attended the 1934 Hanover conference devoted to developing the project suggested at the previous year's gathering; she wrote much of *Sex and Temperament in Three Primitive Societies* (1935) while there. Sapir's notes on his psychology of cultures lecture series ended up in Mead's papers.

Sapir (1949) made several arguments for the usefulness of psychology and psychiatry for anthropology. But, he made perhaps his most important claims in a paper discussing the usefulness of cultural forms for individual lives; this was his essay "Culture, Genuine and Spurious" of 1924. Some lives have a genuine and fulfilling relation to the wider social world; others do not, with Sapir's example a hypothetical telephone operator working at a switchboard. These latter lives bespoke malaise.

Maureen Molloy (2008) has placed Mead within the world of small magazines and the concerns of intellectuals, such as Van Wyck Brooks, Herbert Croly, and Randolph Bourne, with a deep complementarity between cultural and individual, especially intellectual, lives. For Brooks, Croly, Bourne, and others like them, America had as yet not developed its own genuine culture. Life, especially intellectual and artistic life, was too passive to be truly manly; such lives risked the malaise of spurious culture. These intellectuals moved in precisely the same circles as the New York Boasians. Sapir's argument for a genuine culture, one that fulfilled the individual in his endeavors, should also be placed in this context.

Ruth Benedict

Ruth Benedict began studying anthropology under Goldenweiser at the New School for Social Research in 1919. She subsequently wrote her doctoral thesis on

“The Concept of the Guardian Spirit in North America” under Boas. In 1922, an essay on vision quests among Plains Indians quickly followed.

In these works, Benedict (esp. 1922) began to substantially turn the studies of the distribution of cultural traits defused across a landscape inside out. No more would culture be Robert Lowie’s thing of shreds and patches, oddly put together by happenstance. The significance of the vision varied according to how it fit with other elements of a given culture; no two of the Plains societies incorporated the vision into their practices in the same manner. Where in one society, for example, the vision quest might have been accompanied by painful ordeal, in another vision it had been bought and sold. Benedict produced an analysis built around a theme (visions) and its variations or, put another way, a nascent structuralism not beholden to or dependent upon a theory of language.

In contrast, Hallowell’s 1926 dissertation only points toward the necessity of such a nascent structuralism. He showed that ceremonies directed toward bears were not coextensive with the ecological range of bears. In the Northern Hemisphere, such ceremonies could be found only among hunting peoples of the arboreal forests, and neither further north on the arctic fringes nor further south. But for all the extensiveness of his scholarship, his reasoning did not extend further. Nor did Hallowell pursue either the internal relations between various elements of bear ceremonial or the relations between bear ceremonial and other elements of culture aside from its distribution.

Mead’s thesis, like Benedict’s and Hallowell’s, was based on library research. Finished prior to her 1925 trip to Samoa, Mead attempted to discern whether or not changes in cultural complexes—canoes, houses, tattoos—could be used as a kind of clock, with some elements changing reliably faster than others, depending upon how they were integrated into the rest of the cultural pattern. Thus, Mead assumed Benedict’s nascent structuralism. While Mead set out regular patterns of difference between and among various Polynesian societies, she concluded that changes in these complexes could not be taken as a reliable guide to how quickly or slowly such complexes changed.

Sapir thought highly of Benedict’s work. Boas brought Benedict onto the Columbia department’s faculty, albeit, as noted above, for some years without pay.

While assisting Boas with a course at Barnard College, Benedict met the much younger Mead. These two, Benedict and Mead, would not long thereafter begin a collaboration that would last until Benedict’s death in 1948. Subsequently, Mead would serve as Benedict’s literary executor and bring out two volumes (Mead, 1959, 1974) on Benedict and her work. The differences between Benedict and Mead, if not often noted, are every bit as important as their similarities.

As with Sapir, Mead introduced Benedict to Koffka in 1925. But it was not until 1927, according to Mead (1959), that Benedict realized that she could explain differences between Amerindian societies of the Plains and Southwest in ways formally and heuristically similar to those she

might use to explain the differences between individuals; in both cases, what mattered were the selections individuals and collectives made or did not make from the available possibilities, and the applications of the selected possibilities toward life circumstances. In her 1934 *Patterns of Culture*, Benedict relied upon and repeatedly stressed this notion of cultural selection, as well as its corollary: Given enough time and freedom, each person and society would seek out its particular coherence, applying disparate and sundry materials to individual or group ends, individual or collective. One should not neglect the echo of Darwin’s epoch-making notions of natural and sexual selection or the anticipation of Lévi-Strauss’s notion of *bricolage*.

Much later, Mead (1959) would write of this formal and heuristic similarity between individuals and cultures with a shorthand: Culture is “personality writ large” such that by implication personality becomes culture writ small; Mead used the quotation marks rather than explain more fully. This trope has gone largely unexplored. Benedict’s (1959) formulations, for example those found in her essay of 1930, “Psychological Types in the Cultures of the Southwest,” stressed the differences of scale and duration between persons and cultures, as much as the similarities bound up in selection and agency.

In a well-formed culture, where for Benedict (1934), one has had time and relatively beneficial circumstances, most people would find the well springs of their own psychological world in the organization of the culture within which they lived. The society’s myths, folklore, institutions, and practices became psychologically real for people as they lived their lives in ways that were consonant with the order of those lives; in Sapir’s terms, such orders would be genuine cultures.

But not everyone would be so lucky as to live in a society conducive to inclinations. Some societies, like that which Benedict described in *Patterns of Culture* (1934) as the Digger Indians, had been devastated, their earlier ways either forbidden or so at odds with the new world that they found themselves, in these earlier ways, to be nonsensical. It was equally possible for individuals to be drawn to behave in ways quite counter to those publically espoused in their society; Benedict’s repeated example was a homosexual living in the United States of her day. In her terms, such a person was deviant; in the somewhat later terms of Erving Goffman, such persons could find themselves having to live with a spoiled identity or a damaged face, itself the consequent of the stigma their behavior drew toward them, if known, and sometimes even if known only to themselves. Such circumstances were also psychologically real; but rather than being fulfilling, they could render the person severely at odds with his impulses.

Deviance and Relativity

Both Benedict and Mead knew of the power of such deviance upon lives from their direct experiences of discreet,

homosexual encounters. Mead (1959) credited Benedict with teaching her to ask about deviance when Mead was working on *Coming of Age in Samoa*. For Mead, however, deviance came to be not so much a matter of behavior as being emotively at odds with one's society's ethos.

From at least 1928 when *Coming of Age in Samoa* was published, neither Benedict nor Mead worked with the idea of a wholly overdetermining culture. Culture provided context and patterns of significance, but in their thought there was always a concern for individuals and agency; social pressure was only almost irresistible. For Benedict (see Young, 2005), this observation of deviance would lead to her concern with freedom beyond pattern, beyond relativity. Mead (see Sullivan, 2004, 2005) would come to describe personality as arising in the conjunction of biological inheritance and disposition (temperament), the accidents of life, and cultural patterns; she preferred to think of the individual in culture rather than to use, save for purposes of easing communication, the phrase "culture and personality."

For Benedict, unlike Mead, the possibilities for the variety of pattern opened up by cultural selection were, if not endless, at least large. There could be many forms of genuineness, of devastation, and of deviance. Benedict opposed her younger colleague's attempts to introduce any small system of variables; in this matter, Benedict's thought was less like that of her first teacher, Goldenweiser, than Mead's was.

This variety of cultural pattern has led many to think of Benedict as a cultural relativist, meaning that all cultural patterns were for her equally valid expressions of humanity. Benedict is not known to have used such a phrase in her published writings. Furthermore, she wrote extensively on racism in ways that not only provided a cultural analysis of the genesis of racist thought, but also extensively critiqued racism. For Benedict, not everything goes. Nor did her position require her to separate culture from politics, as Melville Herskovits had to in his distinction between German culture and Nazism. Rather, Benedict's thought took her more and more into explorations of the cultural conditions generative of human freedom.

In many ways, Benedict's thought was only a partly psychological understanding. Though she would come to write about raising Japanese children in *The Chrysanthemum and the Sword* (1946), Benedict long found her attitude toward dynamic psychologies—such as those of Sigmund Freud and Erik Erikson, which focused on a sequence of bodily zones and a child's developing powers—to be wasteful. Thus, she allied herself further with the analysis of cultural stimulus rather than interior psychological development. Mead (1946) thought Benedict to be the most sociological, the most cultural, in her understanding of the personality within a group of scholars lumped together under the rubric of culture and personality; by contrast, Karen Horney seemed to Mead to almost lack a working concept of culture.

But, as Benedict's work implies, a human interiority is dialectically related to a particular cultural pattern, and Benedict's thought remains psychological in much the way Oswald Spengler's does. For Spengler, psychology develops within and against a particular image or understanding of the world. Soul varied in relation to nature understood as an image of the world, with that image itself shifting and changing with time. Similarly, for Benedict (1934), personality understood as a counterculture varied as historically cobbled together and culturally selected patterns varied in time and space, and also varied as specific individual's relations toward those patterns, those understandings of the world, embedded in myths, folklore, institutions, practices, and the like.

At least from 1927 and certainly from 1928 with the publication of *Coming of Age in Samoa*, Benedict's and subsequently Mead's analyses presume individuals in specific cultures; in Mead's case, this presumption is readily visible in the surfaces of her texts. Their descriptions of specific cultures have been, and indeed should be, subject to criticism, but their theoretical orientation and contributions do not rely on the accuracy of any specific account of a particular culture.

Margaret Mead

Margaret Mead's ethnographic corpus is perhaps the most criticized in all of anthropology. Some of these criticisms, like that of Derek Freeman in 1983 and 1999, contending that Mead opposed all biological explanation favoring, thereby, a radical cultural determinism, are often repeated but also without merit. Other criticisms are essentially leveled at Mead considered as an icon for this or that position, whether she held such a position or not. Given the number of her publications and the sheer volume of her papers—they are the largest collection held by the Manuscript Division of the Library of Congress—serious criticisms of Mead's work have of necessity been the preserve of specialists, either of one or another of the ethnographic areas in which she worked, or of her scientific project, though this latter specialist is more rare.

Mead came to anthropology from psychology and, so she said (1962), stayed within the realms of psychology for the rest of her life. As was common in her day, her dissertation on social stability in Polynesia was derived from library research. At Boas's instigation, she began her first field research in Samoa. Like all of her subsequent fieldwork, her Samoan research, like her thesis before that, focused on a particular problem; this, in itself, was a significant innovation from which much of American anthropology's problem-oriented fieldwork now derives. This focus on a problem, having to do with individual lives in cultural worlds, also required Mead to develop innovative methods to study what she called informal, or unstressed, elements of social life.

In the Samoan case, Mead (1928) studied the psychological adjustment of adolescent and immediately postadolescent girls to Samoan society. In 1999, Freeman contended that she also tried to undertake a separate study of Samoan social structure. While these two aspects of Mead's studies were funded by separate entities, these two matters, adjustment and social structure, are not really separable, as Freeman would have them be.

In 1925, prior to going to Samoa, Mead read Koffka's (1924) *The Growth of the Mind*. In this work, Koffka developed an analysis starting with the active engagement of very young children with a stimulative world. For Koffka, adaptation was an active process, not a passive one.

According to this analysis, both entities—developing child and stimulus—were psychologically powerful. The qualities of the stimulus (e.g., the nipple of a bottle as opposed to that of a woman) shaped the possibilities for the child's experience. But even a young child engaged such stimulus and shaped her responses. What we see and call behavior arose in this shifting conjunction of forces, both stimulative and responsive or adaptive. The *gestalt* psychologists referred to this shifting conjunction of forces as *struktur*, but for reasons having to do with the internal disputes among American and British psychologists, Koffka and his translator chose to use the term *configuration* instead of *structure*.

Benedict (1934) stressed the relations between parts and wholes, the indivisibility of wholes, while Mead (1928, 1930, 1935; Bateson & Mead, 1942) emphasized the shifting processes of the developing configurations or patterns. Both women approached their analyses structurally rather than statistically.

Freeman's error was, therefore, twofold. He separated adjustment from social structure, when the sort of psychological theory with which Mead worked required that these two be considered together. Furthermore, he ignored the biological aspects of the psychology with which Mead worked. Mead and Bateson's friend, C. H. Waddington, would later coin the term *epigenesis* to refer to precisely these sorts of neonatal developmental processes involving both a stimulative world and an active adaptation. In *Coming of Age in Samoa*, several years before she met Waddington in 1934, Mead asked whether among her Samoan interlocutors there were any temperaments at significant odds with Samoan culture. In one sense, this is Benedict's question about deviance and the place of the deviant within a given social order. But Mead derived the notion of temperament from the work of William McDougall, perhaps in conjunction with that of June Etta Downey, where temperament refers to the innate, heritable disposition or the biological constitution of psychology, as opposed to character, which refers to the organization of habit learned over a lifetime. She was asking whether or not any of her interlocutors showed signs of some disposition—itsself biologically based—at odds with the order or pattern or configuration of the society in which the particular interlocutor lived.

Mead would never leave this interest in biology behind, but equally, given the politics of the era, she would not explicitly publish her developing theories. In 2008, Molloy suggested that biology began playing a larger role in Mead's thought following her research along with Reo Fortune among the Omaha, because Mead's theory was unable to account for cultural change. The subsequent section is more concerned with Mead and Bateson's squares theory.

Regarding the Squares

Mead and Fortune journeyed to New Guinea to undertake fieldwork together in 1932, after earlier working together among the Manus and the Omaha. Their relationship was already strained. They set up first among the Arapesh; Fortune was often away from camp, traveling the roads with various men. They stayed briefly among the Mundugumour, before moving to work among the Tchambuli (now Cambri). Bateson was then nearby amongst the Iatmul. All three of these ethnographers had worked among more than one group; they were respectively an American (Mead), a New Zealander (Fortune), and an Englishman (Bateson). They had only each other for anthropological conversation.

Their relations became volatile, leading them to decamp for Sydney. Precisely what happened between them is now the subject of some disagreement. Molloy and Caroline Thomas, Fortune's biographer (personal communication), suggest that Benedict and Mead put around a story that Fortune had assaulted Mead, leading her to have a miscarriage, in order to preserve Mead's reputation and to explain her separation from Fortune. There can be no doubt that Mead and Fortune explained matters somewhat differently, from one another, to his family. While a concern for Mead's reputation could explain a great deal, this concern need not mean that the tale Mead and Benedict put about was inaccurate. Fortune did strike Mead while in Sydney after these two and Bateson departed the Sepik in 1933. The remaining record has yet to be thoroughly examined in print.

It is clear, however, that Mead and Bateson began developing their squares hypothesis; Fortune thought their line of reason racist and increasingly had little if anything to do with it.

Mead had come to New Guinea intent upon studying the regular pattern of female adjustment to society. She began by assuming that men and women, considered as biological and sexual groups, were temperamentally different from each other. Under the influence of (1) Boas's 1911 doctrines about the nonexistence of biological races, (2) a draft of Benedict's *Patterns of Culture* (1934), (3) C. J. Jung's book *Psychological Types* of 1921, (4) Mendelian genetics as explained by Bateson, and (5) the variety of male and female lives found among the Arapesh, Mundugumour, and Tchambuli, Mead came to think this notion of irreducible

biological differences between men and women to be mistaken. Rather, Western notions of appropriate male and female personalities were versions of temperamental, constitutional, or biological types manifest in the personalities of both men and women.

Developing a corollary of Benedict's (1934) idea of cultural selection, Mead suggested that if a society had enough time and resiliency in the face of external and internal stresses, then it could eventually select for, in Mead's terms stabilize, a preferred type or types of personality. The society would have to be relatively endogamous. Its neighbors could not be too overwhelming, or disruptive militarily or economically. Its people had to be well adapted to local foods and diseases.

Unlike Benedict, Mead preferred to think of a small group of dialectically related types. For Mead, deviance increasingly came to mean that a person's emotional life was at odds with the ethos of their society, rather than a matter of behavior as such (on ethos, see Bateson, 1936; Silverman, 2001). Each of her four primary and four intermediate types had a characteristic developmental tendency that would conform variously to the emotional organization of the society into which a given child was born. Hence, given a particular social organization, children of each type would face characteristic difficulties as they grew, assuming they were healthy rather than ill; on this point, Mead and Bateson would subsequently borrow from Erikson's 1937 zonal-modal theory of early childhood development.

Mead's contribution was to recognize that, unlike a feeding bottle, a woman or any caregiver was already enculturated; her work thus extended Koffka's 1924 notions. Likely influenced by Bateson, she held that characterological development was not reducible to some particular technique. Rather, the interactions between caregiver and child were communicative; the caregiver's emotional tenor formed a stimulus enacted in technique to which the child actively adapted in much the matter suggested by Koffka, and subsequently developed by Kurt Lewin (see Sullivan, 2009).

Embodiment

While *Sex and Temperament* (1935) may well, as Molloy in 2008 suggests, largely concern deviance, it also outlines three general developmental sequences, each set against a different kinship system, with its characteristic stresses and strains, and specific preferred personalities. Bateson and Mead's *Balinese Character* (1942) outlines a fourth developmental sequence against the background of yet another cultural order. Properly read, these books draw attention to the processes leading to a human embodiment of culture. Mead explicitly pointed out in her introduction to *Balinese Character* that the book was not about Balinese culture per se, but rather concerned the processes by which Balinese people came to embody that culture.

She made a similar point in her 1953 defense of Geoffrey Gorer's analysis of swaddling among the Great Russians.

In 1950, Lévi-Strauss favorably compared Mead and Benedict's work with Marcel Mauss's concern to show how individuals in society come to manifest those very bodily reflexes provided by society. At the time, Mauss was writing about techniques of the body, Benedict was bringing out *Patterns of Culture* (1934), while Mead, along with Bateson, was developing the squares hypothesis. Lévi-Strauss considered the Mead of *Sex and Temperament* (1935) to be developing a principled doctrine quite similar to that of Mauss, though she did not seek to produce Mauss's envisioned encyclopedic inventory of the uses to which people have put their bodies.

Thomas Csordas (1994), among others, called attention to embodiment as what he has termed the existential ground of culture and self. But at least in the early work he edited, there are only two brief mentions of Mauss; Bateson receives mention in a single note. Mead went unmentioned. The discussions in this work presumed an adult culture, and thus do not take up the processes by which people learn to be embodied in a specific way. Mead, again, goes unmentioned. Thus, the essays in Csordas's volume could easily be criticized for ignoring children, their culture, and their development.

Mead's work championed the study of children and the ways in which they learn to be enculturated human beings, beginning with her second popular volume, *Growing Up in New Guinea* (1930). Far from hating children, Mead pioneered the study not only of children's culture, but also of children in culture. Her works, then, should be understood as an extended study of the processes of education, their discontents, and the reproduction of character.

Gregory Bateson

If Mead left psychology to remain nonetheless always within its ambit, then Gregory Bateson remained within the domain of biology and natural history. Over the course of his career, Bateson developed a science of the convergence of form, communication, and context.

In its mature form, Bateson's (1979) thought considered learning and evolution to be formally similar. Though these processes occur on very different scales, both are stochastic. That is, both involve the interaction of a tautological inlying system and an external environment. Being external to the inlying system, events arising in that environment would be random to the inlying system. Learning and evolution, then, are the inlying systems of adaptation to random developments within the environment. Such adaptations effect changes in the internal relations between parts of the system and, therefore, within the processes by which the newly reconfigured system regulates itself. Because this new configuration arises out of the conjunction of both the system and the environment, that new configuration need not be

predictable and, in that sense, is underdetermined. Conversely, as the inlying system is a part of its environment considered as a system, any change in the internal relationships constituting the inlying system yields a change in its environment. For this pattern of continuing adjustments to persist, the totality has to become self-regulating; an uncorrected progressive change, on the contrary, generates conditions under which the totality and its parts, jointly or singly, can become disorganized.

While one should not underestimate Bateson's own contributions or the originality of his science of form, communication, and context, his developed position owes much to the era in which he collaborated with Mead and learned from Benedict. In a variety of ways, Bateson's mature position drew together Benedict's concerns with myths, folklore, institutions, practices, and the like considered as the environment for life, as well as Mead's attention to individual development within such an environment. He attempted to devise a way of thinking to both explain the generation of difference, as evolutionary theory does, and concomitantly the development of similarity within that range of differences, as cultural theory requires.

The scion of a great British academic family, Bateson studied anthropology at Cambridge, where he knew Reo Fortune. Apparently unimpressed by the functionalism of Bronislaw Malinowski, Bateson would gravitate toward the psychological laboratory of Frederick Bartlett.

Bateson's first fieldwork among the Baining was something of a disaster; his second field project among the Iatmul was not going much better when Mead and Fortune arrived in the area. Bateson's notes consisted largely of lists of clan names.

In addition to his conversations with Mead and Fortune, Bateson was drawn to the *naven* ceremony with its sequence of a triggering action, transvestism, mockery, building emotion, and an eventual consuming climax. The young Bateson, like certain Marxists, believed such building tensions would push Iatmul society apart. To describe these phenomena, in 1936 Bateson coined the term *schismogenesis*, meaning the generation of faction or schism. To analyze these mutually evoked interactive sequences, Bateson developed two notions: *ethos* and *eidos*. By *ethos*, Bateson meant the organization of emotion; *eidos* referred to the parallel but distinct organization of thought. Roughly then, *ethos* concerned matters central to Mead's pursuits, while *eidos* shared some of Benedict's interests. Bateson also wedded his ideas of *ethos* and *eidos* to notions of social organization derived largely from the work of W. H. R. Rivers and A. R. Radcliffe-Brown, extending thereby Rivers and Radcliffe-Brown's ideas in novel ways, as Mead recognized. Importantly, Bateson's analysis did not concern itself with function.

Determined to work together again, Mead and Bateson by happenstance ended up choosing Bali for their next research. Their research proposals suggest lines of study defined by the squares hypothesis. Bateson also took up

the question of controlling schismogenesis and hinted at the use of cinematography.

By the end of September 1936, however, Bateson's research into the control of schismogenesis had been largely abandoned in favor of Mead's focus on the interactions of caregivers and children. Bateson began taking photographs and short films of these encounters and other elements of Balinese life. He also devised ways of integrating these materials with notes taken by Mead and Madé Kaler, their *aide-de-camp*. The result of these efforts was an unusually large and densely organized body of materials, forming the basis of one of the most unusual books in the history of anthropology: *Balinese Character* (1942).

According to Bateson and Mead (1942), the ordinary, well-adjusted Balinese were affectively unresponsive compared both with Americans and New Guineans. This was not a matter of temperament, since Balinese babies were as emotively engaged as any other babies. Rather, this was a characterological development deriving from extensive, if also frustrated, communications between caregivers and children. Furthermore, the institutional arrangements of Balinese society tended not only to defuse tensions, but also to prevent progressive changes such as those associated with schismogenesis. These social arrangements provided the Balinese with prompts necessary for stable, if emotionally distant, lives. As a result, the character of the Balinese—the ways in which they had come to embody their culture—formed a crucial part of Bali as a self-regulating system.

Mead and Bateson's (1942) research in Bali was largely funded by the Committee for Research in Dementia Praecox, a group of leading American psychiatrists funded by the Masons and interested in all matters pertinent to schizophrenia. Bateson and Mead compared ordinary Balinese to American schizophrenics, noting that whereas Balinese culture provided Balinese people with an environment supportive of a successful Balinese adaptation to life, American society did not so provide for American schizophrenics. This formulation did not hold that ordinary Balinese were psychotic.

Conclusion

Sapir, Benedict, Mead, and Bateson were not the only anthropologists interested in the issues gathered together under the rubric of "culture and personality." Ralph Linton, Cora Du Bois, and Clyde Kluckhohn collaborated with Abram Kardiner; Ruth Landes also did significant work. Among the British, Malinowski and others took up the psychological relations between individuals and society, or as Sapir and Mead would both have preferred to put it, the individual in society. The British and Kardinerian projects came to little success.

In the years after World War II, two separate anthologies appeared: Kluckhohn and Murray (1948) and Haring (1956),

the later being revised several times. Both Mead (1946) and Hallowell (1953) published assessments of the field.

Mead thought that the “and” in “personality and culture” had seduced many into a series of primarily methodological befuddlements—themselves more embarrassing than enlightening. Too often, practitioners forgot that the distinctions between culture and personality were matters of heuristic abstraction, useful only insofar as scholars applied them mindfully, avoiding thereby logical errors associated with a false concreteness. Like much of Mead’s thought from this period onwards, here she showed a decidedly Batesonian influence.

Hallowell (1953) recapitulated much of the best of Benedict, Mead, and Bateson’s advancements while mentioning these three almost not at all. By then, as Hallowell explained without putting matters quite this way, the influence of the *gestaltists*, brought into anthropology many years before initially by Mead during the summer of 1925 and elaborated on by others, had become something of a common sense. Part of a system of integrated wholes, culture, personality, and society arose together in real worlds not wholly or merely human. These three—culture, personality, and society—could not really be separated. Heuristically, as Mead (1946) would have had it, scholars could address those processes by which persons adapted to or adjusted to the social and worldly orders in which they found themselves; this had been Mead’s primary focus. Alternatively, scholars could examine culture as an organization of experience typical of a time and place; here Benedict and Bateson had shown a way forward. But Mead, Benedict, and Bateson were no longer within the circles around Sapir and his younger colleagues.

Even more important, by 1953, Benedict along with both Koffka and Lewin had been dead for several years. Bateson had given up anthropology to work among schizophrenics in Palo Alto, California. Mead still did not have a teaching job and, although she continued her busy schedule from her tower office at the American Museum of Natural History, it was some years before she would emerge, as it were, in her guise as grandmother-to-the-world. The circle of anthropologists and *gestalt* psychologists, Bateson, Benedict, and Mead being prominent members, proved to be too weak to persist.

At Harvard, the Committee on Social Relations, partly under Kluckhohn’s influence, began training a new generation of anthropologists, including David Schneider and Clifford Geertz, who would bring a change of emphasis from psychology to semiotics. Mead brought out two books keeping Benedict’s legacy alive, but Geertz and many others would find Benedict more congenial (for a criticism of Geertz on Benedict, see Young, 2005).

During World War II and subsequently, Benedict and Mead had pioneered studies of culture at a distance, but of these studies only Benedict’s 1946 study of Japan has endured. Mead became embroiled in a dispute over the Great Russians and swaddling. She was often misread

during this dispute, but the studies of national character floundered. Still, there was more to this than a lattice of scholars brought together by common interests and the accidents of biography. Perhaps, for a moment, there was the possibility for what can be called, without necessarily outlining all the specifics one might like, a structuralism not beholden to or dependent upon a theory of language, but rather on patterns of growth, reproduction, and decay that examined the juxtaposition of processes and the emergence therein of proportion. If the sort of history of anthropology presented here proves useful, perhaps such a structuralism might yet develop.

GERMAN ANTHROPOLOGY

DIRK SOLIES

Johannes Gutenberg University of Mainz

Although the development of anthropology as a philosophical discipline is, at least in Germany, closely connected to the anthropological turn that took place in the 1920s and 1930s, there has been a long tradition of the usage of the word *anthropology* in German thought. The term was first used in the writings of Magnus Hundt in Leipzig in 1501, and later specified by Johann Gottfried von Herder, who prepared the prospect of the human being as a creature deficient by nature. Herder did not consider himself an anthropologist but, rather, a theoretician of human culture. His work has proved to be highly influential, especially for the evolution of philosophical anthropology in the 20th century.

Immanuel Kant

As one of the central disciplines of philosophy, anthropology was—in a strict sense—first established by Immanuel Kant. But Kant's famous reflections on philosophical anthropology are to be found not in his *Anthropology From a Pragmatic Point of View* (1798), but in his *Logik* (1800). For Kant, the field of philosophy, in this cosmopolitan regard, is founded upon the following four questions: (1) What can one know? (2) What shall one do? (3) What may one hope? (4) What is the human being?

The first question is answered in metaphysics, the second question in moral philosophy, the third question in religion, and the fourth question by anthropology. Kant

asserts that all these realms may well be subsumed under the name anthropology, because the first three questions refer to the last question.

In his *Anthropology From a Pragmatic Point of View* (1798), Kant also distinguishes between two kinds of anthropology. For Kant, physiological anthropology deals with the question, "What does nature make of a human being?" At the same time, pragmatic anthropology centers on the human as a freely acting being. It is exactly this distinction that gives rise to a philosophical anthropology attempting to derive a philosophical determination of humans from scientific knowledge. For Kant, this knowledge is primarily psychological. Hence, his *Anthropology From a Pragmatic Point of View* is, according to today's standards, a work on empirical psychology rather than on philosophical anthropology. However, it is beyond doubt that, with this distinction, Kant anticipates the central question of 20th-century philosophical anthropology: How does scientific knowledge of a human as a biological being relate to self-conception as an intellectual being?

This question gained a tremendous new relevance through the evolution of 19th-century life sciences (medicine, physiology, pathology, zoology, morphology, anatomy, embryology, cell theory, etc.). The anthropological question was thus intensified by the rise of the natural sciences in the 19th century. On the other hand, the critique of traditional German philosophy (Kant, Hegel, Fichte, Schelling, etc.) led to questioning the determination of humans as rational animals. The reduction of humankind

to a merely rational subject seemed to be insufficient without a theory of human behavior in the world. Thus, both the rise of the life sciences and the critique of traditional German philosophy led to the question of how, in a philosophical sense, the exceptional position of humankind within the biological world, and based on biological categories, could be justified.

The Anthropological Intermezzo: Philosophy of Life

In the late 19th and early 20th centuries, it was especially the philosophy of life that tried to establish a fact-based, but nonreductive, theory of man and human culture. In an ongoing debate with leading biological theories, philosophers such as Friedrich Nietzsche, Georg Simmel, Wilhelm Dilthey, Henri Bergson, and others have outlined a truly comprehensive theory of human culture under the conditions of a *biological* theory of the human species. It was, above all, the discipline of *Volkskunde* that played a tremendous role in the evolution of both *Lebensphilosophie* (life philosophy) and early philosophical anthropology.

The Foundation for Classical Philosophical Anthropology

The bloom of German anthropology is closely connected with the works of Max Scheler, Helmuth Plessner, and Arnold Gehlen. The main anthropological work of Scheler, *Man's Place in the Universe*, appeared in 1928. Plessner's work, *The Stages of the Organic and Man*, appeared the same year. Scheler, who had outlined his own anthropological concept in a lecture some years before, accused Plessner of plagiarism. While there are indeed numerous analogies in the problems, Scheler's and Plessner's given answers differ greatly.

Max Scheler

Both the philosophy of life (Bergson, 1896/1990, 1907/1983; Eucken, 1918) and Husserl's (1901) phenomenology deeply influence Max Scheler's anthropology. Scheler's work, *Man's Place in the Universe* (1928), can be considered the key text of modern German anthropology. Scheler starts with the essential difference between humans and animals; this is the exceptional position of man that derives from the fact that man, as opposed to animals, is the carrier of a mind. This primarily concerns the question of how humankind positions itself in the natural environment. According to Scheler, man is open to the world, which means that human beings, unlike every other group of animals, are not fitted into a natural environment in a strict sense; they are not determined by the limits of their environmental structure. This structure is, from a biological point of view, determined by a close interconnection between perception and action.

The German term for environment, *Umwelt*, means (in this sense) that every perception of an animal refers to a possibility to fulfill a certain set of actions and every action is determined by the limits of perception. In his work *Environment and Inner World of Animals* (1909), Johann V. Uexküll develops a comprehensive theory in which environment (*Umwelt*) is specific to every animal depending on its individual capability to perceive its world. All animals are equally and perfectly fitted into their environment by their capacity to perceive. This perceptibility is furthermore determined by their sense organs. As Scheler puts it, on the basis of Uexküll: Whatever an animal can perceive and grasp from its environment lies in the safe fences and limits of its environmental structure.

This close interconnection between perception and action, which is (according to Uexküll) characteristic for every animal in a biological sense, can be overcome by the human mind (*Geist*). Mind, in this sense, is a nonbiological determination, and Scheler goes so far as to describe it as contrary to every life—even human life. But the central point of Scheler's determination of human behavior is not only expressed in the human being as a possessor of a mind, but also in behavior toward the world, which is specified by world-openness.

According to Scheler, the close relation between the environment and a living being is, in the case of human beings, abolished and transcended. For Scheler, man is the animal able to react to the world in such a world-open way; this means that man's reactions are not determined by the stimuli of his world. Scheler clarifies this with the linguistic distinction between living in and having a world: An animal lives in an environment; man has a world. To stand in (and live in) an environment means, for Scheler, to be determined by the natural stimuli. That man has a world means, in opposition to that, the ability to distance himself from this stimuli; man is able to free himself from these stimuli. This freedom derives from his mind (*Geist*). Mind is the ability to act in a world-open way. This refers to a double way of openness: First, it means that the pool of possible reactions to a stimulus is not limited by instincts. Second, it means that the world itself is open to humans because it is not limited by individual perceptibility. An animal can react only to stimuli that are perceivable by its sense organs. Humankind, in contrast, has a principally unlimited ability to perceive thanks to their technical equipment.

Hence, the technical culture abets for Scheler one of the main accomplishments of mind: the ability to objectify. Objectivation means, as Scheler puts it, to convert the centers of opposition into centers of objectivation. Thus, objectivation is the main activity of the human mind. According to Scheler, every living creature is an individuality, and therefore represents a self-limiting, ontological center. Accordingly, this self-limitation is nothing specific to humans, but concerns all living creatures. Yet, only humans are able to objectify themselves, thus constituting a person. To be a person means, according to Scheler, to transcend the antagonism of organism and environment.

It is interesting that Scheler locates the difference between man and animal in a different spot than contemporary biologists, as did (at that time prominent) Hans Driesch (1929). For Driesch, the essential difference lies between living creatures and nonliving things. For Scheler, the line of demarcation runs between living creatures (animals) and *persons* (humans) objectifying their environment, thus creating a world: The essence of man and what could be called his “exceptional position” stands highly above what is called intelligence and the ability of choice. Also, it would never be reached even if this intelligence and ability of choice were imagined as enhanced to any given measure, even to the infinite. It is therefore neither intelligence nor freedom of choice that constitutes the exceptional position of humankind, but rather humans’ special way of behaving toward their world. Scheler even goes so far to state that there is only a gradual, not a substantial, difference between a smart chimpanzee and Edison, if the latter is considered solely as a scientist.

This somewhat surprising statement coincides with Scheler’s view on whether or not it is legitimate to attribute some kind of intelligence to some groups of animals. Scheler answers this question in the affirmative, stating that not every accomplishment is to be explained by instincts and associative processes. On the contrary, Scheler attributes some kind of practical intelligence to some groups of animals by defining intelligence in the following way: A creature acts intelligently if it fulfills, without trying, a behavior in a new way, that is, neither a typical nor an individually specific situation independent from further attempts to solve a hormic determined task. In order to corroborate this hypothesis, Scheler affirmatively refers to the contemporary work of the German psychologist Wolfgang Köhler (1917), who illustrated in his highly regarded research that some kind of practical intelligence must be attributed at least to some anthropoids. Scheler agrees with this view, stating that in some cases, some of the animal’s acts are true acts of intelligence.

Nevertheless, in Scheler’s view, this is not an argument for an ethical equalization of man and animal. On the contrary, it shows that this difference is not found in intelligence capacities, but rather in man’s specific behavior, referred to previously, called world-openness. With this central concept of world-openness, Scheler expresses that the distinction between man and animal lies neither in their different capability of understanding, nor in their ability to fabricate tools, nor in man’s technological culture altogether. Rather, it is a different kind of behavior that discerns man from animal. This specific behavior is facilitated by man’s mind (*Geist*). According to Scheler, the principle mind is defined by this ability to dissolve from the organic bond.

Thus, mind, in Scheler’s anthropology, does not only refer to a cognitive capability, but also to humankind’s ability to put themselves outside the natural world. Thus, mind stands for Scheler outside the principle of life. With this statement, Scheler (1928) refers to a long tradition in the philosophy of mind in Germany. Unlike the later philosophy of mind, the former tradition focused on the question of how mind (*Geist*) relates to life. In Hegel’s (1807/1977) early philosophy, mind evolves from life just as it is the case in Schopenhauer’s

(1818/1966) philosophy of the will (to mention only two philosophers). On the other hand, there are philosophers such as Friedrich Nietzsche, Georg Simmel, and Ludwig Klages who claimed that the mind is opposed to life. Thus, when Scheler determines mind as a power standing outside natural life, he refers to this ongoing debate in Germany’s 19th-century philosophy. He rejects both what he calls the classical and the negative theory of mind. According to Scheler, the former theory claims that the cosmos is built in a way that the higher forms—from *materia bruta* up to divinity—are at the same time the more powerful ones. In opposition, the negative theory of mind claims that all the culture-building activities of humans derive from their negation of the natural world. Hence, according to the negative theory of mind, this negation is the real culture-building power.

Scheler rejects both competing theories of mind. According to Scheler, mind as an independent anthropological and metaphysical factor owns no power and activity at all; yet, contrary to this, the mind does own substance and laws but no original, owned power. Thus, the activity of mind consists in the negative act of constraining and at the same time directing the natural drives. To denominate the negative theory of mind, Scheler refers to Buddha, Schopenhauer, Sigmund Freud, and the German anthropologist Paul Alsberg. It is especially Alsberg, who has, in his book *The Mystery of Humankind* (1922), developed a theory of supercompensation in order to explain the specific biological configuration of human beings. Scheler refers to Alsberg’s work in order to affirm his position critically. According to Alsberg, the human mind is nothing but a surrogate for the insufficient adaptation to the natural environment. Humans lack prehensile feet, claws, coat, eyeteeth, and many other features. In order to compensate these naturally given deficiencies, humans switch off, or rather disconnect, their organs from the Darwinian struggle for life by using tools, language, and mental concepts instead. Thus, the so-called mind compensates or, rather, as Scheler puts it with regard to the Austrian psychologist Alfred Adler (1956), overcompensates it. With this affirmative reception to Alsberg’s theory of insufficient organic adaptation of humankind, Scheler puts forward one of the central points of philosophical anthropology: The lack of natural adaptation to the natural environment is compensated or rather overcompensated by some mental power, such as mind (*Geist*).

Scheler’s theory of mind in particular, and his philosophical anthropology in general, can thus be understood as a criticism of Darwinism. Insofar as the mind overcompensates the natural lack of human fitness, the principle of mind overrules and abrogates the Darwinian survival of the fittest. Thus, according to the main representatives of philosophical anthropology such as Scheler, Plessner, and Gehlen, the Darwinian rules are not generally applicable to the human world, and especially, to human culture.

However, this is not the only point in which Scheler criticizes Darwinism and biological anthropology. According to Scheler, mind cannot be objectified with any methods and therefore not with scientific methods. Mind is the only being that is itself unable to be objectified; it is pure actuality, and has its being only in the free execution of its

actions. In the same way, person is defined as a mere center of actions. According to Scheler, a person is nothing that can be objectified or subsumed under the categories of the natural sciences. A person, in Scheler's view, is a constellation of regulations, which means that a person is nothing substantial. A person consists in its actions and is nothing else but its actions. With this definition, Scheler develops a *radical nonsubstantial* view of personality. Personality is nothing else but a way to behave toward the world.

This specific behavior is further characterized as a form of ascetism. Ascetism means that humans are able to negate the real world as perceived by the senses. By virtue of this negation, humans are able to abolish the character of reality from the world; they are the animals that, by virtue of their minds, are able to behave toward their world in an ascetic way. Thus, the term *ascetism*, or ascetic behavior, does not primarily refer to a theological theory (although Scheler himself converted to Catholicism in 1899, and has since then avowed himself to the Catholic doctrine), but to a specific way of human behavior, as a central determination of anthropological theory.

This way of ascetism, as it refers to the specific way of mind-guided human behavior, could best be described as a second-order guidance. According to Scheler, mind relates to the animal drives in a twofold way: It blocks and deblocks them (*nonfiat* and *non nonfiat*). Thus, the regulation of drives brought about by the mind is based not on a suppression of these drives, but on the ability to behave oneself toward them. This is what Scheler means with his central concept of sublimation. Sublimation means, as Scheler explains with reference to Freud, that the hardware of lower energies is put into the service of the software of a more complex but powerless guidance.

According to Scheler, the main task of philosophical anthropology is to show how all activities and works of humankind evolve from this framework. Scheler has himself applied his anthropological theory to the fields of philosophy, sociology, and psychology.

Helmuth Plessner

In the reception of philosophical anthropology, Helmuth Plessner takes a somewhat exceptional position. After having stood in the shadow of Scheler and Gehlen for the longest time, the recent debate on anthropology in Germany is to a better part centered on Plessner's theory of the eccentric position of man. This might be due to the fact that Plessner's work shows, in an impressive way, that the anthropological reception of the concept of life aims toward founding a philosophy of culture on a comprehensive and layered organic model. This model was meant to contain approaches to a systematical unity of natural sciences on the one hand, and the humanities, especially philosophy, on the other.

Plessner studied both philosophy and biology. He attended Hans Driesch's lectures on medical science and zoology in Freiburg, Germany, and later changed to philosophy. Among his philosophy professors were the neo-Kantian Wilhelm Windelband and the phenomenologist Edmund Husserl. After having finished his professorial dissertation in

Cologne, he published works such as *The Unity of Senses* (1923) and *The Limits of Community: A Criticism of Social Radicalism* (1924). His main anthropological work is *The Stages of the Organic and Man: Introduction Into the Philosophical Anthropology* (1928). A political application of this theory appears in *Power and Human Nature: An Approach to the Anthropology of the Historical World-View* (1931). Under the National Socialist regime, Plessner was laid off because of his Jewish ancestry and had to emigrate to Turkey and the Netherlands, where he taught sociology. His highly regarded work, *The Belated Nation: On the Seducibility of the Civic Mind*, appeared in 1959.

Plessner's philosophical and sociological approach commits to biological science, in the sense that the empirical results apply to a theory of positionality, which explains the specific human behavior in culture, politics, and sociology. In the foreword to *The Stages of the Organic and Man* (1928), Plessner agrees to the characterization of Egon Freiherr von Eickstedt, who described Plessner's anthropological approach as biophilosophy centered on the position of man. In order to draw upon his philosophical anthropology, Plessner refers to biologists such as Lodewijk Bolck, Adolf Portmann, Hans Driesch, and Konrad Lorenz, to system theoreticians such as Ludwig von Bertalanffy, Erwin Schrödinger, and Nehemiah Jordan, as well as to neo-Darwinians such as Theodosius Dobzhansky and August Weismann.

Plessner states that the theory of humanities needs a philosophy of nature. But this reference to the philosophy of nature is not to be understood as a speculative reflection on the true character of nature and life in general, as undertaken by the idealistic philosophy of nature (e.g., Schelling and Hegel, but as a reflecting adaptation of the given empirical results of life sciences). At the same time, Plessner strongly rejects his teacher, Hans Driesch. Driesch's neovitalism claimed that life processes are not to be explained by physical or chemical analysis, but only by a factor called *entelechy*, which, according to Driesch, is made inaccessible to verification by the natural sciences. This vitalism ignores, according to Plessner, the interim development of the life sciences.

Plessner's central anthropological concepts, namely the eccentric positionality and the double aspectivity of life, reflect this more affirmative attitude toward the natural sciences. The double aspectivity of life refers to the fact that the principally divergent outside-inside relation characterizes living creatures. Thus, to be alive means to stand in and relate to this perpetual relation between inside and outside.

This double aspectivity shows, first and foremost, in the morphogenesis of creatures: The vital morphogenesis is as an autonomous, automorphic one to be contrasted with the dead one which is heteronymous, heteromorphic. With the term *vital morphogenesis*, Plessner refers to one of the most influential disciplines within early 20th-century psychology attempting to describe perception (in contrast to behaviorism) as a holistic process. Thus, by referring to this discipline, Plessner describes his theory of life as a specific, holistic phenomenon.

The exceptional position of creatures derives from their special behavior to their limits. Creatures are, according to

Plessner, limits actualizing bodies, which primarily means that the limits of the body belong to this very body itself. The body is its own and in this regard it is against the self and the other. From this, to be put against the environment derives the positional character or the positionality of the organic.

The determination of creatures as “limits actualizing” implies, according to Plessner, the ability to put itself at a distance. Every living creature is able to distance itself from itself. This ability is not specific to humans, but to all living creatures. The determination specific to human life lies in the term *eccentricity*. Whereas the life of the animal is centric, the life of the human is, without being able to break through this centering, eccentric. Eccentricity is the form characteristic for humankind’s positioning against the surroundings. Although Plessner does use the term *surrounding* instead of environment, it is quite clear that, even though he avoids using the biological term (environment), this theory has strong biological implications. Whereas every animal stands in and is centered within its environment, humans are able to transcend this centeredness by means of his reflection. This center of positionality is distant from itself: A human, as the living thing that is put in the middle of its existence, knows this middle, experiences it, and is for this reason beyond it. This means that humans do not have a natural environment, but instead they make their own surrounding. Placeless, timeless, put into nothingness, the eccentric life-form creates its own ground. Only insofar as this life-form creates it, it has ground, and is carried by it.

Here we have a conception very similar to existentialist theories of man. If, for example, Martin Heidegger (1927/1962) mentions that man is (in a very contingent way) thrown into the world, then the positions seem to be very similar on a first glimpse. (The same seems to be true for Sartre and Camus’s existentialism.) Yet, these existentialists consider themselves (and, in fact, are) strictly non- or antinaturalist thinkers. Even though they agree to Plessner’s point that there is no such thing as a given human essence, all of the mentioned existentialist thinkers do (despite their other diversities) in fact deny that biological research can add to the true knowledge of man.

Plessner refers in detail to Heidegger’s criticism. According to Plessner, the crucial point lies in Heidegger’s methodical primacy of the existence. This would imply (according to Heidegger) that the philosophical analysis of existence antecedes the biological analysis of nonhuman life-forms. Thus, the analysis of life would only be accessible by analysis of the reflecting entity. But even though humans *are* this very eccentric life-form, they remain animals from a biological point of view. Therefore, Plessner’s inquiry takes the opposite direction, as he explains in his annotations to his aesthesiology of mind: As long as humans are not understood as living forms of existence in their nature-grown way and are not submitted to a pre-empiric (i.e., not scientifically attached inquiry), they cannot hope to be above raised questions, such as which layers of the entity they stand in essential coexistence with and how they, as a life unity, have to experience themselves and the world in order to receive a comprehensive answer.

Plessner’s aesthesiology of mind aims at examining humankind as a personal life unity in all layers of his existence. The analysis of culture follows this examination and results from it. According to Plessner, three anthropological laws characterize culture: (1) the law of natural artificiality, (2) the law of mediated immediacy, and (3) the law of utopian place:

1. *The law of natural artificiality.* Man only lives insofar as he leads a life. This principle means, in Plessner’s interpretation, that man has to produce his own existence by means of culture. Thus, culture is understood as man’s distancing from natural liveliness. Plessner explains this artificiality as follows: As an eccentric creature not being in equilibrium, placeless, timeless standing in nothingness, constitutively homeless, he has to become something and create his equilibrium. This implies furthermore a criticism of the so-called naturalist-vitalist explanation of culture, according to which culture is the outcome of a vital climax as assumed by Friedrich Nietzsche (will to power), Georg Simmel, Alfred Adler, and others, most notably radical political tendencies (e.g., in the late 1920s, and early 1930s, emerging National Socialism). With reference to the latter, Plessner states that although the vital climax seems to celebrate orgies in favor of striving for power, it must not be made the foundation for the origin of culture; instead, it must itself be understood as a symptom of the eccentric positionality. Here, it becomes clear that Plessner tries to invent, with this concept of eccentric positionality, a truly fundamental law of human existence. At the same time, Plessner understands his theory of eccentricity as a criticism of the Darwinian theory of culture. According to Plessner, all of these mentioned theories lack a sufficient explanation of culture. Because this *vis a tergo* explanation has proven to be insufficient, we need, therefore, a *vis a fronte* explanation to explain human culture from his eccentric positionality.

2. *The law of mediated immediacy.* This second law points in a similar direction, but stresses more the aspect of communication, expressivity, and sociability. According to Plessner, every technical invention is an example for expressivity; it is an encounter of man and object. The inventor does not find something new; rather, he *expresses* what is already there. But the expressivity derives from the human necessity of expression and therefore from the eccentric positionality itself. This necessity is not only a personal-subjective need but also derives directly from this very fundamental law of human nature. Insofar as man stands in this twofold way toward his world, he despairs of his situation. This despair leads to the necessity of expression. According to Plessner, man expresses himself not because he is lonely or because he needs his fellow humans in order to survive, but because he despairs of his eccentric situation. Only by means of this expressivity can man become a *zoon politikon*—a social creature.

3. *The law of utopian place.* This law transfers the aforementioned determinations to the question of God and belief. Like Scheler, Plessner argues in favor of a theomorphism according to which man, despite his eccentric positionality or

rather because of it, is reliant on God for arranging himself in the world. His eccentricity puts him into an indissoluble conflict. His place is utopian, but at the same time he craves a *definitivum*. The eccentricity of his life-form, his standing in nowhere, and his utopian position force him to aim his disbelief of divine existence against the unity of the world.

Arnold Gehlen

Arnold Gehlen is commonly considered a very distinguished, yet controversial, anthropologist because of his conservative attitude and his attitude toward National Socialism. Gehlen studied philosophy, history of arts, and philology in Leipzig and Cologne. Influenced mostly by Max Scheler, Nicolai Hartmann, and Hans Driesch, Gehlen received his doctoral degree with Driesch, and in 1930 his habilitation degree with a phenomenological work. He then taught as a private lecturer in Leipzig. In 1933, Gehlen joined the National Socialist party in 1933 and was an active member until 1945. He taught philosophy, psychology, and sociology at the universities in Frankfurt, Leipzig, Königsberg, Vienna, and (after an only 2-year compulsory break) in Speyer and Aachen. Gehlen is not known to have been an anti-Semite but he undoubtedly used his membership in the National Socialist party in order to pursue his career goals.

After World War II, Gehlen was one of the leading figures in both philosophy and sociology. His theory of institutions has been very influential, just as his moral theory (*Moral and Hyper Moral*, 1969) and his philosophy of technology (*The Soul in the Technological Age*, 1957) have been. Gehlen's main anthropological work is *Man: His Nature and His Position in the World* (1940). This anthropological theory is at the same time the key to Gehlen's philosophy of culture, morals, and technology. For Gehlen, culture in general is an anthropo-biological concept.

This refers to Gehlen's central anthropological concept that determines a human as a creature deficient by nature. As mentioned above, this idea (but not the expression itself) can be traced back to Herder, but it is Gehlen who brings this concept together with the question of humankind's exceptional position. Gehlen explains that this exceptional position is closely linked to humans' deficient biological configuration. In opposition to Scheler, Gehlen interprets humankind's world-openness as a biologically determined openness of human actions, which is mainly determined by the fact that both men and women are unspecialized regarding their bodily organization and their instincts. According to Gehlen, humankind's morphological setup is mainly determined in an essentially negative way, namely by shortcomings that are, in an exact biological sense, to be characterized as nonadaptive-ness, and nonspecializedness as primitivisms (i.e., as something undeveloped). According to Gehlen, all of these shortcomings (lack of pelage, of escape and attack organs, but also the instinctive weakness and the long need for protection) are compensated and overcompensated by human culture.

To corroborate his theory, Gehlen refers to the contemporary biologists Driesch, Uexküll, Lorenz, Bolk, and others. Gehlen's concept of an anthropo-biological determination of

man implies that man's deficient bodily configuration needs to be seen together with his very complex and complicated inwardness. According to Gehlen, all former anthropological theories have failed because they ascribed specific human characteristics only to particular properties. In opposition to this, Gehlen tries to think man's deficient bodily configuration together with his determination of culture. Gehlen's central concept is exoneration. According to Gehlen, exoneration is a key concept of anthropology. Culture exonerates man from the biological necessities; it removes his burden. For Gehlen, man is a free being because his actions are free. But this freedom emerges from exoneration, namely the liberation from biological forms of behavior and fitness. In this sense, exoneration means that the concentration in human behavior falls increasingly into the "highest," namely the most effortless, only adumbrative functions—surely the conscious or mental ones.

This activity of condensation accomplished by consciousness takes place in the symbolic fields of viewing, speaking, and imagination that allow for a progressive indirectness of human behavior by reducing the stimulus overabundance to a minimum, but a minimum of highest potential developability. Hence, exoneration distances humans from nature, enabling culture and a cultural community. Consequently, Gehlen's concept of exoneration exhibits a deeply dialectic structure insofar as every exoneration must be seen, at the same time, as an additional burden because it inevitably detaches and thus alienates humans from nature.

One outcome of his theory of exoneration is Gehlen's concept of background satisfaction. It means that in higher evolved cultures, the satisfaction of human wishes and needs becomes durable and stable, and is thus displaced in the background in a twofold way: The satisfaction does not need to be conscious, and it does not need to take place in singular actions. The consciousness that the satisfaction of a need is possible at any time we call background satisfaction, whereupon, in the extreme case, the suppositional need does not transfer into an action-positioning actuality.

Thus, Gehlen's concept of background satisfaction is a central element of his theory of institutions. For Gehlen, the freely acting position of man is the main fact of human existence. But according to Gehlen, institutions mainly facilitate this freedom. On the other hand, the allegation cannot be dismissed that Gehlen's determination of human existence results in an apologetic justification for existing institutions. This conservative and apologetic attitude has brought him many criticisms from other philosophers.

Conclusion

After its foundation through Scheler, Plessner, and Gehlen, philosophical anthropology in Germany has become one of the most regarded disciplines in the academic community. It also plays an important role in contemporary pedagogic theories. In an ongoing, rivaling debate with existentialism, many philosophers and biologists have managed to outline an up-to-date framework for a philosophical theory

of humankind that tries to examine and evaluate its special (deficient) biological configuration, its ability to build a culture, and its exceptional position in the world.

One of the most quoted anthropologists is the Swiss biologist Adolf Portmann. He has coined the phrase “extra-uterine early year.” According to Portmann (1944), a newborn human is unfinished and needs, compared to other animals, to catch up on the individual evolution in his or her first year on earth. Thus, the human being is a “secondary nidicolous bird.” Portmann has, in his books and also in many popular articles, tried to make this theory known not only in the academic field but also among the nonacademics.

Ernst Cassirer conceptualized a theory of man based on his cultural philosophy. According to Cassirer (who also refers to the biological works of Uexküll), the exceptional position of man is characterized by his ability to write forms. With this determination, Cassirer applies his philosophy of symbolic form to an anthropological theory. Only man is able to build and to understand (symbolic) forms. Especially in his work *An Essay on Man* (1944), Cassirer outlines this anthropological theory of symbolic forms. The philosopher Josef König (1937) established a theory of a Hermeneutic logic in which the anthropological aspect (determination of man's position in the world) plays a central role.

The neediness of man is also the central building block of Wilhelm Kamlah's anthropology. Kamlah (1972) understands this neediness not only as a biological determination but also as an ethical one. The insight that one's fellow humans are needy creatures summarizes for Kamlah the practical fundamental norm of his moral philosophy and ethics.

Based on the cultural theory of Georg Simmel, the Jewish philosopher Martin Buber (1923/1958) evolved a dialogical anthropology. The central category of this dialogic is the between that actualizes in the encounter of “I” and “you.” Buber's dialogical philosophy sees the existence of man in two different relationships: I-it and I-you. Whereas the former is the regular, all-day relation to the (natural or cultural) environment, the latter is the central category of encounter in which everybody manifests all of their essence. For Buber, this encounter of I and you is only possible because a dialogue between man and God is possible.

VALUES AND ANTHROPOLOGY

RICHARD R. JONES

Lee University

What is the significance of the work done in anthropology? What are the unique contributions of anthropology to science and to the humanities? What principles, ideas, and practices guide the practice of anthropology? Why is it important to continue to do research in anthropology?

The answers to those questions frame what is important about anthropological work. They also highlight the contributions of anthropology to humanity and provide good reasons for continuing to do anthropological work. This chapter will summarize some answers to those questions and demonstrate that anthropological inquiry is an important human activity guided by core principles, ideas, and practices, and that has contributed significantly to science and the humanities, and further, that there are good reasons for continuing to do the work that anthropologists do.

Early anthropologists grounded the study of humanity, that is, anthropology, within the developing philosophies and methods of science in the 19th century. So, it will be necessary to briefly survey how the discipline emerged from the scientific thinking of that time. After that, a series of topics related to the philosophies and methods of science will be covered to illustrate the value of those philosophical perspectives and methods. Then, some of the major concepts, ideas, and methods of anthropology will be discussed. Finally, various contributions of the subfields of anthropology will be covered,

followed by a few comments on the future and continuing importance of anthropology.

Early Anthropology

Anthropology in the 19th century developed as an extension of important and successful work then being done in the “natural sciences,” and was given further impetus by the colonialism of various nations, and by the westward expansion of the United States. While it is true that anthropology has sometimes served the political interests of various governments, that aspect of the discipline will not be covered here. Regardless of how anthropology may have been—or is—involved in Western colonialism, there remains a philosophical, scientific, and humanistic dimension to anthropology that—independent from politics—seeks to understand what it means to be human.

Scientific investigations of the 19th century typically involved collecting and categorizing large volumes of information about the world, and, from that information to then construct explanations, that is, theories, for why the world is the way it is. In 1833, Charles Lyell (1797–1875) wrote *The Principles of Geology: Being an Attempt to Explain the Former Changes of the Earth's Surface by Reference to Causes Now in Operation*, the title of which illustrates well the goals of the Victorian scientists who sought to observe the world and then to explain it in terms

of those observations. Lyell's work influenced that of Charles Darwin (1809–1882), whose investigations as a naturalist aboard the HMS *Beagle* from 1831 to 1836 led to the publication of *On the Origin of Species by Means of Natural Selection* in 1859. The observations and botanical and faunal collections that Darwin gathered during his time on the HMS *Beagle* resulted in a proposed explanation for why life varies as it does and how new varieties of life can emerge. Astronomers, in the 18th and 19th centuries, discovered the planet Neptune, and began to systematically catalogue the objects in the heavens. Friedrich Wilhelm Herschel (1738–1822) discovered the planet Uranus and two moons of Saturn, and he contributed significantly to the theoretical understanding of the universe and to cataloging other astronomical phenomena. In chemistry and physics of the 19th century, fundamental discoveries were made about the nature of matter and energy and their interaction. It seems inevitable that any scientific investigation into humans would follow the patterns already established in other academic disciplines, and that is exactly what happened.

Some of the earliest anthropological works that adopted methods similar to other disciplines and that take a scientific approach to the study of humans are *The League of the Ho-de-no-sau-nee or Iroquois* (1851/1922), *The Indian Journals 1859–62* (1959), and *Systems of Consanguinity and Affinity of the Human Family* (1870/1997), all by Lewis Henry Morgan (1818–1881). *The Indian Journals* was first published in 1959 from a collection of Morgan's papers, edited by Leslie A. White. *The League* is a fairly detailed ethnography that surveys politics, religion, dancing, games, kinship, and other aspects of the Iroquois culture; *The Indian Journals* consists of miscellaneous notes that Morgan took during his travels from 1859 to 1862, which record whatever cultural and linguistic information he had access to and that he had time to record; *Systems* is an impressive compilation of kinship-system terminologies sampled from cultures all over the world and an analysis of that data.

The scientific approach of gathering data, looking for patterns, logical analysis, and suggesting explanations are found throughout Morgan's work, but are, perhaps, best exemplified in the three sources just given. Clearly, Morgan is trying to systematize the study of humans in a way similar to the way that other academic disciplines of the time did their work. In fact, this effort to make humanity the focus of scientific study during the 19th century marks the beginning of a significant shift in how humans perceive themselves in the world. Up to that time, at least in the Western world, humans primarily thought of themselves as separate from nature. Anthropological inquiry in the 19th century began to understand humanity as a part of nature, and just as amenable to objective, scientific study as anything else. Anthropology changed the place of humans in the universe.

This scientific approach to the study of humanity pervades the literature of early anthropology in the late 19th to

early 20 centuries. Herbert Spencer (1820–1903), in an 1860 essay titled *The Social Organism*, suggested that human societies can be understood analogically as living organisms (McGee & Warms, 2008, pp. 11–27). This, undoubtedly, was an effort to apply the recent successes of evolutionary theory in biology to anthropology. Even more transparent is Sir Edward Burnett Tylor's (1832–1917) two-volume *Primitive Culture* (1871), the first chapter of which is called "The Science of Culture." It is not necessary to give an exhaustive listing of examples, but a few other early writers and works of note are: Marcel Mauss's (1872–1950) *The Gift* (1925/1967), Émile Durkheim's (1858–1917) *Rules of the Sociological Method* (1895/1982), and Lucien Lévy-Bruhl's (1857–1939) *Primitive Mentality* (1922/1978).

Of course, it must be mentioned that the values and overall approach to anthropology were significantly shaped by the work of Franz Boas (1858–1942). Boas argued for recognizing four different subfields in anthropology: prehistory (archaeology), linguistics, physical (biological) anthropology, and cultural (social) anthropology (McGee & Warms, 2008, p. 118). He also trained other influential anthropologists, such as A. L. Kroeber, Ruth Benedict, Margaret Mead, and Edward Sapir. His influence has been pervasive in anthropology. His scientific approach led him to reject race as a determining factor in cultural development (McGee & Warms, 2008, p. 119). In this, he was ahead of his time.

Early anthropologists sought to establish their discipline within the larger framework of scientific thought and research. The goal was to establish a science of humanity that would generate a particular kind of epistemology, or body of knowledge, that would lead to a better understanding of and appreciation for what it means to be human. Of course, there are other epistemologies—other ways of "knowing" humanity. Art, poetry, narrative literature, music, philosophy, and theology all suggest ways to know various aspects of the human experience. Science, however, offers an approach that transcends and subsumes those other epistemologies and subjects them to analysis within a larger context. The resulting "scientific perspective" has positively contributed to an understanding of and appreciation for humans and human behavior over the last century and a half in anthropology.

Anthropology as Science

Anthropology is sometimes described as a science and sometimes as one of the humanities. In fact, anthropology programs are located in a variety of departments across colleges and universities in the United States, usually depending on the subfield of anthropology that is being emphasized. Anthropology is probably best understood as both a science and as one of the humanities, with the former perspective philosophically subsuming the latter. There are, however, anthropologists who question whether

or not it is possible to apply the scientific method in some aspects of anthropological research.

J. T. O'Meara (1989), in an article titled "Anthropology as Empirical Science," asserted the value of an empirical approach for the study of human behavior. He refutes the claims of those who suggest that because much of human experience is subjective that the scientific method is inapplicable. Concerning the idea that the study of humans can only be done by subjective interpretation instead of by the scientific method, he concludes as follows:

While these arguments contain important observations concerning the difficulty of acquiring knowledge of human affairs, their conclusions are unnecessarily extreme, being largely based on overstatements and misunderstandings by both science advocates and their interpretive critics. (O'Meara, 1989, p. 366)

Pierre Bourdieu also sees the value of maintaining a scientific approach in anthropology. In *Outline of a Theory of Practice* (1977), Bourdieu suggested that "third-order knowledge" can be derived from both the objective (i.e., scientific) and subjective aspects of human phenomena (p. 4). As an example, he describes the differing explanations of gift exchange offered by Marcel Mauss and Claude Lévi-Strauss. Mauss's explanation is described as phenomenological, that is, a subjective explanation; Lévi-Strauss's explanation is that of an objective observer outside, looking in, positing a mental principle that governs the practice. In this example, Bourdieu suggests people who have some freedom to manipulate the system act upon both the objective and subjective aspects of gift exchange (pp. 5–8). It is in the interplay between model (objective), meaning (subjective), and practice (the actions of people) that the explanation of human behavior is found. The scientific, or objective, perspective is an essential component in Bourdieu's theory.

In June 2002, the *American Anthropologist* published a Special Centennial Issue that contains an article by Susan Trencher titled "The American Anthropological Association and the Values of Science, 1935–70." In it, Trencher concludes, "Despite differences in time and circumstance, the position of anthropologists as articulated through the AAA in the 1930s through 1970 . . . was that anthropology is a science" (2002, p. 459). Of course, in the same passage, she is careful to point out that there is a great deal of variation in "research, methods, practice, professional responsibilities, and ultimately ethics" (p. 459). Those observations also seem to apply to anthropology from 1970 to the present.

The origins of anthropology are rooted in science, and anthropology continues to remain a scientifically oriented discipline. The fact that the methods and theories of anthropologists are subjected to constant critique and analyses is, itself, evidence of a scientific approach, which by its very nature, must be introspective and self-evaluatory.

Value of Science

What is meant by a scientific approach? What is gained from a scientific perspective?

A scientific approach uses the scientific method to construct a body of knowledge about things in the world and an understanding of that knowledge. In the case of anthropology, humanity is the object of the study. To do this, the scientific method employs a number of underlying philosophical assumptions that systematize the method and the knowledge it produces. In other words, the body of knowledge generated by the scientific method is framed within a set of assumptions and principles that exclude some ways of knowing, which, again, does not mean that such other "unscientific" ways of knowing are unimportant.

One important philosophical perspective underlying the scientific approach is that the world can be perceived and measured by observations through our senses. This idea is called *empiricism*. Another perspective is the assumption that the observable natural world and natural processes are the only legitimate focus of the scientific method. This idea is called *naturalism*. Empiricism and naturalism limit the accumulation of scientific knowledge to those things in the natural world that are observable and measurable by anyone. Consequently, the validity of scientific knowledge can be established through repeated observations and measurements.

In addition, the scientific method involves the formulation of hypotheses and the testing of the explanatory success of those hypotheses by gathering additional research data. Thus, scientific knowledge is constructed over time through a dynamic process of hypotheses formation and testing, and data collection that eventually results in the acceptance of theories, which are hypotheses that continue to be successful in explaining and incorporating new data.

So, what is gained from a scientific approach?

While it is true that there are ways of understanding the world that are not scientific, such as in religious cosmologies, there are advantages to the scientific approach, which make it more useful, in many ways, than other epistemological approaches.

Scientific knowledge consists of data that can be verified by other researchers. Scientific research is performed under the scrutiny of a scientific community. Also, scientific conclusions and interpretations are subject to revision in the light of new data. These three things—validity through verification, social accountability, and the constant evaluation and revision of theory—generate a body of knowledge about the world that is objective. Such a body of knowledge in anthropology has been useful in applied areas such as forensic anthropology, medical anthropology, and business anthropology. The scientific approach in cultural anthropology has also been successful in describing and explaining a great deal of the behaviors manifest in political organizations, economic systems, religious beliefs and behaviors, and kinship systems.

In anthropological archaeology, the scientific approach has helped to reconstruct the social history of humanity. In linguistic anthropology, we have come to better understand the social complexities of language and the relationship of language to culture. Finally, in biological anthropology, we have achieved a sophisticated understanding of human origins, human diseases, and human genetic structure.

It is doubtful that a nonscientific approach would have achieved any of these significant discoveries and contributions.

Value of Reason and Logic

Reason, which is our capacity for various kinds of analytical thought, and logic, which is a type of analytical thought, guide the construction of scientific knowledge in anthropology. The application of a general ability to reason and the ability to apply a systematic method of logic are two important characteristics that separate science from pseudoscience. For example, there are some popular writers who suggest that the Egyptian pyramids, or other ancient monuments, could only have been built with the help of extraterrestrial beings who visited the earth in the past. On close examination, however, it is easy to see that the actual archaeological and historical evidence cannot support their hypothesis. Their argument rests on faulty assumptions, biased data selection, false logical premises, and false conclusions. They fail to reason appropriately across the data, and then derive premises from their faulty reasoning, which they then insert into the forms of logical argumentation. Of course, such an approach precludes any hope of successfully arguing to any reasonable conclusion.

Archaeological and historical sources reveal that the pyramids in Egypt are associated with a number of ancient rulers. Burial artifacts, associated funerary temples, hieroglyphic texts on the walls of some chambers in some pyramids, and other monuments clearly indicate that the pyramids were tombs intended for ancient Egyptian rulers. In addition, there are some hieroglyphic depictions of exactly how the ancient Egyptians managed to move large blocks of stone, huge stone statues, and obelisks. On the water, they moved these objects with barges. On land, they did it with sleds, rollers, a little lubrication, and a lot of people pulling with ropes. A reasoned assessment of the data must conclude that ancient humans built the pyramids for the purpose of burying their rulers. From this data, we can make many valid, logical inferences about the social structure and economy of ancient Egypt. This kind of reasoned approach, which does not make unwarranted assumptions and that incorporates all the empirical data, is able to successfully employ logical analysis to further our understanding.

On the other hand, the pseudoscientific approach begins by making the unwarranted assumptions that extraterrestrials are real and that they have visited earth. Neither assumption is demonstrable. Before someone can reasonably

claim that a picture on an ancient object represents an extraterrestrial or its spaceship, it must first be demonstrated that such things are real—by discovering an extraterrestrial's body or spaceship. After all, archaeologists have the mummies of pharaohs, so we can reasonably be assured that pharaohs are real, but the same thing cannot be claimed for extraterrestrials. Therefore, the only reasonable and logical conclusion is that pharaohs, not extraterrestrials, built the pyramids.

In anthropology, all the different theoretical approaches recognize the value of reason and logic. Reason and logic give coherence to our scholarly efforts and enable the sharing of knowledge. Reason and logic also provide a basis for the comparison and evaluation of different concepts and theories. Consequently, the ability to think in a reasoned and disciplined way and the ability to logically analyze research data are important skills that must be mastered by the anthropologist.

Value of Concepts, Ideas, and Comprehensiveness

From its very earliest years, anthropology has aspired to be comprehensive in its understanding of humanity. Every aspect of what it means to be human is considered as a possible focus of inquiry. Anthropologists look at the past, the present, and the future of humanity. They explore the biological, psychological, social, and linguistic aspects of humans. Anthropologists have studied art, literature, music, material culture, philosophy, theology, genetics, and a host of other subjects. Neither do anthropologists restrict themselves solely to a Western perspective. The comprehensive nature of anthropology makes it unique among the academic disciplines, which is probably why the general public usually has a difficult time grasping exactly what it is that anthropologists do. In spite of the breadth of the discipline, there are some key concepts and ideas that have emerged in anthropology that structure the discipline as a whole.

Some important concepts and ideas in anthropology have made their way into modern intellectual discourse across a number of academic disciplines. Perhaps the most significant and widespread of those is the concept of *culture*.

While it is true that there are many definitions of culture in anthropology and that no one definition is generally agreed upon, the concept of culture has proven to be extremely useful in framing the discussion of differences between human societies. Culture is a synthetic idea that is derived from the observation of a variety of human beliefs and behaviors. That is, culture is an abstraction that is inductively reasoned from the sum total of beliefs and behaviors that characterize a group. The concept of culture captures that characterizes a group. The concept of culture captures and expresses the complex and integrated nature of human social interaction within a group, and the concept of culture keys into two other important and closely related ideas.

The first of these ideas is the *holistic perspective*, which is the idea that everything in a culture is interconnected and that in order to study or know another culture, one must, as much as possible, look at everything. This idea causes anthropologists to eschew methods with too narrow a focus in the study of humanity, and to advocate methods that embrace all aspects of social life in a group. Essentially, the holistic perspective calls for an integration of knowledge from all four subfields of anthropology. Some anthropologists observe, however, that anthropology has failed to achieve this perspective. Robert Borofsky, in a survey of 3,264 articles published in the *American Anthropologist* from 1899 to 1998, found that “only 9.5 percent of the articles in AA bring the discipline’s subfields together in significant ways” (2002, p. 463). While it is the case that very few of the journal articles published in the *American Anthropologist* demonstrate collaboration across the subfields of the discipline, it would be hard to conceive of archaeological projects that do not draw upon sociocultural anthropology and biological anthropology; or cultural anthropologists that would not find knowledge of sociolinguistics useful. Much of the collaboration across subfields is more implicit than explicit, but there are some shining exceptions. For example, anthropologists from all four subfields produced the American Anthropological Association’s *Statement on “Race”* (1998).

The second of these ideas connected to the concept of culture is *cultural relativism*, which is the idea that one culture’s way of doing things is just as valid as another culture’s way of doing things, and that we must suspend our own culturally based moral judgments in order to effectively study another culture. This perspective helps create a level playing field, morally and ethically, for the objective study of another culture.

Finally, the concepts of *ethnocentrism* and *ethnicity* shape the way in which anthropologists think about cultural bias and identity. Ethnocentrism is the belief held by all human beings that their particular way of doing things, beliefs, and knowledge are the best or most correct. Understanding that everyone is this way is the first step toward overcoming this bias in ourselves and to seeing past it in others. This commitment by individuals to a particular cultural perspective is an important part of how we locate and identify ourselves in the world and in relation to others. Ethnicity is the idea that the identity of a social group within a culture is socially bounded and that these social boundaries and identities persist through time. Ethnic groups are biologically self-perpetuating social groups identified by themselves, and by others, as members of that group, whose community comprises a network of communication that is socially bounded by marriage practices and other social prohibitions and prescriptions, and whose identity and social boundaries persist despite the occasional movement of people across the social boundaries, such as through marriage, leaving the community, adoption, and so on. (For more information on this topic, a key source is

Frederik Barth’s *Ethnic Groups and Boundaries: The Social Organization of Cultural Difference* [1969/1998]).

The concept of culture, the holistic perspective, cultural relativism, ethnocentrism, and ethnicity are important concepts and ideas in anthropology. The principles and perspectives derived from these shape and guide the work that anthropologists do.

Value of an Evolutionary Framework

As discussed at the beginning of this chapter, evolutionary thinking profoundly influenced the work of early anthropologists, such as Louis Henry Morgan, Herbert Spencer, Edward Burnett Tylor, and others. Also, despite the fact that in the 20th century most cultural anthropologists, from Franz Boas on, have strongly rejected the application of the theory of evolution to explanations of culture change, evolutionary thought remains both useful and in some ways necessary to the study of social and cultural change.

It is true that the early unilineal evolutionary models, such as Morgan’s seven stages of cultural evolution presented in his *Ancient Society*—lower, middle, and upper savagery; lower, middle, and upper barbarism; and civilization—are deficient in that they make sweeping generalizations that fail to explain the variation of cultures in similar environments. However, the theory of evolution is still useful for understanding some aspects of social and cultural evolution. For example, looking at the big picture, human biological evolution and cultural evolution are clearly connected. The technological and social characteristics of Lower Paleolithic culture are manifestations of evolutionary processes—natural selection, genetic mutation, gene flow—on genetically diverse early hominids in central East Africa. The ability to manufacture Oldowan and Acheulean stone tools, to cooperate in hunting, and to live together in social groups are all adaptations brought about by the evolutionary pressures exerted on our early ancestors. Likewise, the cultural changes from the Lower Paleolithic to the Middle Paleolithic correspond to selection pressures acting on genetically diverse populations of *Homo erectus*. Middle Paleolithic Neanderthals are not only biologically different from *Homo erectus*, but their toolmaking skills and cultural behaviors differ, as well. And, finally, the cultural changes associated with the transition from Middle Paleolithic to Upper Paleolithic occur alongside the biological changes associated with the transition to anatomically modern humans. Evolution may not be able to provide a theory of culture, but the evolution of humans and the development of cultures are intrinsically connected.

The theory of evolution provides a way of understanding change. Over time, everything changes: biology, society, culture, and language. The theory of evolution not only clearly helps us understand the biological changes from early hominids to modern humans, but also, by metaphorical extension, it can be useful for talking about society,

culture, and language. Concepts like natural selection, adaptation, and gene flow can be used to help organize our thinking on those topics. Phrases like “genetically linked languages” and “cultural adaptations” are examples of this kind of metaphorical extension.

In terms of the holistic perspective, evolution is the large theoretical framework within which the scientific study of humans must articulate.

Value of Comparative Methods

One of the best and earliest examples of the application of the comparative method in anthropology is Lewis Henry Morgan’s *Systems of Consanguinity and Affinity of the Human Family* (1870/1997), which surveys 196 kinship categories in 39 languages in Table I (pp. 79–127) and 268 kinship categories in 80 languages in Table II (pp. 293–382). From this large body of data, Morgan was able to discern that all kinship terminology systems were reducible to just a few types. This book laid the foundation for the study of kinship systems in anthropology.

The idea of studying another culture in order to learn about our own is also an important aspect of the comparative method that shows up regularly in the work of anthropologists. Margaret Mead studied Samoan culture in the 1920s because she was interested in adolescence in her own culture. By looking at the transition from childhood to adulthood in Samoa, she hoped to shed some light on that process in Western culture. In a similar way, Bronislaw Malinowski (1922/1961) tried to make the practices and beliefs of the Trobriand Islanders comprehensible by showing that the way we do things is very similar to theirs. For example, he compares native sentiments toward the objects of the Kula trade as being just like British sentiments toward the crown jewels:

Every really good Kula article has its individual name, round each there is a sort of history and romance in the traditions of the natives. Crown jewels or heirlooms are insignia of rank and symbols of wealth respectively, and in olden days with us, and in New Guinea up till a few years ago, both rank and wealth went together. (Malinowski, 1922/1961, p. 89)

Indeed, plentiful examples of comparisons of our culture to other cultures are to be found throughout the ethnographic literature.

George Peter Murdock (1897–1985) established the Cross-Cultural Survey in 1937, which was a project to collect ethnographic information for the purposes of comparison. In 1949, the project, with funding from the Social Science Research Council, became the Human Relations Area Files (HRAF). Today, there are two databases in the HRAF collection: the *eHRAF Collection of Ethnography* and the *eHRAF Collection of Archaeology*. These databases are maintained at Yale University and can be accessed by members online.

The comparative method is a key element of the ongoing ethnographic and theoretical work in anthropology.

Cross-cultural comparisons give us insight into some common patterns of human behavior, such as kinship-classification systems. They give us insight into the relationships between different classes of patterns, such as correspondences between residence patterns and economic systems. They give us insight into the relationships between behavioral patterns and the environment, such as correlations between certain religious beliefs and the ecology of where people live. The comparative method makes it possible to see through the diversity of humanity to the things that collectively define us as human.

Value of Theoretical Models

Clifford Geertz’s *The Interpretation of Cultures* (1973) seemed, at the time, to herald the end of theory in ethnographic work. Every culture was to be rendered in “thick description” and that is all that could be done. Every culture was viewed as a unique set of integrated symbols and behaviors that could not be compared to those of other cultures. Coming to the end of the 20th century, at least in cultural anthropology, theory seems to have disappeared in ethnography. The functionalism, structure and function, and structuralism that permeated the ethnographic work of early to mid-20th-century cultural anthropologists had been criticized and rejected. In other areas of anthropology, however, the development of theory has persisted. Archaeology and biological anthropology, in particular, have continued to work on theories related to the origin of the state, the origin of food production, social stratification, the evolution and adaptation of human ancestors, and much more.

Cultural anthropology has, however, turned back to theoretical constructs in order to extend its work beyond just description. The work of Bourdieu has been influential in this regard. Bourdieu’s *Outline of a Theory of Practice* (1977), while criticizing traditional theory in anthropology, offers an alternative theoretical approach that links objective structures to the practices of people.

The construction of theoretical models is an important part of the scientific method. Such models reason across the data, linking it together in a logical fashion that results in some degree of explanatory adequacy. Collection of data and exhaustive descriptions of that data can only be a prelude to the proffering of an explanation.

Theoretical models also give us a basis and a framework for asking new questions, which can further extend our knowledge. Theory also gives us a common intellectual space within which to converse with each other. Theory is essential to practicing the science of anthropology.

Value of Relevance and Application

There are some anthropologists who view the work of anthropology as valuable in its own right, and the pursuit

of knowledge for the sake of knowledge. On the other hand, there are some who believe that the work of anthropology should be relevant to human concerns and have an applied component. Anthropologists who lean more toward the first view fear that the knowledge possessed by anthropologists could be used by governments or by others to cause harm to people, while those who lean toward the second view argue that the same knowledge could be applied to benefit people. Most anthropologists probably believe in both views to one degree or another.

It is true that many anthropologists are privy to sensitive information about the people they study and that anthropological knowledge could be used to manipulate people. Even so, it is also clear that similar observations could be made about other academic disciplines as well. Journalism, political science, and biology, to name a few, have the potential for causing human harm as well as providing human benefit.

As a result of the tension caused by these two views in anthropology, applied anthropology has taken a little longer to become prominent than otherwise would have been the case. Today, business anthropology, as well as forensic anthropology and medical anthropology, have achieved some status in the discipline and there are good graduate programs for their study.

The development of applied anthropology is a natural outcome of anthropology done as science, because, in addition to gaining knowledge and understanding the world, science seeks to solve problems through the application of that same knowledge and understanding.

Anthropological knowledge is both relevant and applicable to the world in many ways. Archaeologists, practicing cultural resource management, act as the conservators of our cultural heritage. Cultural anthropologists, who advocate for the human rights of the groups they study, use their knowledge to achieve moral and political goals. Anthropological linguists, who apply their knowledge to the teaching of social aspects of second-language acquisition, make important applications of anthropological knowledge that meet educational needs. Biological anthropologists working in forensics apply anthropological knowledge to serve human needs in law and justice.

Anthropology has a great deal to offer humanity. The formal recognition and practice of applied anthropology has come about only relatively recently in the discipline—in about the last 30 years. Over time, the effect of applied anthropology will undoubtedly increase. This will probably bring about changes within the discipline itself, especially as to how anthropology is taught, and where anthropologists will be employed.

Value of Ongoing Research

What follows is a brief overview of some contributions that have been made in various areas of anthropology:

biological anthropology, archaeology, sociocultural anthropology, linguistic anthropology, and applied anthropology. The list is certainly not exhaustive, but it does highlight some of the ways in which the product of anthropological research and knowledge has social and scientific value.

Biological Anthropology

Forensic anthropology is enjoying a great popularity today as a result of books, movies, and television shows in which the characters rely upon forensic science to resolve their plot conflicts. While most pop-culture examples of forensic science and forensic anthropology are highly exaggerated, there are real forensic anthropologists whose work has made valuable contributions to law enforcement. Clyde Snow is a forensic anthropologist of note who has worked at mass graves in Central and South America and in the former Yugoslavia to identify the remains of war crime victims. William Bass, who founded the Body Farm at the University of Tennessee in Knoxville, is probably one of the most well-known forensic anthropologists. His book *Death's Acre* (2004) tells the story of how the Body Farm—a laboratory for the study of the decomposition of human remains—came into being. The book also relates some of Bass's most notable forensic cases.

One of the most astounding accomplishments in the last century, and, perhaps, one of the greatest scientific accomplishments ever, is the completion of the Human Genome Project, which was completed in April 2003 (National Human Genome Research Institute, 2009). The Human Genome Project produced a complete map of the human genetic sequence. This genetic map has, in turn, stimulated a lot of further research, especially in medicine, that could not otherwise have been done. Many biological anthropologists participated in this effort.

Archaeology

In the United States and around the world, archaeologists continue to be agents of the discovery and preservation of the past. Archaeologists and archaeology organizations are active in lobbying for changes in the law for the purpose of protecting archaeological sites and artifacts, and some archaeologists are even active in law enforcement, as, for example, archaeologists who work for the Parks Service or for the U.S. Forest Service. Professional archaeologists play a key role in protecting our historical heritage and in helping to understand and appreciate it.

Early in the 20th century, when the Tennessee Valley Authority (TVA) began building dams in the southeastern United States, archaeologists undertook the enormous task of surveying and identifying archaeological sites and excavating those that were considered most important. Their efforts recovered enormous amounts of data and material that otherwise would have been lost forever. The same thing happened in other parts of the United States, at about

the same time, as dam building for flood control and power generation spread across the country's major watersheds.

Archaeologists are also involved in museums as curators of important cultural knowledge. In addition, archaeologists teach at a large number of colleges and universities. Being positioned in museums, and in higher education, means that archaeologists have both visibility and influence. The past can help us make decisions for the future and archaeologists play a role in passing on important culture knowledge.

Sociocultural Anthropology

Anthropologists who study contemporary societies and their cultures have developed very sophisticated theories about power and power relations, social stratification, ethnicity, religion, kinship systems, economic systems, and subsistence patterns, among other things. They have generated a huge body of ethnographic material, much of it in databases such as the HRAF. This huge body of literature alone is an incredible accomplishment that has yet to be fully mined for its total value.

One of the greatest accomplishments and contributions of sociocultural anthropology has been the advocacy of anthropologists on behalf of the people they have studied. Perhaps it goes a bit beyond a strictly scientific approach to practice any kind of moral advocacy for another group, but anthropology is also one of the humanities in the sense that anthropologists, as human beings, are aware of a moral responsibility to others. Many ethnographers have gone on to act as political advocates for the people they have studied. Others have even helped with development projects in the communities in which they have worked. A lot has been written about anthropologists and advocacy. A good starting place for examining this literature is an article by Samuel R. Cook (2003) that takes a look at the positive aspects, as well as the challengers, of advocacy by anthropologists working with Virginia Indians.

Linguistic Anthropology

Many contributions by linguistic anthropologists are more abstract than concrete, but no less important. Linguistic anthropologists have looked at important social issues and have examined the linguistic phenomena associated with them. For example, language plays a role in racism, as well as in sexism. They have also contributed a better understanding of language and identity issues, especially in the case of dying languages, and in attempts to restore languages.

In the 1950s and 1960s, Linguist Joseph Greenberg (1915–2001) sorted out the relationships among the languages of Africa, and classified them into four major groups. He also worked on classifying the Pacific and Native American languages. Though his later work was somewhat controversial, his earlier work with African languages has “become the basis for virtually all subsequent

treatments of the continent and its culture (pre)history” (Silverstein, 2002, p. 632).

Applied Anthropology

The category of applied anthropology usually refers to business, forensic, and medical anthropology, but is not limited to these. Each of the subfields discussed in this section has applied areas; some were discussed, such as forensic anthropology in biological anthropology, but there are others, such as contract archaeology and applied linguistics. Business and medical anthropology are types of applied sociocultural anthropology.

Business anthropology and medical anthropology have proven to be productive areas in applied anthropology. The full impact of applied anthropology on business remains to be seen, but there are a fairly large number of anthropologists who work as consultants in this area. There already exists an immense literature in anthropological publications and in business publications about business anthropology.

Medical anthropology has at least two peer-reviewed journals. The first is called the *Medical Anthropology Quarterly*, published by the American Anthropological Association on behalf of the Society for Medical Anthropology. The second is called *Medical Anthropology: Cross-Cultural Studies in Health and Illness*, published by the University of Lethbridge.

Future Directions

As technology allows us to handle more and more information in newer and more creative ways, the holistic perspective of anthropology will, no doubt, develop a clearer view of humanity, and in ways that are not yet possible. In turn, applied anthropologists will find more ways to use anthropology to serve human needs and to solve human problems. Already there are steps in this direction. Just to mention two, the growing eHRAF files, and the relatively new *AnthroSource* database, which has over 100 years of anthropological publications, are changing the way in which anthropologists do anthropology. In the future, anthropologists will be able to handle more information in even shorter amounts of time than is possible now.

Despite the technological innovations that will speed up and expand some aspects of work in anthropology, there will still be a need, maybe even greater than before, to keep the discipline centered on science and its core concepts, ideas, and values, in order to maintain the discipline's relevance and significance beyond its own boundaries.

Conclusion

From its early years, anthropology has worked toward a scientific understanding of and comprehensive appreciation

for humanity. In its pursuit of that goal, it has embraced methods, practices, concepts, ideas, and principles that have allowed it to make significant social and scientific contributions. Anthropology is continuing to develop as a science, as evidenced by an increasing amount of applied work. Anthropologists are also important advocates for the peoples and groups they study.

The future of anthropology looks bright, and technology is poised to open new horizons for the next generation of scholars. Anthropology will continue to significantly contribute to the solution of human problems and add to our deeper comprehension of humanity.

HUMAN EXCELLENCE

Past and Present

IRINA JOVAN DERETIC

University of Belgrade

The word *excellence* is derived from the Latin word *excellentia*, and it means the quality of being extremely good. Human excellences could be defined as those human qualities that make a person outstanding, exceptional, superior, or, in one word, the best of one's kind in any field of human activities. Frequently, it is synonymously used with the word *virtue*, narrowly meaning moral excellence.

Historical and Cross-Cultural Approach

In this chapter, the accounts of human excellence will be elucidated in the history of human thought, from the ancient Greek and Roman time, through the Medieval Age and Early Modern Age, to the Modern Age and contemporary civilization. The historical approach provides a survey of the various views and concepts on human excellence, which were changing in time. By exploring these concepts, one will find out that there are some constant themes in the considerations of human excellence, despite the shifts in the historical contexts and circumstances. A historical approach will be combined with the cross-cultural approach, which implies a comparison of the accounts of human excellence in different cultures. Further, a cross-cultural approach offers a comparison of the accounts of human excellence in the Western tradition to those of China, India, the Islamic world, and Russia.

Archaic Greece

The Greek word for excellence is *arête* (plural *aretai*), which functions as an abstract noun derived from the adjective *good*, and means the quality of being good. Originally it was not only attributed to human beings, but also to inanimate things, human organs, animals, and so forth. A thing has *arête* if it performs its characteristic function efficiently. The *aretai* do not designate any single human feature, but those features making a person excellent. Thus, it was contextualized to mean competence in any field of military, political, athletic, and ordinary life.

Although the word *arête* rarely appears in Homer's epics, he was the first Greek author to depict it. He talks of a variety of *aretai*: *arête* of gods, women, children, even animals and body parts. Nevertheless, the paradigm of excellence is a man, or more specific, a warrior. His qualities are primarily courage, strength, competitiveness, and cunningness. These excellences are manifested in the actions aimed at honors, glory, and social prestige. The moral *aretai*, like nobility, dignity, and being humane, are not attributed to the Greek heroes, but to Priamus and Hector, the king and the prince from the enemy side.

In two of Homer's epics, two different and central *aretai* are crystallized, and these are characteristic for the two periods of Greek history. Whereas courage and audacity are ascribed to Achilles, a hero of the *Iliad*, cleverness and curiosity are attributed to Odysseus, a hero from Homer's

The Odyssey. Therefore, at the same time, Homer describes the key excellence, courage, from the archaic period of Greek history, and indicates a new one, wisdom, which will be dominant in the new classical period.

Unlike Homer, Hesiod (ca. 700 BCE) portrayed *arête* of the ordinary people, both peasants and craftsmen. Their excellence is to work, and to be efficient and successful in performing that work. According to Hesiod, it is difficult to attain *arête*, and such pursuit always implies diligence and great effort. However, if attained after all, *arête* is connected with fortune, richness, and respect.

According to Pindar (ca. 522–443 BCE), excellence manifests itself primarily in athletic competition. It is most significant to have a competitive attitude, and happiness consists of being better than others, while the worst misfortune is to be defeated by someone. To become excellent, innate talents are necessary, but not sufficient. Their own efforts, with the help of the gods, will enable humans to fully realize their natural gifts.

Simonides (ca. 556–468 BCE) was the only Greek author who was skeptical in respect to attaining *arête*. In his view, being a good person is very hard, and being a good person for a long term is almost impossible, or at least beyond one's own influence. If someone is struck by a misfortune, obstructing the individual to do anything efficiently, then this person necessarily becomes a bad one.

The pre-Socratic philosophers, whose main concern was the physical world, did not pay much attention to the question of *arête* in particular, and moral issues in general. It is, consequently, only randomly mentioned in their works. A common characteristic could be noticed in their reflections on *arête*, and that is the priority given to intellectual over physical, athletic, and competitive excellences. The new model of *arête* is no longer a warrior, but a wise man. For example, Xenophanes (ca. 570–480 BCE), who takes political usefulness as a criterion for *arête*, thinks that the wisdom of poets can contribute to the well-being of the polis more than qualities of an athletic champion. Heraclitus (1987) also held that “highest *arête*” is the intellectual excellence: “sound thinking,” which manifests in our saying, “what is true and acting in accordance with [the] real constitution” (pp. 64–65). In Democritus's philosophy, a specific moral use of *arête* emerges, which is dependent on knowledge and understanding. He also emphasizes the interior character of *arête*, apparent in feelings like shame, particularly in one's own eyes.

Classical Greece

In 5th and 4th centuries BCE, the question of *arête* became one of the central topics of Greek philosophy, and culture in general. The civic duties and obligations, especially in the Greek democratically governed city-states, imposed the questions of social and political *aretai*. The Sophists, professional teachers of *arête* to the young people, introduced this reversal of philosophical interests. The

Sophists were not teaching how excellence in some specific fields can be achieved, but how someone can attain the attributes that make one a good and worthy person. The greatest Sophist, Protagoras (ca. 490–420 BCE), understands the *arête* of a man as a political *arête*, since a human being necessarily lives in a political community. Therefore, in Protagoras's view, being a good person means being a good citizen, whose excellence is cleverness, both in private and city affairs. A person who is clever is also moderate and just, since this individual knows that justice and moderation enable citizens to live together in a community. Unlike Protagoras, Callicles defines the *arête* of a man as indulging his own urges and having power to gain the object that can satisfy his appetites. According to Callicles, justice and moderation are unnatural forms of self-restraint, invented by the inferior majority in order to have dominance over those who are superior in intelligence, courage, and manliness. Thrasymachus (ca. 459–400 BCE), a Sophist, also argues in an immoralist manner. According to Thrasymachus, injustice is a positive *arête*, which he describes as a pursuit of purely selfish interests, without paying any attention to the needs and interests of others.

Socrates (ca. 469–399 BCE) was a person who lived life according to his own reflections, ideals, and values. Unlike Callicles and Thrasymachus, Socrates considers excellences such as moderation, courage, piety, justice, and so on, to be fundamental if one wants to live a flourishing life. He equates *arête* with knowledge, which implies that one who really knows what is good and bad cannot act in a morally unjust way. Consequently, all unjust acts are merely due to the agent's ignorance. Being genuinely virtuous is, for Socrates, solely an intellectual matter.

Although Plato's (ca. 427–347 BCE) reflections upon ethical issues were highly influenced by Socrates, and is particularly noticeable in his early dialogues, in the *Republic*, Plato claims that wrong doing is due not only to ignorance, but also to emotional, irrational drives. In this dialogue, Plato articulated the eminent doctrine of four cardinal excellences, both personal and political, based on the analogy between the city and the soul. Plato's good *polis* consists of three classes: the rulers, the guardians, and the producers. Likewise, the human soul has three parts: reason, spirit, and appetites. Wisdom is an excellence ascribed to the rulers in the polis and to the reason in the soul. It consists in “consulting well” about the way the city-state as a whole should be governed the best, both in relation to itself and in relation to other city-states. Similarly, wisdom attributed to reason is knowledge of what is good for the soul as a whole, as well as for each of its “parts.” Courage is an excellence of the guardians and it is defined both as true beliefs about the things to be feared and as the preservation of these beliefs under any circumstances. The spirited part of the soul is courageous, when, as an ally of reason, it protects our soul from the corruptive influences of our appetites. Moderation is the excellence achieved in the soul when the spirited and appetitive parts of the soul are in harmony with

its rational part and, in the polis, when the subjects obey their rulers. A polis, or a person, is considered to be just only when each of its political classes, or the soul's constituent "parts," performs its own work and does not meddle in the work of the others. Political and personal justice should harmonize our psychological and political activities, thus enabling us to lead a good and prosperous life.

The concept of *arête* also plays one of the most prominent roles in Aristotle's (384–322 BCE) ethics. According to Aristotle, the ultimate good for humans is a flourishing life (*eudaimonia*), which is the actualization of the soul in accordance with complete excellence. Aristotle distinguishes two kinds of excellence, which cannot occur apart: one of character and the other of the intellect. The character excellences embrace: courage, moderation, openhandedness, greatness of soul, mildness, wittiness, and justice. Character virtue is defined as a disposition of an agent to choose a mean between extreme alternatives, relative to abilities and stores of the agent and with regard to what is best. The intellectual excellence that guarantees a good choice is practical wisdom, which is concerned with what can be otherwise (i.e., with the variety of human situations). The highest excellence is, however, theoretical wisdom, which deals with the necessary and universal objects, such as the eternal being, the laws of nature, and mathematical numbers. By emphasizing the highest importance of theoretical excellence, Aristotle reaches the "zenith" of the classical Greek ideals, according to which knowledge, understanding, and insight into the objects of divine nature are considered to be something most valuable.

Hellenistic Age

One of the key ethical questions in Hellenistic thought concerns the role of *arête* in a flourishing life. To that question, Epicurus (341–270 BCE) and the Stoics gave entirely different answers. According to the Stoics, *arête* alone constitutes *eudaimonia*, while all other values, including wealth, reputation, and even health, are irrelevant for a truly flourishing life. Following Socrates, the Stoics argued that *arête* is a kind of knowledge through which one avoids outside influences and reaches *eudaimonia*, the total absence of outside influences. On the other hand, Epicurus argues that *aretai* are valued not for their own sake, but only as instrumental means for attaining pleasure, which he equates with *eudaimonia*. For example, a person strives for courage, not for the sake of being courageous, but because bravery is an instrument for defeating fear, which is one of the main causes of an unhappy life.

In Neoplatonist reflection on *arête*, the tendency toward systematization and harmonization between the classical and the Hellenistic positions is to be noticed. Plotinus's views (ca. 205–280 CE) on *aretai* are determined by his general claim that the intellectual life is the true and proper goal for humans. He distinguishes between political excellences, which are Plato's cardinal excellences, purgative excellences, and the paradigms of excellences at the level

of the intellect. These form a hierarchy of excellences. While the lower excellences are always connected with the changeable conditions of earthly life, the higher theoretical excellences are accessible only in the state of complete freedom from everything material and emotional. The function of the purgative excellences is to reach the state like Stoic *apatheia*, in which the soul will be free from affects. Thereby, the soul will be prepared to perform its highest activity—the thinking of the intellect.

Ancient Rome

The Roman views on excellence were highly influenced by the Greek authors, particularly Plato, Aristotle, and the Stoics. It was the part of the Roman education to be acquainted with Plato's four cardinal virtues and with the Stoics's views on that subject matter. Nevertheless, the Roman practical and energetic spirit is always present in the reflections of their authors. They lived a very active life, and most of their efforts were focused on the organization of life. Therefore, one of the Roman excellences is discipline, which is an ability to bring things in order by obeying the rules and methods, and *ordo*, signifying both psychic and social order, based on well-founded laws and a powerful army. Since the Romans were a military nation, the military excellences were significant in their lives, and those were: *fortitudo* (bravery in dangerous situations), *labor* (endurance in accomplishing tasks), *industria* (zeal in efforts), *celeritas* (quickness in actions), and *consilium* (deliberative planning). Closely connected with their military mentality was one of the vital Roman excellences, *clementia*, meaning generosity toward the conquered from the position of superiority attained in the battlefield. For example, Julius Caesar (100–44 BCE) illustrated this virtue when he released his political enemies after he had conquered the city of Corfinium. Caesar was content with his deed, although his enemies, having been released, took up arms against him. In doing this, he confirms who he is (i.e., a noble and generous person). In time, the concept of *clementia* has acquired broader meaning, referring also to mercy and compassion in both public and private affairs.

Although the Stoic doctrine on virtues and vices was closest to his own views, Cicero (106–43 BCE) criticized their thesis that moral virtue is the sole good and, hence, sufficient for a flourishing life. Nevertheless, he considers that the virtues are not sufficient, but necessary for happiness. In his second speech *Against Catilina*, Cicero gave the list of virtues and vices. The typical Roman excellences are particularly represented in this list. The first on the list is *pudor* (i.e., decency and modesty), then *pudicitia*, meaning both chastity and shame in a narrow sense. While the first two excellences from the list refer to the private domain, the third one, *fides*, refers to the functioning of the Roman community. And, it is a significant notion with a variety of deeply connected meanings: loyalty, honesty, confidence, and also mutual trust between friends, the ruler and his subjects, and among different

people in the community of peoples. Along with *fides*, Cicero mentions *pietas*. In Roman life, this plays a vital function, referring not only to piety, but also to the respect toward someone who really deserves to be respected, like gods, rulers, or the head of a family. The next excellence on the list is *constantia*, which connotes steadiness or being firm and faithful to one's own ideals, principles, and purposes. It is presupposed that if a person is to be *honestas*, or to have an honorable attitude, decency, self-confidence, and respectfulness then it leads to general appreciation and public esteem. The *continentia* is a kind of self-control and self-discipline, and it is, to some extent, equivalent to the Greek arête *sophrosyne*. The next four excellences: *aequitas* (equity), *temperamentia* (moderation), *fortitudo* (bravery), *prudentia* (prudence) are of Greek origin. At the end of this list are excellences such as *bona ratio* (good reason), *mens sana* (healthy mind), and *bona spes* (good hope). The first two are intellectual, yet their intellectualism is more of a practical, rather than of a theoretical nature. This is a characteristic feature of the Roman *Weltanschauung*, which manifests itself not as much in the metaphysical treatises, but rather in the issues of organizing the state and codifying the laws upon which the state should be governed. The *bona spes* is a kind of intelligent optimism, which goes well with a healthy and quick mind as a contributor to attaining good goals.

For the Roman Stoic philosopher Seneca (4 BCE–CE 65), the ultimate good consists exclusively in attaining virtues. He talks of the *virtus perfecta*, which through the knowledge of things, human and divine, is a precondition for leading a harmonious life. The plurality of virtues represents the various aspects of one perfect virtue. In addition to the four cardinal excellences, Seneca emphasizes *patientia* (patience), *tolerantia* (tolerance), *simplicitas* (simplicity or candor), *modestia* (modesty), and *humilitas* (humbleness). The prominent place in his work is given to the virtue *humanitas*, which signifies the sense of solidarity with others. With his humanist ideas, Seneca influenced important authors in Western culture for centuries to come.

Eastern Traditions

China

The core of Chinese thinking in regard to the human excellences lies in the teachings of Confucius (551–479 BCE), along with the contributions of Mencius (372–289 BCE), and Xunzi (298–238 BCE). Significant achievements of the Confucian philosophy are to be found later on in the works of Cheng Hao (1032–1085), Cheng Yi (1033–1107), Zhu Xi (1130–1200), and so forth. Although they developed ethical reflections in a conceptual framework different than the one we find in the Western tradition, the Chinese philosophers also view the virtues as excellences that enable a person to lead a flourishing life. Confucian ethics stress the concept of *junzi*, similar to Aristotle's notion of

phronimos (i.e., an ethically superior or paradigmatic individual). Later on, Confucius and Laoze (6th century BCE) were considered to be closest to the ideal of *junzi*.

De and *ren* are two interchangeably used words for virtue in the Chinese language, and both have a double meaning in Confucian usage. *De* represents moral “force” or “potency,” as opposed to physical force, as well as “virtue” pertaining to the excellence of a character. The word *ren* signifies both the particular virtue of benevolence or humaneness and the sum of all virtues.

A large number of virtues have played a significant role in the history of Confucianism: aforementioned *ren*, *li* (often rendered in English as rules, property, rituals, etc.), *yi* (righteousness), *zhi* (wisdom), *zhong* (devotion), *xin* (faithfulness), and *xiao* (filial piety).

Bearing the highest ethical significance, *ren* is a fundamental virtue upon which all other virtues depend. It seems that already the etymology of the word *ren* discloses its meaning. The combination of the radicals *ren* (person, human) and *er* (two) in this character implies that it is one's relation to others, rather than singleness and individuality, that constitutes what a person really is. What makes a person excellent in his pursuit of *ren* is a particular kind of relation one develops toward others, based on love and respect for one's fellows, and attained by overcoming one's egoism and self-interest.

As a virtue, *li* is a formed disposition of regarding and obeying the set of ritual rules, traditional customs, and other practices that are of no significance in Western ethics. Their role is to establish and maintain the harmonious social order in accordance with the prescriptions of reasons and humaneness (*ren*). If these rules become burdensome and unreasonable, then they should be revised, replaced, or even rejected.

Yi is a cultivated disposition to perform the acts that are just, right, and appropriate to the situation at hand. Like Aristotle and the Stoics, the Confucian philosophers also think that what is right depends on the agent's reasoned judgment. An individual must be led not by one's personal gain, but by the welfare of the entire community. In this case, a very important role is played by the virtue *zhong* (devotion), because it is a commitment to the interest of someone else, especially in cases where this conflicts with one's personal interests.

Generally speaking, *zhi* (wisdom) is a disposition to deliberate well about the best means to achieve given ends, and to determine the consequences of various courses of action. It is also an ability to evaluate the characters of others, as well as oneself.

Xin (faithfulness) is primarily fidelity to words. The most apparent aspect is faithfulness in the sense of honesty: doing what one says one will do, and not promising more than one can give. For Confucianism, faithfulness is of vast importance in interpersonal communication and state administration.

Chinese ethics attach wider significance to the excellence *xiao* (filial piety) than the Western tradition did or

does. It is a cultivated affection and respect that one should display to one's parents. The primacy of xiao derives from the natural feeling of love that each offspring has for the parent. It is fundamental for understanding and forming a society, in the way that social relations are to resemble the relation between children and their parents. They have to mirror its hierarchical structure based on natural and strong devotion. In addition, the Confucian thinkers profoundly remarked that the habitation and cultivation of each excellence began in the family, afterwards substantially influencing our conduct and socialization in general. Nevertheless, according to the Confucians, obeying one's parents is not to be applied absolutely and unquestionably in every situation, but only if it is in accord with what reason judges to be just and appropriate.

By stressing the role of reason, which should deliberate well about practical matters, taking into account the special characteristics of each case, Confucian ethics is similar to that of Aristotle, where practical wisdom plays a crucial role. Like the ancient Greek thinkers in general, Chinese moral philosophers, in particular Mencius, consider that overcoming the passions and instincts is the way one acquires virtues and becomes truly human. The uniqueness of the Chinese account of excellences lies in stressing the significance of family and society, our relations to others in cultivating our own nature. In fact, Chinese thinkers attempt to find a kind of social order in which each person is able to realize her full potential as a human being through mutually beneficial relations with others.

India

The human virtues and excellences in general were not prominent topics in the Hindu tradition. In Indian thought as a whole, there is a lack of reflection on the very essence of virtue, since it was understood as supersensible and thus not entirely knowable by unaided reason; one can get a complete account of it only from revelation. However, a step in the direction of knowing virtues is to identify the moral duties that one should perform, as well as the character dispositions guiding these duties.

In the old Indian text *Bramahas*, devoted to interpreting rituals, virtue is envisaged as ritual excellence, performed, for example, in the acts of sacrifices. This ritualistic concept of virtue is significantly modified in the "Treatises on Dharma" (*Dharmasastras*), composed around 600 BCE. The word *dharma* literally means "what holds together." With its connotation as a sum of all moral duties and our disposition to acquire them, the dharma becomes a basis for either social or moral order. Although the proper performance of rituals is still vital, the disposition for performing the highest rite, according to this text, is a disposition for "good conduct." The text describes caste society consisting of the *Brahmans* (priests and teachers), *Kshatriyas* (warriors), *Vaisyas* (tradesmen), and *Sudras* (laborers and servants). Each of the four castes is distinguished by the

characteristic excellences exhibited by its members: the spirituality of the Brahmins manifests itself in their purity, righteousness, and knowledge; the excellence ascribed to the soldier caste is valor, especially in battle, and lower castes are assigned the virtues of industrious labor. However, it is mentioned in the Hindu texts that along with the excellence of a specific caste, there are the virtues common to all orders. These are forgiveness, self-control, nonviolence to all living beings, self-control of the pleasures, compassion and patience, as well as freedom from anger, envy, and avarice. It seems that these excellences are treated as mere instruments to an end, that is, enlightenment or liberation (*moksa, nirvana*) from the cycle of rebirth.

Buddhism as a religious and philosophical tradition was born in India around 600 BCE, and spread over Asian countries such as China, Korea, Japan, and Thailand. The texts of Buddhism criticized some aspects of the ethical system of traditional Hinduism by recommending universal principles over traditional, caste-specific norms and stressing mental attitude over performance. For example, one should not only avoid taking what does not belong to him, but also avoid having greedy thoughts.

The catalog of fundamental virtues in classical Buddhism could be found in the Holy Eightfold Path, and the doctrine of the Four Noble Truths. These truths are that life is suffering; the reason of this suffering is the "birth sin" of desire; suffering ends only upon nirvana, the annihilation of desire; and nirvana may be achieved only by following the Holy Path. The components of the Eightfold Path have been divided into a three-step plan of action consisting of *sila* (virtue), *samadhi* (meditation), and *prajna* (wisdom). The third (right speech), fourth (right action), and fifth steps (right livelihood) involve virtue; six (right effort), seven (right mindfulness), and eight (right concentration) involve meditation; and one (right understanding) and two (right thinking) involve wisdom. A later Buddhist virtue catalog is given by the so-called Five Virtues or Precepts, which consist of abstaining from harming any living thing, stealing, sexual misconduct, lying, and intoxication. Eventually, there are the four universal virtues of Buddhism. These are also mentioned in different canonical texts, concern the practical aspects of Buddhism, and promote the ideals of humanity. They are *maître* (benevolence), *karuna* (compassion), *mudita* (joy), and *upeksa* (equanimity).

Unlike Western thought, the Indian traditional texts do not take into account the political excellences. Moreover, in contrast to Western accounts of excellences, in Indian philosophical and religious tradition, rituals and ceremonies do play a prominent role. Entire Indian thought views human excellences as belonging to the path of achieving liberation from the restraints of everything belonging to humans. By strongly appealing to almost absolute nonviolence, based upon the view of the interconnectedness of all living creatures, the Indian tradition traces presumably the most valuable account of universal mercy and charity.

Muslim Tradition

The core of the Muslim view of human excellences lies in the Koran, the traditions (*hadith*) of Muhammad, Sufi's writings, and in the scripts of Muslim philosophers like Ibn Sina (980–1037), Al-Ghazali (1058–1111), Ibn Rushd (1126–1198), and so forth. The essential Muslim excellences are those attributed to Allah (i.e., God himself). Primarily, Allah is the *ar-Rahman* (beneficent) and the *ar-Rahim* (merciful). Moreover, Allah is the *al-Mohaymin* (protector), the *ar-Razzaq* (provider), and the *al-Ghafur* (all forgiving). Secondly, Allah is also the *al-Adl* (just), representing the *al-Haq* (truth) and the *al-Barr* (source of all goodness). Since Allah deals with the weak and uncertain humans, he is the *as-Sabur* (patient).

As humans in their relations should emulate these divine attributes, they should accordingly be generous, merciful, benevolent, and just, as well as honest to each other. They should also be patient and wise in their life. The prophet Muhammad exemplifies these virtues, since he is the perfect man par excellence, whom the Koran calls an excellent model to follow.

Apart from moral excellences, the Islamic principles encouraging intellectual flexibility and rational choice are based on *ijtihad* (judgment), *shura* (consultation), and *ijma* (consensus). Clearly, rationality and man's own judgment play a significant part in arriving at decisions. In Islamic culture, the importance of *ilm* (knowledge) was highly appreciated. One of the Muslim ideals is to spend life in a pursuit of knowledge. Sufism, the most profound teaching of Islam, describes the path of attaining the illuminating knowledge of God, which presupposes the cultivation of excellences, spiritual excellences in particular. Although the virtues are human attributes, in their deepest sense, they belong only to God, and what belongs to humans is their "nothingness" before him. In this sense, the Islamic view of virtues distinguishes itself from the other traditions, particularly from the Chinese and Western ones, in which the virtues are attainable primarily in the active engagement of humans.

The ancient Greek philosophers also influenced the Islamic account of virtues. Al-Ghazali's view of happiness is a good example of how the Islam tradition could be creatively combined with Western philosophy. According to Al-Ghazali, happiness, as the highest good, admits two subdivisions, the worldly and the otherworldly. Otherworldly happiness, which is our ultimate end, cannot be attained without certain worldly goods. These include Plato's four cardinal virtues; the bodily virtues of health, good fortune, and long life; the external virtues of wealth, social position, and noble birth; and lastly the "divine virtues" of guidance, good counsel, direction, and divine support, all belonging to the Islam tradition.

Russia: Between East and West

There is no other nation that questions its own values and identity so deeply as the Russians had, thereby

showing one of their virtues. This virtue is a profound self-awareness, which implies inquiring its own scope and merits, and longing for one's true self. In its long history, Russia has formed a unique culture based on the Orthodox Christian religion in the productive, although not always harmonic, dialogue with Western culture and its tradition. This dialogue was important in the formation of the greatest geniuses of the Russian culture, particularly such as Pushkin (1799–1837), Dostoyevsky (1821–1881), Tolstoy (1828–1910), and film director Tarkovsky (1932–1986). Inspired by Western ideas, they critically explored, denied, or creatively assimilated them, introducing, at the same time, something new and unique.

The uniqueness of the Russian view on excellences could be seen in the notion of *svecholovek* used by Dostoyevsky in his *Pushkin Speech*. *Svecholovek* is a person whose excellence is not proved by being superior to others, but by embracing and synthesizing the features of others. In one's attempt to know and experience other nations and cultures, *svecholovek* is both unique and universal. According to Dostoyevsky, such a completely universal person was Pushkin, who transformed and unified in his own spirit as "the spirits of foreign nations" (p. 56).

The Russians are very talented for exact mathematical and natural sciences, and they have had excellent results therein, both in the past and present. Nevertheless, the most prominent Russian thinkers and writers (e.g., Dostoyevsky, Tolstoy, Berdyaev) criticized the pretension of excellences in calculation and the rational sciences in general, to give a full and sufficient account of reality. In criticizing abstract, theoretical reasoning, Tolstoy pointed out the significance of a practical ability, similar to Aristotle's *phronesis*, to instantly grasp the unique features of each particular case.

The most appreciated moral excellence for the Russians is *chelovekoljubie*, meaning to have genuine love for each human being. In particular, this relation manifests itself in the empathy with the insulted and humiliated. There is no human, so miserable, handicapped, even wicked, who cannot and should not be loved. The Russian humanists did not pledge for an abstract humanism, but for one that should be proved in everyday life in terms of helping a concrete person.

As strikingly depicted in Dostoyevsky's novels, the Russian understanding of *vera* (faith) is also specific, since it is not to be grounded only in doctrine, but rather in the living experience of a believer, permeating one's entire life. The importance of *nadezhda* (hope) in Russian thought is expressed in its fundamental orientation toward the future, understood either as heavenly kingdom or communism or a better life improved by science. The most prominent political excellence in the Russian culture is an organic togetherness, as opposed, according to the Russian thinkers, to the Western self-centered individualism.

Medieval Ages

The Apostle Paul's faith, hope, and love from the New Testament became the most significant and unique Christian excellences. The church fathers variously discussed the ancient accounts of virtues and vices, often comparing them to new Christian ideals. Among the early Greek Church fathers, the most original and insightful notion of *arête* is to be found in the writings of Gregory of Nyssa (335–394). For him, Socrates is no longer a paradigmatic individual, as he was for the classical Greeks, but Moses, after whom his major work is entitled. Gregory of Nyssa endeavored to account for the place of *arête* in the spiritual and dynamic progress of the soul attempting to overcome the limits of its own nature. He used the word *epektasis* to signify this paradoxical process of how finite humans can exercise their excellence by progressing into unlimited perfection. According to Gregory of Nyssa, to be fully human is to be in an infinite state of *becoming* ever better or *more* perfect, without ever *being* best or perfect. This process of human divination was conceived by Gregory of Nyssa as the cooperation of God combined with the effort of a human himself. By the belief that the human side is very active in acquiring virtues, Gregory of Nyssa was closer to the Greek classical tradition than to Augustine and the later Christian authors, who considered that this process is sorely dependent on God's mercy.

Saint Augustine (354–430) critically discussed and eventually rejected classical Stoic and Platonic accounts of virtue as rational self-mastery, substituting instead an account of virtue as *ordo amoris*, "rightly ordered love." This right ordering of love reflects the divinely ordained hierarchy of nature, with God at the peak. Augustine defined the four classical virtues of courage, moderation, justice, and wisdom as forms of this love of God. By defining *virtus* in terms of correct love, Augustine made it into a divine gift, rather than a human achievement. This implies that there is a categorical difference between genuine virtue, based in God's "pouring" love into human souls, and the cardinal virtues grounded on any other love. Although it is certainly true that Augustine viewed pagan virtues as superior to pagan vices, such virtues remain always imitation compared with the authentic virtue of divine love in our souls.

Among the early Scholastics, two opposite views on human virtue are to be noticed. While for Anselm of Canterbury (1033–1109) the notion of virtue was of no significance, and even justice is not conceived as virtue, Peter Abelard (1079–1142) attempted to connect Aristotelian concept of virtue with the elements of Augustinian ethics, by claiming that the virtues are those qualities that make human life worthwhile. He productively developed Augustine's criticism of the Stoics's thesis that all virtues are equal.

Aristotle and the Neoplatonists, were an inspiration to Bonaventura (1217–1274) in his account of human excellences, as he attempted to reconcile them with Christian doctrine. In his view, human excellences participate in divine exemplars to various degrees. The cardinal virtues

of wisdom, justice, moderation, and courage may be possessed at any of three levels. At the lowest level, they are "political" and belong to us insofar as we are political animals; at the next level, they are "cleansing" and belong to us insofar as we are fit for God; and at the next level, they belong to those already entirely cleansed. At all levels of the hierarchy, human virtues depend on the exemplars for their reality. The cardinal virtues likewise also depend on the theological virtues of faith, hope, and charity to attain their perfection and achieve their ends. According to Bonaventura, the virtues are not only the products of God's grace, but are also rooted in *liberum arbitrium* (free decision). Thus, the cardinal virtues can belong only to the intellect and the will—those powers of the soul that share in free decision.

Saint Thomas Aquinas (1225–1274) was a great Christian synthesizer of the Medieval Ages. He combined the two lists, saying that there are four cardinal virtues and three theological virtues. According to Aquinas, the theological virtues, having God as their object, are prior to all other virtues. Due to the fact that God, as an ultimate end, must be present in the intellect before it is present in the will, and since God is present in the will by the reason of hope and charity, faith is prior to hope and charity. Hope is the theological virtue through which we trust that, with divine assistance, we will attain the ultimate good—the eternal enjoyment of God. In the order of generation, hope is prior to charity, but in the order of perfection, charity is prior to both hope and faith. While neither faith nor hope will remain in those who reach the eternal vision of God in the life to come, charity will endure in blessedness. It is an excellence that is infused into the soul by God and that inclines one to love God for God's own sake. If charity is more excellent than faith and hope, then through charity the acts of all other excellences are ordered to God.

Early Modern Age

The Renaissance

During the Renaissance, the virtues became the theme of poetic imagination, the question for philosophical thinking, and the subject matter frequently represented by the painters. For example, the Italian artist Antonio da Correggio (1489–1534) painted the three ancient moral excellences (justice, courage, and moderation) in his famous work, *Allegory of the Virtues*. Persons of distinguished excellences—both intellectual and artistic—represent the Renaissance, such as Marcilio Ficino (1433–1499), Leonardo da Vinci (1452–1519), and Michelangelo di L. Buonarroti (1475–1564).

The direct approach to the sources of the ancient Greek texts produced a huge diversity in the Renaissance, both in the accounts and evaluations of excellences. While Francesco Petrarca (1304–1374) held that virtue is a cure for vicissitudes of *fortuna*, Leon Battista Alberti (1404–1472), in his

Intercoenales, represented virtues in confrontation with fortuna as helpless and inferior.

The Italian humanist Lorenzo Valla (1407–1457) decisively rejected the Stoic concept of virtue as happiness by reevaluating the Epicurean views of instrumental nature of virtues. In rejecting the Stoic equation of virtue with happiness, Valla pointed out that apparently selfless, virtuous actions are in fact very often performed out of egoistic, self-interest reasons. By refuting the Stoics, Valla was affirming the insufficiency of humans to achieve happiness outside the Christian dispensation. He advocated the Christian pleasure that does not exclude the joys of life, yet its highest peak is heaven's delight. Although Valla's ranking of pleasure as the ultimate end has an Epicurean flavor, his equation of heavenly delights with pleasure is of a Christian nature.

Niccolo Machiavelli (1469–1527) created a novel political theory presenting how politics could be practiced outside the boundaries of morality and virtue, by redefining the very notion of virtue. According to Machiavelli, virtue is an excellence in achieving desirable goals, which are, however, not necessarily morally acceptable. The moral indifference of the ruler can help him in various struggles with the changeable circumstances of fortuna. The requirements for leading a country successfully are not traditional virtues, like piety, humanity, and honesty, but cleverness in making things useful and efficient. In sum, political excellence for Machiavelli presupposes power and intellectual excellences, but it is indifferent to moral ones.

Michel de Montaigne (1533–1592), a French Renaissance thinker, held that each excellence, whether moral or intellectual, entails struggle and difficulty. He explained his assumption by stating that even-minded people with good intentions find it easy to act justly, while virtuous persons are those who are able to actively overcome the difficulties when acting rightly. Thus, he implicitly criticized the Aristotelian thesis that a virtuous person is recognized by the fact that he readily performs his virtuous acts, whereby he could be seen as a precursor of Kant's concept of "moral value" of each act.

Age of Discovery

In the European culture of the 16th and 17th centuries, the human mind's scope and limits were "discovered," and became the focal topics of the age. Rene Descartes (1596–1650), the "father" of modern philosophy, saw virtue as a firm and contestant determination to act in accordance with what reason judges to be the best. It is an unconditioned and supreme good, entirely dependent on our free will. Being a cure for the aberrations of passions, the key moral excellence is generosity described as a kind of appropriate self-esteem and as a the perfection both of the intellect and of the will.

Similar to the Stoics, Baruch de Spinoza (1632–1677) considered that exercising one's excellence is acting according to the laws of one's own nature, guided by

reason. Being in harmony with one's own reason is nothing but knowledge, which is both the major weapon against the misleading passions and the source of the highest happiness, since it is directed to God or the necessary order of nature. Spinoza distinguished between two classes of virtuous actions, both of which are in accord with reason: (1) those due to tenacity, aimed at preserving one's being; and (2) those due to generosity, aimed at helping and cooperating with others. According to Spinoza, a genuinely virtuous person does pursue his or her own interests, but also takes care of the well-being of others, acting always honestly, nobly, and altruistically.

For the English philosopher Thomas Hobbes (1588–1679), virtues are those character dispositions that produce appropriate actions easily, without any resistance by reason. Due to the fact that there were no generally accepted standards in the prepolitical period, each person considered something different to be good and virtuous. Only in the civil society did laws impose standards, and virtue consisted in respecting such laws that ensure the stability of a society. Apart from political excellence, which Hobbes equated with justice, he also considered *caritas*, interpreted as a kind of solidarity among humans, to be a moral excellence.

Age of Enlightenment

In their pursuit of reason and liberation, the thinkers of the Age of Enlightenment very seriously questioned the generally accepted beliefs on values and virtues. In the French Enlightenment, the traditional views on moral excellences were sharply criticized. For example, F. de Rochefoucauld (1613–1680) held that egoism is a driving force of numerous seemingly selfless actions. J. O. de Mettrie (1709–1751) argued that virtue does not have any intrinsic value, since it exists exclusively due to social interests.

Ch. L. Montesquieu (1689–1755) viewed virtue as a political excellence that he understood as "the love of the laws and of our country" (1777, p. 67). It is a moving force in republics, honor in monarchies, and fear for despotic regimes. On the other hand, J. J. Rousseau (1712–1778) described virtue as something internal, as a "sublime knowledge of simple souls" (2002, p. 67). Its laws are inscribed in our hearts, and only if we turn to our true self and conscious, can we learn what it is. Nevertheless, the pure tendency toward exploring one's own conscious is not sufficient for attaining virtue, since it always requires strength and hard labor. While Rousseau thought that virtues could take the place of natural laws, Voltaire (1694–1778) was more skeptical about the status of virtue, by claiming that it is only a socially useful behavior.

Moral and intellectual virtues have a prominent place in David Hume's (1711–1776) philosophy, who is considered to be a representative of the Scottish Enlightenment. Hume's concept of virtue embraces not only moral virtues, but also excellences of all kinds, including intellectual talents and social virtues. He defined it as "quality of the mind agreeable to or approved of by everyone who considers or contemplates it" (1975, p. 261). Hume distinguished

the “natural virtues” (benevolence, charity, prudence, good sense, wit, temperance, courage, etc.) from “artificial” virtues (justice, allegiance, chastity, etc.). The former are rooted in our nature and based on our natural tendency to prefer and to approve, while the latter are dependent upon convention. All the artificial virtues arise from the circumstances and necessities of life, and they take different specific forms in different societies and historical conditions. They consist in conventions, generally accepted to be socially beneficial, like respect for traditional property, and “fidelity to promises.” Contrary to the artificial virtues, the “natural” virtues are invariant across cultures; they always produce good outcomes.

Modern Age

According to Immanuel Kant (1724–1804), the founder of the modern ethics and philosophy in general, *Tugend* (virtue) cannot depend merely on a benevolent tendency, but exclusively on general and strict principles. Kant (1797/1996), therefore, thought that the traditional account of virtue should be redefined. Kant conceived a morally relevant virtue as a kind of strength of will to do what is right, and distinguished the duties of right and duties of virtue. Whereas the former are eternally imposed laws, which requires the coercive order, the latter are self-imposed and aim at self-perfection and the happiness of others. By introducing the duties of virtue, Kant developed the concept of moral excellence, which consists of the enhancement of one’s dispositions of mind and certain moral duties of respect and charity. A rational agent with more or less excellence performs the duties of virtue. However, our duties to perfect ourselves and to realize the happiness of others are imperfect. While perfect duties of right allow no exception for one’s inclination, the imperfect duties of virtue are circumstantial and sometimes dependent on one’s preferences.

In modern utilitarian ethics, virtue is interpreted as an instrument in attaining an external end, such as benefit, power, or happiness. John Stuart Mill (1806–1873) had a more profound view of the role of virtues in one’s life. He distinguished between desiring a thing as a “part” of our happiness and desiring it as a means to our happiness. Virtues are the constituent part of one’s happiness, since they are also desired for the sake of themselves. In contrast to Mill, G. E. Moore (1873–1958) considered that virtues are not good as such; they are rather certain instruments for attaining the good. The evaluation of virtues depends on how efficient they are in accomplishing goals.

In his philosophy, Friedrich Nietzsche (1844–1900) gave priority to the excellences of all kinds over the traditionally conceived virtue, concurrently aiming at demystification and overcoming its double-faced morality. While compassion and charity are the most valuable virtues for Christians, Nietzsche believed them to be nothing but the sign of human weakness. He vividly portrayed an *overman* as a being equipped with everything best, with

all the excellences like courageousness, great creativity, uniqueness, healthy, life affirming, and practicing self-reverence. The overman has to possess his peculiar virtue, belonging only to himself. He looks into the future and not to the past; his main task is to overcome his own self (i.e., to make his own self better, even almost perfect). Nietzsche’s words about the future of morality and virtues were prophetic. He attached to them little power to inspire humans, and since they no longer represented great ideals, which can make people become more than what they are, he thought that in the 20th and the 21st centuries the civilization would be faced with an eruption of barbarism.

The flourishing of all kinds of intellectual excellences and human achievements in science, technology, and the arts distinguishes the 20th century. At the same time, this was the century of the most horrible wars and massive killings, the century in which humanity could have been destroyed. Perhaps that is why virtues were not the dominant theme in the previous century, neither in philosophy nor in culture in general. This, however, does not imply that they were not treated at all. In his material value ethics, M. Scheler (1874–1928) thought that virtue should be rehabilitated. According to Scheler, it is a vivid consciousness of good, the quality of a person as such, who is a bearer of moral values. On the other hand, M. Weber (1864–1920) advocated a utilitarian view of virtue in the manner of “the spirit of capitalism.” On the example of B. Franklins, he showed that moral excellences, such as honesty, diligence, and punctuality are beneficial only because they gain profit.

In the mid-20th century, an almost forgotten virtue was revived in the works of E. Anscombe, A. MacIntyre, P. Foot, and B. Williams. As R. Hursthouse (1999) suggested, the virtue of ethics for these authors was initially endorsed to distinguish a position in normative ethics, which puts the emphasis on a person’s virtues, in contrast to deontology, a theory which stresses duties and rules, as well as utilitarianism, which emphasizes the consequences of actions. The source of inspiration for these authors is ancient Greek ethics, Aristotle in particular. The central issues of their concern, although treated differently, are the following: the nature of virtue, formation of character, practical reason, moral education, and thereto connected feelings such as loyalty, shame, and guilt. The discussion initiated by these philosophers is still going on, showing that our culture, at least in the eyes of some intellectuals, is concerned with the fact that moral virtues are almost nonexistent in our lives.

Future Directions

It seems that our modern age is focused on the body, rather than the mind or the soul. In contrast to the previous centuries, intellectuals, state representatives, or even ideologies do not form our views of what is valuable today. The electronic mass media, though profoundly influenced by the political and economic powers, has the

key role in forming our evaluative beliefs. The excellences promoted by the media are excellences or perfections of the body rather than those of the soul or the mind. One of the ideals followed by many people is a perfectly shaped, young, and fresh body and the face of a model. Also, entertainers and athletes who prove their excellences in competitions are today's heroes, rather than scientists or philosophers. For instance, not many people know the name Z. I. Alferov, a Russian physicist and the Nobel prize winner in physics (2000), and even fewer people know that his invention, the heterotransistor, revolutionized mobile phone and satellite communications—but almost everyone is very well-informed about David Beckham, Brad Pitt, Madonna, and so forth.

Now, we face a kind of paradoxical situation where the excellences essentially enhancing our lives, such as scientific and technical expertise in the first place, do not seem to be the most esteemed in the system of values held by the majority of the population. Moreover, despite the fact that these excellences are not too popular, they truly contribute to the march of human progress. They presuppose the scientific exactness and application of skills connected with the inventiveness of their creators in all fields of human knowledge. What is missing, although not entirely, is a comprehensive, sufficiently systematic, and critical awareness of these fast processes, followed by the question of the meaning and the appropriate ethical evaluation of such development.

One step in that direction is transhumanism, an intellectual and cultural movement aiming at improving human mental and physical capacities, and thus prolonging human life by the use of science and technology. This movement attempts to find out how the emerging biotechnologies could be used in our struggle with human disabilities, diseases, and even death. By improvements of all kinds, including genetic improvement, it is apparent that the qualities of the human mind and character will be enhanced, too. However, we do not know exactly what will be the final result of such biotechnological processes: an improved human being equipped with all excellences, or an entirely new being belonging to another form of evolution yet to be created by ourselves. What remains open, regarding the latter alternative, is whether these excellences are in any way human. If not human excellences, then future science and ethics will have a delicate task to evaluate these excellences properly.

PART IX

EVOLUTION

FOSSIL PRIMATES

IGNACIO ARENILLAS AND JOSÉ ANTONIO ARZ

University of Zaragoza

Primates are mammals included in the order Primates, which was defined by Carolus Linnaeus in 1758 in order to group lemurs, monkeys, apes, and humans. Except for humans, most Primates live in the tropical or subtropical regions of Africa, Asia, and the Americas. The Primates have been traditionally subdivided into two main informal groups: prosimians and simians. Members of the first group have traits most like those of the earliest Primates; they include tarsiers, lemurs, galagos, lorises, and aye-ayes (among others). The second group includes the New World and Old World monkeys in addition to the apes and humans.

Primates have a general morphology but exhibit a wide range of characteristics. Many species are sexually dimorphic, with females and males differing in size, certain physical traits, and coloration. This dimorphism is mainly exhibited in simians and humans. Primates are characterized by their large brains (particularly in anthropoids) and stereoscopic vision, and most have opposable thumbs. Most of them live in trees, possessing adaptations for climbing. They have various locomotion techniques, such as leaping from tree to tree, walking on four or two limbs, knuckle-walking, and brachiation (swinging between branches of trees).

The order Primates is included in the superorder Euarchontoglires, infraclass Eutheria, class Mammalia, phylum Chordata, and kingdom Animalia. In addition to Primates, the superorder Euarchontoglires (also called

Superprimates) includes rodents, rabbits, tree shrews, and colugos. This superorder is divided into two clades: glires and euarchonta, the last of which includes two other sister clades, scadentia (tree shrews or tupaiis) and primatomorpha. This last clade includes three orders, two of them extant: Dermoptera (flying lemurs) and Primates and one fossil, Plesiadapiformes.

Although they do not possess a common diagnostic character, Primates can be grouped together because all of them have a common origin. They show some distinctive progressive evolutionary trends, such as toward the enlargement of the brain, predominance of the visual sense, and improved manipulative capacities. The most primitive Primates may have existed more than 65 million years ago, in the late Cretaceous, and even 85 million years ago according to some DNA molecular-clock studies. The Cretaceous ancestors of Primates were small and generalists in diet and behavior. This allowed them to survive the Cretaceous/Tertiary mass extinction, which ended the dinosaur era. Our ancestors survived by being small, omnivorous, and flexible in their behavior within diversified environments.

The late Paleocene *Plesiadapis* is suggested as the oldest known fossil Primate (55–58 million years ago), although most paleoprimatologists consider it belonging to a different order (order Plesiadapiformes) closely related not only to the Primates but also to the flying lemurs (order Dermoptera) and perhaps to the bats (order Chiroptera).

They are characterized by long tails, agile limbs, rodentlike jaws and teeth, eyes at the side of the head, and no post-orbital bar. The order Plesiadapiformes diverged during the Paleocene into several families such as Plesiadapidae, Carpolestidae, Saxonellidae, Microsyopidae, Paromomyidae, and Picrodontidae. *Purgatorius*, a 65-million-year-old fossil primatomorph, might be the precursor to the Plesiadapiformes and all Primates. They have primatelike characteristics, such as enlarged central incisors and molarlike terminal premolars.

Primates are subdivided into two great suborders: Strepsirrhini and Haplorrhini. Both sister clades, strepsirrhines and haplorrhines, parted ways about 63 million years ago, according to molecular-clock analyses. The first representatives of both groups were prosimians, which have adaptations to preying on small, quick-moving prey in an arboreal setting (visual predation): grasping hands and feet, nails instead of claws, eyes rotated forward (enhancing stereoscopic vision), and the elaboration of visual-sensory pathways. Both strepsirrhines and haplorrhines evolved from the ancestral Primates' lineage (Plesiadapiformes), which included the most primitive strepsirrhines and the extinct Adapiformes as well as the most primitive haplorrhines and the extinct omomyids. These early Primates split off during the Eocene, an epoch characterized by climatic warming. The Primates' rain forest habitat was very widespread during the Primates' acme of the Eocene.

Strepsirrhines

The suborder Strepsirrhini includes the “wet-nosed” Primates (lemurs, lorises, galagos, aye-ayes, indris, etc.), which are considered the most primitive in features and adaptations. Their brain capacity tends to be smaller than that of the haplorrhines, indicating a lower intelligence. Their nose is connected to the upper lip, which is connected to the gum. Their nickname “wet-nosed” comes from the presence of a rhinarium, that is, the wet, naked surface around the nostrils of the nose typical of many mammals. Almost all strepsirrhines have a toothcomb, that is, tightly clustered incisors and canine teeth.

Strepsirrhines are composed of four infraorders: Adapiformes, Chiromyiformes, Lorisiformes, and Lemuriformes. The first group is a fossil taxon typically called adapids; the second includes the enigmatic, extant aye-ayes; the third group is typically called lemurs; and finally, the fourth group includes lorises, indris, and galagos. Strepsirrhines also include some *incertae sedis* fossil taxa, such as *Azibius* (middle Eocene), *Panobius* (middle Eocene), *Lushius* (late Eocene), and *Shizarodon* (early Oligocene).

Adapiformes

Infraorder Adapiformes, also called adapids, primarily radiated during the Eocene between 55 and 34 million years

ago, although an endemic Asian group, the sivaladapids, survived into the Miocene. Adapid fossils are found in all Holarctic continents (Africa, Eurasia, and North America), together with the great fossil group of Eocene Primates, the omomyids. Adapids have small eye orbits and elongate skulls and were adapted to folivorous or frugivorous diets, which is indicated by their cheek teeth.

Adapiformes are subdivided into five families: Caenopithecidae, Nothactidae, Sivaladapidae, Omanodontidae, and Adapidae. They also include a group of *incertae sedis* genera, such as *Simonsia*, *Alsatia*, and *Kohatius* of the late Eocene; *Hallelemur* and *Chasselasia* of the middle Eocene; and *Petrolemur* of the late Paleocene to middle Eocene. The family Caenopithecidae includes four genera: early middle Eocene *Aframoni*, middle Eocene *Caenopithecus*, and late Eocene *Mahgarita* as well as middle Eocene *Adapoides*, whose fossils come from Africa, Eurasia, and North America. They lacked some of the typical specialization of the Adapiformes (in the dentition) but have affinities with the cercamoniine and nothactids.

The family Nothactidae is an extensive group of adapiforms, which is subdivided into three subfamilies, each one with several genera: early Eocene–early Oligocene subfamily Cercamoniinae (including the genera *Anchomomys*, *Buxella*, *Barnesia*, *Donrussellia*, *Europolemur*, *Agerinia*, *Pronycticebus*, *Cercamoni*, *Protoadapis*, *Periconodon*, and *Wadilemur*), early middle Eocene subfamily Nothactinae (including the genera *Cantius*, *Notharctus*, *Pelycodus*, *Copelemur*, *Smilodectes*, and *Hesperolemur*), and middle late Eocene subfamily Pondaunginae (including the genera *Siamopithecus*, *Amphipithecus*, *Bugtipithecus*, and *Pondaungia*). They possessed a generally long muzzle, opposable thumbs, big toes, flexible limbs, a long tail, and a supple back. The most famous nothactid is the middle Eocene *Notharctus*, which had extremely long digits and skeletal proportions that resemble the living lemurs (about 7 kg in weight). Older and smaller (1–3 kg in weight) was the early middle Eocene genus *Cantius*, a diurnal, arboreal, and quadrupedal prosimian. The primitive cercamoniine *Donrussellia* might be close to a common ancestor of the adapids.

The family Adapidae includes species that are characterized by forward-facing eyes, a postorbital bar, a large brain, a reduced snout, and vertical incisors. It has been subdivided into two subfamilies: the early late Eocene subfamily Pronycticebinae (including the genera *Pronycticebus* and *Agerinia*) and the early Eocene–early Oligocene subfamily Adapinae (including the genera *Microadapis*, *Leptadapis*, *Adapis*, *Palaeolemur*, *Cryptadapis*, and *Godinotia*). The most characteristic member was the late Eocene genus *Adapis*, a prosimian that was diurnal, folivorous, and a slow arboreal quadruped similar to the slow lorises. Their dental formula was 2/2 (incisors), 1/1 (canines), 4/4 (premolars), 3/3 (molars) = 40 teeth.

Adapiform evolutionary relationships are controversial, but it is widely accepted (according to the postcranial

skeleton characteristics) that they belong to the strepsirrhines. However, the most primitive adapiforms lacked many of the anatomical specializations of present strepsirrhines (e.g., lack of a toothcomb), suggesting that they are the basal group of strepsirrhines.

During the late Eocene and mainly during the Eocene-Oligocene transition, the climate changed, becoming very cool. It was a large extinction episode in which many large mammals disappeared, including almost all the adapiforms. The mid- to high-latitude vegetation changed dramatically from broadleaf evergreen rain forest to deciduous forest. Remnant Primates were forced to cluster into smaller forest areas near the equator. Among the survivors, there was a reduced group of adapiforms belonging to the families Omanodonidae and Sivaladapidae. The family Omanodonidae includes only one known genus, the early Oligocene *Omanodon*, which was related to primitive anthropoids. The family Sivaladapidae includes late Miocene adapiforms of 2 to 5 kg in weight and adapted to a folivorous diet. It has been subdivided into two subfamilies: the middle late Eocene subfamily Hoanghoniinae (including the genera *Hoanghonius*, *Guangxilemur*, *Rencunius*, and *Wailekia*) and the middle late Miocene subfamily Sivaladapinae (including the genera *Sivaladapis*, *Indraloris*, and *Sinoadapis*).

Lorisiformes

The infraorder Lorisiformes includes African and Asian strepsirrhines typically known as galagos or lorises. They are closely related to both the Chiromyiformes (aye-ayes) and the Lemuriformes (lemurs), but it is currently unknown whether the Chiromyiformes (aye-ayes) represent a form ancestral to both the Lemuriformes and Lorisiformes or are simply related more closely to the Lemuriformes. DNA molecular-clock analyses suggest that chiromyiforms and lemuriforms constitute a clade that diverged from the Lorisiformes about 50 million years ago. The infraorder Lorisiformes included three families, two of them extant: Lorisidae and Galagidae and the fossil family Plesiopithecidae.

The family Plesiopithecidae includes only one known fossil genus: *Plesiopithecus* (late Eocene species *P. teras*). The 36-million-year-old genus *Plesiopithecus* is clearly a strepsirrhine prosimian, although mandibular and molar morphologies resemble those of the archaic members of the anthropoids. Its dental formula was 2/0 (incisors), 1/1 (canines), 4/4 (premolars), 3/3 (molars) = 34 teeth, the canines being very large. It was a frugivorous, lorislike prosimian, probably without close ties to extant strepsirrhines. Molecular-clock analyses suggest that lorises and galagids diverged about 23 million years ago, so the plesiopithecids may be the last common ancestor of both extant families.

The family Lorisidae includes the modern lorises, such as lorises, pottos, and angwantibos, which live in tropical central Africa and south Asia. They are arboreal, diurnal, and predominantly insectivorous, but they can also consume

bird eggs, small vertebrates, fruits, and sap. Their size is short, between 17 and 40 cm in length, and 0.3 to 2 kg in weight. Their face is forward and their eyes are large. Their dental formula is 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 36 teeth. Their thumbs are opposable, but their index fingers are short. They are subdivided into two great subfamilies: Lorisinae, which includes the extant genera *Arctocebus* (angwantibos) and *Loris* (slender loris), and Nycticebinae or Perodicticinae, which includes the extant genera *Perodicticus* (pottos), *Pseudopotto* (false pottos), and *Nycticebus* (slow loris). The first subfamily, Lorisinae, includes besides two other fossil genera, *Mioeutoticus* (early Miocene) and *Karanisia* (late Eocene); the second subfamily includes Nycticebinae and the other fossil genus *Nycticeboides* (late Miocene).

The family Galagidae includes the small, nocturnal lorisiforms known as galagos. They are agile leapers and run swiftly along branches and are omnivorous but mainly insectivorous. They have large eyes, strong hindlimbs, and long tails. Like lorids, their dental formula is 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 36 teeth. Galagids include four extant genera, *Otolemur* (greater galagos), *Euoticus* (needle-clawed bush babies), *Galago*, and *Galagoidea* (lesser galagos), as well as the three fossil genera *Saharagalago* (late Eocene), *Progalago* (early Miocene), and *Komba* (early middle Miocene).

Chiromyiformes

The infraorder Chiromyiformes includes only one extant species (*Daubentonia madagascariensis*), which is included in the family Daubentoniidae. They are the aye-ayes, dwellers of rain forests or deciduous forests. They do not exhibit sexual dimorphism, being of 30 to 40 cm in body length and 45 to 55 cm tail lengths. Their face and teeth are rodentlike and their body squirrel-like. The teeth number of Chiromyiformes is very reduced, their dental formula being 1/1 (incisors), 0/0 (canines), 1/0 (premolars), 3/3 (molars) = 9 teeth. They possess opposable thumbs much like other Primates, although both the hallux and fingers are long and slender.

This is an enigmatic group whose phylogenetic relationships are not clear. No fossils of Chiromyiformes have been found. The only other known species, *Daubentonia robusta* (giant aye-aye), became extinct at the beginning of the 20th century. If they represent a basal group to all the strepsirrhines, then they might have evolved 63 million years ago; but if they are simply a sister clade to Lemuriformes, then they might have evolved 50 million years ago. Molecular-clock analyses suggest that Chiromyiformes and Lemuriformes diverged more than 45 million years ago.

Lemuriformes

The infraorder Lemuriformes includes the typically known lemurs, nicknamed as spirits of the night, or ghosts,

due to their large, reflective eyes that shine at night. The infraorder is subdivided into five families: Cheirogaleidae, Megaladapidae, Lepilemuridae, Lemuridae, and Indridae. The scheme of evolutionary relationships supports the hypothesis that strepsirrhines had an African Arabian origin and that lemuriforms likely colonized Madagascar by crossing the Mozambique Channel. DNA molecular-clock analyses suggest that indrids are the more primitive among the extant lemuriforms; indrids are derived from lemuriids, as were the cheirogaleids 28 million years ago.

The family Cheirogaleidae includes the dwarf and mouse lemurs, small lemuriforms living in Madagascar that are nocturnal, arboreal, and omnivorous. Their size is only 15 to 30 cm, and they weigh no more than 0.5 kg. Their dental formula is 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 36 teeth. They comprise five extant genera, *Cheirogaleus*, *Microcebus*, *Mirza*, *Allocebus*, and *Phaner*, and one known fossil genus, *Bugtilemur* (the late Oligocene species *B. mathesoni*). Although they include the earliest known fossils of lemuriforms, DNA molecular-clock analyses suggest that they are a more derived group.

The family Megaladapidae is extinct and includes only one genus: *Megaladapis* (Pleistocene-Holocene species *M. brachycephalus*, *M. dubius*, *M. edwardsi*, *M. grandidieri*, *M. insignis*, and *M. madagascariensis*). Its species lived in Madagascar and became extinct only 500 years ago. They were large, between 1.3 and 1.5 m in length, and had long arms and fingers (specialized for grasping trees) and legs adapted for vertical climbing. They are closely related to the lepilemurs, which were for a time included with the megaladapids. The family Lepilemuridae includes the sportive lemurs (*Lepilemur*), a medium-sized lemuriform with a 30 to 35 cm length and 0.9 kg weight. They are herbivorous, strictly nocturnal, and predominantly arboreal. No fossil species belonging to this family has been found, and sportive lemurs are known only during the recent Holocene.

The Pliocene-Recent family Lemuridae includes the typical lemurs. They are medium-sized lemuriforms, arboreal, quadrupedal, agile, and herbivorous. They are 30 to 55 cm in length and 0.7 to 5 kg in weight. Their hindlimbs are slightly longer than their forelimbs. Their dental formula is 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 36 teeth. The family includes five extant genera, *Hapalemur* (bamboo lemurs), *Prolemur* (greater bamboo lemurs), *Lemur* (ring-tailed lemurs), *Varecia* (ruffed lemurs), and *Eulemur* (brown lemurs), and one recently extinct genus, *Pachylemur* (Holocene species *P. insignis* and *P. jullyi*), which lived in Madagascar and is closely related to *Varecia*.

The Pleistocene-Recent family Indridae includes large-sized lemuriforms known as indrids. There are three extant indrid genera: *Indri* (indrids or babakotos), *Avahi* (avahis or woolly indrids), and *Propithecus* (sifakas). They are arboreal and herbivorous, and they are large in size but vary in

size considerably from species to species. While the avahis are only 30 to 50 cm in length and 0.6 to 1.2 kg in weight, the sifakas are 45 to 55 cm and 4 to 6 kg and the indrids are 65 to 80 cm and 8 to 13 kg. Their hind legs are longer than their forelegs, with long and thin hands. Their thumbs cannot be opposed to the other fingers correctly. Their dental formula is 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth. There is a fossil genus, with close ties to extant indrids, called *Mesopropithecus* (Pleistocene–middle Holocene species *M. pithecoides*, *M. globiceps*, and *M. dolichobrachion*), a larger and longer-armed indrid, which became extinct only 500 years ago.

The three extant genera mentioned above and *Mesopropithecus* have been grouped in the subfamily Indridinae. In addition, another two extinct indrid subfamilies have been considered: Archaeolemurinae, which includes the fossil genera *Hydropithecus* (Pleistocene-Holocene species *H. stenognathus*) and *Archaeolemur* (Pleistocene-Holocene species *A. majori* and *A. edwardsi*); and Palaeopropithecinae, known as “sloth lemurs,” which includes the fossil genera *Archaeoindris* (early Holocene species *A. fontoynti*), *Babakotia* (Holocene species *B. radofilai*), and *Palaeopropithecus* (Holocene species *P. ingens* and *P. maximus*). All of them document a wide adaptive radiation of lemuriforms in Madagascar from their arrival on the island to little more than 1,000 years ago. *Hydropithecus* was a large lemuriform up to 13 kg in weight, probably terrestrial, that lived until recently (less than 1,000 years ago), becoming extinct probably before the arrival of humans to the island of Madagascar. *Archaeolemur* was semiterrestrial, about 17 kg in weight, and clearly related to the living indrids. Both archaeolemurine genera belonged to the ancestral group of the indrids. *Palaeopropithecus* was a large-sized, climber-hanger lemuriform, with a dental formula of 2/2 (incisors), 1/0 (canines), 2/2 (premolars), 3/3 (molars) = 30 teeth, that is, with a canine lacking on the lower jaw. *Archaeoindris* was the largest of the Primates of Madagascar, which weighed almost 200 kg and measured around 1.5 m in height. Due to its weight, it should be near-exclusively terrestrial or adapted to slow, ponderous climbing, like the sloths. *Babakotia* was a medium-sized (approximately 15 kg in weight) indrid whose inferred positional behaviors were primarily slow climbing and hanging. The indrid genus *Mesopropithecus* was close to these more primitive paleopropithecines.

Haplorrhines

The suborder Haplorrhini includes the “dry-nosed” Primates, that is, prosimian tarsiers and simians, also called anthropoids. Their brain capacity is significantly greater than the strepsirrhines’ brain capacity. Haplorrhines include two great groups or clades sometimes considered as suborders: Tarsiiformes and Anthropoidea. In the latter case,

both haplorrhines and strepsirrhines should rise to an upper category, perhaps as semiorders. DNA molecular-clock analyses indicate that tarsiiiforms and anthropoids parted ways 58 million years ago.

Tarsiiiformes

The Tarsiiiformes include the modern tarsiers (genus *Tarsius*), living on the islands of southeastern Asia. They are the most primitive group of the haplorrhines. They were widespread in the past, their fossils being found in Eurasia and North America and perhaps in Africa. This group is often classified as an infraorder although others consider that this group should be elevated to an upper category (suborder Tarsiiiformes). Tarsiiiformes represent a link between toothcombed strepsirrhines and the anthropoids. They include only one infraorder: Tarsioidea.

The carpolestid is an extinct family traditionally included in Plesiadapiformes, but it has been considered on some occasions as belonging to Tarsiiiformes. Carpolestids are relatively late Paleocene–early Eocene Tarsiiiformes-like Plesiadapiformes of Eurasia and North America. Their size was similar to that of a mouse, approximately 0.02 to 0.15 kg in weight. They were characterized by two large upper-posterior premolars and one large lower-posterior premolar. Carpolestids have been considered the ancestor of both tarsoids and anthropoids and classified as a second infraorder (Carpolestoidea) within the clade tarsiiiforms. Nevertheless, the phylogenetic relationships of these groups are not clear. Among the known genera are the *Carpodaptes* of the early Paleocene to early Eocene (62–50 million years ago), *Elphidotarsius* of the early to the late Paleocene (62–56 million years ago), *Carpolestes* of the middle to late Paleocene (60–56 million years ago), and *Chronolestes* of the early Eocene (55–49 million years ago).

The infraorder Tarsioidea includes the modern tarsiers or prosimian haplorrhines, which are grouped in the family Tarsiidae. It also comprises fossil species of two other extinct families: Omomyidae and Afrotarsiidae. The family Omomyidae is the most primitive and includes the typically known omomyids, all extinct, that radiated during the Eocene between 55 and 34 million years ago. Their fossils have been found in North America, Eurasia, and possibly Africa and are the most remarkable Primates of the Eocene together with the strepsirrhine adapids. Their size was relatively small, with a weight less than 0.5 kg, although some reached more than 1 kg. They had a large brain, large eye orbits, a narrow gap between the eyes, and a short face with dental arcades. Their dental formula was 2/2 (incisors), 1/1 (canines), 2/2 or 3/3 (premolars), 3/3 (molars) = 32 to 34 teeth. They were frugivorous or folivorous and presumably still had a rhinarium, that is, a wet nose, indicating that they were a very primitive haplorrhine. Many paleoprimatologists consider them a basal member of all haplorrhines, that is, the base of both tarsiiiforms and anthropoids. However, others consider them a

basal member of only the tarsiiiforms, whereas still others consider them related to adapids and carpolestids.

Omomyids have been subdivided into three subfamilies, Anaptomorphinae, Microchoerinae, and Omomyinae, and a group of *incertae sedis* genera, probably primitive members of the family Omomyidae. Among these last are included *Altiatlasius* of the late Paleocene (58–56 million years ago) and *Altanius* of the early Eocene (58–56 million years ago). The age of these fossil genera is consistent with the DNA molecular-clock analyses, whether or not they are considered the ancestor of both tarsiiiforms and anthropoids. The subfamily Anaptomorphinae includes an extensive group of primitive omomyids, which include *Troglemur* of the middle and late Eocene (48–40 million years ago), and both *Teilhardina* and *Tetonius* of the early Eocene (58–56 million years ago). *Teilhardina*, an insectivorous tarsier-like omomyid of 0.1 kg in weight, may also be near the base of the radiation that produced all living haplorrhines. Among the genera of the subfamily Microchoerinae are included *Pseudoloris* of the middle Eocene to early Oligocene and *Necrolemur* of the middle to late Eocene. The most extensive group of omomyids is the subfamily Omomyinae, which includes well-known genera such as *Omomys* and *Shoshonius* of the early Eocene, *Utahia* of the early to middle Eocene, *Macrotarsius* of the middle Eocene to early Oligocene, and *Rooneyia* of the late Eocene to early Oligocene. The approximately 50-million-year-old genus *Shoshonius* was a 0.15-kg-in-weight prosimian with a very similar morphology to the modern tarsier. The 50- to 45-million-year-old genus *Omomys* was more similar to galagos than to tarsiers in its morphology, being 0.3 kg in weight.

The family Tarsiidae includes small prosimians with enormous eyes, very long hindlimbs, and extremely elongated feet. Unlike other prosimians, tarsiers have no toothcomb for which they were definitively classified within haplorrhines and not within the strepsirrhines like the rest of the prosimians. Their dental formula is 1/1 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 32 teeth. They are primarily insectivorous, although they also eat small vertebrates. The family Tarsiidae includes eight species, including *Tarsius syrichta* (Philippine tarsier), *Tarsius bancanus* (Horsfield's tarsier), *Tarsius tarsier* (spectral tarsier), and *Tarsius pumilus* (pygmy tarsier). *T. bancanus* is a fossil species from the middle Eocene about 45 million years ago. Other extinct fossil species have been found, such as *Tarsius eocaenus* of the middle Eocene (about 45 million years ago) and *Tarsius thailandica* of the early Miocene (about 20 million years ago). The other extinct family of the infraorder Tarsioidea, the family Afrotarsiidae, is closely related to extant tarsiers. It is a fossil group of particular interest in questions about the origin of tarsier specializations and the early tarsiod radiations during the early and middle Oligocene (33–26 million years ago). Only one genus, *Afrotarsius*, and only one species, *Afrotarsius chatrathi*, of this family are known to date.

Anthropoids

The anthropoids, also called simiiforms, include the simians, that is, the higher Primates, such as the familiarly known monkeys, apes, and humans. Like Tarsiiformes, this group is often classified as an infraorder, the infraorder Anthropoidea, although others consider that it should be elevated to an upper category (suborder Anthropoidea). This taxon is traditionally subdivided into two great infrarorders, Platyrrhini and Catarrhini, but there are some primitive fossil anthropoids whose assignment to one of these two infraorders is debatable.

The most primitive anthropoids belong to the group called informally palaeoanthropoid, which could be considered a new infraorder (“Palaeoanthropoidae”). It includes two families: “Palaeoanthropidae” and Pondaungidae. The first family includes genera such as *Myanmarpithecus* (middle Eocene species *M. yarshensis*) and *Djebelemur* (early Eocene species *D. martinezi*). The second family has been subdivided into two subfamilies: Siamopithicini, which includes the genus *Siamopithecus* (late Eocene species *S. eoacenus*), a primitive, medium-sized (7 kg in weight) palaeoanthropoid; and Pondaungini, which includes the genera *Amphipithecus* (late Eocene species *A. mogaungensis*) and *Pondaungia* (middle late Eocene species *P. cotteri* and *P. savagei*) as well as other palaeoanthropoids of medium size (7 kg in weight) and frugivorous.

Platyrrhines and catarrhines split from the ancestral simian line about 50 million years ago (late Eocene), the first ones occupying the New World and the second ones occupying the Old World. DNA molecular-clock analyses suggest that platyrrhines and catarrhines diverged about 40 to 45 million years ago. Earlier fossil members of anthropoids of both platyrrhines and catarrhines had small brain sizes, but the larger brain sizes seen in both groups today must have arisen independently. This documents that large brains evolved separately several times within the Primates.

Platyrrhines

The infraorder Platyrrhini includes the New World monkeys of Central and South America, such as the titis, tamarins, marmosets, capuchins, and so on. They are small or medium-sized anthropoids, which differ from catarrhines mainly by a flat nose and by having 12 premolars instead of 8. Their dental formula is 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 40 teeth. Almost all platyrrhines are arboreal and show substantial paternal care of the young.

About 50 million years ago, the ancestral anthropoids split into platyrrhines and catarrhines. The first platyrrhines surely migrated across the Atlantic Ocean from Africa to South America, perhaps on a raft of vegetation similar to the vast pieces of floating mangrove forest that storms occasionally break off at present from the tropical African coast. The infraorder Platyrrhini is subdivided into six families:

Branisellidae, Callitrichidae, Atelidae, Pitheciidae, Cebidae, and Aotidae (the first of which is one fossil group of primitive platyrrhines). DNA molecular-clock studies indicate that cebids, aotids, and callitrichids constitute a clade, diverging one from another 20 million years ago; cebids are the most primitive group of this clade and callitrichids the most derived. In addition, atelids and pitheciids form other clades. Both clades diverged 25 million years ago.

The extinct family Branisellidae is composed of a single genus, *Branisella* (late Oligocene species *B. boliviana*). This genus lived 26 million years ago in South America, and it is an interesting fossil because of its dental similarity with the Oligocene *Proteopithecus*, a primitive catarrhine. This has allowed paleoprimatologists to hypothesize that the primitive platyrrhine ancestors came to South America from Africa. The modern platyrrhines, which are most closely related in morphology to *Branisella*, appear to be the callitrichids. Nevertheless, the first platyrrhines should be primitive monkeys close to the branisellids that shared traits common to all the first representatives of each platyrrhine family.

The family Cebidae is an extensive group that includes the capuchin and squirrel monkeys. They are generally arboreal, diurnal, and omnivorous and mainly eat fruits and insects. Their dental formula is 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 or 2/2 (molars) = 40 to 36 teeth. The family has been subdivided into two extant subfamilies (Saimiriinae and Cebinae) and three other fossil subfamilies (Palaeocebinae, Tremacebinae, and Lagonimiconinae). According to molecular-clock analyses, the two extant subfamilies, saimiriines and cebines, diverged about 20 million years ago.

The subfamily Saimiriinae includes the present *Saimiri* (squirrel monkeys), which live in tropical forests of Central and South America. They are small, diurnal, arboreal monkeys of 60 to 75 cm (of which 35–40 cm are the tail) and 0.8 to 1.1 kg in weight. They appeared in the middle Miocene, and an extinct species (*S. fieldsi*) is known. A fossil genus of Saimiriinae is also known, *Laventiana* (middle Miocene species *L. annectens*). *Laventiana* is closely related to *Saimiri* and *Cebus*, and it has been considered an intermediate taxon between squirrel monkeys (*Saimiri*) and callitrichids. The subfamily Cebinae includes the modern *Cebus* (capuchin monkeys or capuchins), which appeared in the Pleistocene, and a fossil genus *Dolichocebus* (late Oligocene species *D. gaimanensis*). Capuchins are small monkeys of about 30 to 45 cm in body length and 4 kg in weight. They are characterized by a prehensile tail and a small brain capacity (about 80 cm³). *Dolichocebus* lived 25 to 24 million years ago, and it is strongly related to the Saimiriinae lineage.

The extinct subfamily Palaeocebinae includes three genera: *Chilecebus* (early Miocene species *C. carrascoensis*), *Patasola* (middle Miocene species *P. magdalanae*), and *Antillothrix* (late Pleistocene–middle Holocene species *A. bernensis*). The 20-million-year-old genus *Chilecebus* was a

small monkey of about 0.6 kg, with a smaller relative brain size than the brain of modern Cebidae. *Patasola* shares dental features with callichitrids and saimirines, suggesting that they are the first descendants of the cebids. *Antillothrix* has close ties to cebid capuchins and is nicknamed the Hispaniola monkey since it was found on the island of Hispaniola.

The extinct subfamily Tremacebinae includes only one genus, *Tremacebus* (late Oligocene–early Miocene species *T. harringtoni*), a Patagonian monkey of about 1 m in length closely related to modern night monkeys (*Aotus*). The extinct subfamily Lagonimiconinae includes a single genus, *Lagonimico* (middle Miocene species *L. conclutatus*), a giant tamarin-like cebid of about 1.2 kg that lived 13.5 million years ago.

The family Aotidae includes the modern *Aotus* (from the middle Miocene). They are the night monkeys, also called owl monkeys or douroucoulis, living in the forests of Central and South America. They are nocturnal, arboreal, quadrupedal, and omnivorous monkeys, including insects and small vertebrates in their diet. They are small to medium-sized monkeys of 50 to 100 cm in length (including a 20–50 cm tail) and 0.5 to 1.3 kg in weight. One fossil species of the middle Miocene is known, the 12-million-year-old *Aotus didensis*. It could be related to primitive atelid *Xenothrix*.

The family Callitrichidae includes some types of marmosets and tamarins, which are the smallest of the anthropoids. All of them are arboreal and mainly insectivorous and frugivorous, although some also eat small vertebrates. The family consists of two subfamilies: Callimiconinae and Callitrichinae, which diverged 13 million years ago according to molecular-clock studies. The first one includes the modern genus *Callimico* (species *C. goeldii* or Goldey's marmoset) and the fossil genus *Mohanamico* (middle Miocene species *M. herskovitzi*). *Callimico* is a small Amazonian marmoset of 50 cm in length (30 cm of which are the tail). The second family includes three extant genera, *Leontopithecus*, *Saguinus*, and *Callithrix*, and one fossil genus, *Micodon* (middle Miocene species *M. kiotensis*). *Callithrix* includes the marmosets and is sometimes divided into four species: *Callithrix* (Atlantic marmosets), *Mico* (Amazonian marmosets), *Callibella* (Roosmalen's dwarf marmosets), and *Cebuella* (pygmy marmosets). They are very small monkeys, most of which are about 15 to 25 cm in body size and about 0.4 kg in weight. *Saguinus* includes the tamarins, small omnivorous monkeys of 50 to 70 cm in length (30–40 cm of which are the tail) and about 0.3 to 0.9 kg in weight. *Leontopithecus* are the lion tamarins, small, diurnal, tree-dweller monkeys of 75 cm in length (45 cm of which are the tail) and about 0.9 kg in weight. No fossil species are known of these genera although the living species have fossils known from the Pleistocene. The middle Miocene genus *Mohanamico* was a small extinct marmoset of about 1 kg in weight that lived in Amazonia.

The family Pitheciidae includes the titis, saki monkeys, and uakaris. They are small or medium-sized monkeys,

diurnal, arboreal, quadrupedal, and predominantly herbivorous (fruits and seeds), although some also eat insects. The family consists of two subfamilies: Pitheciinae and Callicebinae (or Homunculinae). DNA molecular-clock analyses indicate pitheciines and callicebines parted ways 17 million years ago.

The subfamily Pitheciinae consists of three extant genera, *Pithecia*, *Chiropotes*, and *Cacajao*, all of which are known only from the Holocene. *Pithecia* includes the sakis or saki monkeys, which reach 60 to 100 cm in length (of which 30–50 cm are the tail) and about 1.8 to 2.2 kg in weight and are omnivorous (including small rodents and bats in their diet). They have close ties to *Chiropotes*, the bearded sakis, medium-sized monkeys of similar length but more weighty (2–4 kg) than *Pithecia*. *Cacajao* includes the uakaris, which have tails (15–18 cm) of substantially less length than their bodies (40–45 cm). According to the DNA molecular-clock analyses, the *Chiropotes-Cacajao* group diverged from the *Pithecia* group about 10 million years ago. In addition, five extinct genera have been recognized within the pitheciines: *Soriacebus* (early Miocene species *S. ameghinorum* and *S. adriane*), *Proteropithecina* (middle Miocene species *P. neuquenensis*), *Cebupithecia* (middle Miocene species *C. sermientoi*), *Nuciraptor* (middle Miocene species *N. rubricae*), and *Mohanamico* (middle Miocene species *M. herskovitzi*). Some of the dental and mandibular characteristics of *Soriacebus* resemble the callichitrids, while those of *Proteropithecina* suggest a relationship with callicebines. *Mohanamico* is a problematic genus that has been related to the callichitrids but also to *Aotus*.

The subfamily Callicebinae consisted of one modern genus: *Callicebus* (from the Pleistocene), which is sometimes subdivided into two genera (*Callicebus* and *Torquatus*). They are the titis or titi monkeys, small monkeys that have a furry tail (25–55 cm) longer than the body (25–45 cm). The subfamily Callicebinae also includes two extinct genera: *Homunculus* (early middle Miocene species *H. patagonicus*) and *Carlocebus* (early Miocene species *C. carmenensis* and *C. intermedius*). The first genus was a diurnal, omnivorous monkey, which seems to be related to both the cebid *Tremacebus* and the atelid *Brachyletes*. *Carlocebus* was another callicebine, predominantly frugivorous, closely related to the modern *Callicebus*.

The family Atelidae includes the only Primates whose tails are prehensile (in addition to capuchins). They are the howler, spider, and woolly monkeys, which live in the dense rain forests of Central and South America. Atelids are small to medium-sized monkeys, arboreal, diurnal, quadrupedal, and predominantly frugivorous and folivorous, although some species also eat insects. The family Atelidae is subdivided into three subfamilies, one extinct, Xenotrichinae, and two extant, Alouattinae and Atelinae. The subfamily Xenotrichinae recently became extinct, with only one genus and species known: genus *Xenothrix* (Pleistocene-Holocene species *X. mcgregori*). Members of *Xenothrix* are nicknamed

the Jamaican monkeys, which share a close affinity with both pitheciids and aotids. According to DNA molecular-clock analyses, the two extant subfamilies, alouattines and atelines, diverged about 16 million years ago.

The subfamily Alouattinae includes the modern *Alouatta* (from the Pleistocene), familiarly called howler monkeys. They have prehensile tails, move quadrupedally (but do not brachiate), and are only folivorous. Alouattines also include three extinct fossils: *Protopithecus* (late Pleistocene–early Holocene species *P. brasiliensis*), *Paralouatta* (early Miocene–late Holocene species *P. veronai* and *P. marinae*), and *Stirtonia* (middle late Miocene species *S. tatacoensis* and *S. victoriae*). *Protopithecus* was a large monkey (25 kg in weight), with characteristics resembling the two atelid subfamilies. *Paralouatta* seems to be intermediate between the xenotrichines and modern alouattines. *Stirtonia* could be near the ancestry of the atelines.

The subfamily Atelinae includes the modern *Ateles* (spider monkeys) and the group formed by the genera *Brachyteles* (muriquis), *Lagothrix* (woolly monkeys), and *Oreonax* (yellow-tailed woolly monkeys). In addition, one extinct genus is known, *Caipora* (late Pleistocene–early Holocene species *C. bambuitorum*). The living species are diurnal, arboreal, and omnivorous monkeys, characterized by prehensile tails capable of supporting their entire body weight. Spider monkeys (*Ateles*) are known from the Pleistocene and are medium-sized monkeys about 90 cm in length (including a 40-cm tail) and 6.5 kg in weight. Muriquis (*Brachyteles*), also known as woolly spider monkeys, are mainly folivorous monkeys of 40 to 60 cm in length (without their tails) and 4.5 to 9 kg in weight. Woolly monkeys (*Lagothrix*) are also medium-sized monkeys of 100 to 140 cm in length (of which 60–80 cm are their tails) and 4 to 10 kg in weight. The fossil ateline *Caipora* seems to be related to the alouattine *Protopithecus*.

Catarrhines

The infraorder Catarrhini includes the Old World monkeys from Africa and Eurasia (colobus, mandrills, langurs, macaques, baboons, etc.) grouped in the superfamily Cercopithecoidea; the apes (gibbons, orangutans, gorillas, and chimpanzees) and humans are grouped in the superfamily Hominoidea, and other fossil taxa are grouped in several superfamilies: Parapithecoidea, Propiopiithecoidea, Pliopiithecoidea, Dendropithecoidea, and Proconsuloidea. According to DNA molecular-clock analyses, the two living subfamilies, cercopithecoids and hominoids, parted ways about 25 million years ago. According to morpho-cladistic analyses, the parapithecoids are the most primitive, and from them evolved the propiopiithecoids. Both superfamilies have been sometimes grouped as the paracatarrhines, whereas the four other more modern ones represent the eucatarrhines. Among the eucatarrhines, the most primitive are the pliopiithecoids, from which evolved the dendropithecoids. These last ones may be the last common

ancestor of the cercopithecoids and hominoids, proconsulooids being intermediate between the dendropithecoids and the hominoids.

Parapithecoids

Some paleoprimatologists have considered that the parapithecoids are the last common ancestor of both platyrrhines and catarrhines, although they are probably only the basal group of all catarrhines. The superfamily Parapithecoidea consisted of two families, Eosimiidae and Parapithecoidea. The first, Eosimiidae, comprises very small primitive parapithecoids, between 0.03 and 0.3 kg in weight. They were predominantly arboreal and frugivorous. Eosimiids might be close to the ancestors of all catarrhines. Six genera are known: *Bahinia* (middle Eocene *B. pondaungensis*), *Eosimias* (middle Eocene species *E. sinensis* and *E. centenicus*), *Biretia* (late Eocene species *B. piveteaui*, *B. fayumensis*, and *B. megalopsis*), *Phenacopithecus* (middle late Eocene species *P. krishtalkai* and *P. xueshii*), *Anthrasimias* (early Eocene species *A. gujaratensis*), and *Phileosimias* (early Oligocene species *B. kalami* and *B. brahuiorum*). The 55- to 54-million-year-old genus *Anthrasimias* is probably the earliest eosimiid and has strong ties to the omomyids, such as *Altiatlasius*. The 40-million-year-old genus *Phenacopithecus* also resembles the omomyids and tarsiers, at least in its jaws, but unlike those had relatively small eyes. The 48-million-year-old genus *Eosimias* was a small primitive prosimian, 0.07 to 0.16 kg in weight, with catarrhine-like dental and mandibular characters. The 42-million-year-old genus *Bahinia* also possessed small eyes, suggesting both genera were diurnal. On the contrary, the 37-million-year-old *Biretia* apparently had orbits nearly as large as those of the tarsiers, evidencing nocturnality. Other traits suggest that *Biretia* is phylogenetically more advanced in the direction of the parapithecoids. The 30-million-year-old *Phileosimias* is a clear eosimiid, being the latest one, but some dental characteristics still resemble the earlier omomyids and adapiforms.

The family Parapithecoidea comprises small, early catarrhines that still retained three premolars. Their dental formula was 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 36 teeth. They are therefore primitive catarrhines that retained ancestral features like the eosimiids. The family Parapithecoidea has five genera known to date: *Qatrania* (late Eocene–middle Oligocene species *Q. wingi* and *Q. fleaglei*), *Parapithecus* (early middle Oligocene species *P. fraasi* and *P. grangeri*), *Arsinoea* (late Eocene–middle Oligocene species *A. kallimos*), *Serapia* (late Eocene–middle Oligocene species *S. eocaena*), and *Apidium* (early middle Oligocene species *A. phiomense*, *A. moustafai*, and *A. bowni*). The most well-known genera are *Parapithecus* and *Apidium*, the first probably near the base of the parapithecoid radiation. The 36- to 32-million-year-old genus *Apidium* was the smallest known of the catarrhines, approximately 30 to 40 cm in body length and 0.7 to 1.5 kg

in weight. It has a short snout, small eyes, and canine sexual dimorphism. Its individuals were diurnal, quadrupedal, and frugivorous. It seems to have certain affinities to the more modern propiipithecoid *Aegyptopithecus*. Certain dental characteristics of *Apidium* also resemble the oreopithecoids and cercopithecoids but may well have evolved in parallel or convergently in these groups. The 36- to 32-million-year-old genera *Qatrania* and *Arsinoea* were also frugivorous but resemble *Parapithecus*. The 36- to 30-million-year-old genus *Parapithecus* was a small prosimian (1.5–3 kg in weight) and surely folivorous or a seed eater. The 36- to 32-million-year-old genus *Serapia* has been considered allied to the propiipithecoids, mainly to *Proteopithecus*, but its dental traits have allowed it to be grouped with the other parapithecoids.

Propiipithecoids

The family Propiipithecoidea may be close to the common ancestry of the later catarrhines (eucatarrhines). They were primitive arboreal catarrhines the size of small cats, with apelike teeth, a small brain, and limbs similar to those of the acrobatic platyrrhine atelines. Their dental formula was already the catarrhine type: 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth. Propiipithecoids consisted of two important families, Oligopithecidae and Propiipithecidae.

The family Oligopithecidae is an extinct propiipithecoid family that includes late Eocene–middle Oligocene species. Its members were mainly insectivorous, according to its dental morphology. They split off the lineage of Old World monkeys and apes sometime after the New World monkeys split off. The family has three genera known to date: *Proteopithecus* (late Eocene–middle Oligocene species *P. sylviae*), *Catopithecus* (late Eocene–middle Oligocene species *C. browni*), and *Oligopithecus* (late Eocene–early Oligocene species *O. savagei* and *O. rogeri*). The 36- to 32-million-year-old genus *Oligopithecus* is the best known oligopithecoid. They were small monkeys, being 1 to 2 kg in weight, that lived in Africa. Their canines resemble those of the platyrrhine and callitrichines more than those of the catarrhines, their teeth being primitive compared with other haplorrhines. As propiipithecoids, they are older than Old World monkeys and apes but are already nearer the common ancestor of the extant catarrhines and cercopithecoids and hominoids. The 37- to 32-million-year-old genus *Catopithecus* was a 1-kg-weight arboreal, diurnal, quadrupedal oligopithecoid. There is an apparently evolutionary transition from primitive *Catopithecus* to relatively apelike *Aegyptopithecus*. Similar in morphology and age to *Catopithecus* is *Proteopithecus*. Both genera have been sometimes grouped in a new family called Proteopithecidae and considered an intermediate group between propiipithecoids and oligopithecoids. The evolutionary transition between primitive oligopithecoids and derived propiipithecoids requires little more than increased body size and the concomitant shift to greater frugivory.

The family Propiipithecidae includes arboreal, quadrupedal, frugivorous catarrhines with characteristics typical of the entire superfamily Propiipithecoidea. It consists of four genera known to date: *Algeripithecus* (middle Eocene species *A. minutus*), *Moeripithecus* (Oligocene species *M. markgrafi*), *Aegyptopithecus* (late Eocene–early Oligocene species *A. zeuxis*), and *Propiipithecus* (late Eocene–middle Oligocene species *P. haeckeli*, *P. chirobates*, and *P. ankei*). The most famous propiipithecoid genera are these two last ones. *Aegyptopithecus*, nicknamed dawn ape and with a single known species (*A. zeuxis*), is a propiipithecoid that lived 35 to 31 million years ago, predating the divergence between cercopithecoids and hominoids. It is a crucial link between both Eocene cercopithecoids and Miocene hominoids. Its body was small, being around 6 to 8 kg in weight, but with a long tail. Its cranium had a sagittal crest, and its brain capacity was very small (30 cm³ on average), although the brain contained advanced traits when compared with the strepsirrhines. Its canines showed sexual dimorphism. Its individuals were frugivorous (also folivorous), diurnal, arboreal, and quadrupedal, and they practiced suspensory behavior. *Propiipithecus* was a typical propiipithecoid, resembling the present gibbons. They were 40 cm in length, 4 to 6 kg in weight, and diurnal, frugivorous, arboreal, and quadrupedal, with hind-climbing suspensory behavior. *Algeripithecus* is a single taxon because it is probably the earliest known anthropoid, living 45 million years ago. *Moeripithecus* is close to *Propiipithecus*, and some have suggested that it is a juvenile specimen of the genus.

Pliipithecoids

The superfamily Pliipithecoidea is closer to the modern catarrhines or eucatarrhines (cercopithecoids and hominoids) than to the earliest catarrhines or paracatarrhines (parapithecoids and propiipithecoids). Some pliiipithecoids had shorter faces and larger brains than propiipithecoids, their brain capacity being larger (around 100 cm³). They participated in the anthropoid Primates radiation that occurred just after the middle Oligocene extinction that was caused by increased glaciation, worldwide cooling, and floral turnovers. The pliiipithecoids' and later anthropoids' body size, like their brain capacity, was larger than that of earlier anthropoids. They became primarily frugivorous, and their sexual dimorphism suggests that the anthropoids began to live in large, complex, polygamous groups. Learning and social complexity may have served to buffer them from the extremes of the increasing variability of the Oligocene climate.

The superfamily Pliipithecoidea consisted of three families: Palaeopliipithecidae, Pliipithecidae, and Crouzeliidae. The palaeopliipithecoid group includes several *incertae saedis* genera, such as *Paidopithecus* (late Miocene species *P. rhenatus*), *Kalepithecus* (early middle Miocene species

K. songhorensis), *Limnopithecus* (early middle Miocene *L. legetet* and *L. evansi*), and *Kamoyapithecus* (late Oligocene *K. hamiltoni*). The genus *Kamoyapithecus* is the oldest pliopithecoid, living 28 to 24 million years ago. It was a large-sized catarrhine, being 30 to 40 kg in weight. The 22- to 17-million-year-old genus *Limnopithecus* has some morphological similarities to *Dendropithecus*, suggesting phyletic relationships. It was a small African catarrhine of 4 to 5 kg in weight, arboreal, quadrupedal, and frugivorous. *Kalepithicus* was another small frugivorous palaeopliopithecoid, being approximately 5 kg in weight and probably related to the dendropithecoids. The 10- to 9-million-year-old genus *Paidopithecus* shared some traits with both pliopithecids and crouzeliids, but its phyletic relationships are not clear.

The family Pliopithecidae is composed of the earliest apes that combined primitive features (small brain, long snout, and a tail in some species) with more advanced features (stereoscopic vision, apelike teeth, and jaws). Their dental formula generally was 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth. Pliopithecids are subdivided into two subfamilies, early middle Miocene Dionysopithecinae and early late Miocene Pliopithecinae. The first one has two known genera: *Platodontopithecus* (early middle Miocene species *P. jianghuaiensis*) and *Dionysopithecus* (early middle Miocene species *D. shuangouensis* and *D. orientalis*). The 18- to 17-million-year-old genus *Dionysopithecus* was a small pliopithecoid closely related to the dendropithecoid *Micropithecus* (both genera have been proposed as possible gibbon ancestors).

Another pliopithecoid with similar characteristics and age was *Platodontopithecus*. Three genera are known of the subfamily Pliopithecinae: *Egarapithecus* (late Miocene species *E. narcisoi*), *Epipliopithecus* (early middle Miocene species *E. vindobonensis*), and *Pliopithecus* (middle late Miocene species *P. antiquus*, *P. platyodon*, *P. zhanxiangi*, and *P. piveteaui*). The most well-known pliopithecoid genus is *Pliopithecus*, which lived in Eurasia 17 to 15 million years ago. Its specimens are characterized by long arms that are well adapted to climbing trees. They seem to have links to the crouzeliid *Anapithecus*. The 16- to 15-million-year-old genus *Epipliopithecus* had long hands and feet and long, curved fingers compared with *Pliopithecus* and some postcranial characteristics resembling the hominoids. These individuals were very likely agile climbers. The 9-million-year-old genus *Egarapithecus* had many similarities with the crouzeliids, and some paleoprimateologists include it within this family.

The family Crouzeliidae differs from its ancestors the pliopithecids mainly in dental traits. It has three known genera: *Anapithecus* (late Miocene species *A. hernyaki*), *Laccopithecus* (late Miocene *L. robustus*), *Plesiopliopithecus* (middle-late Miocene species *P. lockeri* and *P. priensis*), and *Crouzelia* (middle-late Miocene species *C. auscitanensis* and *C. rhodanica*). The 16- to 14-million-year-old genera *Plesiopliopithecus* and *Crouzelia* are today

considered congeneric. They were small pliopithecoids with smaller teeth than *Pliopithecus* but with a similar dental formula. The 9- to 8-million-year-old genus *Anapithecus* was a medium-sized anthropoid, larger than all other pliopithecoids. Finally, the 8-million-year-old genus *Laccopithecus* was another similar crouzeliid, with canine sexual dimorphism similar to nearly all the other anthropoids. The characteristics of crouzeliids such as *Anapithecus* are consistent with the general conclusion that the pliopithecoids contain the last common ancestor of the cercopithecoid lineage and the dendropithecoid-proconsuloid-hominoid lineage.

Cercopithecoids

The superfamily Cercopithecoidea comprises the familiarly known Old World monkeys, such as baboons, mandrills, and macaques, which appeared between 25 and 22 million years ago. They are today native to Africa and Asia, inhabiting tropical rain forests, savannas, scrublands, and mountainous terrains. Nevertheless, they are also known in the European fossil record. Cercopithecoids are Primates of medium to large size, being the smallest of the talapoin (*Miopithecus*) at 35 to 40 cm in length and 0.7 to 1.3 kg in weight, and the largest of the mandrills (*Mandrillus*), whose males are 90 to 100 cm in length and 30 to 40 kg in weight. Unlike apes, they have a tail, for which they are also nicknamed tailed apes. Their dental formula is 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth, which differentiates them from apes. Most cercopithecoids are at least partially omnivorous, but they prefer a vegetarian diet. The superfamily Cercopithecoidea is composed of three families, one fossil, Victoriapithecidae, and two extant, Colobinidae and Cercopithecidae. Molecular-clock analyses suggest that the two extant families, colobinids and cercopithecids, diverged around 14 million years ago.

The family Victoriapithecidae has three known genera: *Victoriapithecus* (early middle Miocene species *V. macinnesi*), *Prohylobates* (early middle Miocene species *P. tandyi* and *P. simonsi*), and *Adelopithecus* (late Miocene species *A. hypsilophus*). *Victoriapithecus* is a single fossil, and it is the oldest cercopithecoid known to date, living 22 million years ago. It already has the typical cercopithecoid dental formula. It showed sexual dimorphism in its canines, its body mass was around 7 kg, and its mandibles were relatively deep compared with other cercopithecoids. Most famous is *Prohylobates*, a small to medium-sized monkey (4–25 kg) of frugivorous and folivorous diet. The victoriapithecids are the oldest cercopithecoids, all of them coming from Africa. They lived between 22 and 15 million years ago, predating the divergence of the modern families Colobinidae and Cercopithecidae. *Prohylobates* has been considered a possible ancestor of the colobinids, whereas *Victoriapithecus* could be a possible ancestor of the cercopithecids.

Unlike the cercopithecids, the colobinids are more restricted in morphology, range, and behavior pattern, and

all are leaf eaters with a complicated digestive tract to facilitate the low-nutrition diet. The family Colobinidae is subdivided into three subfamilies: Palaeocolobinae, Colobinae, and Presbytinae, the two last of which have extant species. DNA molecular-clock analyses suggest that colobines and presbytines diverged 10 million years ago.

The subfamily Palaeocolobinae has two extinct genera: *Dolichopithecus* (late Miocene–late Pliocene species *D. gallicus* and *D. rusciniensis*) and *Mesopithecus* (late Miocene–late Pliocene species *M. pentelicus*, *M. delsoni*, and *M. monspessulanus*). This last genus, *Mesopithecus*, is a primitive colobinid that lived 11 to 5 million years ago, surely one of the first cercopithecoids entering Eurasia from Africa. It looks similar to the macaque, with a 40-cm length. Their individuals were semiterrestrial and adapted to both walking and climbing. They were probably ancestors of the current gray langurs (*Semnopithecus*). Another possible descendant is *Dolichopithecus*, which lived in Eurasia from about 4.5 to 2.5 million years ago. It was terrestrially adapted, even more so than any living colobine.

The subfamily Colobinae includes Old World monkeys, such as the colobines and the langurs. They are medium-sized colobinids with long tails. Most species are arboreal, but some live a more terrestrial life. They are exclusively herbivores (leaves, flowers, fruits), although they occasionally eat insects and other small animals. Colobinids are composed of three extant genera: *Colobus* (late Miocene–Recent), *Ptilocolobus* (Recent), and *Procolobus* (Recent). *Colobus* are the black-and-white colobus and guerezas, which are closely related to the two other genera: *Ptilocolobus*, the red colobus, and *Procolobus*, the olive colobus. They are medium- and large-sized cercopithecoids, about 125 to 150 cm in length (including a 70–80 cm tail), and between 9 and 20 kg in weight. Five extinct colobin genera are known to date: *Microcolobus* (late Miocene species *M. tugenensis*), *Cercopithecoides* (late Pliocene–middle Pleistocene species *C. williamsi* and *C. kimeui*), *Libypithecus* (late Miocene–early Pliocene species *L. markgrafi*), *Rhinocolobus* (middle late Pliocene species *R. turkanensis*), and *Paracolobus* (early Pliocene–early Pleistocene species *P. chemeroni* and *P. mutiwa*). In addition, one fossil species of *Colobus* has been found, *C. flandrini*.

The subfamily Presbytinae includes seven extant genera: *Presbytis* (late Miocene–Recent), or gray langurs; *Semnopithecus* (Pliocene–Recent), or surilis; *Trachypithecus* (late Pliocene–Recent), or lutungs; *Pygathrix* (early Pleistocene–Recent), or doucs; *Rhinopithecus* (early Pleistocene–Recent), or snub-nosed monkeys; *Simias* (Recent), or pig-tailed langurs; and *Nasalis* (Recent), or proboscis monkeys, also known as long-nosed monkeys. They are medium- to large-sized, diurnal, arboreal, herbivorous or frugivorous monkeys of 90 to 180 cm in length (including a 50–100 cm tail) and between 5 and 25 kg in weight. Like the colobines, they show sexual dimorphism in size. Presbytines also include one extinct genus, *Parapresbytis* (late Pliocene species *P. eohanuman*), which seems to be phylogenetically close to

the palaeocolobin *Dolichopithecus*. Several fossil species of *Presbytis* (*P. sivalensis*), *Trachypithecus* (*T. robustus* and *T. sangiranensis*), and *Rhinopithecus* (*R. lantianensis*) have been also been identified.

The family Cercopithecidae includes a wide variety of forms, all of which share cheek pouches for temporary food storage and usually large incisors reflecting a frugivorous diet. It is subdivided into four subfamilies: Macacinae, Papioninae, Theropithecinae, and Cercopithecinae. Cercopithecids are represented first by the fossil papionine *Parapapio*, which was a semiterrestrial monkey probably close to the common ancestor of later forms, and then by several species of the highly terrestrial living *Theropithecus*. DNA molecular-clock analyses indicate that macacines, papionins, and theropithecines constitute a clade that diverged from cercopithecines 10 million years ago. These studies also suggest that macacines, papionins, and theropithecines parted different ways around 7 million years ago.

The subfamily Macacinae is probably the most conservative of the cercopithecids, most species retaining ancestral traits in teeth, skull, and other structures. They are closely related to *Parapapio*. The subfamily has one extant genus, *Macaca* (late Miocene–Recent), the macaques, and two fossil genera, *Paradolichopithecus* (late Pliocene–Pleistocene species *P. arvernensis*) and *Procynocephalus* (late Pliocene–early Pleistocene species *P. wimani* and *P. subhimalayensis*). In addition, seven fossil species of *Macaca* have been found: *M. florentina*, *M. prisca*, *M. majori*, *M. libyca*, *M. anderssoni*, *M. jiangchuanensis*, and *M. palaeindica*. The macaques are diurnal, arboreal, rain forest dwellers, omnivorous, medium-sized monkeys of 50 to 130 cm in length (including a 2–70 cm tail) and between 3 and 10 kg in weight, with sexual dimorphism in size and tail size varying considerably from species to species. They are the most widespread of the Primates, aside from humans. The fossil record of the modern *Macaca* indicates that they were once even more widespread than today, living in Europe in addition to North Africa and eastern Asia. A large and semiterrestrial relative, *Paradolichopithecus*, inhabited Europe, central Asia, and perhaps eastern Asia 4 to 1.5 million years ago. *Procynocephalus* was a terrestrial, large-sized macacine savanna dweller and a root, fruit, and grass eater.

The subfamily Papioninae includes species that are omnivorous, diurnal, and mostly terrestrial or semiterrestrial, although most mangabeys are arboreal and frugivorous. It has five extant genera: *Papio* (early Pliocene–Recent), or baboons; *Mandrillus* (Recent), or mandrills and drills; *Lophocebus* (Recent), or crested mangabeys; *Rungwecebus* (Recent), or kipunjis; and *Cercocebus* (late Pliocene–Recent), or white-eyed mangabeys. They are medium- to large-sized monkeys of 90 to 180 cm in length (including a 50–100 cm tail) and between 8 and 60 kg in weight. They have a pronounced sexual dimorphism. No fossil species of *Mandrillus*, *Lophocebus*, *Rungwecebus*, or *Cercocebus* have been found. However, two fossil species of *Papio* are known, *P. izodi* and *P. robinsoni*. The subfamily Papioninae

comprises, besides three extinct known genera, *Parapapio* (late Miocene–lower Pleistocene species *P. broomi*, *P. joseni*, *P. whitei*, *P. antiquus*, and *P. ado*), *Dinopithecus* (late Pliocene–lower Pleistocene species *D. ingens*), and *Gorgopithecus* (late Pliocene–lower Pleistocene species *G. major*). *Parapapio* was a medium- to large-sized, semiterrestrial cercopithecoid, and appears to be near the common ancestor of all papionines. *Dinopithecus* is one of the largest cercopithecoids known, except for modern *Theropithecus*, is also semiterrestrial, and has a robust skull including a sagittal crest and strong nuchal crest. *Gorgopithecus*, nicknamed the giant baboon, was a large papionine, probably semiterrestrial, and inhabited an open environment.

The subfamily Theropithecinae is probably a recent descendant of the papionines. They are very close to *Papio* as suggested by molecular studies; both theropithecines and papionines diverged 4 million years ago. Theropithecinae has one extant genus: *Theropithecus* (early Pliocene–Recent), known as geladas, and two fossil genera, *Simopithecus* (Pliocene species *S. darti*, *S. oswaldi*, *S. leakeyi*, and *S. delsoni*) and *Omopithecus* (Pliocene–early Pleistocene species *O. brumpti*, *O. baringensis*, and *O. quadrirostris*). No fossil species of *Theropithecus* has been found, but the genus is known from 4 million years ago. Geladas are herbivorous, largely terrestrial, large-sized monkeys of 65 to 75 cm in body length, 45 to 50 cm in tail length, and between 12 and 20 kg in weight, with sexual dimorphism in size. They have the most opposable thumbs of any of the catarrhines, except for humans. The 4- to 2-million-year-old genus *Simopithecus* is closely related to *Theropithecus*, with identical terrestrial locomotor strategies, although *Simopithecus* possibly used arboreal substrates. The 3.5- to 1.5-million-year-old genus *Omopithecus* has close ties to *Papio*, showing the close phylogenetic relationship between papionines and theropithecines.

The subfamily Cercopithecinae is the least represented in the fossil record, except for some fossils of *Cercopithecus*. It is composed of four living genera: *Allenopithecus* (Recent), or Allen's swamp monkeys; *Cercopithecus* (late Pliocene–Recent), or guenons and Mona monkeys; *Chlorocebus* (Recent), or vervet monkeys; *Erythrocebus* (Recent), or patas monkeys; and *Miopithecus* (Recent), or telapins. Most are omnivorous and arboreal although *Erythrocebus* is among the most terrestrial of all cercopithecoids, and some *Cercopithecus* are partially folivorous. Except for the telapins, they are medium-sized monkeys of 90 to 140 cm in length (including a 50–75 cm tail), and between 4 and 8 kg in weight, with great sexual dimorphism. Telapins (*Miopithecus*) are the smallest Old World monkeys, with typically 30 to 45 cm in body length and between 0.8 and 1.3 kg in weight.

Dendropithecoids

The extinct superfamily Dendropithecoidea is composed of one family, Dendropithecidae, with three genera:

Dendropithecus (late Oligocene–middle Miocene species *D. macinnesi*), *Micropithecus* (middle Miocene species *M. clarki* and *M. leakeyorum*), and *Simiolus* (early middle Miocene species *S. enjiessi*). They possessed significant sexual dimorphism in size, and their dental formula was 2/2 (incisors), 1/1 (canines), 3/3 (premolars), 3/3 (molars) = 34 teeth. Their canines were strongly bilaterally compressed, their limb bones were slender, and the humerus had a relatively straight shaft.

The African genus *Dendropithecus*, the most typical dendropithecoid, lived 25 to 17 million years ago. It was a small to medium-sized anthropoid, approximating to macaques and gibbons in size (5–9 kg in weight). Its individuals were active, arboreal, quadrupedal Primates, capable of powerful climbing activities and with at least some degree of forelimb suspension. Many traits resemble *Proconsul*, with which they seem to be closely related. The 20- to 19-million-year-old genus *Micropithecus* was a small dendropithecoid 3 to 4 kg in weight and more adapted to a folivorous diet. Finally, *Simiolus* was the other small African dendropithecoid (4–7 kg in weight) that lived 18 to 16.5 million years ago. It had a face shorter than that of other dendropithecoids, and like them, its individuals were arboreal and quadrupedal. It is closely related to *Dendropithecus* but also probably to the proconsulid *Rangwapithecus*.

Many of the dendropithecoid characteristics can be interpreted as being primitive traits of the catarrhines. The primitive pliopithecoid *Kamoyapithecus* seems to be related to the dendropithecoids. Therefore, they are surely an intermediate group between primitive propiopithecoid-pliopithecoids and more modern proconsuloids.

Proconsuloids

Proconsuloids have been considered for a long time to be the earliest probable members of the family Hominoidea. Nevertheless, many paleoprimateologists and paleoanthropologists prefer to consider them, at the moment, within a separate family, the family Proconsuloidea. It comprises taxa that range in size from small chimpanzees to small gorillas. They were members of a major radiation of catarrhines that occurred during the early Miocene, which resemble modern species. The Miocene climate became warmer and drier than the previous cool Oligocene, and the African collision with Europe allowed faunal dispersion from Africa to Eurasia. New, more modern anthropoids, such as the proconsuloids, appeared. Proconsuloids have postcranial skeleton traits more derived than those of their probable ancestors, the dendropithecoids, mainly in the forelimbs. Their dental formula was 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth, that is, with a reduced premolar compared with the dendropithecoids.

The superfamily Proconsuloidea includes African Arabian taxa and is composed of two families: Proconsulidae and Griphopithecidae. They are often placed in the superfamily

Hominoidea because they share derived dental features with the modern great apes. Nevertheless, many paleoprimateologists have questions considering whether they are hominoids because they lack apelike features in the postcranial skeleton, such as the elbow, shoulder, hip, and knee joints.

The family Proconsulidae is subdivided into three subfamilies: Proconsulinae, Afropithecinae, and Nyanzapithecinae. It is accepted that the proconsulines are the most primitive and evolved from afropithecines to nyanzapithecines. The first subfamily has two known genera: *Morotopithecus* (early Miocene species *M. bishopi*) and *Proconsul* (early Miocene species *P. africanus*, *P. nyanzae*, *P. major*, and *P. heseloni*). The 21- to 15-million-year-old genus *Morotopithecus* was a large-sized catarrhine (35–55 kg in weight) and comparable to *Proconsul major* in dental size but possibly smaller in body size. The femoral and phalangeal bones are similar to *Proconsul*, suggesting an arboreal habit. *Morotopithecus* has been considered as a possible ancestor of the hominoids based on the presence of shared, derived characteristics of the postcranial skeleton, particularly the lumbar vertebra, linking it with extant apes. The genus *Proconsul* is the best known proconsulid, and its species lived in the rain forests of Africa between 20 and 17 million years ago. They were medium-sized anthropoids with a range in weight from 10 to 40 kg and up to 60 kg in weight in *Proconsul major*. They have thin tooth enamel, a light build with narrow chest, short forelimbs, and sexual dimorphism in their teeth (mainly in canines). Their brain was slightly larger than the brains of other catarrhines, except for the hominoids. For example, the brain capacity of *P. africanus* was approximately 170 cm³. They were arboreal, quadrupedal, and frugivorous. Unlike other *Proconsul* species, *P. nyanzae* might have lived in a dry, open woodland environment. *P. major* is considered to be the probable ancestor of *Afropithecus*.

The subfamily Afropithecinae has five genera known to date: *Heliopithecus* (early middle Miocene species *H. leakeyi*), *Nacholapithecus* (middle Miocene species *N. kerioi*), *Equatorius* (middle Miocene species *E. africanus*), *Afropithecus* (early middle Miocene species *A. turkanensis*), and *Otaviopithecus* (middle Miocene *O. namibiensis*). The most representative member of the subfamily is *Afropithecus*, an African Arabian proconsulid that lived 18 to 16 million years ago. Except for *P. major*, it was generally larger than *Proconsul* (about 20–50 kg in weight) and possessed a long, narrow snout and small eye orbits. Based on its teeth, it is known that its diet consisted of nuts, as well as frugivorous and herbivorous foodstuffs. Its individuals were arboreal and quadrupedal. They had affinities with *Heliopithecus*, and their distinctive teeth morphology aligns them toward the kenyapithecid-hominoid lineage. The 17- to 16-million-year-old genus *Heliopithecus* was smaller than *Afropithecus*, with premolars relatively large compared with *Afropithecus* and *Proconsul*. It seems to be related to the proconsulid *Morotopithecus*, which differs in

its dental morphology. *Heliopithecus* is surely the most primitive afropithecine. The 15- to 14-million-year-old genus *Nacholapithecus* was a medium-sized afropithecine about 11 to 22 kg in weight. It had proportionally large forelimbs and long pedal digits, suggesting it was a good climber adapted to an arboreal life. The 15.5- to 14-million-year-old genus *Equatorius*, approximately 25 to 30 kg in weight, is also related to *Kenyapithecus*. It was more terrestrial than *Afropithecus*. The 13- to 12-million-year-old genus *Otaviopithecus* was another large-sized (14–20 kg in weight) arboreal, quadrupedal primitive proconsuloid. It has certain mandibular similarities with the griphopithecid *Kenyapithecus* and even the hominoid *Sivapithecus*, although it seems to be an afropithecid.

The subfamily Nyanzapithecinae differs from other proconsulids mainly by the dental morphology (molars and premolars). It has four known genera: *Nyanzapithecus* (early middle Miocene species *N. vancouveringorum*, *N. pickfordi*, and *N. harrisoni*), *Mabokopithecus* (middle Miocene *M. clarki*), *Rangwapithecus* (Miocene species *R. gordonii*), and *Turkanapithecus* (early Miocene species *T. kalakolensis*). The 18.5- to 13-million-year-old genus *Nyanzapithecus* was a small to medium-sized proconsulid, being 6 to 11 kg in weight. The three species of *Nyanzapithecus* seem to represent a phyletic series of increasing specialization from early Miocene *N. vancouveringorum* through *N. pickfordi* to *N. harrisoni* in the middle Miocene. Another proconsulid, the 16- to 15-million-year-old *Mabokopithecus*, was smaller than *Nyanzapithecus*; both genera are closely related. The 18- to 16.5-million-year-old genus *Turkanapithecus* had a body size comparable to the modern colobus, being approximately 10 kg in weight, with a face relatively shorter than the other proconsulids. Its individuals were typically arboreal, quadrupedal proconsulids but possibly with enhanced climbing capabilities. The oldest proconsulid was the 20- to 19-million-year-old *Rangwapithecus*, which had a similar morphology to *Proconsul* and like it was also arboreal. It was a rain-forest-dweller proconsulid of medium size, being about 15 kg in weight, whose dental morphology suggests a folivorous diet.

The family Griphopithecidae, also called Kenyapithecidae, has been often included within the superfamily Hominoidea since it is the proconsuloid group with more ties to the apes. Whether the representatives of proconsulids or afropithecids can be considered the earliest hominoids still remains problematic, but the griphopithecids, or kenyapithecids, seem to be the basal group from which the earliest hominoids originated. The family Griphopithecidae comprises two African genera, *Kenyapithecus* (middle Miocene species *K. wickeri*) and *Griphopithecus* (middle Miocene species *G. darwini*, *G. alpani*, and *G. africanus*), and perhaps also includes a third genera, *Samburupithecus* (late Miocene species *S. kiptalami*). *Kenyapithecus* is a significant griphopithecid that lived 14 million years ago. Its dental morphology is similar to that of the modern Old World monkeys. It has macaque-like

limbs adapted for a knuckle-walking mode of semiterrestrial locomotion. These individuals probably inhabited drier, more open woodland environments. *Kenyapithecus* had thicker molar enamel, a more robust mandible, and large upper premolars compared with those of the early Miocene proconsulids. Some paleoprimatologists suggest that this taxon is the common ancestor of all the great apes (hominoids), but others consider that it is more primitive and only slightly more modern than *Proconsul*. The 17- to 16-million-year-old genus *Griphopithecus* is poorly known, but it was a large European proconsuloid closely linked to the African *Kenyapithecus*, although probably more primitive. The 11- to 10-million-year-old genus *Samburupithecus* resembles modern African apes, and some paleoprimatologists have suggested that it is also close in morphology to the possible ancestor of hominoids.

Hominoids

The superfamily Hominoidea comprises the small and great apes, which are agile climbers of trees except for gorillas and humans. They are omnivorous, with a diet mainly consisting of fruits, seeds, and leaves, although in most cases some quantities of meat and invertebrates are included. Except for humans, which have spread to all parts of the world, the hominoids are native to Africa and Asia. Most species have a tropical rain forest habitat.

All members of this superfamily have a large braincase. Except for humans, most have a prominent face and prognathous jaw, that is, their mandible protrudes farther out than the maxilla, and their nostrils are close together and face forward and downward. The dental formula is the same for all hominoids: 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth. Generally, their incisors are broad, and their canines are never developed into tusks. Nevertheless, their size varies greatly among species, being especially large in gorillas and markedly small in humans. The small size of human teeth and jaws could be adaptations due to eating cooked food, which may have begun as far back as millions of years ago. Unlike the hylobates, the pongids and hominids are larger Primates with great sexual dimorphism, the males being on average larger and stronger than the females. Nevertheless, the degree of sexual dimorphism varies greatly from species to species.

Although the evolutionary history of the hominoids is poorly known, it is accepted that the earliest fossil apes can be linked to the modern hylobates. In contrast to the paucity of available fossils of hominoids over the past 5 million years, there is much evidence from the Miocene (23–5 million years ago). This fossil record shows that hominoids were much more common and diverse than they are today. The superfamily Hominoidea includes five families, three of them extant, Hylobatidae (gibbons), Pongidae (orangutans), and Hominidae (humans, chimpanzees, and gorillas), and two extinct, Oreopithecidae and Dryopithecidae. Other

classifications also include orangutans in the hominids, using the names Ponginae and Homininae to subdivide Hominidae into two subfamilies. Molecular-clock analyses suggest that the hylobates and the pongid-hominid clade diverged about 18 million years ago, and pongids and hominids diverged from each other about 14 million years ago. These molecular data would be consistent whether or not the 17- to 14-million-year-old proconsuloid family Griphopithecidae, or Kenyapithecidae, is included within the superfamily Hominoidea as its basal group. Probably the entire superfamily Proconsuloidea should be included within the hominoids, which has been often proposed, since the 21- to 15-million-year-old *Morotopithecus* seems to be very near to the probable ancestor of the hylobates, whereas the kenyapithecids could be ancestors of the rest of the hominoid families.

Hylobatids

The hylobates are the small or lesser apes of the family Hylobatidae, extensively known as gibbons and siamangs. They are smaller than the great apes, and their anatomical characteristics are superficially closer to the monkeys than they are to the great apes. They have long hands and feet, and their fur is usually black, gray, or brownish, often with white markings on the hands, feet, and face. Hylobate skulls resemble those of the rest of the hominoids (short rostra, enlarged braincase, and large orbits that face forward). Generally, they do not exhibit sexual dimorphism, with males and females being very similar in size and shape. Nevertheless, some gibbon species have sexual dichromatic differentiation in the male and female fur. They are social animals and strongly territorial, defending their boundaries with vigorous visual and vocal displays. They are habile in their primary mode of locomotion, that is, brachiation, swinging from branch to branch for distances of up to 15 m. They are the fastest and most agile of all tree-dwelling, nonflying mammals. Their diet consists mainly of fruits but also includes insects and leaves.

The hylobates appeared in the middle Miocene and include four extant genera, *Hylobates*, *Nomascus*, *Symphalangus*, and *Hoolock*, although some taxonomists consider that these are merely four species of only one genus, *Hylobates*. The genus *Hylobates* includes several species of Southeast Asia gibbons (*H. lar*, *H. moloch*, *H. pileatus*, *H. agilis*, *H. muelleri*, and *H. klossii*), which often have a ring of white fur around their face, and a size range of 40 to 70 cm in height and 5 to 8 kg in weight. The genus *Nomascus* includes six species of southeastern Asia gibbons (*N. concolor*, *N. leucogenis*, *N. siki*, *N. nasutus*, *N. hainani*, and *N. gabriellae*), some black with a distinct black tuft of crown fur (black crested gibbons) and some with distinct light-colored cheek patches (white-cheeked and yellow-cheeked gibbons). The genus *Symphalangus* includes the siamangs (*S. syndactylus*) of Thailand, Malaysia, and Sumatra; they are larger (twice the size of

other gibbons, reaching 1 m in height and 23 kg in weight), with two fingers fused together on each hand, and they have large gular sacs (which can be inflated to the size of their heads to make loud resonating calls or songs). The genus *Hoolock* includes the hoolocks or hoolock gibbons (*H. hoolock* and *H. leuconedys*) of northeast India, Bangladesh, southwest China, and Myanmar; they reach a size of 60 to 90 cm in height and 6 to 9 kg in weight, and they are the only gibbons that have sexual dimorphism (males are black colored with considerably white brows, and females have a grey-brown fur, which is darker at the chest and neck). There is another gibbon genus called *Bunopithecus*, which includes the extinct species *B. sericus*, discovered in China but found all over southern Eurasia. The two hoolock species were once included in this genus, but they have recently been removed from *Bunopithecus* to be grouped in the genus *Hoolock*.

Dryopithecids

The family Dryopithecidae comprises the best-known European fossil hominoids, but they also lived in eastern Africa and Asia. Their dental morphology is roughly intermediate between the early Miocene proconsulids (e.g., *Proconsul*) from Africa and the later pongids (e.g., *Sivapithecus*) from Asia. They had thin rather than thick enamel in their cheek teeth, gracile canines, narrow incisors, relatively short premaxilla, and a relatively gracile mandible. Their dental formula was 2/2 (incisors), 1/1 (canines), 2/2 (premolars), 3/3 (molars) = 32 teeth. They resemble the hominoids in many cranial features, including the development of a supraorbital ridge. Their postcranial skeleton is similar to the pongids (e.g., modern orangutans), indicating that they were suspensory. They may include the ancestor of all hominoids, which include the lesser apes (gibbons and siamangs), the great apes or pongids (orangutans, gorillas, chimpanzees, and bonobos), and humans. Many paleoanthropologists consider that the dryopithecids are, in fact, in the evolutionary direction toward hominids.

Dryopithecids include two known genera, *Pierolapithecus* (middle Miocene species *P. catalaunicus*) and *Dryopithecus* (early late Miocene species *D. wuduensis*, *D. fontani*, *D. brancoi*, *D. laietanus*, and *D. crusafonti*), and perhaps also include *Udabnopithecus* (late Miocene species *U. garedziensis*). *Dryopithecus*, the most well-known dryopithecid, lived 13 to 7 million years ago in Europe and Asia; these individuals were about 70 to 120 cm in length and 35 kg in weight. They had a 150-cm³ brain capacity, large eye orbits, and a light supraorbital ridge. The face exhibited certain klinorhynch, that is, the face tilted downward in profile. They were brachiators, like modern orangutans and gibbons, but were never knuckle-walkers like chimpanzees and gorillas. They were tree-dwelling apes that ate berries and fruits. *Dryopithecus laietanus*, also called *Hispanopithecus laietanus*, seem to be more like

orangutans than the other apes, with very long forelimbs and relatively short femora. The 13-million-year-old genus *Pierolapithecus* is closely related to the common ancestor of pongids and hominids. They were 30 to 35 kg in weight and 120 cm in length and had a wide, flat rib cage, a stiff lower spine, flexible wrists, and shoulder blades that lay along the back. These are special adaptations for tree climbing, just like those found in the great apes of today. The 8.8-million-year-old genus *Udabnopithecus* is an interesting fossil since it could be a link between the dryopithecids and pongids in Eurasia. Its individuals inhabited a semiarid environment.

Oreopithecids

The family Oreopithecidae includes a single known fossil genus, *Oreopithecus*, which is represented by only one known species, *O. bambolii*. *Oreopithecus* evolved in isolation, over at least 2 million years, on an island in the Mediterranean where Tuscany (Italy) is found today. It lived between 10 and 8 million years ago (late Miocene) in a swampy habitat and adapted to both suspensory arborism and bipedalism. *Oreopithecus* was 30 to 35 kg in weight and 1.10 to 1.20 m in height. Its skull possessed a small and globular neurocranium, with a cranial capacity between 275 and 530 cm³. Moreover, it had a relatively short snout, elevated nasal bones, vertical orbital plane, gracile facial bones, a large attachment surface for the masseter muscle, and a sagittal crest, indicating a heavy masticatory apparatus. Its canines had a size comparable to the rest of its dentition. Its postcranial anatomy was characterized by a broad thorax, a short trunk, and long fingers. It had a lumbar curve, suggesting that it adapted to upright walking. Because of these characteristics, this species is a considerable anomaly since it represents an independent development of bipedality, and its taxonomic placement is unsettled. Most paleoanthropologists consider it an extinct great ape without descendants, perhaps derived from *Dryopithecus* just before the split from the orangutans. Some paleoanthropologists include the oreopithecids within the family Dryopithecidae as a very derived group.

Pongids

The family Pongidae contains several genera, and all but one are now extinct. The extant genus is *Pongo* (orangutans) with two known species: *P. pymaeus* and *P. abelii*. They are native to Indonesia and Malaysia, being *Pongo pymaeus* from the island of Borneo and *Pongo abelii* from the island of Sumatra.

Orangutan skulls have a prominent sagittal crest, which is a ridge of bone running lengthwise along the midline of the top of the skull at the sagittal suture, whose presence indicates that there are exceptionally strong jaw muscles (mainly temporal muscles, which are one of the main

chewing muscles). Orangutan brain capacity is 275 to 500 cm³. Orangutans are large apes and exhibit considerable sexual dimorphism in size, with the *P. abelii* adult males 1.65 to 1.75 m in height and 90 to 120 kg in weight and the adult females 1.25 to 1.35 m in height and 40 to 50 kg in weight. *P. pymaeus* individuals are smaller, with adult males 1.30 to 1.40 m in height and 50 to 100 kg in weight and adult females 1.10 to 1.20 m in height and 35 to 45 kg in weight. Their arms, which can grow up to 2 m in length, are twice as long as their legs. Their feet are designed like hands, and both their hands and feet are long, narrow, and strong, being used in a hooklike fashion when grasping branches. Their thumbs are fully opposable. Orangutans are quadrupedal when on the ground, but unlike chimpanzees and gorillas, they are not true knuckle-walkers; they walk on the ground by shuffling on their palms with their fingers curved inward. Males have secondary sexual characteristics, such as long fur, cheek pads, and a throat pouch.

Orangutans are arboreal dwellers, spending nearly all of their time in the trees, living typically in tropical-subtropical moist broadleaf forests. They are mainly frugivorous. Sumatran orangutans (*P. abelii*) are more frugivorous and especially more insectivorous than the Bornean orangutans (*P. pymaeus*). The Borneo orangutans have a more varied diet, which includes leaves, shoots, seeds, birds' eggs, insects, and bark. Their gestation period is 8.5 months, and their life span is between 35 and 40 years. The individuals are sexually mature at the age of 6 to 7 years. They are infants from 0 to 4 years, juveniles from 4 to 7 years, adolescent males from 7 to 10 years, and adolescent females from 7 to 12 years. Several genetic differences separate the two species of orangutan (*P. abelii* and *P. pymaeus*). The species parted from one another 2.3 million years ago. The DNA sequences of humans and orangutans differ in only 3.6% of their genomes, that is, in their complete DNA sequences, suggesting that pongids and hominids (the orangutan-gorilla-chimpanzee-bonobo and human group) diverged about 10 to 11 million years ago. Like the other great apes, orangutans are very intelligent, being capable of using feeding tools. Some psychology specialists consider that the orangutan is the most intelligent extant animal in the world other than the human being; therefore, the orangutan is more intelligent than the chimpanzee, bonobo, or gorilla. They have developed a great symbolic capability and even a complex culture in which adult orangutans teach younger ones how to make tools and find food.

The family Pongidae comprises two subfamilies, Palaeoponginae and Ponginae, which include preponderantly fossil species. The subfamily Palaeoponginae includes four known genera: *Rudapithecus* (late Miocene species *R. hungaricus*), *Bovdapithecus* (late Miocene species *B. altipalatus*), *Graecopithecus* (late Miocene species *G. freybergi*), and *Ouranopithecus* (late Miocene species *O. macedoniensis*). The 11- to 10-million-year-old genera *Rudapithecus* and *Bovdapithecus* were palaeopongines of 45 to 60 kg in weight and have been considered closely related to

the dryopithecids. The 10- to 8-million-year-old genus *Graecopithecus* shows the downwardly bent face (klinorhynchy) typical of African apes and also very thick molar enamel, as expected in an early hominid. The 10- to 8-million-year-old genus *Ouranopithecus* was a larger-sized pongid, with males probably between 80 and 100 kg in weight. It also has intermediate traits between the dryopithecids and the pongids. It has a large, broad face with a prominent supraorbital ridge and square-shaped eye orbits and exhibits clear sexual dimorphism. Some paleoanthropologists have considered that it also has a relationship with hominids, particularly with gorillas. *Graecopithecus* and especially *Ouranopithecus* may lie near the split between the Pongidae and the Hominidae or already be in the hominid lineage.

The subfamily Pongidae includes three Asian groups, two extinct (Lufengpithecini and Sivapithecini) and one extant (Pongini). The group Lufengpithecini is apparently the most primitive. It includes two genera: *Lufengpithecus* (late Miocene species *L. lufengensis*, *L. keiyuanensis*, and *L. hudienensis*) and *Ankarapithecus* (late Miocene species *A. meteai*). The 8- to 7-million-year-old genus *Lufengpithecus* was a large pongid about 50 kg in weight, with slightly greater sexual dimorphism than in living apes. Its cranial characteristics show greater similarities to *Dryopithecus*, such as a broad interorbital region, vertical frontal, and the lack of a broad interorbital torus. The 10-million-year-old genus *Ankarapithecus* appears to be intermediate between the dryopithecids-paleopongines and the sivapithecins. Lufengpithecini are considered a primitive sister group to the clade formed by the sivapithecini and pongini, with *Ankarapithecus* more closely related to this clade.

The group sivapithecini includes two genera: *Sivapithecus* (middle late Miocene species *S. brevirostris*, *S. punjabicus*, *S. indicus*, *S. sivalensis*, and *S. parvada*) and *Gigantopithecus* (late Miocene–middle Pleistocene species *G. blacki*, *G. giganteus*, and *G. bilaspurensis*). The genus *Sivapithecus* was an arboreal pongid that lived between 13 and 8.5 million years ago. It was the size of a chimpanzee (50–90 kg in weight), but with the facial morphology of an orangutan. It shows facial, palatal, and dental architectures clearly specialized in the orangutan direction. However, unlike the great apes, *Sivapithecus* lacks the complex arm-bone features related to suspensory behavior and forelimb flexibility, suggesting the pongid was more adapted to quadrupedalism. The genus *Gigantopithecus* was a huge, herbivorous ape that lived between 1 and 0.3 million years ago in southeastern Asia. Its specimens represent the largest apes that ever lived, reaching 1.8 to 3 m in height and about 250 to 550 kg in weight, the largest being three times heavier than a modern gorilla. They coexisted with *Homo erectus* in Asia, and some cryptozoologists have related them to legendary Primates like Yeti and Bigfoot.

The group Pongini includes two genera: the fossil *Khoratpithecus* (late Miocene species *K. chiangmuanensis*

and *K. piriyai*) and the above-mentioned extant *Pongo* (from middle Pleistocene to Recent). The 9- to 7-million-year-old genus *Khoratpithecus* shares unique derived characteristics with orangutans, supporting the close relationships of both taxa. It was a large ape of approximately 0.9 to 1.2 m in height and 40 to 80 kg in weight. Its traits suggest that it is an intermediate between *Lufengpithecus* and modern *Pongo*. The genus *Pongo* originated during the Pleistocene 2 million years ago. Although modern *Pongo* are currently found only on Borneo and Sumatra, the *Pongo* fossil record indicates that orangutans once had a wider distribution, also having been found in Java, Vietnam, and China. A 1-million-year-old fossil species, *Pongo hooijeri*, is known from Vietnam, and several Pleistocene fossils of extant species have been described from southeastern Asia.

Hominids

The earliest evolution of the hominids is not well-known, with the notable exception of humans, which have a relatively complete fossil record extending back more than 4 million years. The evolutionary history of the pongids is, by comparison, much better documented. Most hominid species are omnivorous, but their feeding base is vegetarian (mainly fruits). The smallest living species of hominids is the bonobos (*Pan paniscus*), also known as pygmy chimpanzees, weighing 30 to 40 kg. The largest ones are the gorillas, with males weighing 140 to 180 kg.

The family Hominidae is subdivided into two subfamilies: Gorillinae and Homininae. The first one includes the genus *Gorilla* and a recently discovered fossil genus, *Chororapithecus* (late Miocene species *C. abyssinicus*). The genus *Gorilla* includes two extant species: *G. gorilla* and *G. beringei*. The first are known as the western gorillas (living in the Republic of Congo, Gabon, Equatorial Guinea, and Cameroon), the most populous species of gorillas, while the second ones are the eastern gorillas (living in the eastern Congo, Kinshasha, Uganda, and Rwanda).

Gorillas are the largest of the living Primates with great sexual dimorphism in size, the adult males 1.65 to 1.80 m in height and 140 to 210 kg in weight and the adult females 1.35 to 1.45 m in height and 90 to 120 kg in weight. The cranial capacity of gorillas is 340 to 750 cm³. The eastern gorilla (*Gorilla beringei*) is more darkly colored than the western gorilla (*Gorilla gorilla*). Gorilla skulls have a prominent mandibular prognathism and a great supraorbital ridge and a prominent sagittal crest. The gestation period of the gorillas is 8.5 months. Infants stay with their mothers for 3 to 4 years, and the females mature sexually at 10 to 12 years and males at 11 to 13 years. Their life span is between 30 and 50 years. Gorillas, like chimpanzees, move around quadrupedally by knuckle-walking. They are fundamentally herbivores, eating leaves (foliovores) but also fruits and shoots. Their large sagittal crest and long canines allow them to crush hard plants. Nevertheless,

some gorillas may ingest small insects. Gorillas are considered highly intelligent, with some individuals in captivity being capable of using a subset of sign language.

The DNA sequences of humans and gorillas differ in about 1.6% of their genes, but in only 2.3% of their genomes, that is, in their complete DNA sequences, thus being the next closest living relative to humans after the chimpanzees. This suggests that the human-chimpanzee clade and the gorilla shared a common ancestor about 8 million years ago. However, a significant fossil species of about 11 to 10 million years ago has been recently discovered: *Chororapithecus abyssinicus*. Its dental traits strongly indicate that it is the earliest species of the subfamily Gorillinae, suggesting that the last common ancestor between hominines (chimpanzees and humans) and gorillines may have lived more than 10 million years ago, that is, 2 million years earlier than the previously believed date of divergence based on DNA molecular-clock calibrations.

The subfamily Homininae is subdivided into two groups: Panini and Hominini. The group Panini consists of the genus *Pan*, which includes two extant species commonly named chimpanzees: *P. troglodytes* and *P. paniscus*. The first one is the common chimpanzee, which lives in the forests of central and West Africa. The second one is the bonobo, or pygmy, chimpanzee, which lives in the Congo. *Pan troglodytes*, or the common chimpanzee, is found not only in the tropical forests but also on the savannas of central and West Africa, although its habitat has been dramatically reduced in recent decades. Adults can measure up to 1.60 m in height in males and 1.30 m in females and weigh 40 to 70 kg in males, and 25 to 50 kg in females. The cranial capacity of chimpanzees is 275 to 500 cm³. Except for the face and palms of the hands and soles of the feet, the common chimpanzee body is covered by coarse, dark brown hair. They are omnivorous, eating small prey and insects, but their diet is mainly vegetarian (fruits, seeds, leaves, etc.). Common chimpanzees are both arboreal and terrestrial, their habitual gait quadrupedal although they can walk upright for short distances. They live in communities that range from 20 to more than 150 members in fission-fusion societies (the social groups sleep in one locality together but forage in small groups, going off in different directions during the day). Their gestation period is 8 months and their life span is 40 to 45 years. They are infants from 0 to 4 years, juveniles from 4 to 7 years, adolescent males from 7 to 15 years, and adolescent females from 7 to 13 years in age. The individuals (females and males) mature sexually at 9 to 10 years. It has been long known that the chimpanzees use tools, including modified branches to capture squirrels; recent studies suggest that the chimpanzees made stone tools at least 4 million years ago. It has been shown that they have an incipient consciousness, being manipulative and capable of deception as well as being capable of using symbols and understanding aspects of human language.

Bonobos (*Pan paniscus*) are smaller and more gracile than common chimpanzees, 75 to 85 cm in height and 35 to 45 kg in weight in adult males, and 70 to 75 cm in height and 25 to 35 kg in weight in adult females. They have brow ridges above the eyes less prominent than those of the common chimpanzees and black faces with pink lips, small ears, wide nostrils, and long hair on their heads. They walk upright about 25% of the time during ground locomotion. Their physical characteristics (slim upper body, narrow shoulders, thin neck, and long legs when compared with the common chimpanzees) and posture give the bonobos an appearance more closely resembling humans. Bonobos are mainly frugivorous, but they supplement their diet with leaves, meat of small vertebrates, and invertebrates.

The DNA sequences of the human and the common chimpanzee are very similar, differing about 2.7% in their genes and only 1% in their genomes. This suggests that humans and chimpanzees are more closely related than humans are with the gorillas, and they shared a common ancestor about 5 to 6 million years ago. Moreover, DNA molecular-clock evidence also suggests that *Pan troglodytes* and the other chimpanzee species *Pan paniscus* (bonobos) separated from each other less than 1 million years ago. It's possible that the formation of the Congo River 1.5 to 2 million years ago led to the speciation of *P. paniscus*. Until recently, no fossils of chimpanzees had been found. However, middle late Pleistocene fossils found in Uganda and Kenya may become the first fossils of the genus *Pan*.

Finally, the group Hominini includes seven known genera: *Sahelanthropus*, *Orrorin*, *Ardipithecus*, *Australopithecus*, *Paranthropus*, *Kenyanthropus*, and *Homo*, of which only the last one has extant species, our own (*Homo sapiens*). It is notable that the 7.4- to 6-million-year-old genus *Sahelanthropus* has been considered the last common ancestor of *Pan* and *Homo*. The hominin lineage has a trend toward a larger and more developed brain, shorter legs and arms, and ever more complex social behavior, intelligence, and technology. The description, fossil record, and evolutionary history of this hominid group are analyzed in the chapter "Hominid Description."

HUMAN EVOLUTION

JEFFREY H. SCHWARTZ

University of Pittsburgh

It might seem unnecessary to begin by stating that our species, *Homo sapiens*, is the sole surviving species of a once diverse group of now extinct relatives. For after all, the media is not shy about promoting the assertions of human paleontologists (paleoanthropologists) who claim to have finally discovered the long sought ancestor of our group or a missing link in the chain of human evolutionary succession. Even the repudiations of evolution by the scientific creationists and intelligent designists cannot derail the paleoanthropologists' pursuit of human fossils or submerge the widespread public interest in our evolutionary heritage. Yet for all the publicity that follows the discovery of and supposedly scientifically well-founded pronouncements about previously unknown potential human relatives, many of the assumptions on which paleoanthropology is grounded differ significantly from those that inform the rest of paleontology. And these differences have had profound intellectual consequences for the discipline of anthropology at large.

Before Human Evolution

Among the earliest preserved writings from the Western world that relate to considerations of human history are those from the Greeks (for example, Hippocrates and Herodotus) and Romans (for example, Lucretius) that discuss differences between known groups of humans in both

physical and psychological attributes. Common to all was a theme we might identify as adaptation. That is, people as well as other animals look and behave as they do because of the effects of their specific local circumstances. Consequently, for example, Herodotus believed that Egyptian soldiers had thick cranial bones because men typically shaved their heads, which were fully exposed to the beating rays of a strong sun. Scythian soldiers, however, had softer skulls because they wore hats and lived in less sunny climes.

Perceptions of the place of humans in nature were also based on attempts to understand something of the biology of our own and other species. As such, the Greek philosopher Aristotle, for instance, sought to organize animal life in anatomically meaningful ways, with the result that he defined a group we would call tetrapods on the basis of its members articulating with the world around them via four "points." For unambiguously quadrupedal animals, such as dogs or deer, all four limbs communicate with the ground via feet. But Aristotle's perspective also allowed him to include in this group birds because although not "footlike," their wings connect them with their surroundings as well as hands connect humans with their surroundings. Aristotle was not, however, immune to error. Thus, for example, he believed that the bipedal or two-legged stance of a bird differed from a human's because of differences in their knee joints. Not knowing the actual anatomy of the hindlimb, Aristotle thought that the "knee" of a bird, as

well as the knee of other quadrupeds, such as a dog or deer, bent backward, whereas a human's knee bent forward. This confusion was not corrected until the late 15th century when Leonardo da Vinci pointed out that the "knee" of a bird or any other nonhuman animal was actually its ankle; the true knee joint, which was situated higher up along the limb, bent in the same direction as the human knee joint. But the spirit of discovery that guided the Greek and early Roman method of scientific inquiry, particularly with regard to humans and their place in nature, was unfortunately squelched from the 2nd to 3rd CE centuries with the institution of Christianity, which demanded that "science" could be pursued only through acts of revelation and that its "discoveries" were in keeping with scripture.

One consequence of this credo was the concept of a sequence of creation or Great Chain of Being first proposed by Aristotle. Beginning in force in the 15th century, taxonomists sought to demonstrate this sequence of creation through a hierarchical arrangement of creatures from the perceived lowest to the highest—the lowest often being tied to the inorganic and the highest being the white male Western European who was generating his own particular and idiosyncratic classification of life. Although seafarers exploring far-off lands with the intention of establishing outposts and trade routes continually brought back to their countries examples of previously unknown plants and animals (including humans) that taxonomists eagerly inserted into the gaps in their classifications, there remained many missing links in the Great Chain of Being.

Fortunately, in 1669, Danish geologist and anatomist Nicolaus Steno published a treatise in which he demonstrated that not all rock-hard objects that came from the earth were indeed rocks and minerals. Rather, rock-hard objects with the shapes of bones, teeth, and shells characteristic of living vertebrates and invertebrates were actually the fossilized ("petrified") remains of once-living organisms. Suddenly, there was a new and vast source of missing links that taxonomists could include in their classifications as they strove to flesh out the picture of creation. As practitioners of the nascent discipline of paleontology quickly realized, the picture of past life mirrored that of the present: Not only is there now a diversity of plant and animal species; such taxic diversity had always existed.

But this treasure trove of extinct life went only so far. It did not include humans because according to the book of Genesis, they had been created last, and therefore, their history did not extend into antiquity. For all intents and purposes, Adam and Eve and their immediate descendants barely preceded the Great Flood of the Old Testament, and thus, no specimen of a human could be appreciably antediluvian. Consequently, while the evolutionarily uninformed 18th and early 19th centuries witnessed the development of nonhuman paleontology as a scholarly endeavor that sought to refine its understanding of the diversity of life in the past, even if actual

human fossils had been discovered, they would not have been identified as such.

The Feldhofer Grotto Neanderthal: The Test Case of Human Antiquity

In 1857, two years prior to the publication of the first edition of Charles Darwin's *On the Origin of Species*, miners quarrying limestone at the Feldhofer Grotto in the Neander Valley (*Thal* in German) near Düsseldorf, Germany, uncovered a skullcap and various parts of a skeleton of a human-like individual. They gave the remains to Carl Fuhlrott, a local schoolteacher, who in turn presented them to his country's most eminent human anatomist, Professor Hermann Schaaffhausen at the University of Bonn. Because of the state of "petrification" of this specimen and its obvious morphological differences from humans, Fuhlrott concluded that the Feldhofer Grotto Neanderthal represented an extinct race of a human relative. Schaaffhausen, however, brought all his resources and clout to argue that this was not a specimen of any antiquity; rather, it merely represented a member of a recent savage and barbaric race, not unlike the living Australian Aborigines.

It would not be until 1886, when Julien Fraipont and Max Lohest published incontrovertible evidence from the Belgian site Spy of the contemporaneity of Neanderthal remains with the bones of acknowledged extinct mammals, that it became difficult for dissenters to sustain the notion that humans could not be antediluvian. Nevertheless, before then, a few scholars did accept the antiquity of the Feldhofer Neanderthal. One of them was Thomas Henry Huxley, who maintained this position in "On Some Fossil Remains of Man," one of three essays published collectively in 1863 in the volume *Man's Place in Nature*.

Thomas Henry Huxley and the Stultification of Paleoanthropology

It is an odd twist of fate that while Huxley (1863) unabashedly accepted the Feldhofer Grotto Neanderthal skullcap and postcranial bones as representing the fossilized remains of a being of some antiquity at a time when few scholars did—one of the few, the geologist Charles Lyell, had visited Feldhofer Grotto and concluded that the bones were ancient—Huxley's interpretation of them could not have been predicted. As a salvationist who believed that novel features and thus species emerge abruptly as a result of a prenatal reorganization of developmental pathways, a comparative anatomist who reached national prominence while still in his twenties, and a systematist who undertook a reclassification of all vertebrates, one could reasonably characterize Huxley as having a critical eye when it came to interpreting morphological differences between organisms. Yet when Huxley turned to the clearly

distinctive features of the Feldhofer remains, he abandoned his approach to nonhuman organisms and discussed the Neanderthal from an entirely unexpected perspective.

Similar to Fuhlrott and Schaaffhausen, Huxley (1863) was clearly impressed by the features of the Feldhofer skullcap. It was long, elliptical in outline, flattened both in lateral profile and when viewed from the rear, and of unusually large size. The brow ridges met in the midline of the skullcap, and their extraordinary prominence was accentuated by a depression on the frontal bone behind and another depression below at the root of the nasal bones. In seeking a suitable modern human skull for comparison, Huxley focused on perceived similarities between the Neanderthal and an Australian Aborigine, which he took as the most primitive living human. But prior to embarking on this comparison, he discussed and then dismissed the ways in which other scholars had tried to equate human variation with racial distinctiveness. To the contrary, Huxley argued, upon comparing the “lowest” through the “highest” forms of the human skull, one was confronted with a continuum, not unlike that which he had constructed between the “lower animals” and “man.” And it was on to this continuum that Huxley appended the Feldhofer Neanderthal, stating with assuredness that all it would take to convert the most primitive living human—which Huxley took to be the Australian Aborigine—into the aberrant fossil would be some flattening and lengthening of the skull with an increase in brow ridge size. In turn, Huxley could proclaim that even though the Neanderthal skullcap was the most “pithecoïd,” or apelike, of known human skulls, which might at first glance lead one to classify it in its own species and thus apart from living humans, this specimen was actually one end of a series that led gradually from it to the most modern-looking human cranium.

The effect this perspective had on the study of human evolution was, unfortunately, long lasting. For even though he briefly considered that possibility that the Feldhofer Neanderthal represented an “intermediate” between “man” and “apes,” by diminishing the unique and distinctive features of the fossil to the status of racial difference, Huxley conflated *within* species differences due to individual variation (i.e., differences in the degree of expression of a particular feature—as in robustly versus weakly developed brows) with *between* species differences that reflect taxic diversity (i.e., differences of kind or configuration of a feature—as in partitioned versus continuous brow). The year after Huxley’s publication, professor of geology William King at Queen’s College, Galway, Ireland, would criticize Huxley’s oversimplification of the differences between the Feldhofer Neanderthal and any *Homo sapiens*, Australian Aborigines included. King proposed a separate species, *H. neanderthalensis*, to receive the extinct human. However, Huxley’s perspective has persisted in light of the analysis of more evidence. A version of the racial bias that Huxley had inserted into the interpretation of human evolution would reemerge less than a century later, largely through the efforts

of two of the “fathers” of the so-called modern evolutionary synthesis, Theodosius Dobzhansky and Ernst Mayr.

Human Evolution After Huxley and Before the Synthesis

In 1871, Darwin published his thoughts on human origins in the first part of *The Descent of Man*. But contrary to received wisdom, this was not a treatise on human evolution as much as it was a discourse on the development of “civilized” from “primitive” humans. True, Darwin did suggest that the African apes (chimpanzees and gorillas) were the closest living relatives of “man,” but the basis for this claim was anything but morphological. Guided by his belief that one should find the fossilized remains of the common ancestor of living forms in the same geographical region as its descendants, as well as Huxley’s 1863 essay “On the Relation of Man to the Lower Animals” detailing similarities between humans and the large-bodied apes, Darwin faced a dilemma. While humans were distributed widely across the globe, orangutans were restricted to Southeast Asia and African apes to sub-Saharan Africa. Darwin chose to resolve this problem by arguing that humans could not have evolved in Southeast Asia because its lush tropical environment would not have afforded the kinds of dangers and thus selection pressures (for example, from predators) that abound in southern Africa. Although African apes are primarily distributed throughout the tropical evergreen forests of central Africa and not in the open savannas of South Africa, this inconsistency did not prevent Darwin from arguing that since Africa was also home to the “most primitive” humans, humans and African apes had shared a common African ancestor. It is perhaps also worth mentioning the obvious: Darwin’s primitive humans and African apes are “black,” whereas the orangutan has reddish hair.

While paleoanthropologists of the 20th century increasingly cited Darwin’s genius in suggesting that human evolution began in Africa, historical accuracy demands recognizing that until the beginning of the concretization of the modern synthesis around Darwinism in 1941, with the publication of the second edition of Dobzhansky’s *Genetics and the Origin of Species*, most evolutionists—the German anatomist, embryologist, and paleontologist Ernst Haeckel (1876) being the leading exception—were not Darwinians. Consequently, it is not surprising that efforts to discover fossils that might represent links between humans and Neanderthals on the one hand and the apes on the other were concentrated not in Africa but in Asia, which had long been believed to be the seat of human antiquity.

Thus, the Dutch polymath Eugène Dubois, with the sole purpose of finding ancient human relatives, traveled to Southeast Asia where at the site of Trinil on the island of Java, he discovered two isolated teeth, a skullcap, and a number of variously preserved femora. He believed both

that these fossils represented a single entity and that it was the missing link between Neanderthals and apes: In cranial shape and size it seemed rather pithecoïd, but the human-like femur suggested that its bearer had walked upright and bipedally. In 1892, Dubois allocated these specimens to a new species, *erectus*, of the genus *Anthropopithecus*, which was often used to subsume the chimpanzee. Two years later, Dubois referred his species *erectus* to a genus Haeckel (1876) had invented in anticipation of the discovery of a then unknown human ancestor: *Pithecanthropus* (“ape-man”). Thus, *Pithecanthropus erectus*, or “Java Man,” was born, and the picture of human evolutionary history was changed forever.

By the 1930s, paleontological excavations had resulted not only in the discovery of additional Neanderthal specimens in western and eastern Europe but also in the discovery of specimens of human relatives of different and diverse morphologies from far-flung Old World sites: from Western Europe, the Mauer, or Heidelberg, mandible (the holotype of *Homo heidelbergensis*); from what is now Zambia, a skull that was given the species name *Homo rhodesiensis*; from northern China, an isolated molar that served as the basis of the genus and species *Sinanthropus pekinensis*, to which a number of partial craniums were subsequently added; and from various sites in South Africa (first, Taung, followed closely by Kromdraai, Sterkfontein, and Swartkrans), cranial and mandibular specimens that became the holotypes of various species distributed among three different genera (*Australopithecus*, *Plesianthropus*, and *Paranthropus*). During the 1940s, the discovery of new and often unexpectedly different-looking specimens fueled the practice of erecting new species or even new genus and species names, often for each specimen (e.g., a somewhat crushed mandible with some teeth from the South African site of Swartkrans was named *Telanthropus capensis* because it was smaller and less robust than specimens from the same site allocated to *Paranthropus crassidens*). When in 1950 Ernst Mayr, the systematist of the synthesis, turned his sights on the field of paleoanthropology, he was appalled at what he characterized as a “bewildering diversity of names.” Following a path already taken by the geneticist of the synthesis, Theodosius Dobzhansky, Mayr waded into an area about which he knew absolutely nothing: human evolution.

Ernst Mayr and Theodosius Dobzhansky: Where Angels Fear to Tread

In 1944, the year the vertebrate paleontologist George Gaylord Simpson published *Tempo and Mode in Evolution*, which was the last of the three volumes that became the foundation of the synthesis, Theodosius Dobzhansky began to speculate about the course of human evolution. As a fully converted selectionist by the time he published the second edition of *Genetics and the Origin of Species* in 1941,

Dobzhansky proposed that culture-bearing humans, with their cognitive and musculoskeletal abilities to create and manipulate their own environmental circumstances, were exempt from the Darwinian process of change that resulted from adaptation by means of natural selection. Moreover, any human relative with these neurological and anatomical proclivities was also protected and exempted from the whims of selection. Consequently, since living humans are such a geographically varied but single species, it is likely that this was always the case with hominids.

In 1950, Mayr added his reasons for thinking that human evolution was merely a single, nondiversifying continuum of change. First, Mayr claimed, a “real” systematist would see that regardless of differences, all hominids shared the same adaptation: bipedal locomotion. Consequently, since a real systematist knows that a genus is best defined by its ecological specialization—which bipedalism would constitute—all known hominids should be subsumed in the same genus, in this case, *Homo*. Second, humans today are an amazingly varied and geographically widespread species, occupying all available ecomiches. By extension, hominids of the past must have been at least as varied (Mayr even went so far as to proclaim without justification that earlier humans were even more variable than living humans) and thus must also have occupied all ecomiches available to them. Since, as Mayr had argued in his 1942 opus, *Systematics and the Origin of Species*, in order for speciation via diversification (rather than via unilinear transformation) to occur, a subspecies had to be able to invade a vacant ecomiche so that it could fall victim to new selection pressures and subsequent adaptations, it was clear that hominids had never speciated and never would. Consequently, there was always only one hominid species at any point in time, and the entire picture of human evolution could be thought of as a highly variable continuum of transformation through time. The upshot of Mayr’s speculation was translated taxonomically into three time-successive species: *Homo transvaalensis* (to receive the earliest hominids, which at the time were known from sites in South Africa), *Homo erectus* (which subsumed all specimens from Asia as well as the Mauer jaw from Germany), and *Homo sapiens* (which was the wastebasket for everything younger than *H. erectus*, including Neanderthals).

As if this series of untested (and untestable) assumptions weren’t sufficient to convince paleoanthropologists of the errors of their ways, Mayr (1942, 1950) added another element to his case for a unilinear picture of human evolution, namely, the ugly face of “race” and “racism.” For, he claimed, even though we know that “Congo pygmies” and Watusi are members of the same species, *Homo sapiens*, it is likely that without this knowledge a systematist confronted with their skeletal remains might allocate them to different species. More subtly, though, the implication of Mayr’s folding morphologically disparate living humans and Neanderthals into the same species or the diverse array

of earlier hominids into *H. transvaalensis* was the following: If very morphologically distinctive hominids are members of the same species, then it is ludicrous to pretend that any perceived differences between groups of living humans are biologically and thus evolutionarily significant. Although in hindsight, one can interpret Mayr's taxonomic action as a reaction to the racism and ethnic cleansing that fueled the Nazism of the recently ended Second World War, it nonetheless had a long-lasting and intellectually stultifying effect on the field of paleoanthropology.

Ernst Mayr Meets Louis Leakey

For more than a decade thereafter, most paleoanthropologists followed Mayr's taxonomic revision of hominids. The notable exception was Louis Leakey, who, together with his wife, the prehistoric archaeologist Mary Leakey, had returned from England to the East African country of Tanzania (formerly Tanganyika) to excavate a portion of the Great Rift Valley system known as Olduvai Gorge. Beginning in the late 1950s and continuing into the early 1960s, Louis and Mary discovered specimens of fossil hominids at various sites distributed throughout the uppermost portion of the lowest and thus earliest of the four deposits, or beds, that make up Olduvai. Although the specimens would change the picture of human evolution, the date obtained from the lava flow that capped this stratum, which was identified as Bed I, shocked the world by providing the first evidence of deep antiquity for human relatives. Upper Bed I dated to approximately 1.75 million years ago (mya)—more than three times the length of time previously allotted to human evolution.

At one Upper Bed I locality, which became known as the "Zinj" site, Mary Leakey found a virtually complete cranium, replete with teeth. The incomplete eruption of the last or third molar and the patent sutures of this specimen indicated that the individual had not been fully adult at death. The cheek teeth (premolars and molars) were huge while the anterior teeth (incisors and canines) were so small that all six of them fit easily in the front of the upper jaw. The face was massive, somewhat so across the rather flat midface but especially in the distance from the brows (supraorbital margins) to the teeth; the rounded supraorbital margins themselves, while not anteriorly protrusive, were quite tall, and where they met in the midline above the nasal region, the bone swelled out. The top of the skull bore a midline (sagittal) crest, to which huge masticatory muscles (the temporal muscles) had attached, and markedly expanded mastoid regions, which lie posterior to the ear region and to which the thick bandlike muscles on either side of the neck attach. Louis Leakey coined the genus and species names *Zinjanthropus boisei* to receive this specimen, which was catalogued as Olduvai Hominid (OH) 5. Being the only skull of its kind then known from East Africa, he had to turn to the South African hominids for comparison.

Although Mayr (1942, 1950) had placed all early hominids from South Africa in the same species—*Homo transvaalensis*—the obvious morphological differences between groups of hominids were considerable. One type, represented by the first skull discovered at the site of Sterkfontein, had a small and modestly domed cranial vault, thin supraorbital margins that swelled where they became confluent above the nasal region, and slightly expanded mastoid regions. Although the midface of this specimen was relatively flat across, the lower face curved outward somewhat so that the dental margin extended in front of the nasal opening (aperture). In the Zinj cranium, the lower face region was about as flat and vertical as the midface.

When he was first presented with this Sterkfontein specimen, which was catalogued as Sts 5, physician cum paleontologist Robert Broom (1951) thought it might be a species of the hominid genus his younger colleague, the neuroanatomist Raymond Dart, had created 11 years earlier—in 1925 to be exact—for a partial child's skull that had come from the lime works at the site of Taung, farther to the south and west of the Sterkfontein site. Dart had been impressed by this small specimen's human rather than apelike features, such as smooth supraorbital margins that flowed into a domed frontal region, a very mildly protrusive lower face, small canines (especially uppers), and judging from a mold of the inside of the right side of the braincase that formed as once-dissolved limestone hardened, a very large brain with what seemed to be an apparently greatly expanded cerebral cortex (the "thinking" part of the brain). As such, and because he believed the Taung child was more ancient than Dubois's *Pithecanthropus erectus*, Dart declared his South African specimen to be the missing link between apes and humans and the true ancestor of modern humans for which he created the genus and species *Australopithecus africanus* ("southern ape" from "Africa"), which he placed in a new family, Homosimiadae. Although Broom (1951) provided only conjecture that his Sterkfontein specimen was a species of *Australopithecus*, he nonetheless allocated it to a new species, *A. transvaalensis* (the species in which Mayr would subsume all South African hominids). In 1946, with coauthor G. W. H. Schepers, and again without justification, Broom declared that Sts 5 actually represented a distinct genus. Thus, *Plesianthropus transvaalensis* was born. Taxonomy aside, the Leakeys' Zinj specimen was not even a close match for the Sterkfontein specimen. But it did seem to be relatable to the other type of hominid represented in South African deposits.

Not too far from Sterkfontein in the Transvaal lies the site Kromdraai, which beginning in 1938 had attracted Broom's attention and at which a partial facial skeleton and palate, some isolated upper teeth, and a partial lower jaw had been discovered by a schoolboy. Although it was obvious that the isolated upper teeth had been purposefully removed from the former specimen, it was a mere assumption that the lower jaw also went with it. Nevertheless, in

their 1946 publication, Broom and Schepers referred both the partial face and the mandible to the new genus and species *Paranthropus robustus*, so-named because while larger and seemingly more robust in its features (and presumed tooth size) than Sts 5, its inferred smaller upper canine was taken as indicating its greater centrality to human evolution.

More specimens attributed to *Paranthropus*—but to the species *P. crassidens*—were soon discovered at Swartkrans, which is within view of Sterkfontein and which Broom excavated from 1948 through 1949. Of the various cranial specimens, one (SK 48) was particularly well preserved. It had thin supraorbital margins that swelled out where they merged over the nasal region, a low braincase that bore a midline sagittal crest, a very broad face that was relatively flat and vertical across its midregion and down to the margin of the upper jaw, and an inflated mastoid region. Of the preserved teeth, the upper canine was tiny and the premolars and especially molars relatively much larger. Vacant root sockets (alveoli) demonstrated that all four incisors and the pair of canines had sat along the front margin of the upper jaw. The only mandible with all teeth preserved had similar anterior versus posterior tooth proportions.

In spite of Mayr's (1942, 1950) collapsing this diverse lot of specimens into a single species, those who actually studied them—which Mayr had not—could not avoid recognizing at least some of their differences. And thus it was that Louis Leakey and subsequently other paleoanthropologists found a better comparison between the Zinj specimen and the Swartkrans kind of skull than between Zinj and the Sterkfontein type. Shortly thereafter, paleoanthropologists began to refer to the Sts 5 type as “gracile australopithecine,” the SK 48 type as “robust australopithecine,” and the Zinj type as “hyperrobust australopithecine.”

But Zinj was not the only discovery at Olduvai that revised the picture of human evolution. A few years later, Louis Leakey found at various locales throughout Upper Bed I a partial mandible, fragments of cranial bone, foot and ankle bones, and crudely manufactured stone tools that he, together with anatomists Phillip Tobias and John Napier, published as representing a new and different hominid—one that had a larger brain than any australopithecine, had been a more proficient biped than any australopithecine, and had the capacity to manufacture rather than merely use objects as tools. Following Dart's suggestion, Leakey, Tobias, and Napier gave their constructed hominid the species name *habilis* (“handy man”). Since they had succumbed to the general belief that only one humanlike hominid could exist at any point in time—and Zinj with its chunky cranial features and large cheek teeth did not look the part—Leakey et al. felt justified in placing *habilis* in the genus *Homo*. Since, however, the definition of *Homo* had come to include not only toolmaking but also a brain size (cranial capacity) of at least 800 cc (which accounted for the smallest specimen of *Homo erectus* as well as the large-brained Neanderthals), Leakey et al.

lowered this “cerebral Rubicon” to 600 cc, which was Tobias's estimate for *habilis* based on reconstructing the cranial fragments into pieces of what he thought were paired right and left parietals (the largest cranial bones, which meet along the sagittal suture). A variety of specimens from the lower portion of Bed II were also placed in *H. habilis*, not because they were similar to the original specimens or even similar to one another but because they were not Zinj-like.

Faced with these Olduvai finds and Louis Leakey's interpretation of them, Mayr (1942, 1950) recanted a bit. He allowed that at least early in human evolution there could have been some diversity in perhaps two or three species of *Australopithecus* (*A. africanus*, *A. robustus*, and *A. boisei*). However, Mayr remained firm in his belief that there was always only one species of genus *Homo* extant at any point in time. Thus, *H. habilis* had evolved into *H. erectus*, which evolved into *H. sapiens*.

Paleoanthropology After Mayr

Although discoveries of fossil hominids continued apace—especially of early hominids by Camille Arambourg, Yves Coppens, and F. Clark Howell in southern Ethiopia at Omo and Richard Leakey, Alan Walker, and later also Meave Leakey in northern Kenya at sites on the east and west shores of Lake Turkana into which the Omo River flows—there was no permanent deviation from Mayr's second assault on paleoanthropology until 1974. In November of that year, Donald C. Johanson (Johanson & Edgar, 2006) discovered the partial skeleton nicknamed “Lucy” at Hadar, eastern Ethiopia, for which with Coppens and his colleague at the time, Tim White, he created the species *Australopithecus afarensis*. Although Johanson had initially thought that more than one early hominid was represented in the Hadar sample, he ended up following White in allocating all somewhat contemporaneous Hadar hominids to this single species. The matter of one or more species of Hadar hominid aside, the naming of a new hominid species could be accepted because Lucy et al. were older than any other hominid fossils (dating close to 3 mya) and this taxonomic deed did not affect the genus *Homo*.

Coppens and Howell had coined the genus and species *Paraustralopithecus aethiopicus* for their Omo specimens, but these fragmentary mandibles were quickly subsumed in *A. boisei*, and Richard Leakey avoided the issue of classification for years by referring to his hominid fossils either by their catalog numbers or in vague reference to the species in Mayr's scenario. A proposal in 1975 by Colin Groves and Vratilov Mazák that one of the mandibular specimens from the site of Koobi Fora (east Turkana)—KNM-ER 992—represented not *H. erectus* but a new species, *H. ergaster*, lay dormant until the 1990s when Bernard Wood applied this species name to two cranial specimens from Koobi Fora (KNM-ER 3883 and 3733)

as well as to a fairly complete skeleton from west Turkana (KNM-WT 15000) that Leakey and Walker were content to place in *H. erectus*. But a partial skull—KNM-WT 17000—that Leakey and Walker discovered in the 1980s at a locality in west Turkana and initially referred to as *Australopithecus boisei* would lead to further reconsideration of early hominid systematics.

WT 17000 differed from both Zinj and also specimens from Koobi Fora allocated to *Australopithecus boisei* in having a smaller braincase that bore a very tall sagittal crest. Further, at least as Walker had reconstructed the pieces, while the midface was very broad and flat, the lower face and massive palate projected far forward. Since at 2.5 mya, WT 17000 predated Zinj and many of the presumed hyperrobust specimens from Koobi Fora by about 0.75 million years, and the South African robust hominids by about 1 million years, a number of paleoanthropologists accepted WT 17000 as the ancestor of both *A. boisei* and *A. robustus*. Other paleoanthropologists, however, thought that WT 17000 had given rise to *A. boisei*, which had been ancestral to *A. robustus*. In either scenario, WT 17000 was seen as the morphologically most primitive of the lot and thus deserving of its own species. Since the Omo mandible that was the type specimen of *Paraustralopithecus aethiopicus* was essentially contemporaneous with WT 17000, most paleoanthropologists were comfortable with using that species name for the Turkana specimen in the binomen *Australopithecus aethiopicus*. This act led to a discussion of the existence of a robust-type australopith clade (evolutionary group) that was very different from the gracile-type australopith, which in turn led to the resuscitation of the genus *Paranthropus* to accommodate the species *robustus*, *boisei*, and *aethiopicus*; only *africanus* and *afarensis* remained in *Australopithecus*. By this time, the late 1980s, paleoanthropologists were generally amenable to a broad picture of early hominid evolution in which *A. afarensis* (at approximately 3 mya) could have given rise to *A. africanus* (possibly as old as 2 mya) and perhaps also *Paranthropus*, with *A. africanus* giving rise to *Homo*.

It seems that once the fear of identifying taxic diversity was overcome, recognition of new species if not new genera (pl. genus) and species became acceptable. There were even tentative forays into the genus *Homo*, with Wood's 1991 allocation of various Turkana specimens from *H. erectus* to *H. ergaster* and yet others to a species that V. P. Alexeev had created for the KNM-ER 1470 cranium, *H. rudolfensis*. Two years later, Friedeman Schrenk allocated a specimen from Malawi to the latter species. In 1994, from 4.4 to 4.5 mya deposits in the Ethiopian Middle Awash, Tim White, Gen Suwa, and Berhane Asfaw published work on various isolated teeth and cranial fragments that together they thought represented a new species of *Australopithecus*—*A. ramidus*—that had been ancestral to *A. afarensis*. The following year, White et al. transferred *ramidus* to a new genus, *Ardipithecus*. Although stating that *A. ramidus* was still a hominid on the basis of presumed

nonapelike features of the canine first-premolar complex and an inferred anterior position of the foramen magnum (through which the spinal cord exits the skull into the vertebral column—its anterior position in humans is associated with bipedalism), the absence of thick enamel on the molar teeth represents a major stumbling block for attributing hominid status to it.

Also in 1995, Meave Leakey, Alan Walker, and colleagues announced the discovery of various jaws, isolated teeth, and a few bones from two sites in west Turkana, Kanapoi and Allia Bay. The approximately 4 mya age of these specimens—which put them chronologically in between *Ardipithecus* and *Australopithecus afarensis*—led Meave Leakey et al. to argue that they had discovered a species—*A. anamensis*—that was more primitive in jaw and tooth than *A. afarensis* and thus ancestral to it. A potential problem here was that, judging from the lower part of a humerus that had previously been discovered at Kanapoi and a newly discovered upper part of a tibia, the specimens were humanlike, not australopith-like.

In 1999, Asfaw et al. proclaimed that a 2.5 mya upper jaw with teeth from the Ethiopian Middle Awash represented a new species, *Australopithecus garhi*. Two years later, Johannes Haile-Selassie announced a new 5.8 to 5.2 mya subspecies of *Ardipithecus*, *A. ramidus kadabba*, based on a mandible and worn teeth. But two other events in 2001 also affected paleoanthropology. Brigitte Senut and Martin Pickford pushed further the time depth of human evolution with various jaw, tooth, and postcranial specimens they found near Lake Baringo, Kenya, that dated to just under 6 mya and that formed the basis of their new taxon, *Orrorin tugenensis*. They argued that a reasonably well-preserved upper femur had hominid-like attributes, and unlike *Ardipithecus*, the molars bore thick enamel. Also in Kenya, Meave Leakey and colleagues made public a 3.5 to 3.2 mya skull from a site in west Turkana that, although severely cracked, was sufficiently preserved to show that the face was quite flat and the ovoid orbits devoid of supraorbital development. They assigned this specimen and two mandibles to a new taxon, *Kenyanthropus platyops*, to which they also referred the KNM-ER 1470 cranium, which had already gone through the taxonomic ringer, having been interpreted first as *Homo habilis*, then *Pithecanthropus rudolfensis*, and then *H. rudolfensis*.

At this writing, only one other putative hominid remains to be discussed: a rather crushed skull and presumably associated specimens from Chad, probably closer to 6 mya than its claimed 7 mya age, to which the name *Sahelanthropus tchadensis* was given. Prior to this discovery, which Michel Brunet and collaborators announced in 2002, Brunet had found only one very fragmentary specimen—the front of a lower jaw missing most teeth—which he made the type specimen of a new species, *Australopithecus bahralghazali*. Brunet's interpretation of *Sahelanthropus* as a hominid and ancestral to

all other hominids rested on the antiquity of the specimens as well as canine shape and tip wear, molar enamel being intermediate in thickness between chimpanzees and undisputed hominids (and thicker than that of *Ardipithecus*), and an inferred anterior position of the foramen magnum. If a hominid, then the skull bears the thickest and most prominent brow ridges of any (even more so than gorillas), which would make it the most derived of its putative clade and thus unlikely to have been ancestral to any known hominid.

As this overview demonstrates, in contrast to the 20 years that preceded them, the last 20 have witnessed a flood of newly named hominid taxa. This may give the impression that paleoanthropologists eventually shed the shackles of taxonomic truncation that Mayr (1942, 1950) had imposed, but it should be noted that the recognition of hominid diversity has largely been confined to the older fossils. All things considered, the situation with regard to later hominids is not that different from Mayr's formulation. Wood's revival of *Homo rudolfensis* fell on deaf ears, and even though his effort to recognize *H. ergaster* as an African counterpart to Asian *H. erectus* has been embraced by some paleoanthropologists, a survey of the most popular human evolution textbooks reveals that the *H. habilis*-evolving-into-*H. erectus* scenario is still going strong. So too with regard to *H. sapiens*, which by subsuming such morphologically disparate specimens as Cro-Magnon 1, the Feldhofer Grotto Neanderthal, the Kabwe skull, and the Javanese Ngandong skulls, to name but a few, sports a range of variation otherwise unknown in the animal kingdom.

Granted, some paleoanthropologists have tried to deal with our own unwieldy species. For example, over the past two decades, there has been a growing appreciation of just how different Neanderthals and we are, not just in features of the skull, jaws, and teeth but also in most of the bones of the postcranial skeleton. Consequently, while a handful of stalwart multiregionalists hold steadfastly on to the notion that there was always only one middle Pleistocene hominid—*H. erectus*—that evolved en masse, albeit in regionally different stages, into *H. sapiens*, William King's *Homo neanderthalensis* has enjoyed increasing recognition among paleoanthropologists.

In addition, the name *Homo heidelbergensis*, which Otto Schoetensack created in 1908 for a 0.5 mya mandible excavated near Heidelberg, Germany, has in recent years been applied to various 600 to 300 kya (thousand year old) skulls, most notably those from Kabwe (Zambia), Petralona (Greece), Arago (France), and Bodo (Ethiopia). Yet although superficially similar in having robust faces and tall brows, these skulls do not present a relatively uniform picture when details, especially of sinuses and the inside of the cranial vault, are considered. In addition, and more important, with the exception of specimens from Arago, which include mandibles, none of the other craniums can be compared with the type specimen of *H. heidelbergensis*—which

makes allocating them to this species impossible. Nevertheless, it is probably better to have some recognition of the potential diversity that exists among the specimens attributed to *Homo* than not.

But the recognition of new species of *Homo* has languished. Indeed, although from the 1980s on, Juan-Luis Arsuaga and colleagues (Arsuaga & Martínéz, 2005) have amassed a large collection of specimens of the same hominid dating to about 350 to 320 kya from the site of Sima de los Huesos, which is in the Sierra de Atapuerca in northern Spain, they have inclined toward regarding it as *H. heidelbergensis* or vaguely as something Neanderthal-like. However, in 1997, José María Bermúdez de Castro and collaborators did claim that they found the remains of the common ancestor of *H. neanderthalensis* and *H. sapiens* at the minimally 780 kya site of Gran Dolina in the Sierra de Atapuerca; they called it *H. antecessor*. Since then, in 2002, only one other species of *Homo* has been proposed: *H. georgicus*, based on a large mandible with massive but very heavily worn teeth from the 1.8 mya Georgian site, Dmanisi. The morphologically very diverse craniums from this site have all been referred to *H. erectus*. More than 50 years after Mayr (1942, 1950) imposed the picture of unilinearity on the human fossil record, his influence is still keenly felt in the taxonomic realm of genus *Homo*.

Future Directions

The reader has no doubt noticed that most of this review is the iteration of taxonomic names. That this form of presentation is particularly characteristic of human paleontology, in contrast to the broader domain of nonhuman paleontology, is reflective of the odd history of the former discipline—in which taxonomic minimalism and the perception of unbounded interindividual variation within any taxon has dominated. Consequently, the focus when studying hominid or potential hominid fossils has been less on morphological detail and a concern with systematic theory and practice than on constructing scenarios of how, why, when, where, and from whom a sequence of modern human ancestors evolved. Were this not the case, we would not find that so many type specimens—which are the name bearers of their species or genus and species—are either so fragmentary or devoid of preserved anatomical detail that comparison with other specimens, which would seem a necessary requisite to assigning them to a given taxon, is often impossible. Were this not the case, we would not see the oft-repeated practice of lumping specimens from the same site or the same time period into the same taxon, which gives the locale of discovery or the ages of specimens priority over morphology—which is the only meaningful reflection of evolutionary history. Were this not the case, we would not see the widespread resistance to restudying and reinterpreting the fossils that were discovered

during the 1800s and much of the 1900s. If virtually every newly discovered fossil can be regarded as representing a new taxon, especially if it is well over 1 mya, then why should not the already known human fossil record provide a wealth of information that was overlooked in the past? The problem with paleoanthropology in general has been that most practitioners have left observation behind, and instead, they have focused on evolutionary explanation. This problem is, however, easy to remedy. One need only begin by using one's eyes rather than being influenced by either the past or the perceived weight of received wisdom.

CULTURE CHANGE

ROBERT BATES GRABER

Truman State University

What is culture change? In a way, the phrase itself is problematic; after all, culture was formulated as a scientific concept partly for the very reason that customs seemed *resistant* to change—at least compared with the confusing blur of particular people and events traditionally studied by historians (Tylor, 1871/1924, p. 5). Indeed, some anthropologists have tried to analyze cultures as if they did not change at all; such approaches, however, seem ever less relevant in the rapidly globalizing world of the 20th century.

In the phrase “culture change,” *change* has its usual meaning; *culture*, however, is being used in a sense technical enough to need a bit more discussion here at the outset. Culture, as classically defined by Edward B. Tylor in 1871, refers to “that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities and habits acquired by man as a member of society” (1871/1924, p. 1). Once we realize that by the word “art” Tylor meant all the artifacts customarily made and used by a society, we see that this is a broad definition indeed: It includes the customary things with which people surround themselves, the customary ways they interact with one another behaviorally, and the ideas that are more or less shared among them.

There are anthropologists, it should be said, who consider culture to be things that only an *individual* can acquire by virtue of being a member of society. One problem with this is that it excludes features that inherently

characterize groups rather than individuals—some of which certainly would seem to be fundamental features of a society’s way of life, such as economic inequality, an elaborate division of labor, or (group) religious ritual.

Some anthropologists think of culture not only as an acquisition of individuals but also as a particular kind of individual acquisition, namely, mental. Culture, for them, is strictly in our heads. From their standpoint, neither the automobile nor the computer, say, would be part of American culture in the early 21st century; rather, only the underlying *ideas* of which the things themselves (they maintain) are realizations deserve to be considered culture. This, however, makes culture difficult to study empirically by making it outwardly unobservable.

Defining culture as strictly mental also encourages an oversimplified and misleading conception of culture change. Anthropologists who think of culture as essentially mental tend to think of culture change as essentially due to new ideas. This focus distracts our attention from, if it does not quite deny, three key points about culture change. First, what ideas are “thinkable” depends partly on existing cultural arrangements. Ideas do not really come “out of the blue”; there is cultural wisdom, then, in the scriptural claim that there is “nothing new under the Sun”—nothing totally new at least. Second, new ideas are by no means sufficient in themselves to bring about culture change. The greatest idea in the world must somehow be *acted* on before it has any chance to change culture. Ideas that remain trapped in

their thinkers' heads, issuing in neither new behaviors nor new artifacts, are of no cultural consequence whatever. Third, behavioral or artifactual consequences are also insufficient for culture change. These consequences must be greeted by significant social acceptance; and this, like the occurrence of the new ideas in the first place, depends to some degree on existing cultural arrangements.

In any case, when the subject is *culture change*, it seems that anthropologists (and journalists) today usually use—whether they admit it or not—a more general definition along Tylor's lines; and this appears to have been true in the past as well. For present purposes, then, the *constituents* of culture are not only ideas about things but also about the things themselves—objectively observable artifacts and behaviors. By *artifactual* is meant the world around us insofar as it is built or manufactured by humans: T-shirts and tuxedos, furniture and appliances and buildings, cornfields and computers, automobiles and highways, pencils and power plants, cell phones, baseball bats, factories, and baptismal fonts. By *behavioral* is meant the observable motion of our bodies through space, usually oriented to the artifactual world and/or literally manipulating artifacts. By *ideational* is meant everything that goes on in our heads: thoughts about artifacts and behaviors (of one another and ourselves), about thoughts (again, of one another and ourselves) and even thought itself, and about the rest of the universe. (Feelings, which also may be said to go on in our heads, are important in social interaction and are influenced *by* culture; they are not, however, properly considered as themselves constituents *of* culture.) Because this trichotomy is essential in understanding a current approach to culture change, we shall return to it after examining past approaches.

Past Approaches to Culture Changes

Although its roots naturally lie deeper in the past, anthropology took shape as a scholarly discipline in the 19th century. From the late 15th century on, exploration and colonization—led by Spain, Portugal, the Netherlands, France, and Great Britain—had produced a large and growing body of information about how different were the customs in the various parts of the world. Much of this consisted of reports by explorers and missionaries; systematic anthropological fieldwork was an achievement largely of the 20th century. Not entirely wide of the mark, then, is the image of the so-called 19th-century evolutionists as scholars in their studies poring over fanciful accounts of exotic peoples in faraway places. It sounds a rather far cry from scientists in their laboratories conducting meticulous experiments; indeed, critics later would charge that it in fact had been nothing more than “armchair speculation.” Yet real progress was made. Judicious handling of the material, after all, could go some way in separating truth from falsehood. Tylor pointed out that when

two or more visitors independently of each other had reported the same custom in the same place, it was unlikely to be a fabrication—especially if the custom seemed odd.

In terms of theory, Tylor and others found themselves facing *degenerationism*. Inspired by the biblical book of Genesis, the idea was that all humans had practiced agriculture and achieved a modest level of civilization not too long after creation itself. Then, with the dispersion of people throughout the world, some of them degenerated to lower levels (some forgetting even how to grow food), while others rose to higher levels. Degenerationism, one might say, was the first grand theory of culture change. Foremost among scholars putting it to rest was Edward B. Tylor. Using his extensive knowledge of the anthropological evidence that already had accumulated by around 1865, Tylor showed that “high” cultures quite certainly had originated in a state resembling that of the “low” cultures still observable in some parts of the world and that there was no evidence that any of the latter had come into being by degeneration from a higher condition of culture (Tylor 1865/1964).

The 19th Century: Beyond Degeneration's Defeat

Strictly speaking, the defeat of degenerationism was perhaps more a step in separating science from religion than a step in science itself. Quite different in this respect were the debate over the relative importance of diffusion and independent invention and attempts to characterize the cultural past as a series of stages.

Independent Invention and Diffusion

Tylor and other leading 19th-century evolutionists were united against degenerationism but divided on this question. The issue arose when among the glaring differences between human cultures, striking similarities also appeared. Boomerangs, for example, were reported not only for Australia but also for regions of India and Egypt. How was this distribution to be explained? Had this weapon been invented only once, then spread to the other two regions, or had it been invented independently three times? Those inclined to stress the importance of diffusion would prefer the former explanation, claiming that it is much easier for humans to copy something than to invent it. Those favoring independent invention would prefer the latter explanation, claiming that the human mind is sufficiently alike everywhere (“psychic unity”) that it will tend, when faced with similar problems under similar conditions, to produce similar solutions.

Toward the extremes were two German scholars: Adolf Bastian argued that independent invention should be presumed unless strong evidence for diffusion could be produced, while Henry Balfour argued that diffusion should

be presumed until overwhelming evidence for independent invention was put forth (Lowie, 1937). Most of the 19th-century evolutionists were less extreme. In the case of the boomerang, for instance, they would by no means rule out the possibility that it had originated independently in two of the regions and diffused from one of these to the third region.

Stages

Associated rather closely with a stress on independent development was the idea that human culture everywhere tended to advance through broadly similar *stages*. The most famous formulation was Lewis Henry Morgan's (1877/1985) sequence, savagery, barbarism, civilization. (Morgan subdivided the first two of these stages into lower, middle, and upper for a total of seven stages.) While debates over independent invention versus diffusion often centered on particular cultural features (as in the boomerang example), the concept of a stage involved a vast pattern of cultural features—that is, an entire kind of cultural system. Still, the *defining* of such stages did require reference to at least some particular features; and Morgan chose, for this purpose, mainly items of material technology. The transition from lower savagery to middle savagery, for example, was marked in part by the use of fire and from upper savagery to lower barbarism by the invention of pottery. Civilization was reached, in Morgan's view, not with a technological achievement but rather with the development of a phonetic alphabet. His reliance on primarily technological markers helped make the stages more objectively identifiable and was quite convenient for archaeologists, who after all can recover neither behavioral nor ideational evidence but material evidence alone. Though the terms *savage* and *barbarian* sound ethnocentric today, anthropology still recognizes general stages through which culture change has tended to pass; and they are not entirely different from Morgan's. Pottery, for example, being heavy and fragile, is not highly functional for the mobile way of life characteristic of foragers; Morgan's use of pottery to mark the end of savagery therefore makes this stage broadly comparable to the long period (evidently around 99.8% of our evolutionary past) before settling into villages and growing food—what is today termed the hunting-gathering era, or Paleolithic (Old Stone Age) (Harris, 1968, pp. 185–186).

Some 19th-century evolutionists proposed stage sequences of other kinds. Herbert Spencer (1897) proposed that human political culture had advanced through four progressive stages: simple, compound, doubly compound, and trebly compound. These stages resemble more recent sequences such as band, tribe, chiefdom, and state (Service, 1962) and village, chiefdom, state, and empire (Carneiro, 2003). More important than the specific stages delineated, however, are these two facts stressed by Spencer: First, political evolution does not occur by the simple increase in population of a small society (a band or

village) until it has become a large one (a state or empire); rather, it occurs by the combining of smaller societies. Second, this combining is stepwise, with little room for skipping steps. That is, we know of no cases in which bands or villages have combined directly into states or empires; rather, they combine into chiefdoms, which then may (or may not) combine into states. Similarly, chiefdoms do not combine directly into empires but into states, which then may (or may not) combine into empires. Political evolution thus has a unilinear quality: Any society reaching a later stage will have done so by having passed thorough earlier stages. This assuredly does not mean that all societies at an earlier stage will advance to a later stage! In the human past, there must have been, after all, vastly more bands and villages that never helped compose chiefdoms than those that did, far more chiefdoms that never helped compose states than those that did, and many more states that never helped compose empires than those that did. The unilinearity of political evolution, with respect to a given society, we might well say, is not predictive but retrodictive: Though we cannot be sure a given small society will ever become part of a larger one, we can be sure a large society originally became large by the compounding of smaller ones. Spencer's picture of political evolution as having progressed by the stepwise unification of units (mainly through military conquest) remains influential today (Carneiro, 2003).

Other stage sequences have not held up so well; their main role proved to be stimulating research that led to their own rejection. The greatest is J. J. Bachoffen's (Partenheimer, 1861/2007) set of stages based on gender relations. He argued that humans originally lived in a state of unregulated sexual promiscuity. Females, finding themselves too much at the mercy of the physically stronger males, managed somehow to gain control and institute religion and marriage; but the "male principle" ultimately proved even higher and purer, and the stage of matriarchal culture gave way to patriarchal culture. By around 1900, this theory of culture change as an epic three-stage battle between the sexes had proven untenable: It had been based on conflating matrilineality (tracing family lines through females) and matriarchy (sociopolitical rule by females) and on Bachoffen's having relied heavily on Greco-Roman myths to reconstruct the past. Still, the idea that humans had passed through a matriarchal stage had been embraced by the leading cultural evolutionists of the late 19th century: Edward B. Tylor, Herbert Spencer, and Lewis Henry Morgan.

Errors such as this rather glaring one, a growing suspicion that delineating evolutionary stages was inherently ethnocentric anyway, the misconception that the evolutionists had argued for a kind of rigid unilinearity in all aspects of culture change, and probably increasing contact between societies thanks to dramatically improved means of transportation and communication were among the forces that moved 20th-century anthropology to approach culture change in new ways.

The Early 20th Century

Dissatisfaction with the 19th-century orientation to culture change appeared earlier in the United States than in Europe. Sometimes, it presented itself as choosing a new battle instead of taking sides in the old one. In a highly influential paper of 1920, Franz Boas wrote as follows:

American scholars are primarily interested in the dynamic phenomena of cultural change, and try to elucidate cultural history by the application of the results of their studies. . . . They relegate the solution of the ultimate question of the relative importance of parallelism of cultural development in distant areas, as against worldwide diffusion . . . to a future time when the actual conditions of cultural change are better known. (p. 314)

This sounds evenhanded enough; but in fact, the concept of independent invention (or as Boas here calls it, parallel development) was intimately bound up with that of cultural evolutionism. Part and parcel of discrediting the latter, then, was a growing stress on contact between societies as key to understanding culture change. Boas (1920) went on in the very same paper to admit this stress; but he carefully ascribed it to methodological considerations rather than to any animosity toward cultural evolutionism: “It is much easier to prove dissemination than to follow up developments due to inner forces, and the data for such a study are obtained with much greater difficulty” (p. 315). Boas seems here to have been thinking of the contrast between directly observing how cultures vary over space and using archaeological evidence—laborious to obtain and relatively fragmentary at best—to try to piece together how a culture has changed over time.

By 1924, Boas seems to have decided that more than methodological considerations were involved. A paper titled “Evolution or Diffusion?” argued in effect that when societies appear to be culturally mixed, intermediate, or transitional, this nearly always should be taken as evidence of diffusion of traits from less culturally mixed societies, not as evidence of evolution from an earlier to a later condition of culture; to exemplify the danger of the evolutionary assumption, he discussed the old—and evidently misguided—interpretation of matrilineal customs as indicating transitionality between supposed matriarchal and patriarchal stages.

The Diversity of Diffusion

As part of the general reaction of the anthropological world against cultural evolutionism, then, culture change came to be thought of by anthropologists as primarily a matter of diffusion. In one of the more famous passages ever penned by an anthropologist, Ralph Linton (1936) wrote of how a typical adult male in the United States (of the 1930s) started his day. The flavor—if not the full

effect—of this virtuoso performance can be appreciated from the final paragraph:

When our friend has finished eating he settles back to smoke, an American Indian habit, consuming a plant domesticated in Brazil in either a pipe, derived from the Indians of Virginia, or a cigarette, derived from Mexico. If he is hardy enough he may even attempt a cigar, transmitted to us from the Antilles by way of Spain. While smoking he reads the news of the day, imprinted in characters invented by the ancient Semites upon a material invented in China by a process invented in Germany. As he absorbs the accounts of foreign troubles he will, if he is a good conservative citizen, thank a Hebrew deity in an Indo-European language that he is 100 percent American. (p. 327)

It is one thing to think of a culture as a product of diffusion; it is another to think about the process of diffusion itself. One can usefully distinguish four forms: direct contact, immigrant diffusion, intermediate contact, and stimulus diffusion.

Direct contact describes the case in which a cultural feature spreads from one society to adjacent societies and from those to other more distant ones. The basic type of medieval castle (“motte-and-bailey,” in which the structure stands atop a mound [the motte] surrounded by a ditch, surrounded in turn by a palisaded courtyard [the bailey]), for example, originated in northern France in the 10th century and gradually spread through most of western Europe. On a larger geographical scale, paper, having originated centuries before in China, underwent diffusion from the 8th century through the 15th to the Arab world and then to Europe. Three recurrent steps (in this as in other cases where the feature is a commodity) were (1) importation of small amounts as a luxury item, (2) importation of larger amounts as the item became widely used, followed eventually by (3) internal manufacture supplementing or replacing importation.

A particularly important way that diffusion occurs, often overlooked, is along with the expansion or migration of populations. One example of this *immigration diffusion* is the availability in American cities of “ethnic” options when people are choosing a restaurant. Very often this availability reflects the immigration of people who have opened restaurants serving the cuisine of the nations from which they have come. Another example of immigrant diffusion would be the enormous number of English cultural features—implements, customs, and beliefs (and the language)—that came to North America as a matter of course along with the colonists themselves. Immigrant migration is easily overlooked perhaps because the word “diffusion” conjures up an image of a cultural feature spreading mainly *between* people rather than mainly *with* them. In fact, without historical records it is often difficult to tell whether a cultural feature long ago moved across a resident population or simply along with an expanding one; the spread of motte-and-bailey castles, for example, seems to have been more or less

closely associated with the geographic expansion of the ethnic group known as the Normans.

Ethnic foods nicely exemplify another important point. Though some food critics may complain about, say, the amount of beef in our “Mexican” food, the sugary sauces in many “Chinese” dishes, or the quantities of sour cream in our “Japanese” sushi, such changes seem to appeal to the American palate (so to speak). And for cultural features to undergo such modification as they become accepted in a new social environment is more the rule than the exception when it comes to diffusion. Of course, this often involves cultural features more important than details of cuisine; a good example here would be the changes undergone by capitalism as it was culturally incorporated by Japan after the Second World War (Okumura, 2000).

Intermediate contact refers to the spread of cultural features by such agents as explorers, sailors, traders, or missionaries. This kind of diffusion reflects the fact that by the time societies have grown large enough to have an elaborate division of labor, some occupational specialties routinely position individuals to serve as diffusers of cultural elements. In the 1500s, for example, sailors, having gotten tobacco (and the practice of smoking it) in the New World, introduced it into the great port cities of Europe. Meanwhile, many European things were being introduced into the New World—notably, horses by Spanish explorers and Christianity by the missionaries. (The first Catholic missionaries arrived within a few years of Columbus’s initial voyage.) Another famous example, very important in the evolution of science and technology, was the diffusion of India’s decimal system (along with “Arabic numerals”) into Europe by way of a small number of books imported from the Middle East. Though written before CE 1000, these books’ influence was not widely felt in Europe—where Roman numerals remained customary—until the advent of the printing press centuries later.

Stimulus diffusion refers to situations in which an idea from outside triggers a society to develop and incorporate something new into its culture. A classic case is the development of writing among the Cherokee stimulated by a man named Sequoya from his observations of Europeans. Though the system used some symbols from the English alphabet, they represented not individual sounds but entire syllables; the writing system, that is, was syllabic rather than alphabetic. A “mere” idea from outside had sufficed to inspire a novel cultural development. But some degree of modification in a new environment is, as we have seen, a common aspect of diffusion; therefore, stimulus diffusion can be understood essentially as taking this aspect to an extreme.

Competition among peoples has given rise to important examples of stimulus diffusion. The ancient Hittites, first to develop iron chariots for war, tried to keep iron smelting a military secret and of course were not about to export iron chariots to surrounding societies; but eventually, the other societies developed (or otherwise acquired) them on

their own. Fear of being conquered is a powerful stimulus! Some 4,000 years later, biological weapons, space programs, and nuclear power often have been developed more by stimulus diffusion than by direct diffusion though it seems likely that indirect contact by way of espionage has played no small role as well.

Intrasocietal Diffusion

In anthropology, diffusion traditionally has been thought of as between social groups, especially between entire societies—typically nations. This form of diffusion may be termed *intersocietal*; as such, it contrasts with *intrasocietal* diffusion. Intrasocietal diffusion refers to the spread of an innovation within one group rather than from one group to another. Disciplines such as economics and sociology have given more attention to intrasocietal diffusion than have anthropologists. One of the most interesting things to emerge is a characteristic *S-shaped curve* describing the extent of an innovation’s adoption with respect to time. Some authorities consider this curve to result from innovativeness being a normally distributed trait (that is, a trait fitting the “bell curve”) within human populations. An innovation diffuses slowly at first because early-adopter types are fairly rare, gains “speed” as less atypical people adopt it, and levels off as the later-adopting, relatively rare “laggards” finally adopt it. There is evidence that early adopters tend to be higher in terms of education and income than do later ones (Rogers, 2003). The anthropologist H. G. Barnett (1953) suggested several “ideal types” of innovator or early adopter: the dissident, who is simply a nonconforming kind of individual; the indifferent, who is for some reason—perhaps merely by virtue of still being young—not strongly committed to conventionality; the disaffected, for whom certain experiences have loosened the commitment to conventionality (e.g., leaving home to go to college); and the resentful, embittered by having failed to achieve success in conventional terms. The final three of these would seem somewhat age graded in the sense that young, middle-aged, and older individuals, respectively, would be most likely to fit the description. By reminding us that people of all ages can have reasons for desiring change, Barnett’s typology perhaps helps account for the otherwise surprising failure to find a general tendency for innovators to be relatively young.

The Limits of Diffusionism

While diffusion has been and remains an important process of culture change, it can be overemphasized. Its easy comprehensibility may help explain the popularity, with the public, of fanciful images of lost continents or intercontinental raft voyages. In a somewhat more scholarly vein, the English biologist G. Eliot Smith (1928) tried to show that civilization had originated only once, in ancient Egypt; significant signs of civilization anywhere else in the

world he attributed to diffusion from the fertile floodplain of the Nile. The German priest Wilhelm Schmidt (1939) attempted to account for particular cultures as the intermingling of customs resulting from the overlapping of cultural “circles” radiating from a small number of centers. Another feature of diffusionism was its almost studied neglect of the systemic aspect of culture as if a culture were not so much a system of interrelated elements as a mere collection of juxtaposed borrowings—a “thing of shreds and patches” (cf. Harris, 1968, pp. 353–354).

There is at least one respect in which it *is* instructive to think of culture as a collection or stock of elements. As early as 1877, Lewis Henry Morgan suggested that culture change naturally tends to accelerate over time because any element of “knowledge gained” has the potential to become a “factor in further acquisitions” (1877/1985, p. 38). Innovations, that is, often involve combinations of pre-existing elements; therefore, the more cultural “material” there is available, the more innovations there will be. Culture, then, is somewhat like a snowball: The more of it there is, the faster it grows. It is important to remember, however, that this “growth” should not be presumed to constitute progress, at least morally, and that this snowballing tendency does not mean that “culture changes itself” since the innovations involved in the process are not themselves cultural unless and until they have been incorporated into a group’s way of life.

Acculturationism and Its Limits

Professional anthropologists, of whom there were by now a growing number (due especially to Boas’s efforts at Columbia University), tended to be skeptical of such extremes; they were more bothered by the observable facts that diffusion was not inevitable when cultures came into contact (whether indirect or direct) and that it was, in any case, only one of several possible results of such contact. The emphasis accordingly shifted from diffusion to *acculturation*, authoritatively defined as “those phenomena which result when groups of individuals giving different cultures come into continuous firsthand contact, with subsequent changes in the original cultural patterns of either or both groups” (Redfield, Linton, & Herskovits, 1936, p. 149).

This broadening of emphasis was to some extent a matter of convenience for American graduate students studying native peoples since these peoples by then had been long subject to the shattering effects of the Euro-American expansion into the New World. But the broadening also redirected attention from cultural elements as such to situations (and even particular events) on the one hand and to groups and individuals and their reactions on the other. Thus, studying acculturation so defined might entail as much attention to history and psychology as to culture!

As a significant example of how the study of acculturation leads to psychological issues, we might begin by

observing that people seem in most times and places to have found it easy to assume that their own culture or subculture is somehow essentially better than most or all other ways of life. Since this interpretation places one’s own culture at the center of the moral universe, it is termed *ethnocentrism*. Ethnocentrism ordinarily brings with it judgmental attitudes; sometimes, it even brings feelings of disgust. Presumably, all humans have ethnocentric tendencies, unconscious if not conscious; these perhaps stem from the fact that each of us is necessarily enculturated from infancy on in some particular way of life rather than in all possible ways.

Scientists, including anthropologists, generally agree in defining culture as a social rather than a genetic acquisition; and they generally regard ethnocentrism, whatever else it may be, as a barrier to the successful study of other cultures or subcultures. Arrogance, judgmentalism, and disgust reduce one’s chances of gaining a more accurate and deeper understanding of other ways of life. To counteract their own ethnocentric tendencies, anthropologists adopt the assumption that no culture or subculture is basically better or worse than any other. This assumption is known as *cultural relativism*. In reference to culture change, ethnocentrism would be expected to create resistance to diffusion. Other things being equal, unfamiliar cultural elements from outside might appear undesirable or threatening simply because they are unfamiliar. There also may be outright hostility toward the out-group itself that would foster a desire to be as different from them culturally as possible. Thus it is that acculturation phenomena include not only diffusion but also intentional resistance to diffusion (Loeb & Devereux, 1943).

Much depends, however, on the attitude of the borrowing society toward the lending one. Although it is common for in-groups to look down on out-groups and their ways, it can happen that an in-group actually looks up to an out-group. Prestige attaching to an out-group of course would facilitate adoption of its cultural elements by an in-group, thus promoting diffusion.

It is sometimes argued that acculturation studies were ideologically tainted by denying or glossing over the effects of exploitation on indigenous peoples and cultures. It is important to recognize, however, that many anthropologists were not only acutely aware of this danger but also actually engaged in lively, open debate about it; an excellent example is the exchange between Victor Barnouw, Bernard J. James, and Harold Hickerson about Chippewa personality (Barnouw, 1979).

The Mid-20th Century

The limitations of acculturation as a focus for studying culture change were sufficiently grave that by the time the concept was achieving clear formulation, some younger anthropologists already were heading in a different

direction—a direction reasserting the importance of focusing on culture itself rather than on psychology or history and on culture as a system of interacting elements. Julian Steward (1955) stressed that a culture's first order of business, so to speak, was to adapt a human group successfully enough to its environment for the society to survive; he paid special attention to the way in which specific environments called forth specific kinds of cultural adaptations. Leslie A. White (1949) shared Steward's stress on culture as a survival mechanism but was more interested than Steward in the trajectory of human culture as a whole—a contrast sometimes connoted by “Culture” compared with “cultures.” The notion of a single human culture may seem odd. Yet it seems likely that no human group is or ever has been *completely* isolated from all others; so if humans are connected, even if only indirectly by patterned interaction, it makes sense to consider us a single social group; in which case, the concept of *a* or *the* socially acquired human way of life, no matter how diverse, finds justification. White argued forcibly that the most important innovations in cultural evolution have been those that led to greater control and consumption of energy; indeed, he wrote of culture as being at heart an energy-capturing system. White and Steward often were termed “neoevolutionists” because their work in some respects constituted a return to the search for scientific laws that had inspired the 19th-century evolutionists.

Leslie White (1949) and Julian Steward (1955) engaged in vigorous debates that tended to enlarge on their differences and minimize their similarities. This situation was to some extent clarified when Marshall Sahlins (1960) proposed calling Steward's focus “specific cultural evolution” and White's, “general cultural evolution.” In a highly influential book, *The Rise of Anthropological Theory*, Marvin Harris (1968) argued convincingly that Steward and White actually had in common what was important and fundamental and new: not that they both believed culture evolved but that they both believed the best way to analyze culture was to begin with the tools and techniques through which people met their everyday survival needs in the environment they inhabited. Changes in (or differences of) environment would mean technological change; technological change would bring change in how people interacted and even in the kinds of groups they lived in; and these changes would trigger changes in how people thought about the world, one another, and themselves. To understand culture change, these materialists taught, we need to acknowledge the primacy of the technological linkage between people and environment; changes in that linkage will be the most potent innovations of all.

Contemporary Approaches to Culture Change

For a time in the years leading up to 1970, it appeared that the anthropological study of culture (and culture change)

might be unified under the evolutionist/materialist banner. The approach was especially appealing to archaeologists (Steward had begun his career as one); the artifactual evidence to which they have direct access is material indeed, so according theoretical priority to technology appealed to them. And indeed, the evolutionist-materialist approach, looking at cultures as adaptive systems, has vanished from the anthropological landscape. But something quite different was also astir, especially among cultural and linguistic anthropologists affected by certain countercultural trends of the 1960s. Thus, we may think of two broad contemporary approaches to culture change: the new acculturationism and the continuation of evolutionism/materialism.

The New Acculturationism

Published only a year after *The Rise of Anthropological Theory* was a very different book indeed: an edited volume titled *Reinventing Anthropology* (Hymes, 1969). Here was revealed a profound skepticism toward and even indictment of the effort to study human culture scientifically. Science, reason, and anthropology (and anthropologists) were associated not with the liberation of human minds but with the exploitation of colonized populations.

Of special importance for the study of culture change was the idea that cultural anthropologists were mistaken about what they had been studying. Though they thought the hunting-gathering people, the pastoralists, the villagers, or the peasants they observed provided glimpses into more ancient ways of life, what they principally offered, it is proposed, are insights into the effects of colonialism and capitalist exploitation. In a sense, the argument is that we have always been essentially studying acculturation, whether we knew and admitted it or not. In part, this is because the anthropologist herself or himself is—and must to some extent remain—a stranger; and whatever he or she writes is not so much an objective picture of the observed by an observer but a subjective account of an interaction between the two.

We noted that diffusionism was taken to its greatest extremes not by professional anthropologists but by a biologist and a priest; similarly, the extreme of this new acculturationism was reached by a journalist, Patrick Tierney (2000), who argued that it was anthropologists themselves (along with journalists) who were responsible for the devastation—by the outside world—of the Amazon and its native peoples. Anthropologists have argued, more modestly, that in past studies the effects of contact (colonization and exploitation) sometimes have been seriously underestimated (e.g., Ferguson & Whitehead, 1992); and many have been at pains, in their own recent work, to highlight rather than ignore the inequality built into the contact situations they study (and in which they participate). Sherry Ortner (1999), for example, introduces her study of mountain climbers and their Sherpa guides by noting that one group has “more money and power than the other.” She

goes on to suggest that whether one is dealing with a colonial, postcolonial, or globalizing context, “what is at issue are the ways in which power and meaning are deployed and negotiated, expressed and transformed, as people confront one another within the frameworks of differing agendas” (p. 17). Greater sensitivity to such issues is an important development. At the same time, declaring that *nothing* about earlier human cultures can be learned by studying recent band, pastoral, and village peoples seems at least as extreme and implausible as considering them to be perfectly preserved “fossils” of those cultures.

Evolutionism-Materialism

Evolutionism-materialism continues to see cultures as adaptive systems and to see this as the key to understanding culture change. There have been ongoing efforts, however, to demarcate subsystems of the system and to interpret culture change as resulting from interaction of these subsystems.

A system is a set of related parts such that change in one part can bring about change in another part. Is culture a system? Here is an example suggesting that it is. Prior to around 1850, most American families lived on farms. On the farm, children were an economic asset because they enlarged the “work force” for what was essentially a family-owned, family-operated business. Children became economically productive at an early age by doing chores such as gathering eggs and feeding animals and of course became more valuable as they matured. One’s children also provided one’s care in old age. Urban life, however, converted children from economic assets to economic liabilities; to feed, clothe, and educate each one takes a lot of money. Parenting of course has its rewards in urban society, but those rewards do not usually include economic profitability! As a result, large families and therefore large households were far more common 2 centuries ago than they are today. On the farm, children commonly grew up alongside their parents and several siblings and sometimes grandparents, too. Today, households on the average are much smaller. One- or two-children households are common, and indeed, about one fourth of American households contain only one person. Thus, the shift in what people do for a living has brought dramatic changes in how children grow up and in home life more generally. Yet one can think of changes in one part of culture that have little or no apparent effect on other parts of culture. In recent decades, for example, the technology for recording and listening to music has changed rapidly from vinyl records to tapes to compact discs; yet it is difficult to think of significant changes in our way of life that have been triggered by these changes. Another contrast of this kind is the transformative effect that the acquiring of horses famously had on the cultures of the American Great Plains compared with the relatively modest effect that acquiring tobacco had on the cultures of Europe. Such contrasts raise the possibility that

there are certain *kinds* of culture changes that tend to be more potent than other kinds in triggering further cultural changes. In other words, considering a culture as a partially integrated system, are some subsystems more determinative than others of the characteristics of the system as a whole? If so, which one or ones?

Several divisions of cultural systems into subsystems have been suggested; especially important and illuminating has been a division into three subsystems designated most simply as technology, social organization, and ideology. Karl Marx (1867/1906), who usually distinguished only two subsystems called base and superstructure, suggested this one in a footnote to Chapter 15 of *Capital*:

Technology discloses man’s mode of dealing with Nature, the process of production by which he sustains his life, and thereby also lays bare the mode of formation of his social relations, and of the mental conceptions that flow from them. (p. 406, note 2)

Note that “technology” here does not refer to everything to which we might commonly apply the term such as the latest leisure devices for watching movies or listening to music but to artifacts and processes more essential to our survival: the technology involved in “dealing with Nature” so as to sustain the lives of human beings—that is, the means by which food is produced and by which raw materials are extracted and made into the things we need and want. Especially fundamental is the tapping of energy sources: getting food to fuel our own bodies, gathering and burning firewood, domesticating plants and animals, mining and burning coal, drilling and burning oil, trapping sun or wind, and even the controlled splitting of atoms (White, 1949).

Note that this seminal sentence not only suggests three subsystems but also places technology in the “driver’s seat” or in the role of what is sometimes called, in analogy to energy production, the “prime mover.” This idea, that how people use the physical environment in order to survive is basic to understanding entire cultural systems, is often known as the principle of infrastructural primacy as suggested by Marvin Harris in his extensive writings on the subject.

But technology includes also the means we use for literally moving ourselves from place to place physically and for staying in touch; thus, there are technologies of transportation and communication. Technology includes, too, some of the means we apply directly to ourselves as physical beings to foster health and control reproduction; there is, then, such a thing as medical technology. And of course when societies pursue their own interests—at least as defined by leaders—as over against those of other societies, they may resort to the weapons of war and hence the importance of military technology.

We might be tempted to think of technology as essentially artifactual; but note that technology here refers not only to the kinds of artifacts employed as societies go

about the business of surviving but also to the behavior patterns required for making and using the artifacts involved: it was not only just stone tools long ago, for example, but also the ways of making and using them; not only just the food—then or now—but also the ways of finding or growing it; not only just the oil drills but also the ways of finding, drilling, and refining the oil.

A complementary point must be stressed regarding social organization: Though we might be tempted to think of it as entirely behavioral (consisting of the patterned ways people interact with one another), “social organization” nearly always takes place in a more or less human-altered (artifactual) environment and often directly involves artifacts, whether a frisbee thrown between friends, the money exchanged in a cash transaction, or the paraphernalia used in a church service. Admittedly, we might say that technology has a kind of artifactual “focus,” social organization a behavioral one; but as cultural subsystems, both technology and social organization are simultaneously artifactual and behavioral.

The situation is different with ideology. Widely shared ideas and beliefs can be associated to a certain extent with artifacts in the form of such documents as constitutions or holy books; but so long as we are thinking of behavior in physical *rather than* mental terms, the ideological subsystem is inherently nonbehavioral. This subsystem is best thought of as essentially neither artifactual nor behavioral but ideational—though it certainly includes ideas *about* artifacts and behaviors. (The idea that cars have four wheels is an obvious example of the former, that people should treat others as they would like to be treated of the latter.) It is important to remember, however, that as a subsystem of *culture*, it includes not any and all ideas but only those we would be willing to say have become part of a way of life—that is, that have undergone cultural incorporation.

At first glance, then, the trichotomy of technology, social organization, and ideology sounds rather like that of artifacts, behaviors, and ideas; it turns out, however, that the trichotomy of artifacts, behaviors, and ideas, helpful as it is for thinking about innovations and about the kinds of things that constitute culture, differs quite significantly from this new trichotomy. We are thinking now not so much about the kinds of elements that compose a system as about the kinds of subsystems whose interaction constitutes the functioning of the system. A biochemical analogy may be helpful: The *constituents* of a single-celled organism are atoms and molecules, but understanding the organism as a functioning system requires identification of major *subsystems*, such as the cell wall, the nucleus, and the cytoplasm. Serving different purposes, the classifications are complementary rather than contradictory. (The terms technology, social organization, and ideology as used largely this way are from Gerhard Lenski [1970], which closely resemble Leslie A. White's [1949] technological, sociological, and

ideological systems; Marvin Harris [1979] coined infrastructure-structure-superstructure while I and my coauthors have offered interfaces-interactions-interpretations [Graber, Skelton, Rowlett, Kephart, & Brown, 2000].)

Among the various contexts in which customary social organization expresses itself (e.g., economic, political, domestic, and ritual), political organization holds a place of special interest with regard to culture change. For one thing, political leaders in large societies can legislate—and have legislated—programs aimed at making individuals or groups who differ culturally from the wider society “fit in.” Such programs, often involving reservations and/or missions and schools for educating children and young people on a nonvoluntary basis, may be termed “forced assimilation”; it cannot be said they have a very proud history.

A very different effect of political organization on culture change occurs when a revolutionary government seeks not to adapt individuals to the prevailing culture but to bring dramatic change to the prevailing culture itself. In the 20th century, for example, several peasant societies underwent rapid industrialization in what may well be termed, after the Chinese case, “cultural revolutions” (Wolf, 1969). This reminds us that culture, though by definition relatively resistant to change, not only does change but also can even do so quite rapidly.

The Course of Culture Change

When we turn to consider the overall course followed by the development of human culture, we find that both the evolutionist-materialist and acculturationist approaches are illuminating.

The earliest solid evidence of human culture consists of simple stone tools dating back to between 2 and 3 million years ago. Our closest living relatives, the chimpanzees, exhibit elementary cultures; but their artifacts are fashioned of perishable materials and therefore would not be archaeologically recognizable. It seems quite likely, then, that culture itself is even older than the stone tools left to us by our early ancestors.

Between 2 million and 1 million years ago, early humans expanded from the tropics of Africa into the rest of the Old World. Because this expansion was chiefly into colder environments, it must have been greatly facilitated by the control of fire, which probably had been attained by half a million years ago and possibly had been attained much earlier. Judging from fire's centrality—literally as well as figuratively in terms of domestic interaction—in the culture of recent hunting-gathering peoples, we can imagine that the acquisition of fire was of enormous significance.

Although our ancestors all remained hunter-gatherers for over 99% of the time since the appearance of the first stone tools, they expanded into many different environments. This

expansion was made possible not only by control over fire but also by the development, probably generally over many generations of trial and error, of different kinds of tools suited to gathering, hunting, and fishing whatever the local physical environment offered. The considerable extent to which culture change was driven by radiation of humans into new environments—achieved, among other life-forms, overwhelmingly by biological rather than by cultural change—goes far to vindicate the evolutionist-materialist view of culture as *essentially* an adaptive system. (Further vindications come from the fact that anthropologists, when they write descriptions not only of bands but also of pastoralists and village peoples, nearly always deem it most enlightening to begin with the physical environment and how the people interface with it to survive; then, they proceed to describe how people interact with one another and only then to focus on how the people interpret reality—their religious and philosophical conceptions. Ethnographically, it works better, as a Marxian metaphor puts it, to ascend from the earth to the heavens than to descend from the heavens to the earth.)

Between 10,000 and 15,000 years ago, populations had grown sufficiently dense in some parts of the world that people had begun settling into villages and growing food in addition to hunting and gathering it. In some places, the natural environment created population “pressure cookers” in which competition for ever scarcer farmland led to warfare between societies, followed by the displacement, destruction, or subjugation of the vanquished. Culture then not only had to accommodate the physical environment but also had to allow for the existence of human groups large enough and well coordinated enough to compete successfully with surrounding groups (Carneiro, 1970). Thus began the process of transforming a large number of small societies into a small number of large ones (Carneiro, 1978; Graber, 1995). With this growth in the size of societies came the complex division of labor and the stratification into rich and poor, powerful and powerless that still characterize human culture today.

By 500 years ago, a few societies had grown large and technologically advanced enough to cross oceans. What we know as the modern system of nations began taking shape. Soon, the steam engine was powering the Industrial Revolution. Transportation and communication accelerated, bringing people together even more than did the increasing density of the population itself; and increased trade made a society’s culture less and less dependent on its own physical environment. Spurred by warfare and the threat of war, science and technology advanced so rapidly that nuclear war, and perhaps other threats of which we are not even aware, confront us with the possibility of self-extinction; and recently, we have learned that centuries of burning hydrocarbons have contributed to depleting earth’s ozone layer and are significantly altering the climate. Fortunately, we also have much greater (and constantly growing) knowledge of our effects on the physical environment,

of how the ever more integrated global economy works, and of how societies and cultures have affected—and continue to affect—one another, reflected in the greater sophistication and sensitivity of the new acculturationism. If this growing knowledge (perhaps aided by good luck) allows us to avoid disaster, we bid passage to continue on the path to becoming a single world society (Carneiro, 1978; Graber, 2006).

Stone tools, agriculture, the steam engine and industrialization, nuclear power—these changes in the technological subsystem of human culture have triggered vast changes throughout all three subsystems. Already making their mark are computers and genetic engineering; on the horizon are, for example, developments including nanotechnology and controlled nuclear fusion. For better or worse, technology seems destined to play a major role in future culture change; but—as Leslie White (1949) observed—whether as hero or villain, we do not know.

Conclusion

To sum up, then, by definition (1) culture resists change; but in fact, (2) it does change; indeed, (3) it can even change rapidly; (4) its overall rate of change appears to have increased; and (5) it differentiated as humans expanded into and exploited different environments and then began integrating as global population density increased; (6) integration continues to dominate the culture-change picture as we enter the 21st century as a major dimension of “globalization.”

Will cultural integration eventually eradicate all cultural differences? This seems unlikely. After all, different households even of the same social class and in a single neighborhood acquire rather different ways of going about the business of everyday life—differences that become quite clear when, say, schoolmates visit each other’s homes; even greater is this impression when new roommates or couples first attempt setting up a new household of their own! The deep similarities of human beings placed limits on the cultural differentiation that allowed our ancestors to *occupy* our planet; our persisting individual differences place limits on the cultural integration that will allow us, we hope, to *live together* on it for a long time to come.

SOCIAL EVOLUTION

ROBERT BATES GRABER

Truman State University

Social evolution refers to social or cultural change over relatively long periods of time. By *social* is meant having to do with two or more organisms of the same species engaged—directly or indirectly—in patterned interaction; by *cultural* is meant having to do with the way of life of a social group, insofar as that way of life is a social rather than a biological acquisition.

If the price of gasoline goes up, that is a social change (specifically, an economic one). If the price goes high enough and stays high, people's travel habits may actually change; that would be a cultural change. If the means of transportation themselves undergo significant change, that would be a cultural evolutionary change. These distinctions, though not exact, are clear enough to prove useful.

Note that "social," as generally used, is a more encompassing term than is "cultural." Since its culture clearly is a characteristic of a social group, the cultural realm can be considered a subset of the social realm. There seem to have been few if any attempts to systematically distinguish between social and cultural evolution; many scholars, finding it more useful to integrate rather than differentiate the two, have used the hybrid term "sociocultural evolution."

Early Contributions

Ancient treatments of social evolution still worth reading were produced by the Roman writer Lucretius and more

than a millennium later by the Saracen Ibn Khaldun. Famous French writers of the 18th century, including Montesquieu, Turgot, and Condorcet, offered optimistic analyses tending to celebrate what was seen as the inexorable march of *reason*; notably more scientific was Scottish writer John Millar in his 1771 book, *Observations Concerning the Distinction of Ranks in Society* (Harris, 1968, pp. 48–52). More closely associated with social evolutionism today, however, are 19th-century writers. Most often identified explicitly as social evolutionists are the British writers Herbert Spencer and Edward B. Tylor and the American Lewis Henry Morgan; less often classified as social evolutionists but making major contributions nonetheless are England's Robert Malthus and two German authors, Karl Marx and Theodor Waitz.

Spencer, Tylor, and Morgan

Herbert Spencer

When people hear the phrase "survival of the fittest," they are likely to think of the great biologist Charles Darwin; the phrase in fact appears to have been coined by a contemporary of Darwin's, the philosopher Herbert Spencer.

Spencer (1897, 1851/1969) thought of evolution as involving much more than biology. For him, evolution pervaded the inorganic as well as the organic realm.

His voluminous work also treated “superorganic evolution” (which we today would term social evolution) and evolution of “superorganic products” (what we call cultural evolution). Much as cells combine to make up organisms, organisms themselves combine in some species to make up “superorganisms,” or societies. The comparison of societies to organisms has roots in ancient Greece, but Spencer elaborated this idea in greater detail than anybody else before or since. He emphasized three developmental tendencies shared by societies and organisms: (1) growth in size, (2) increasing complexity of structure, and (3) differentiation of function. Generally speaking, larger life-forms, unlike smaller ones, have several types of tissues and organs, each suited to perform its special function; similarly, larger societies, unlike smaller ones, have specialized arrangements for performing different functions. Examples include factories, stores, schools, and churches; less concrete arrangements, such as economic and political systems; the occupational division of labor; and the division of society into rich and poor, powerful and powerless.

Yet this analogy, like any, has its limits—some of which Spencer recognized and discussed, others of which he overlooked or ignored. He admitted, for instance, that the parts of an organism are in direct contact, while the members of a society are not; but he argued that communication considerably reduced this difference. He seems not to have confronted the related—and scientifically awkward—fact that societies by having no membrane or skin are less identifiable entities than are organisms. Spencer’s work had a political as well as a scientific dimension. Unfortunately, he regarded the “survival of the fittest” as a sort of guide for governmental policy, which often led him to oppose programs to assist the poor. His skepticism about the ability of government to do more good than harm—concerning not only poverty but also quite generally—has made him an important inspiration of what today is called libertarianism. Also unfortunately, these rather extreme political views helped cause Spencer’s more scientific writings, such as *Principles of Sociology* (1897), to fall into neglect for several decades. Since the revival of cultural evolutionism in the mid-20th century, however, Spencer has been rediscovered; much of his most valuable work appears in two excellent anthologies (Carneiro, 1967; Peel, 1972).

Spencer’s greatest contribution perhaps was to encourage people to try thinking of society and culture, no less than stones and pinecones, as belonging to the natural world. “Civilisation,” he declared, “is a part of nature; all of a piece with the development of the embryo or the unfolding of a flower” (Spencer, 1851/1969, p. 65).

Edward B. Tylor

If any one person deserves recognition as the founder of anthropology, it is Edward B. Tylor. To students wondering

why they should be expected to learn yet another science, Tylor (1881/1909) suggested that anthropology resembled a backpack. A backpack adds yet more physical weight to be carried, but it more than pays for itself by making everything else so much easier to carry; likewise, he suggested, anthropology more than pays for itself by tying together diverse subjects, thereby making the educational load not harder but easier to bear (p. v).

Anthropology, in the United States, has four subfields: biological, archaeological, cultural, and linguistic. Together they comprise the “study of humanity.” Largest of the four subfields, in number of anthropologists specializing in it, is cultural anthropology. People have followed different ways of life in different times and places; making sense of this diversity is the central task of cultural anthropology. Its key concept is culture itself, for which Tylor (1871/1924) furnished the most famous definition. Culture, he wrote, is “that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities and habits acquired by man as a member of society” (p. 1).

Cultural evolutionism’s great early achievement was the defeat of *degenerationism*. According to this theory, human culture had originated at a fairly “high” level after which some cultures “degenerated” to “lower” levels while others “rose” to yet “higher” ones. Foremost among scholars putting degenerationism to rest was Edward B. Tylor himself. Using his extensive knowledge of the anthropological evidence that already had accumulated by around 1865, Tylor (1865/1964) showed that high cultures quite certainly had originated in a state resembling that of the low cultures still observable in some parts of the world and that there was no evidence that any of the latter had come into being by degeneration from a higher condition of culture.

Evidence overwhelmingly favors the conclusion that up until only 10,000 or 15,000 years ago all humans had lived, from our very beginnings as a distinct form of life, in small, nomadic bands that survived by hunting and gathering the wild food sources around them. In view of the ingenuity and durability of foraging culture, anthropologists no longer call it low, our own culture high; but looking past the ethnocentric terminology, we can see that the conclusion drawn by Tylor and others has been reinforced by all subsequent findings. Social evolution surely began everywhere with very small societies; and culture has been transformed in those times and places where, for reasons still being vigorously investigated, societies grew into villages, chiefdoms, nations, and empires.

Though degenerationism had been motivated by religion (especially the story of the Tower of Babel in the Book of Genesis), it did have testable implications; therefore, it could be—and was—rejected through the application of reason to empirical evidence. The defeat of degenerationism was a great step in science.

Lewis Henry Morgan

The surprising facts that a few basic patterns occur over and over and that each pattern has a logical structure of its own were among the discoveries of Lewis Henry Morgan, a prosperous attorney who lived in 19th-century Rochester, New York. As a young man Morgan had taken great interest in the Iroquois Indians of New York, and in 1851, he published a book about them highly respected even today. His anthropological interests reached full flower, however, in his 1877/1985 book, *Ancient Society*. To organize the growing body of knowledge about human cultures of the past and present, Morgan carefully defined three main cultural stages: savagery, barbarism, and civilization. Savagery and barbarism he divided into sub-stages of lower, middle, and upper for a total of seven stages. These terms sound ethnocentric, or culturally biased, to us today; but in Morgan's time and certainly in his usage, they were technical terms carrying but little of the pejorative connotation they later acquired. It is not sufficiently appreciated that Morgan, especially for his time and place, had a very tolerant, sympathetic attitude toward cultural differences. The preface to his book on the Iroquois (Morgan, 1851/1901), for example, declares that "the public estimation of the Indian, resting, as it does, upon an imperfect knowledge of his character, and tinted, as it ever has been, with the coloring of prejudice, is universally unjust" (pp. ix–x).

Morgan's seven stages (1877/1985), partly for reasons of convenience and clarity, were defined mainly with reference to specific elements of technology. Barbarism, for example, was distinguished from savagery by the presence of pottery. This had some strange consequences. Peoples of Polynesia, for example, despite living in large chiefdoms consisting of several permanent villages, were classified as "savages" along with small, nomadic bands of foragers simply because they happened to lack pottery. Yet the criticism later heaped on Morgan for this and other failings was not quite fair; he himself had looked forward to a time when fuller evidence would allow more satisfactory classifications than his own. Recognizing the limitations of both his own scheme and the Stone Age/Bronze Age/Iron Age scheme introduced by Danish archaeologists, he suggested that general subsistence patterns rather than specific artifacts or materials ultimately would provide "the most satisfactory bases for these divisions. But investigation has not been carried far enough in this direction to yield the necessary information" (p. 9).

This was an accurate prediction. Anthropologists now agree that it is not ground-stone tools or pottery that most basically signal the Neolithic but the transition from foraging for food to growing it. The archaeological appearance of pottery around the world correlates fairly well with this transition probably because pottery is too heavy and fragile to have been of much use before people began

settling into villages and growing food some 10,000 years ago; so even in emphasizing pottery, which got him into such trouble over the Polynesians, Morgan had not been too wide of the mark.

Malthus, Marx, and Waitz

Robert Malthus

Thomas Robert Malthus's father held liberal views and was optimistic about the prospects for the betterment of human society. Malthus himself, even in his youth, suspected that social problems were deeply rooted and that there must be real limits to the improvement of society. One theological argument, of course, is that social problems are inevitable because human nature is sinful. One might think this should have settled the matter for Robert, who after all had been ordained at around age 22 in the Church of England. But he also had studied mathematics and shown scientific inclinations; neither he nor his father seems to have regarded the issue as essentially theological.

Searching constantly for stronger arguments, Robert Malthus eventually hit on an idea so persuasive that in 1798 he published an essay laying it out in detail: *An Essay on the Principle of Population*. Humans, he noted, along with other forms of life, tended to reproduce in numbers greater than could be easily supported by available resources. Population inevitably would be "checked," whether by higher mortality (due to famine, disease, or war) or lower fertility (due to abstinence, contraception, or nonreproductive forms of sexual behavior, such as masturbation and homosexuality). These checks on population all entailed either misery or—in Malthus's judgment—wickedness ("vice"); and even at that, they left the population so high, relevant to resources, that social problems, such as poverty and crime, would be chronic. True, periods of relief occasionally would occur after plagues had sharply reduced the population or technological breakthroughs had abruptly increased available resources (especially food); but the power of population was so great that soon there once again would be too many people. Population again would stabilize via the miserable and vicious checks, but it would do so at a level above that of "easy support"; relief from social problems, then, would be rare and temporary.

A key point in Malthus's argument (1798/1993)—which has been under nearly nonstop debate for two centuries now—has been widely overlooked: his claim that population tended to stabilize at a level greater than what resources could easily support meant that there would be not only social problems but also nearly constant pressure for culture change. As he wrote toward the end of *An Essay on the Principle of Population*, the press of population "is constantly acting upon man as a powerful stimulus, urging him to the further cultivation of the earth, and to enable it, consequently, to support a more extended

population” (p. 147). The idea that population pressure could help explain cultural evolution would lie in neglect until the 1960s; when recovered, it was labeled rather misleadingly “anti-Malthusianism.”

Karl Marx

“So what do you want to be when you grow up?” Pressure to find an occupation begins early in our own enculturation. In the small societies in which all people lived until around 10,000 years ago, such a question made no sense; all people grew up to engage in pretty much the same range of activities (except for differing sex roles). The young Karl Marx (Tucker, 1972) hoped—and believed—that society was evolving toward a way of life that would be far more fulfilling than either the modern or ancient situation—a society in which the individual, far from being forced to become one certain “thing” in the division of labor, would be free “to do one thing today and another tomorrow, to hunt in the morning, fish in the afternoon, rear cattle in the evening, criticise after dinner, just as I have a mind, without ever becoming hunter, fisherman, shepherd or critic” (p. 24).

Marx and his collaborator Friedrich Engels (Tucker, 1972) believed that conflict between haves and have-nots was the prime mover of social evolution; and it was class struggle, they thought, that soon would usher in a very different kind of society. The productive powers of industrialization harnessed to a centrally planned economy would ensure that the merely animal needs of all people were efficiently met. People then would work not out of “mere animal necessity” but to fulfill their essential nature. Marx and Engels despised Malthus for his pessimism about improving society; in their view, ideas like his hindered positive social change by making excuses for the status quo. On the other hand, they found some inspiration in the work of Lewis Henry Morgan; they particularly liked his emphasis on the importance of technological changes in the human past. They too constructed a set of stages; it differed somewhat from Morgan’s, however, and has been less influential.

When moralists condemn modern society for its “materialism,” they usually are referring to love of physical things—cars, clothes, boats, or condominiums. In intellectual history, however, the word *materialism* has a rather different meaning. The materialist perspective is well suggested by a declaration of the ancient Greek philosopher Democritus: “Nothing exists but atoms and the void.” In this spirit, Karl Marx thought that the mental world created by a human society must be understood in terms of how the organisms composing the society were managing to survive and reproduce. As Marx wrote in 1859, “It is not the consciousness of men that determines their being, but, on the contrary, their social being that determines their consciousness” (Marx as cited in Tucker, 1972, p. 4).

Marx and Engels believed that materialism had both political and scientific implications. Though they considered

these deeply intertwined, their subordination of the scientific to the political is clear. “The philosophers have only interpreted the world, in various ways; the point, however, is to change it” (Marx as cited in Tucker, 1972, p. 109). It remained for the Russian leader V. I. Lenin to reach the extreme conclusion that the scientific search for truth must not be allowed to stand in the way of political revolution. In anthropological theory, the main political and scientific developments of materialism sometimes are distinguished respectively as dialectical materialism and cultural materialism. Cultural materialism refuses to subordinate scientific analysis to political agendas (Harris, 1979, pp. 157–158). Our understanding of social evolution has been invigorated by the cultural-materialist attempt to understand culture and culture change as reflecting the actual conditions—demographic, environmental, and technological—in which people as creatures struggle to survive and reproduce.

Theodor Waitz

Theodor Waitz was the precocious descendant of a long line of German Protestant preachers and teachers. His intellectual maturation took him from theology to philosophy, then to psychology, and finally to incipient anthropology. Showing superb intellectual judgment, Waitz (1859/1975) proved ahead of his time (1) in conceiving of general anthropology as a new empirical science, (2) in stressing the biological unity of humankind as one species, and (3) in arguing that what biological differences there were between human populations (“races”) were *not* relevant to accounting for their observable cultural differences. The usual idea, he noted, was that a people’s conditions of culture reflected their basic capacities; he reversed this by arguing that the relevant capacities actually resulted from the conditions of culture. Franz Boas, often credited with this breakthrough, acknowledged that it was Waitz who actually had been first to express clearly what would become fundamental to modern anthropological research. Robert Carneiro’s *Evolutionism in Cultural Anthropology* (2003) is helping secure for Waitz the credit he deserves in this regard. When Waitz died of typhoid fever at only 44, anthropology lost perhaps its greatest mind.

Recent Theories

In the early 20th century, anthropology turned away from cultural evolutionism. Though the 19th-century evolutionists had been among the most enlightened people of their time, their work inevitably was tainted by the prevailing interpretations of reality, including assumptions of racial and cultural superiority. Even the great evolutionists Spencer, Tylor, and Morgan were disparaged as “armchair speculators”; what was needed, it was asserted, was actual fieldwork in order to learn firsthand about the history and

functioning of small-scale societies before they disappeared from the face of the earth forever.

The emphasis on fieldwork produced mountains of new and better information about the cultures of the world; yet the urge to make systematic sense of all this new, chiefly descriptive material soon gave rise to a resurgence of cultural evolutionism. Early contributors—most notably, perhaps, Spencer—were resuscitated, their more promising ideas reconsidered, reformulated, and extended. This movement, sometimes termed *neoevolutionism*, was led by two American anthropologists, Julian Steward and Leslie A. White. Most of Steward's work (e.g., 1955) had the modest goal of elucidating the effects of specific environments on the cultures of the people inhabiting them (cultural ecology). White's work (e.g., 1949) offered more ambitious generalizations about the course of human culture as a whole; he was impressed especially by the relationship between cultural evolution and how—and how much—energy was used by human societies. Steward and White and their followers engaged in vigorous debates, which, though initially fresh and illuminating, eventually seemed to be generating more heat than light. In 1960, a small but influential book of essays titled *Evolution and Culture* argued cogently that the approaches of Steward and White were better seen as complementary than as opposed (Sahlins & Service, 1960). Though this cleared the air, it pointed no new direction.

In 1965, a new path was opened when American anthropologist Don E. Dumond and Danish economist Ester Boserup independently proposed that population growth under certain conditions could be an important cause of certain kinds of culture change. (That they had been unaware of each other's work was confirmed in conversation with Dumond in 1994. Their insight had been hinted at as early as 1798 by Malthus himself; but the scholarly world had long overlooked this, in part because what Malthus *stressed* had been the dependence of population on cultural conditions rather than the converse.) Impressive theories soon were proposed for the major transformations of cultural evolution. Though “population pressure theory” attracted the most attention in the 1970s, it continues to be a significant and promising specialty within sociocultural evolutionism.

Agricultural Origins

The old theory of agriculture was that it was a difficult invention, which once achieved spread rapidly from a single origin because it made life much easier and more secure. Anthropological progress in the 20th century made this less and less tenable. In several parts of the world, archaeologists accumulated evidence that the domestication of plants and animals had been a long, gradual process of change in which species found wild in local environments came slowly to resemble the domesticated forms of today.

Cultural anthropologists, meanwhile, were learning that hunting-gathering peoples possess extensive knowledge of the plant and animal life around them. The fact that plants grow from seed, for example, was not a profound mystery but common knowledge. Furthermore, the foraging life, even in marginal environments, such as the Kalahari Desert in South Africa, proved to be considerably less difficult than had been believed. Neither the archaeology nor the ethnology seemed to fit with the old theory. If foraging for food was usually a relatively easy lifestyle, why did people ever begin growing food? And why, when they finally did (after millions of years of foraging), did it happen so slowly and in so many places?

The pieces of the puzzle were assembled neatly by the archaeologist Mark Nathan Cohen. Influenced by earlier writers, especially Ester Boserup, Cohen (1977) proposed *population pressure* as the key. The beginnings of agriculture some 10,000 years ago approximately coincided, Cohen pointed out, with the end of the long process of human expansion throughout the habitable portions of the planet. As population continued to grow with nowhere new to go, global density would have begun to increase rapidly; wild plant and animal food sources gradually were ever less sufficient for human survival. Our ancestors took up farming only when and to the extent that they had to.

An especially nice feature of this theory is that it explains why, after several millions of years of human existence, agriculture cropped up in so many places within a mere few thousand years. Study of recent foragers demonstrates that individuals move rather freely between bands and that the bands themselves move frequently over the landscape. Both kinds of movements often are in response to resource distributions. (Among the Mbuti pygmies, for instance, newlyweds go to live with either the bride's or groom's band, depending usually on where food is most plentiful at the time.) These “flux” mechanisms, then, distribute population relative to resources (Turnbull, 1968). During the human expansion out of the tropics into the rest of the world, an expansion that began 1 to 2 million years ago, our ancestors had been foragers too; it therefore is a safe bet that flux mechanisms operated day in and day out over the millennia, constantly distributing and redistributing population relative to food resources. When expansion at last had to end but population kept growing, the pressure on wild resources would have increased sharply all over the world. Cohen's (1977) theory thus tied together findings of archaeologists and cultural anthropologists to produce the best general theory we have of this great transformation in cultural evolution.

A genuine problem, however, is the fact that archaeological evidence of hunter-gatherers throughout the New World is not as ancient as the theory implies. However, if new findings continue pushing back our estimates for the peopling of the New World, Cohen's (1977) theory will be more strongly confirmed.

Agricultural Intensification

Before 1965, social scientists long had thought of agricultural change as a cause of population increase rather than as an effect of it. More food would mean more people—that was the whole story, and its author was believed to have been Malthus. In 1965, however, Danish economist Ester Boserup argued that the evolution of agriculture was less a cause than an effect of increasing density of human population.

Boserup (1965) noticed that small-scale societies growing food without plows and draft animals often resisted this seemingly superior technology even when it was offered free by the government. She suspected that this was more than blind adherence to traditional ways. The technology being offered could squeeze more food from a given amount of *land*; but what if traditional methods yielded more food for a given amount of *labor*? Boserup's detailed study of several forms of agriculture convinced her that those involving simple tools and long periods of fallow indeed were more labor efficient. The greatest single reason seemed to be that at low population densities, people could afford to farm only a small portion of their land each year. By the time they returned to a given plot to plant a garden, forest had reclaimed it. This seeming disadvantage was in fact a huge advantage: Forested land could be cleared well enough for planting merely by slashing down the young forest vegetation, burning it, and sowing seed in the ash. Stumps of larger trees were simply planted around. Neither plowing nor even hoeing was necessary. Such "low-tech" farming paid off very handsomely for no more labor than it took. Fire was the key, and low population density was the necessary precondition.

So why had agriculture in fact changed in some parts of the world? Probably, Boserup wrote, due to increasing density of human population (1965). When land had to be planted before forest had had time to reclaim it, fire was less effective for clearing because fire does not destroy the roots of thick grass (not a problem once forest has taken over). Hoes and eventually plows had to be adopted due to increasing population pressure.

Before Boserup (1965), scientists had thought of land as either cultivated or uncultivated. An important feature of her analysis was a five-stage sequence based on the *frequency* with which land was cultivated. The least intensive stage involved cropping about once every 20 years, the most intensive more than once a year, which usually required much labor for fertilizing and irrigating. In presenting this set of progressive stages, Boserup's work harked back to a 19th-century approach used by such scholars as Lewis Henry Morgan that had fallen into prolonged disfavor among anthropologists. But Boserup's stages allowed land use to be measured more accurately than ever before; her work deservedly had a large and continuing effect on anthropology in general and on sociocultural evolutionism in particular.

Political Evolution

For most of the human past, people lived in small bands, each containing no more than a few dozen individuals controlling their own affairs entirely locally. Even when people in some places began settling in villages some 10,000 years ago, the local community remained self-governing. Perhaps 7,000 or 8,000 years ago, there arose the first multicommunity societies: chiefdoms in which one person had achieved effective political control over two or more villages. In the following millennia, some of the chiefdoms coalesced into states: multicommunity societies with a central government strong enough to tax, draft, and legislate. With this came social cleavages—familiar to us today—between town and country, rich and poor, rulers and ruled. The cultures of state-level societies differ greatly from the cultures of band and village societies; they differ much less among themselves. When Cortes first encountered the Aztecs, for example, he found that their society reminded him of life back in Spain: fields, markets, churches, and—sad mark of civilization!—beggars in the streets. Social growth indeed causes culture to evolve dramatically in certain definite ways, as Herbert Spencer had insisted; to this extent, cultural evolution may be considered a function (in the mathematical sense) of social evolution.

Chiefdoms and especially states developed independently in several places around the world; but in most places, humans continued living in bands or villages. What made the difference? In 1970, Robert L. Carneiro identified three kinds of circumstances that seemed to foster political evolution. The first is environmental circumscription—fertile land more or less hemmed in by mountains, deserts, or water. Here, as agricultural intensification made land ever more scarce, defeat in war increasingly would leave the losers with nowhere to go to escape subjugation. Chiefdoms and eventually states would result. A second circumstance is resource concentration—productive resources, such as lakes or streams rich in seafood, so attractive that people try to stay near them. A third circumstance is social circumscription—being hemmed in not by geographical features but by other societies.

The term *social circumscription* is one Carneiro borrowed from Napoleon Chagnon (1974), who had observed that population growth among the Yanomamo Indians of the Amazon Basin led to villages splitting and spreading more deeply into the tropical forest around them. Due to such splitting, the average village size—around 100 people—seemed fairly stable through time. At any given time, though, the more centrally located villages were the largest. Perhaps, Chagnon suggested, this was because, being surrounded by other villages (usually hostile), central villages were less able than peripheral ones to resolve internal conflicts by splitting.

It is tempting to think that human societies, like complex organisms, have a natural tendency to grow larger. Chagnon's (1974) work suggests instead that the natural

tendency is for societies to stay about the same size, even when overall population is growing, due to splitting. It seems possible that the tendency to resolve social conflict by splitting is a deep and universal propensity that had had to be suppressed before large societies ever could evolve in the first place. If a growing population is surrounded by rich, unoccupied territory, it will expand easily into that territory; but it will do so Yanomamo-like, and the average society size will remain approximately constant due to splitting. Increase in this average size would be expected only when the opportunity to expand was somehow inhibited. Inhibited expansion would lead to inhibited splitting; if societies could no longer split fast enough to offset population growth, larger societies—chiefdoms, states, empires—eventually would be forged, and culture would have to be transformed concomitantly. This process would tend to unfold in precisely the kinds of conditions Carneiro had identified: environmental circumscription, social circumscription, and resource concentration.

It is possible to formulate mathematical definitions for inhibition of both geographical expansion and political splitting. The assumption that splitting would not be inhibited until expansion was inhibited proves fruitful and leads to an exact mathematical theory of the relationship between population density and political evolution (Graber, 1995). This theory fits, in a general way, with evidence not only on prehistory but also on the 20th century (Graber, 2006); but this general fit scarcely constitutes a rigorous test of the theory.

Industrialization

Coal might appear obviously superior to firewood as an energy source for an industrializing society; but historically, industries initially shifted to coal only because firewood grew scarce. In some—not all—the transition was easy to make, and in some industries, coal ultimately proved superior in some ways; but the shift originally was prompted not by coal's superiority but by firewood's scarcity (Wilkinson, 1973).

Rural life, requiring much physical labor, might appear intrinsically harder than urban life; one therefore might assume that people gladly took advantage as industrialization afforded growing opportunities to move from country to city. Yet British historian Joan Thirsk showed that the earliest industrial centers in England took root in regions in which agricultural populations had grown so dense that families no longer could survive on their meager acreages. As centuries passed, people grew accustomed to having to hold a job to earn a living and generally accepted it as a fact of life (with occasional objectors, including the young Karl Marx). But the "opportunity" to become paid workers rather than self-sufficient farmers appears to have been, in the first place, a matter not of preference but of survival.

Poverty in the countryside, however, was only part of the story. The other side was capitalists who could employ those needing work and make other investments of resources, without fear of being taxed or "plundered" to death by authoritarian governments as soon as big profits began rolling in—as seems to have happened in the states and empires of antiquity, such as China, as Marx and others have suggested.

Ancient civilizations also had had a plentiful supply of both poor people and profit seekers. Why had industrialization not occurred? Possibly because most governments, by controlling the huge irrigation systems on which everyone's survival depended, had nearly absolute power; and they could not resist using this power to limit commerce whenever doing so was in their short-term interest. In western Europe, however, agriculture was based not on irrigation but on rainfall, which no government could control. Accordingly, commerce could flourish (Harris, 1977).

As Richard G. Wilkinson argued in his 1973 book, *Poverty and Progress*, it appears that industrialization had important roots in population pressure. Pressure on firewood caused the turn to fossil fuel, pressure on land, the turn from farm to factory. Industrialization has transformed how humans live—our culture. This cultural evolutionary transformation in its dependence on population pressure resembles earlier key transformations: agricultural origins, agricultural intensification, and political evolution.

Ongoing Processes

Sociocultural evolution has not stopped; here are four important ongoing processes, the first of which, however, is not itself essentially sociocultural.

Biological Evolution

The roots of cultural evolutionism are intertwined with the biological theory of natural selection—a theory arrived at independently by A. R. Wallace and Charles Darwin and made famous by Darwin's book of 1859, *On the Origin of Species*. Yet biological and cultural evolution each have "rules of their own"; confusing the two is a grave error—one that marred the work of thinkers such as Herbert Spencer, and that has reappeared in recent decades.

A key difference is that once a species is intelligent enough for its ways of life to depend greatly on learning, those ways of life can change far faster than can the species's biological makeup; the steam engine, the automobile, and the computer clearly did not need to wait on biological evolution in order to transform our way of life. Artifacts, customs, and ideas can spread rapidly within a generation; biological evolution happens only over generations. Biological evolution can occur rapidly but only in simple life-forms, such as microorganisms, that have very short generation times. Indeed, the rapid evolution of microbes is

what causes our antibiotics to “wear out” so quickly. By filling certain microbes’ environment (our own bodies) with drugs, we wipe out all those that have no resistance to that drug; but if even a single “bug” contains a gene making it resistant to the drug, that is precisely the one that will survive and reproduce, giving rise to a new strain—a resistant strain, for which a new antibiotic will have to be sought. Thus, there is an ongoing war between us and the germs that infect us, a war in which they fight with the weaponry of biological evolution, and we, of cultural evolution.

Yet biological evolution is a continuing process even within large, slowly reproducing species like our own. No generation has exactly the same genetic makeup as did the previous generation; chance alone is sufficient to guarantee this. Life, Darwin wrote, is somewhat like a great, ancient tree in which existing species are the green buds. Wherever the tree is growing, evolution is occurring. But are biological changes taking human evolution in any particular *direction*? This is a difficult question. Scientists used to speculate that humans of the distant future may be small-bodied, swollen-headed, toothless and hairless creatures with senses so weak that everyone would require extensive artificial assistance of the kind pioneered by eyeglasses and hearing aids. Yet such speculations seem outmoded now that genetic engineering is beginning to bring our genetic makeup as a species under our own conscious control—a rather forbidding responsibility.

It is tempting to believe that history could easily have developed in a way quite different from what it has. According to this view, we would not now face the unsettling prospect of engineering human genes had biology’s history been different—if, for example, Darwin had died, as did many in his time of some childhood disease. Social evolutionism, however, offers a different perspective. It is well to remember, after all, that another biologist of the time, Alfred Wallace, quite independently hit on basically the same theory at around the same time. And in fact, history presents many examples of similar occurrences, treated in the writings of William F. Ogburn, A. L. Kroeber, and Gerhard Lenski. Social evolutionists find the dependence of individuals on cultural conditions a more illuminating perspective than the conventional one according to which great individuals mysteriously “produce” history and culture as if by magic.

Population Growth

Destruction of the ozone layer, pollution of the environment, reduction of biodiversity—while these ominous processes seem to continue, the number of human beings keeps growing. Are we indeed, as some would have it, a kind of “cancer” on the planet, an uncontrolled malignancy that destroys the “healthy tissue” around it?

This gloomy image is quite misleading. Though human population is still growing, it is doing so at a slower rate.

As industrialization spreads, children change economically from being valuable assets to being expensive liabilities; accordingly, people have fewer of them. Dozens of the advanced industrial societies already are producing too few children to maintain their population. Meanwhile, many social problems have causes unrelated to so-called overpopulation. Some of the poorest people in the United States occupy some of the least populated areas, and some of the world’s poorest nations are among the least densely populated.

It might be objected that even if population growth is slowing and even if it alone is not responsible for all social problems, things might be better if there were fewer people. Some people, on hearing that the world’s population is expected to increase by about 50% in the coming decades, may be inclined to declare, “Our systems simply cannot support that many people!” Such people, however, are forgetting a key fact: *Culture evolves*. The population of the future will be supported not by *our* way of life but by *theirs*. Artifacts, customs, and beliefs will have changed; and for all we know, those future people will be better off, on the whole, than we are today.

Sociocultural evolution provides some reason to suspect that a stable population, which sounds so good to most people, would deprive human culture of its greatest single source of dynamism—population growth itself. The origins of agriculture, agricultural intensification, political evolution, industrialization—all appear indebted to population growth. However, population growth’s role in a few major cultural transformations of the past does not mean that it is essential for all culture change; it scarcely seems likely that people would stop seeking better cures for disease, for example, simply because population had stabilized. Furthermore, the absence of population growth does not necessarily mean the absence of population pressure. Indeed, Thomas Robert Malthus (1798/1993) believed that populations, when they do stabilize, tend to do so at a level too high to be easily supported by existing resources, creating constant pressure for culture change. If he was right, then even a population stable numerically is inherently unstable culturally.

Technological Evolution

Technology keeps changing; the evidence surrounds us. One need not have lived long, for example, to have seen the spread of personal computers, microwave ovens, and cell phones. These innovations alter how we live just as life in the early 20th century was altered by, say, automobiles and telephones. Of course, some innovations prove more far-reaching than others; the microwave oven, a welcome convenience, seems unlikely to reshape life to the extent that the automobile has.

Is it possible to identify a class of innovations that are of particular cultural evolutionary significance? Some

anthropologists, following Leslie A. White (1949), believe that breakthroughs in energy use are just such a class. From this perspective, four milestones of technological evolution can be identified: use of tools, control of fire, application of the steam engine, and control of nuclear power (Asimov, 1972). Human societies always have relied heavily for survival on the making and using of tools. Stone tools date back over 2 million years; tools of softer materials, such as digging sticks, spears, and clubs may be much older still. Indeed, it is quite possible (as Darwin himself speculated) that an increasing reliance on tools created the evolutionary pressure that made us into upright bipeds: Tool users with hands and arms less used for locomotion would have survived and reproduced better than tool users who continued getting around on all fours.

Tools allow the body's energy to be concentrated on small areas—points and edges that can cut and penetrate where the unaided body would fail. Teeth are hard and sharp but very limited. Consider the difference between a stone chopper held in your hand and an incisor tooth held in your gums. The power of your swinging arm can be transferred to the edge of the chopper; but if you tried to swing your head in a similar arc to cut a branch from a tree or smash open a bone, the results would be less satisfactory.

The energy driving hand tools is generated in the human body. Use of energy generated outside our bodies originated when humans got control of fire—a milestone probably reached by half a million years ago. Getting energy by burning firewood is chemically similar to getting energy by eating food; but the former allowed our ancestors to expand out of our tropical evolutionary cradle.

Useful as fire was (especially in helping trigger the Bronze Age and Iron Age a few thousand years ago), it began to significantly replace animal—including human—muscle power only with the refinement of the steam engine in the 1700s. As firewood became scarce in England, people turned to coal; and as coal mines deepened, water seepage and flooding of the mines became a chronic problem. Pumping water from coal mines was the necessity that mothered the refinement of the steam engine; because steam engines increasingly were fueled by coal, coal mining itself helped increase the demand for coal. The steam engine, meanwhile, found innumerable industrial applications by converting heat energy to mechanical energy, as in textile factories, where it was used to drive huge looms; indeed, the steam engine often is considered to have been the most important single innovation for industrialization.

When we burn either firewood or fossil fuel (coal, oil, natural gas), we are indirectly using solar energy “trapped” by photosynthesis. (The same applies when we energize our bodies by eating food.) The first genuine departure in this respect occurred only with control over nuclear power achieved a few decades ago. Fission, used to generate electricity in coal-poor societies, is efficient; but fuel is expensive, and hazardous wastes are produced. Nuclear fusion—the means by which stars produce heat and light—is

even more efficient; moreover, the fuel is cheap, and wastes are not hazardous. The problem is containing the extremely high temperatures involved: So far, fusion literally remains too hot for us to handle. In future decades, however, controlled fusion could become a practical energy source. Cultural evolutionism can suggest that so fundamental a change in energy use could usher in a new stage of cultural evolution; foreseeing what that stage would be like, however, is well beyond its current ability. Meanwhile, we must cope with the fact that nuclear power's unprecedented potential for destruction places our very survival in doubt. As Leslie A. White wrote in 1949, concerning the advent of nuclear power,

The mastery of terrestrial fire was tolerable, but to create energy by the transformation of matter is to play with celestial fire. Whether it can be done with impunity remains to be seen. The new Prometheus may also be the executioner. (p. 362)

Adaptive Radiation

Mammals are ubiquitous. After the dinosaurs died out some 60 million years ago, mammals underwent a spectacular process of expansion into different environments. Many lived on the ground; some burrowed into it. Some, like the whale, returned to the water where life had originated eons earlier. Others took to living in the trees; these are the Primates from which we humans recently sprang. (Our grasping hands, rotating arms, and stereoscopic vision all reveal our tree-dwelling roots.) Mammals even took to the air as the bats of today remind us.

When a life-form expands into a new environment, any traits that happen to help individual organisms survive and reproduce there will grow more common as generations pass. Assuming the form does not die out, then, it will be modified by natural selection for living ever more effectively in the new environment. When a single form of life successfully expands into many environments, the process is termed *adaptive radiation*. Adaptive radiation ordinarily involves the development of new species in the new environments. That is, the cumulative effects of natural selection eventually make the populations in different environments so different from one another that interbreeding between them is no longer possible—that is, they have become separate species.

A few human traits, such as skin color, do appear to reflect natural selection in different environments. Near the equator, where the sun's rays strike the earth directly year-round, a dark skin aids survival and reproduction by affording protection from skin cancer; far from the equator, though, a light skin seems to offer protection against rickets, a bone disorder, which can result from too little exposure to sunlight. Yet this and other geographically based differences between human populations are quite superficial; the ultimate biological proof of this lies in the fact that a healthy male and female from anywhere in the world are capable of mating to produce fertile offspring.

Clearly, humans have managed to go “all over the place” while remaining a single species.

That a single species—especially a large-bodied one—should have done this is remarkable indeed from a zoological and ecological standpoint. Other large-bodied species remain confined to relatively narrow environmental ranges. Chimps and gorillas, our closest living kin, inhabit still the tropical forests of our early ancestors.

Clearly, the secret of our success is culture. Humans have adapted to new environments, for the most part, not biologically but culturally. Culture allows us to create, within hostile environments, a “little environment” friendly to us. Control of fire, for example, meant we could create little enclaves of warmth in the coldest corners of the earth. Now, half a million years later, we live with the fish, not by evolving fins and gills but by surrounding ourselves with submarines; and we are venturing into airless space, not by evolving the ability to do without oxygen but by surrounding ourselves with space shuttles and stations. It even is conceivable that we will be able to modify other planets to suit our needs.

Conclusion

Human social evolution up to the present dramatically suggests the value of culture in promoting the survival and reproduction of culture bearers. Biological evolution adapts species to environments; cultural evolution adapts environments to species. Long before the advent of space stations, Herbert Spencer (1897) had seen deeply into the profound significance of culture as an adaptation allowing our species to venture into new environments by creating the following:

A secondary environment, which eventually becomes more important than the primary environments—so much more important that there arises the possibility of carrying on a high kind of social life under inorganic and organic conditions which would originally have prevented it. (Vol. 1, pp. 13–14)

As an approach, social evolutionism is historically associated especially with the 19th century; but the approach is still alive because social evolution itself is a continuing process.

EVOLUTION

Science, Anthropology, and Philosophy

H. JAMES BIRX

Canisius College and State University of New York at Geneseo

The fact of evolution pervades modern thought from astronomy to psychology. It is safe to assume that no academic discipline has escaped the influence of an evolutionary framework. Our present worldview is grounded in a serious consideration of time, change, and evolution; it is a remarkably different explanation for this universe, life-forms on earth, and our own emerging species than was given by natural philosophers only 2 centuries ago.

Rocks, fossils, artifacts, and genes offer compelling and sufficient evidence for a dynamic view of this planet and those organisms that have existed before and do now live on it (Coyne, 2009; Dawkins, 2009; Fortey, 1998; Mayr, 2001; Ridley, 2004). Yet facts do not interpret themselves. Consequently, interpretations of evolution vary greatly from materialism through vitalism and spiritualism to mysticism (Birx, 1984). In this arc of evolution (Birx, 2006a), there is a glaring difference between the materialist stance of Charles Darwin and the mystical outlook of Pierre Teilhard de Chardin (Birx, 1991). Each interpreter of evolution comes to the theory with a different set of ideas, issues, and values within a specific orientation. Perspectives range from a planetary focus to a cosmic approach.

Modern anthropology embraces the fact of evolution, viewing the recent appearance of humankind within a sweeping geological framework. Our biological structures and functions, as well as societies and cultures (Harris, 1968;

Morgan, 1877/1963; Tylor, 1871/1958; White, 1949, 1959), have changed throughout time and will continue to do so. One fascinating prospect for our species is its future adaptation to and survival in outer space, whether for living on neighboring planets or elsewhere in this expanding universe.

Earliest Speculations

The idea of evolution did not originate with the thoughts of Charles Darwin in the middle of the 19th century. Nor did this naturalist have the last word on his own theory of “descent with modification” (as he put it). Yet in terms of science and reason, the conceptual revolution of organic evolution received its factual foundation with Darwin’s pivotal writings on the history and diversity of life-forms on this planet.

In fact, the idea of evolution had been glimpsed by several natural philosophers in ancient Greece during the pre-Socratic Age (Whitlock, 2009): Thales, Anaximander, Heraclitus, Xenophanes, and Empedocles. They recognized the biological similarities between the human being and other animals and held to the dynamic history of this universe. One is tempted to refer to them as protoevolutionists, since they anticipated (to varying degrees) the thoughts of Darwin and Alfred Russel Wallace more than 2,000 years later.

The emerging concept of organic evolution received an unfortunate intellectual impediment with the philosophical writings of the ancient Greek thinker Aristotle (384–322 BCE), who taught that species are eternally fixed in the natural world. However, he did acknowledge the biological similarities among groups of animals thereby fathering both comparative biology and a natural taxonomy. Even so, he ignored the biohistorical significance of fossils, referring to them as being merely chance aberrations in rock strata. Aristotle's interpretation of life-forms as representing a static hierarchy of fixed species (his comprehensive concept of the great chain of being, or so-called ladder of nature) had an enormous influence on later naturalists, philosophers, and theologians; subsequently, these thinkers were not predisposed to accepting the mutability of species throughout earth history.

The Roman philosopher Lucretius (96–55 BCE) wrote that this planet itself, over time, had produced plants and animals. He also claimed that organisms, including intelligent beings, inhabit other worlds in this universe. But his anti-Aristotelian worldview was not taken seriously by those thinkers who dogmatically clung to the traditional interpretation of life-forms as fixed species.

During the Italian Renaissance, Leonardo da Vinci (1452–1519) did recognize both the biological and historical significance of fossils as the remains of once living organisms. He had discovered marine fossils embedded in the top rock strata of the Alps; three centuries later, Darwin would have a similar experience in the Andes. Unfortunately, Leonardo never recorded his own thoughts on the history of changing life-forms throughout the thousands of years of geological time; he thought our earth to be at least 200,000 years old. His genius may have imagined the mutability of species but, if so, he never wrote about this idea in his notebooks.

Age of Enlightenment

Following the so-called Dark Ages and Middle Ages, the Enlightenment represented an exciting time for academic scholars during which serious thinkers criticized the dogmatic church and oppressive state in favor of science and reason (Cassirer, 1955). The courageous French philosophers of this time called for open inquiry and the extension of the scientific method from the natural sciences to the emerging social sciences. By taking a historical perspective, emphasizing the value of freedom and individualism, and anticipating ongoing progress in the special sciences (both natural and social), these enlightened thinkers established an intellectual atmosphere that paved the way for the coming of anthropology as a distinct discipline.

With the natural philosopher Denis Diderot (1713–1784) as its major editor, the *Encyclopédie* (1751–1772) represented a practical outcome in the devotion to both scientific research and critical thinking, and it was a project exemplary

of this age. In fact, achieving the completion of this unique project was Diderot's supreme accomplishment. With the publication of this multivolume work, extensive knowledge was now accessible for both academic scholars and general readers.

The nature-oriented thoughts of the Enlightenment gave a major impetus to the growth of several earth sciences: historical geology, comparative paleontology, and prehistoric archaeology (as well as ongoing advances in biology). Rocks, fossils, and artifacts were revealing an incredible explanation for life-forms on earth that was far different from the biblical story of Creation in Genesis. Furthermore, extensive travels by naturalists led to the discovery of other societies with different cultures subsequently contributing to the need for a specific science of humankind itself.

Representative of the optimistic outlook during the Enlightenment is the future vision presented by Marquis de Condorcet (1743–1794), who is remembered primarily for his extraordinary book titled *Sketch for a Historical Picture of the Progress of the Human Mind* (1795/1980). As a result of astonishing advances in science and technology throughout the forthcoming centuries, Condorcet held that one practical consequence would be that human beings will eventually achieve and enjoy an indefinite life span.

Influential Scientists and Provocative Philosophers

Once the fact of evolution was established, it had an overwhelming influence on several major thinkers in science, philosophy, and theology. The pivotal writings of Charles Darwin represented a scientific revolution that seriously challenged those ideas, beliefs, and values that were embedded in the traditional, static worldview, an outlook that had stymied both creative and critical thought for centuries. A dynamic interpretation of nature now replaced the old conceptual framework grounded in fixity and permanence. Some naturalists were eager to consider the far-reaching implications of evolution for understanding life, our species, and this universe. Some philosophers and theologians were courageous enough to consider the startling consequences of evolution for appreciating reality itself.

Jean-Baptiste de Lamarck

In 1809, following the Enlightenment, the French natural philosopher Jean-Baptiste de Lamarck wrote the first serious work on organic evolution, titled *Zoological Philosophy* (1809/1984). This book appeared exactly 50 years before the publication of Charles Darwin's major work, *On the Origin of Species* (1859). However, Lamarck's interpretation of evolution was essentially conceptual and speculative, lacking the sufficient empirical evidence and a testable explanatory mechanism that Darwin would later

offer to convince other biologists of the fact that species are mutable and have evolved throughout natural history.

To his lasting credit, Lamarck had studied the fossil record in rock strata. He correctly concluded that the sequence of remains in the geological column clearly demonstrated that life-forms have evolved during earth history. His idea that plants and animals are mutable and change over time challenged the entrenched concept of fixed species. Unfortunately, Lamarck was unable to persuade his contemporary naturalists that species have evolved throughout planetary time. His explanation for organic evolution in terms of the inheritance of acquired characteristics through use and disuse was not convincing; for example, his own idea that the long neck of a giraffe is directly due to the accumulated results of stretching, over countless generations, to reach the leaves of ever-higher trees remains a preposterous explanation in the history of biology. In addition, Lamarck's vitalist orientation was not in step with the naturalism espoused by most biologists. Likewise, his ludicrous claim that complex animals, such as our human species, can actually will those biological changes that are needed by them to adapt and survive in changing environments has been verified neither by evidence nor by experience since his time.

In fact, at first, Darwin was reluctant to acknowledge the influence that Lamarck had had on the early development of his own evolution framework. Nevertheless, Lamarck had been brave enough to maintain the heretical idea that species change through time.

Charles Darwin

Charles Darwin (1809–1882) is referred to as “the father of evolution,” a designation he richly deserves for his life-long dedication to science to substantiate the mutability of species (Birx, 2009a). With focused energies, he was able to amass overwhelming empirical evidence from various fields, thereby documenting the fact of evolution for other naturalists. His scientific theory of organic evolution and explanatory mechanism of natural selection represented a conceptual revolution in both science and philosophy, with devastating consequences for traditional theology.

As a young naturalist in England, Darwin was primarily interested in rocks and beetles; over the years, his research shifted from geology to biology. After university studies in medicine and theology, his comfortable life was altered dramatically when captain Robert FitzRoy accepted him for the position of a naturalist aboard the HMS *Beagle*; this survey ship would sail for 5 years (1831–1836) in the Southern Hemisphere, with its primary purpose being the mapping of the coastlines of South America. This extensive trip would prove to be a voyage of discovery for the emerging scientist (Darwin, 1839/2000; McCalman, 2009).

When Darwin boarded the *Beagle*, he was an amateur geologist who accepted both the then-taught fixity of species and the beliefs of Christianity. But his own

worldview would change radically as a result of three fortuitous events: his critical study of Charles Lyell's three-volume *Principles of Geology* (1830–1833), his unique experiences as an astute observer of nature in the Southern Hemisphere (especially during his 5-week visit to the Galapagos Islands), and his beneficial reading of Thomas Robert Malthus's *An Essay on the Principle of Population* (1798/1803).

Questioning and then rejecting the story of Creation as presented in Genesis, Darwin began to envision a dynamic web of life-forms changing over space and throughout time. Lyell's sweeping geological framework offered an immense period of planetary history within which Darwin could imagine the slow and continuous mutability of species. Furthermore, not only the fossil record in rock strata but also the geographical distribution of different organisms argued for the evolution of life-forms throughout biological time. In short, the earth is a massive graveyard of past species and a changing stage for the emergence of new ones, as well as a global museum of previous cultures and human activities. Finally, in 1838, Darwin's reflections on Malthus's vivid description of the living world as a “struggle for existence” gave to him his explanatory mechanism of natural selection. Thus, in merely 7 years, Darwin the geobiologist had become convinced that species either evolve or become extinct within changing environments throughout organic history. He referred to his evolution theory as “descent with modification,” but he had no immediate plan to get his disturbing interpretation of life into print.

With the luxury of time, Darwin's ongoing scientific research in biology and critical reflection on dynamic nature included the rigorous study of worms, pigeons, orchids, and barnacles as well as numerous other species (Boulter, 2009). Suddenly, in 1858, his scientific life of isolated contentment was abruptly disrupted when he learned that the naturalist Alfred Russel Wallace, while living in Indonesia, had come forth with both a theory of evolution and the same explanatory mechanism of natural selection to account for the history of life on earth.

Consequently, in 1859, Darwin quickly published his major work, *On the Origin of Species* (Darwin, 1859), which saved his priority as being the father of evolution. He was also fortunate to have three major naturalists defend his counterintuitive and most controversial theory: Thomas Huxley in England, Ernst Haeckel in Germany, and Asa Gray in the United States. Even so, Darwin had deliberately left out any consideration of the human animal. However, 12 years later, his *The Descent of Man* (1871) actually focused on our own species (Darwin, 1871).

Darwin's materialist theory of organic evolution held incredible, if not disquieting, ramifications for viewing the place of our human species within earth history. As had Huxley and Haeckel, Darwin himself now wrote that our species is closest to the three great apes (orangutan, gorilla, and chimpanzee), with which the human animal shares a common ancestral origin. And he thought that the

remains of this shared group would be found in the fossil record of Africa. Also, Darwin maintained that the human being differs merely in degree rather than in kind from these three great apes. This was not a claim that endeared him to those who believed that our species is unique and therefore occupies a special position in this universe. Nevertheless, Darwin's evolution theory gave to the emerging discipline of anthropology a scientific foundation that is quintessential for understanding and appreciating the origin and history of humankind.

With dynamic integrity, Darwin clung to his materialist outlook, thereby giving an atheistic interpretation of organic evolution, while his cosmological perspective remained agnostic at best. He even reflected on the evolution of the human brain with its mental activity, as well as pondering the emergence of moral conduct from earlier ape behavior.

Following the pervasive and overwhelming influence of Darwin's writings, the early anthropologists speculated on and searched for fossils and artifacts to document the biological and sociocultural evolution of the human animal, respectively. Other anthropologists wrote about the evolution of languages, kinship systems, political organizations, and magical-religious belief systems. Evolution research continues to enlighten and inspire the science of anthropology, with remarkable evidence discovered each year. One may eagerly anticipate new findings in genetics, paleontology (Brasier, 2009), primatology, and evolutionary psychology.

No doubt, during his frequent strolls down the Sandwalk behind Down House, the aging Charles Darwin reflected on his incredible experiences during his voyage on the HMS *Beagle* (especially his visit to the primeval-like Galapagos Archipelago). Yet one may argue that it was Lyell's geological perspective that had had the greatest lasting influence on the young naturalist. It gave to Darwin in particular, and to anthropologists in general, a vast framework of time and change within which one could comprehend organic evolution and the recent appearance of humankind on planet earth.

Herbert Spencer

Today, the English thinker Herbert Spencer (1820–1903) is primarily remembered for coining the famous expression “the survival of the fittest,” a phrase that Darwin himself later used in his own writings on organic evolution. But Spencer's greatest achievement was authoring a 10-volume work titled *Synthetic Philosophy* (1862–1893), a comprehensive interpretation of reality that dealt with cosmology and biology as well as sociology, psychology, and ethics. This worldview is grounded in a universal force and a crucial distinction between the now knowable world of human experience and the forever unknowable realm of ultimate reality.

Taking time and change seriously, Spencer presented his cosmic perspective in *First Principles* (1862/1958),

Volume 1 of the 10-volume grand synthesis (Spencer, 1862–1893). In it, he offers his evolutionary view of this dynamic universe. He speculates that the cosmos evolves from maximum simplicity (homogeneity) to maximum complexity (heterogeneity), as does the history of life on earth. Then, the cosmos and life devolute back to ultimate simplicity. He further speculated that there is an endless series of cosmic cycles, each finite cycle identical in structure but different in content.

Spencer likened the evolution of a society to the evolution of an organism, referring to a human society as the *superorganic*, which is distinct from nature itself but follows the same progressive process from simplicity to complexity and then devolutes back to simplicity. Thus, planetary evolution is from the inorganic through the organic to the superorganic. Spencer rejected religious creationism in favor of scientific evolutionism. In anthropology, he called for the empirical description and comparative study of societies and their cultures within an evolution framework. Ultimately, his ruthless individualism became the foundation for social Darwinism. Nevertheless, his ideas paved the way for the sociocultural evolutionists of the 20th century, for example, V. Gordon Childe, Marvin Harris, Julian H. Steward, and Leslie A. White (among others). No doubt, ongoing research in anthropology will provide an even clearer view of human evolution in all of its aspects.

Thomas Huxley

Referred to as “Darwin's bulldog” in England because of his enthusiastic support for the fact of evolution, Thomas Henry Huxley (1825–1895) contributed to science through his own comparative research in anatomy and paleontology. He accepted the evolution framework, with its vast geologic perspective and compelling paleontological record. His scientific imagination could even see earth history represented in a piece of chalk, even though our present knowledge of rocks, fossils, and genes was not available to him. At a time when most naturalists still held to the fixity of species, Huxley boldly argued that organisms either evolved throughout earth history, or they became extinct. His writings and lectures greatly helped to spread the scientific theory of biological evolution to both academic specialists and the general public.

Huxley is best remembered for defending the scientific theory of biological evolution at the University of Oxford's Museum of Natural History in the summer of 1860 (Darwin was ostentatiously absent). The heated confrontation between biblical fundamentalist Samuel Wilberforce, Bishop of Oxford, and materialist evolutionist Thomas Huxley ended with a victory for science and reason over religious shortsightedness and myopic beliefs. Nevertheless, the “battle” between religious creationists and scientific evolutionists continues, and it is as contentious today as it was during Darwin's time.

In 1863, concerning our own species, Huxley presented his pithecometra hypothesis (1863/1959): The human animal differs merely in degree rather than in kind from the two African great apes (gorilla and chimpanzee), and, in turn, our species is closer to these great apes than they are to the two lesser apes (gibbon and siamang). This position was also maintained by Ernst Haeckel and several years later by Charles Darwin himself. No doubt, the disturbing claim that the human animal is closely related to the living apes through organic evolution has contributed significantly to the continuing outrage against evolutionary biology and biological anthropology.

To represent his own position of scientific naturalism, Huxley coined the term *agnosticism*, as he was not certain whether a personal God exists or not. Even so, Huxley never believed that the process of evolution represented a divine plan or intelligent design. The philosophical scientist Ernst Haeckel was a pantheist (God is nature), while Charles Darwin kept his atheism to himself.

Huxley's interpretation of evolution differed from Darwin's view. Influenced by Charles Lyell's theory of uniformitarianism in historical geology, which held that geological structures change slowly over immense periods of time due to natural forces, Darwin's support of gradualism in organic evolution held that species change slowly over vast periods of time due to biological variation and natural selection. However, doubting that natural selection alone could account for the transformation of species, Huxley thought that new species could have "suddenly" appeared as a result of periodic rapid changes in biological evolution. Considering the enormous age of this planet and the awesome number of species that have existed on it (almost all of them having become extinct), it seems reasonable to assume that different rates of evolutionary change are represented in the fossil record.

Ernst Haeckel

Known as "Germany's Darwin" for daringly advocating and rigorously defending organic evolution, Ernst Haeckel (1834–1919) dedicated his research activities to many scientific areas, especially comparative embryology and marine biology. He not only contributed to the empirical evidence that supported organic evolution, but also seriously considered the far-reaching consequences of the evolutionary sciences for both philosophy and theology. His most successful book was *The Riddle of the Universe* (1899), in which he presented an evolutionary worldview that courageously challenged those traditional ideas and embedded beliefs that had pervaded Western thought for centuries (Haeckel, 1899).

Haeckel's evolutionary philosophy is grounded in a process monism (his law of substance); this position claims that dynamic reality is essentially a cosmic unity. Therefore, he held that human existence is a product of and totally within material nature. Moreover, for him, the evolving universe itself is eternal in time and infinite in space.

Haeckel had no patience for those thinkers who ignored the fact of evolution and its atheistic consequences. He rejected the common earth-bound and human-centered view of reality, which had taught that our species holds a special place in cosmic immensity. Moreover, by extending the fact of evolution beyond earth, Haeckel speculated that life-forms, including intelligent beings, exist on other planets elsewhere in this universe. As such, he anticipated the new research area of exobiology.

Inspired by Charles Darwin's *On the Origin of Species* (1859), Haeckel expanded the evolution theory to include the emergence and history of the human animal. He claimed that the evolution of our species could be traced back to a "missing link" represented by an ape-man without speech, *Pithecanthropus alalus*, whose fossil remains he thought would be found somewhere in Asia. (Darwin held Africa to be the cradle of humankind.) For Haeckel, this ape-man once existed between the earlier prehistoric apes of the alleged Asian landmass Lemuria (now vanished) and our own species of today. In the early 1890s, the naturalist Eugene Dubois discovered the hominid specimen *Pithecanthropus erectus* at the Trinil site on the island of Java in Indonesia. This remarkable find inspired other naturalists to search for similar fossil evidence in Africa and Asia. Haeckel also claimed that the human animal and the two African great apes (gorilla and chimpanzee) differ merely in degree rather than in kind.

In fact, as an artist in science, Haeckel drew the first tree of life diagram and, subsequently, many other illustrations that showed the evolutionary relationships among organisms as naturalists understood the historical web of life at that time. In general, Haeckel's basic ideas remain in step with modern thought. Today, his rigorous evolutionism may be seen in the writings of Richard Dawkins and Daniel C. Dennett (among others).

Peter Kropotkin

In Russia, Prince Peter Alekeyevich Kropotkin (1842–1921) became known for his original research in geography, zoology, anthropology, and sociology. He spent time in Siberia, where he studied the influence of past glaciers on its environment. He also carefully observed the group behavior of tribal communities and wild animals, deriving an important generalization about the adaptation and survival of societies, that generalization being his concept of mutual aid (social cooperation).

Although an evolutionist, Kropotkin differed from Darwin in maintaining that the natural selection of individuals was necessary but not sufficient to account for the survival and therefore successful evolution of social animals, including our own species. Kropotkin stressed that mutual aid is also crucial for the adaptation and reproduction of species (Kropotkin, 1902/1914; Montagu, 1952). In fact, for him, mutual aid is the key to understanding and appreciating the evolution of the human being; in human

social evolution, from bands and tribes to chiefdoms and states, mutual aid has played a crucial role in both protecting individuals and ensuring the survival of groups.

Kropotkin (1922/1968) even held that the biological origin of mutual aid was the foundation of a universal ethics for our own species. Therefore, he saw a sound anthropology resulting from the convergence of evolutionary science and a community ethics grounded in mutual aid. For him, collective thought and social action enhances the life, harmony, unity, and evolution of human communities. Extending his naturalism and humanism into politics, Kropotkin advocated communist anarchism.

In the 20th century, evolutionary biology in Russia received a devastating setback due to the politically motivated ideas concerning heredity defended by Trofim D. Lysenko (1898–1976), who sided with the philosophical views of Jean-Baptiste de Lamarck and Ivan Vladimirovich Michurin rather than the scientific discoveries of Gregor Johann Mendel and Hugo DeVries.

Yet it was the Russian biochemist A. I. Oparin who proposed a scientific explanation for the material appearance of life on this planet. In his groundbreaking book *The Origin of Life* (1923), he extended Darwin's naturalist theory by arguing that inorganic development had paved the way for the emergence of organic evolution in terms of biochemical advances in the waters of a primordial earth billions of years ago. Oparin had rejected all nonmaterialist explanations for the origin and evolution of life on this planet, as well as the assumption that life on earth is unique in this dynamic universe.

Friedrich Nietzsche

One may argue that the German philosopher Friedrich Nietzsche (1844–1900) is the most influential thinker of the recent past. Yet it is not often realized that he was greatly influenced by the evolution theory of Charles Darwin (Birn, 2006c). Reminiscent of Heraclitus in ancient Greece, Nietzsche took time and change seriously, seeing our species as being totally within the flux of reality. And like the scientist Darwin, the philosopher Nietzsche presented a strictly naturalist worldview. Nevertheless, Nietzsche's vitalistic interpretation of organic evolution is far removed from Darwin's materialist explanation for life-forms on earth (including the human animal).

Nietzsche was deeply concerned with the cosmological implications, ethical ramifications, and religious consequences embedded in the fact of evolution (as he saw them). For him, "God is dead!" and, therefore, this dynamic world has no meaning or purpose other than those values that humankind creates for its existence (Nietzsche, 1883–1885/1993). Likewise, if everything changes, then ideas and beliefs and values also change throughout time. In fact, Nietzsche called for a rigorous reevaluation of all values to overcome the complacency and mediocrity that he held to be pervasive in modern civilization.

Darwin neither concerned himself with questions about the beginning of this universe and the origin of life nor speculated on the future of our species and the end of this cosmos. Instead, he focused his time and effort on demonstrating (as best he could) the fact of evolution in terms of empirical evidence and logical argumentation. In sharp contrast, however, Nietzsche was always eager to grapple with those metaphysical issues that the evolution framework posed for both philosophy and theology.

Nietzsche's philosophical anthropology gives priority to no particular society or specific culture. His own position emphasizes the value of human creativity within the history of a creative universe in general and the process of creative evolution in particular.

Nietzsche's worldview stresses three essential ideas that are compatible with the evolution theory as he interpreted it: The dynamic universe is ultimately a will to power; the further evolution of the human animal will bring about a superior form, the *overbeing*, which will be as intellectually advanced beyond our species of today as the human being is now biologically advanced beyond the lowly worm, and the eternal recurrence of this same universe as his all-encompassing conception of reality itself.

In his sweeping vision of the eternal recurrence, Nietzsche maintains that this finite cyclical universe will repeat itself forever. He argued that space and the amount of matter or energy in reality is finite, but time is eternal. Therefore, only a finite cosmic series of objects and events and relationships is possible. Consequently, this identical sequence repeats itself an infinite number of times; there was no first sequence and there will be no last sequence. Since each cosmic cycle is absolutely identical, there is no evolution from universe to universe within this endless repetition. As a result, Nietzsche himself and everything else in reality has a form of natural immortality.

The eternal recurrence remains an engaging idea in modern cosmology, especially in terms of an oscillating model for this dynamic universe.

Henri Bergson

Critical of Charles Darwin's mechanistic and materialistic interpretation of organic evolution, the French philosopher Henri Bergson (1859–1941) offered a vitalistic explanation for biological history in his major work, *Creative Evolution* (1907/1998). Unlike the early scientists who defended Darwin's naturalism, for example, Huxley and Haeckel, Bergson argued that it was only a philosophical interpretation of organic evolution that would disclose the essential aspect of diverging life-forms on earth over countless millions of years and, furthermore, would reveal the unique value of the human being in terms of its immediate awareness of real time and creative evolution.

Bergson set forth his essential philosophical stance in his book *An Introduction to Metaphysics* (1903). To grasp

the significance of his conceptual orientation, it is necessary to understand Bergson's crucial distinction between science and metaphysics: Science is interested in a rational (mathematical and logical) analysis of the appearance of diverse and fixed material objects in external space; in sharp contrast, metaphysics is concerned with intuitively grasping the creative flux of events in the unity of reality as evolving consciousness in internal time or duration. Bergson gave preference to intuition over reason, that is, metaphysical insights over scientific information. He argued that it was only through intuition that a human being could appreciate both the flux of time and the creativity in evolution.

As a vitalist, Bergson (1907/1998) held that an invisible life force, or *élan vital*, causes the awesome creativity throughout organic evolution on our planet. He maintained that this metaphysical principle is needed to account for the emergence of an enormous diversity of species that has appeared over countless millions of years on earth. For him, the diverging evolution of life-forms has taken three major directions: plants with torpor, insects with instinct, and animals with consciousness. Bergson focused on the evolution of animals, which demonstrated (for him) a direction toward ever-increasing complexity and ever-increasing consciousness. So far, this direction has reached its peak in the human animal with its self-consciousness. In fact, in our own species, Bergson maintained that self-consciousness is the *élan vital* conscious of itself. He even envisioned, as human evolution continues, the emergence of a community of mystics.

Vitalism is not taken seriously by most modern evolutionists, who give priority to science and reason rather than to metaphysical speculations and mystical beliefs. Thus, neo-Darwinists interpret organic evolution within a strictly naturalistic framework.

John Dewey

Greatly influenced by the Darwinian theory in science, the American philosopher John Dewey (1859–1952) presented his own dynamic outlook as “instrumentalism,” a version of pragmatism. Having abandoned his early interest in Hegelian idealism, he wholeheartedly embraced the evolutionary paradigm with its far-reaching naturalistic implications for comprehending the place of humankind within this universe. Therefore, he saw our species within the organic history of this planet and earth within the cosmic history of this universe. His mature position gave no credence to idealism or spiritualism.

In his essay, “The Influence of Darwin on Philosophy” (1910), Dewey had called for philosophers to take the fact of evolution seriously (Dewey, 1965). In doing so, the entrenched two-world interpretation of reality as matter and spirit is discredited, as is a dualistic view of the human being as mortal body and immortal soul. Dewey best presented his own philosophy in *Experience and Nature*

(1925/1958), a book that rigorously advocates the value of human experience and scientific inquiry.

Dewey understood the human animal as the recent product of biological evolution, a natural process within which there is always an interaction between organisms and their environments. He saw the discoveries in anthropology as being crucial for any sound interpretation of humankind within nature. Additionally, Dewey appreciated both the scientific method and the use of human concepts as means for solving problems in the natural and social worlds. For this philosopher, knowledge and wisdom come from experiencing nature itself; facts and concepts and values are derived from reflecting on experiences within nature. For Dewey, ideas and beliefs and hypotheses have adaptive value, as do critical thinking and social action. He claimed that advances in science and philosophy are only possible when there is an active community of free inquirers in a democratic society. Not surprisingly, Dewey completely rejected both Spencer's social Darwinism and Nietzsche's ruthless individualism.

John Dewey remains an inspiration for all naturalists and humanists, particularly those dedicated to education. For the scientific philosopher as active pragmatist, the evolutionary perspective allows for the ongoing transformation of our species in terms of adapting to and surviving in an endlessly changing universe. Thus, the enlightenment and fulfillment of humankind requires taking seriously both philosophical reflection and scientific research.

Božidar Knežević

In Serbia, the historian Božidar Knežević (1862–1905) developed a unique interpretation of evolution that grew out of the ideas of Charles Darwin and Herbert Spencer (among others). Although he adopted a cosmic vision, his bold speculations focused on the history and future of life on earth. Within the ascent and then descent of this immense universe, Knežević saw our species as being only a part of the evolution and then the devolution of organisms on this planet. As such, the naturalist taught that neither the planet earth nor the human animal is at the center of cosmic reality; consequently, he held that each is an ephemeral event in the material universe.

Knežević (1901/1980) saw both cosmic and planetary history as a semicircle of evolutionary ascent from an initial chaos followed by a devolutionary descent back to an ultimate chaos. He held that this universe is utterly indifferent to the fleeting incident of human existence, and in time, everything will disappear in the endless flux of cosmic reality.

Even so, Knežević was convinced that other planets, stars, galaxies, and universes exist and undergo this pervasive semicircular history within the infinity of superspace and the eternity of supertime. On earth, after the appearance of vertebrates from invertebrates, the fossil record shows the sequential emergence of these groups: fishes, amphibians,

reptiles, birds, and mammals. Most recently, one sees the appearance of the human animal. Subsequently, when planetary devolution sets in, our species will be the first organism to vanish, followed by this series of extinctions in the remaining groups: mammals, birds, reptiles, amphibians, fishes, and lastly all of the invertebrates. This semicircular process will occur on other planets with life-forms, including intelligent beings superior to our species (in each case, the last form to appear is the first form to disappear).

Božidar Knežević was a brave spokesperson for science, reason, evolution, and open inquiry. He was a futurist who courageously advocated naturalism and humanism. His acknowledgement of the inevitable extinction of our own species and, in fact, of all that exists is a sobering but relevant reminder of the finitude of life-forms, which needs to be taken seriously in our modern worldview (particularly with the present growing concern for the environment).

Alfred North Whitehead

With its emphasis on time and change, the evolution framework had a significant influence on 20th-century thought. This outlook inspired serious thinkers to see creativity in this world in terms of an expanding universe and emerging species; it also resulted in a deep concern for dynamic philosophy and process theology. This focus on pervasive change throughout cosmic time is exemplified in the impressive writings of Alfred North Whitehead (1861–1947), who was interested in not only scientific discoveries but also metaphysical speculations. He sought to include the recent findings of both relativity physics and evolutionary biology in his comprehensive worldview that reflects their implications for understanding and appreciating the value of human experiences and feelings within an ever-changing universe. Whitehead taught first in England and then in the United States, distinguishing himself at the University of Cambridge and later at Harvard University. His academic life passed through three distinct stages; it moved from mathematics and logic, through a concern for education and the history of science, to natural philosophy and metaphysics (Whitehead, 1920/1964, 1925/1967, 1929/1969).

Whitehead's major work is *Process and Reality: An Essay in Cosmology* (1929/1969). It is a systematic interpretation of change that aims to incorporate both the being of eternal objects and the becoming of actual occasions. This ongoing interaction between being and becoming results in the all-encompassing creativity of endless reality. In terms of pervasive experiences and feelings, all objects and events continuously interact in the evolutionary advance of this eternal and infinite universe. As such, there is an integrated and essential unity (through experiencing and feeling) of human perception and reality itself, that is, a unity of internal mental activity with external physical activity throughout the extensive continuum of this cosmic epoch.

As a panentheist, Whitehead merely distinguished between God and Nature (for him, they are neither separate nor identical entities); both are interacting forever, as there is no ultimate end or final goal to the creative process of an endless reality. However, there have been and will be other finite cosmic epochs, each with its own physical laws and unique creativity. In short, Whitehead's dynamic cosmology clearly illustrates how extremely abstract an interpretation of evolving nature may become. Within this philosophy of organism, the experiencing human being is the concrescence of all its actual occasions within a continuously flowing space-time continuum.

Pierre Teilhard de Chardin

There is a crucial distinction between the fact of evolution in science and those interpretations of evolution that exist in the philosophical literature. Evolutionary viewpoints range from materialism through vitalism and spiritualism to mysticism. Furthermore, for some thinkers, there is a serious need to synthesize science and theology into a comprehensive philosophical system that will embrace both established facts and personal beliefs. Such an audacious attempt had been made by Pierre Teilhard de Chardin (1881–1955), an eminent French geopaleontologist and devout Jesuit priest, who accepted both the truth and challenge of evolution, despite the inevitable problems and tragic consequences his unique vision would cause him from some myopic religionists and his intolerant superiors (Birn, 2006d).

Because of his interest in both science and theology in terms of evolution, Teilhard was eventually silenced by the Roman Catholic Church for his unorthodox views on original sin. He was then exiled from France to China, where his geological research at Zhoukoudian, the significant fossil hominid site near Peking (now Beijing), and his subsequent scientific writings made him world famous (Aczel, 2007). Teilhard's involvement as a geologist with this *Sinanthropus pekinensis* discovery resulted in his intense reflections on the meaning and purpose of human evolution within dynamic reality. Consequently, he authored his major but controversial philosophical book, *The Phenomenon of Man* (1975; written in 1938–1940, 1947–1948, and first published in 1955 in French). Unfortunately, the Vatican denied him permission to have it published. Quintessentially, the book argued for a teleological and mystical interpretation of human existence on earth based on theistic evolution (what today is referred to as an appeal to an intelligent design within the historical process of the natural world).

Teilhard worked with those geologists, paleontologists, and anthropologists who were dedicated to unearthing the remains of fossil hominids in the Eastern Hemisphere, from Africa to Indonesia. He himself spoke of an anthropogenesis, that is, the emergence and ongoing evolution of our species. He also called for an ultra-anthropology, that

is, a rigorously comprehensive view of humankind within this evolving world. Of course, for many, evolution was a devastating challenge to traditional theologies and religious beliefs. It required a reinterpretation of God, personal immortality, human free will, and the divine destiny for our species. In their dynamic worldview of reality, both Teilhard and Whitehead were panentheists, seeing God and Nature as continuously interacting in an ongoing process of creative evolution.

Teilhard's unique synthesis (1975) is based on four fundamental conceptual assumptions: (1) The unity of this process universe is ultimately grounded in spiritual energy; (2) cosmic evolution reveals the design of ever-increasing complexity and ever-centralizing consciousness; (3) organic evolution on the finite, spherical earth reveals three consecutive and essential layers (matter or the geosphere, life or the biosphere [Vernadsky, 1926/1998], and thought or the noosphere); and (4) the end goal of human evolution will occur on this planet with the formation of a theosphere. For this Jesuit scientist, converging and involuting human evolution will eventually form a collective consciousness at the Omega Point, which is the ultimate destiny for our species on the earth. Then, this collective consciousness will detach itself from this planet, transcend space and time, and unite itself with a personal God as a result of a final mystical synthesis.

In the last analysis, Teilhard's cosmology (Heller, 2009) is actually a planetology. Incredible as his vision may seem, it is nevertheless to Teilhard's lasting credit that he accepted the fact of evolution at a time when the worldwide religious community was either skeptical of it or rejected it outright. Actually, by foreseeing the future unity of our human world through converging advances in science and technology, Teilhard had glimpsed our age of the Internet.

Marvin Farber

In the history of philosophy, there has been a contentious debate between the objectivists who gave preference to the natural world and the subjectivists who gave preference to the human mind. This clash in metaphysics continues today; some philosophers claim that the material universe is the starting point for any sound cosmology, while others ground their worldview in the reflective ego as the alleged center of any true ontology. However, if philosophy takes the factual theory of organic evolution seriously, then any metaphysical framework must embrace both a dynamic universe independent of human thought and the recent emergence of our species within the sweeping history of life-forms on this planet.

As a distinguished American philosopher, Marvin Farber (1901–1980) devoted his academic activities to the intellectual defense of a cosmic naturalism over a myopic subjectivism (Farber, 1968a, 1968b). Although he studied and contributed to phenomenology as a method of inquiry, his own refreshing naturalist standpoint recognized the

severe limitations of restricting philosophical investigations to merely the content of a human mind. Farber accepted the fact of evolution, realizing the far-reaching implications that this scientific theory holds for philosophical ideas and religious beliefs. Consequently, his unabashed atheism and pervasive naturalism were in stark contrast to all idealist positions in the philosophical literature and all theistic interpretations in religious thought.

Farber had been greatly influenced by the writings of Ludwig Feuerbach and Karl Marx (among others). He was indebted to the cosmic perspective of Giordano Bruno and the evolutionary framework of Ernst Haeckel. His inquiring mind was always open to crucial findings in the natural and social sciences, as well as advances in logic. He was particularly receptive to the ongoing discoveries in anthropology, a discipline he thought to be especially important to any sound understanding of and proper appreciation for human existence in terms of both science and philosophy. To him, the facts and concepts of scientific anthropology are indispensable for modern philosophy.

Incorporating the evolutionary perspective, Farber held that humankind is merely a newcomer in earth history, and its vulnerable existence is a fleeting event within the flux of cosmic reality. Therefore, one must come to grips with the ephemeral status of mental activity in this universe. Moreover, for him, the ongoing discoveries in paleo-anthropology, as well as research in primatology and genetics, offer a striking confirmation of human evolution and the close relationship between our own species and the great apes.

Because of his commitment to the special sciences, uncompromising materialism, and sobering interpretation of human evolution, the wise Marvin Farber stood almost alone in modern philosophy. Nevertheless, his enlightened stance against ignorance and superstition would gladly welcome all forthcoming findings in scientific anthropology and evolutionary science. As Farber saw it, the goal of human research is to increase freedom, happiness, and longevity (with the issues in ethics taking priority over those themes that still surround epistemology and metaphysics).

One may anticipate a neo-Enlightenment with a renewed emphasis on science, reason, and humanism. For now, however, and with prudent courage, our species must have the will to evolve and fulfill itself on earth and later elsewhere in a godless universe.

Research and Speculation

The ramifications of evolution open up new areas for scientific research, especially in anthropology with its focus on humankind. Although opposition to the fact of evolution continues, it does not stifle rational speculations on the awesome possibilities that evolution holds for both the future of our species and the probable existence of life-forms on other worlds.

The Neo-Darwinian Synthesis

At the beginning of the 20th century, scientists were divided into two distinct groups concerning the primary force behind organic evolution: One group argued that the explanatory mechanism of natural selection accounted for the emergence of new species over vast periods of time, while the other group maintained that genetic variation held the key to understanding and appreciating biological evolution. However, before 1959, it became obvious that genetic variation and natural selection, taken together, explained the appearance of new species throughout the history of life-forms on earth. As a result, populations (or gene pools) became the focus of evolutionary research, particularly in terms of probability and statistics. As such, neo-Darwinism, or the so-called synthetic theory of organic evolution, now represents the scientific foundation for modern biology.

The writings of several scientists helped to popularize the emerging synthesis in evolution theory: Theodosius Dobzhansky, Sir Julian Huxley, Ernst Mayr, and George Gaylord Simpson (among others). Their informed books spread the facts and concepts of evolution theory, as well as defended evolutionary biology from the uninformed positions of dogmatic biblical fundamentalists and myopic religious creationists. Ongoing discoveries in paleoanthropology and human genetics, as well as improved dating techniques, gave greater empirical evidence to support the fact of human evolution (despite those attacks that still challenge the enormous age of this earth, the mutability of species, and the great antiquity of our own species). The recent completion of the Human Genome Project opens up new areas of research for the genetic engineering of species, including our own.

Sociobiology: Nature and/or Nurture

In 1975, the appearance of a groundbreaking book titled *Sociobiology: The New Synthesis*, from the American naturalist Edward O. Wilson, caused a major debate among anthropologists, including other scientists and philosophers (Wilson, 1975). A specialist in entomology who focused on the biology and behavior of ants, Wilson boldly extended organic evolution in order to include our own species in terms of seeing human behavior influenced by the inherited genetic makeup of the human animal. His position intensified the nature versus nurture controversy in the academic world, with Wilson himself giving priority to genetic inheritance over sociocultural influences. He has also rigorously advocated protecting and preserving the diversity of life-forms on earth (Wilson, 1992).

Since 1975, and especially with the mapping of the human genome, it is becoming clearer that genes play a substantial role in providing the propensity for causing favorable and unfavorable variations, for example, illness and disease, as well as both desirable and undesirable

behavior in species (including in our own). Not surprisingly, some thinkers vehemently object to manipulating the human genome, despite those incredible advantages that this scientific breakthrough will offer for human existence and evolution. Admittedly, sociobiology holds great promises and serious perils. Of course, determining the biological characteristics and behavior patterns of the human being through genetic engineering necessitates that sociobiological research follow stringent ethical guidelines.

As with the origin of any science, there are those people who are at first skeptical of the value of a new field of inquiry and protest the emerging science. However, as time passes and the overwhelming benefits become obvious, the new science is accepted and eventually praised. One may assume that this change of attitude will be true for the emerging science of sociobiology, as well as evolutionary psychology and genetic engineering.

The human being is a complex product of both biology and culture. For the anthropologist, as well as the scientist and philosopher, the fact of biocultural evolution makes it clear that inherited and learned mental activity are grounded in the material brain and that the material organism (no matter how complex) is grounded in the DNA molecule. Consequently, all aspects of the human being are the result of evolution and, therefore, they are subject to scientific inquiry within a naturalist framework.

Anthropology: Facts, Concepts, and Perspectives

As the comprehensive study of evolving humankind, anthropology is that discipline that is devoted to research in those areas that are relevant to understanding and appreciating *Homo sapiens sapiens* within the natural world (Bollt, 2009; Hublin, 2006). These areas range from genetics, paleontology, and archaeology to sociology, psychology, and linguistics. The more anthropologists search, the more fossils and artifacts they find that shed light on the emergence of our species over several million years. Each discovery helps to complete the developing picture of hominid evolution (Birn, 1988; Shubin, 2009; Tattersall & Schwartz, 2000). Of particular significance are those discoveries in primatology that clearly show the undeniable similarities between our human species and the four great apes in terms of genetics and psychology. Research in cross-cultural studies reveals the astonishing diversity of human thought and behavior from society to society throughout history.

In paleoanthropology, three discoveries have been especially important: *Ardipithecus ramidus* ("Ardi"), *Astralopithecus afarensis* ("Lucy"), and *Homo floresiensis* ("Hobbit"). Although interpretations of these three hominid species vary among anthropologists, who debate specific conclusions from the fossil specimens, there is no

denying the empirical evidence itself. Today, it is exciting to speculate on what remarkable fossil specimens are still in the earth waiting to be discovered by future anthropologists.

A perplexing question still haunts some anthropologists: What is the uniqueness of our species? One answer offered was that the human animal is the only toolmaker—until it was discovered that chimpanzees make and use simple tools (as do a few other animals). A second reply was that only our species has self-consciousness that allows it to communicate through language—until ape studies showed that the pongids have self-awareness and are capable of learning symbolic communication. More recently, it has been argued that only humans stand erect and walk upright with a bipedal gait; that is, only humans are capable of sustained bipedality. However, chimpanzees and bonobos are able to walk erect for short distances. It seems that the only uniqueness of our species that separates us from the other living hominoids is about 6 million years of biological evolution (Rachels, 1999). Huxley, Haeckel, and Darwin himself got it correctly back in the 19th century: Man differs merely in degree rather than in kind from the great apes.

Religious Creationism or Scientific Evolutionism

During the 19th century, two fundamental questions remained to be answered: What is the age of this planet? Have species always been fixed throughout earth history? As evidence accumulated in geology and paleontology, it became increasingly obvious to naturalists that our planet is millions (actually billions) of years old and that species have changed over time (with most species eventually becoming extinct). This emerging evolution framework held devastating consequences for all orthodox conceptions of earth, life-forms, and our species. In 1860 at the University of Oxford, England, the infamous Thomas Huxley and Samuel Wilberforce confrontation exemplified the intense conflict between the new evolution paradigm in science and an outmoded static worldview in religion.

The fact of evolution challenged not only traditional science and philosophy but also natural theology. Darwin himself was disturbed by the materialist implications of his own evolution theory for religious beliefs. In fact, his wife, Emma, even felt compelled to delete all of her husband's views on theology and religion from his *Autobiography*, which was published posthumously in 1887; not until 1958 did an unexpurgated edition of Darwin's life, written by himself in 1876, appear in print (Darwin, 1969).

In England, to reconcile evolutionary science with Christian faith, religious naturalist Philip Gosse argued that God had placed fossils in the earth in order to merely suggest that organic evolution had taken place, although in reality (so thought Gosse) species are fixed and earth had been suddenly created only about 6,000 years ago. Not surprisingly, his bizarre but provocative book *Omphalos: An*

Attempt to Untie the Geological Knot (1857) convinced neither scientists nor theologians.

During the 20th century, reacting to the materialist ramifications of organic evolution, some religionists argued against the new dynamic outlook by first defending biblical fundamentalism and then advocating so-called scientific creationism (Isaak, 2007). Both viewpoints gave priority to beliefs rather than to facts. In 1925 at Dayton, Tennessee, the infamous John Scopes "Monkey Trial" had best represented this ongoing clash between science and religion over the factual theory of organic evolution.

In an attempt to reconcile modern science with traditional theology, some religionists now maintain that the universe in general and evolution in particular manifest an intelligent design (Petto & Godfrey, 2007). Ultimately, this is a religious position not supported by scientific evidence. Despite all the ongoing attacks, continuing research in all areas of science (from genetics to paleontology) confirms the fact of evolution and the close biological relationship between our species and the great apes. In fact, an honest examination of human history clearly shows that even complex religious beliefs and theological systems have evolved, over thousands of years, from simplistic explanations for interpreting the natural world. No doubt, exciting discoveries in the future will further strengthen the evolution framework. Finally, in light of ongoing changes in human societies and their cultures, one wonders what the religious beliefs and theological systems of human beings will look like 2,000 years from now.

Evolutionary Humanism, Transhumanism, and Posthumanism

Grounded in science, reason, and an open-ended perspective, evolutionary humanism emphasizes the ongoing development of human beings within a strictly naturalistic framework. It maintains the unity of mental activity and the organic brain, and places our species totally within biological evolution. With optimism, evolutionary humanism argues for the improvement of our species in order to increase its health, happiness, and longevity (overcoming illness, disease, and physical disability). With the advances in science and technology since the middle of the 20th century, especially in genetics, the innovative ideas and pragmatic values of this movement for human enhancement would seem increasingly plausible for guiding our evolving species.

Extending the evolutionary framework, some scientists and philosophers see the human being as an unfinished species that will continue to change as a result of implementing nanotechnology and genetic engineering (Harris, 2007; Savulescu & Bostrom, 2009; Sorgner, 2006; Young, 2006). Both the ideas and values of transhumanism (going beyond the human of today) have been put forward by several visionary thinkers: Nick Bostrom, Fereidoun M. Esfandiary, Sir Julian S. Huxley, Michel Houellebecq,

and Julian Savulescu (among others). Through human intervention, these thinkers argue, our species will be improved in its biological and psychological makeup, just as *Homo sapiens* of today is a biopsychological advance over *Homo erectus* of the distant past.

Reminiscent of Friedrich Nietzsche's conception of the overbeing, some thinkers even speculate that the transhuman will be the "missing link" between the human of today and the posthuman of the remote future. In fact, the posthuman may even be a new species far beyond both humans and the following transhumans. Of course, one cannot imagine the nature of the posthumans. It is likely that these cosmic overbeings will travel to and live among the stars.

Exobiology and Exoevolution

In 1836, during the end of his 5-year voyage on the HMS *Beagle*, Charles Darwin revisited the tropical Brazilian rainforest. He admired this lush environment and thought how great it would be, if it were ever possible, to experience the scenery on another planet. Therefore, at least once, the young naturalist glimpsed the forthcoming science of exobiology or astrobiology as the search for life-forms on other worlds (and if they are found, their study).

In the history of philosophy, major thinkers like Giordano Bruno (1548–1600) and Immanuel Kant (1724–1804) envisioned living beings inhabiting other planets. Today, with advances in technology, scientists are seriously scanning the heavens in hopes of detecting indisputable evidence that organisms exist elsewhere in sidereal reality (Boss, 2009; Lamb, 2001). The size and age of this material universe, with its billions of galaxies each having billions of stars, argues for the existence of countless planets. If the same physical laws and chemical elements pervade this cosmos, then it seems reasonable to assume that earthlike worlds harbor life-forms among the stars, perhaps even sentient beings similar to or even advanced beyond ourselves.

In our own solar system, the earth has those necessary natural conditions that have allowed for the origin and evolution of biological forms over the past 4 billion years. Beyond this solar system, extrasolar planets may have similar life zones that permit the existence of organisms. Thus, planetology becomes cosmology as the probability of and interest in biological evolution are extended to include this entire universe. Likewise, exobiology implies exoevolution, that is, the evolution of life-forms on different worlds, where organisms are adapting to changing habitats far different from those environments on earth (Birx, 2006b). In the distant future, both exobiology and exoevolution may offer intriguing areas for scientific research.

Even if forms of life are never found elsewhere in this universe, it does not mean that they do not exist on worlds that will remain beyond the detection of our human species

(Webb, 2002). Moreover, organisms may have existed in the remote past before the formation of the present galaxies or will emerge in the distant future in new galaxies. And there may have been, are, or will be other universes with life-forms very similar to or far different from those organisms that have inhabited or are now inhabiting earth. One can only speculate on what the consequences might be if our human species ever encounters superior intelligent beings evolving among the stars.

Conclusion: Ongoing Reflections and Open Inquiry

Since the convincing writings of Charles Darwin, interpretations of organic evolution have evolved from the narrow materialism of early evolutionists to the comprehensive naturalism of modern neo-Darwinists. Advances in those special sciences that support biological evolution include ongoing discoveries in paleontology, comparative biology, anthropology, and population genetics, as well as more accurate dating techniques in geology and biochemistry. Progress in these special sciences is an increasing challenge to vitalistic, spiritualistic, and mystical interpretations of our species and organic evolution.

Two exciting and promising but controversial areas in modern evolution research are transhumanism and exoevolution. With the rapid advances in nanotechnology and genetic engineering, an increasing ability to design the DNA molecule will allow humans to alter and improve species, including our own, and to design new organisms for specific purposes both on earth and in outer space; as such, one may speak of emerging teleology in terms of human intervention and technological manipulation. The successful journey of human beings into outer space will require our species to adapt to and survive in different environments, both artificial and natural. If life-forms are discovered elsewhere in this universe, then scientists and philosophers will be able to study the evolution of organisms on other worlds.

Quo vadis, Homo sapiens? In those countless centuries to come, the human being may even transform itself into a new species, *Homo futurensis*. Of course, designer evolution will require establishing ethical guidelines while promoting open inquiry. For now, the primary focus must be on those steps that need to be taken to ensure the continued biodiversity of life-forms on this planet, including the ongoing fulfillment of humans on this earth before they venture to the stars.

EVOLUTION/CREATION CONTROVERSY

LAURA M. BOLT

University of Toronto

The evolution/creation controversy is an acrimonious debate that has been ongoing since 1859, particularly in the United States of America. This debate contrasts the biological theory of evolution with a literal interpretation of the creation story in the Judeo-Christian Bible, asserting these views as incompatible. Although largely about the validity of the biological theory of evolution, this debate also encompasses subjects ranging from cosmology through geology to physics. The media has so sensationalized this debate that it is important to set aside common misconceptions about the nature of this controversy to view it from a broader perspective. The theory of evolution has long been widely adopted by the world's scientific community. Evolution has been taught without dispute in most of the world's developed nations. It has also been accepted by the majority of world religions. The Catholic Church and most Protestant denominations, for example, find no conflict between their theological beliefs and evolutionary theory. In the United States, many deeply religious people view the theory of evolution as a compelling scientific explanation for the diversity of life on this planet.

The evolution/creation controversy is not a debate of faith versus science. Rather, it is a political and legal war involving some fundamentalist Christians, mostly situated in the United States, who are opposed to the theory of evolution on the grounds that it contradicts their specific interpretation of the account of Creation found in the Judeo-Christian Bible.

This chapter will outline the evolution/creation controversy, providing summaries of the theories under debate, definitions of belief systems involved in the debate, an overview of debate history and important events in the United States, reasons why this controversy continues today, and ways that this controversy can be alleviated. This chapter closes with a list of the most relevant references and suggestions for further reading.

Theory of Evolution

The Development of the Theory of Evolution

The theory of evolution was first presented by British naturalist Charles Darwin in his 1859 book, *On the Origin of Species by Means of Natural Selection*. Prior to Darwin, several scientific findings from the late 1700s set the stage for the theory of evolution. These included fossils and geological formations suggesting an ancient earth. The idea of species transmutation was discussed by philosopher Erasmus Darwin, grandfather to Charles, and Charles was influenced by these ideas as he traveled around the world as a naturalist in the 1830s, regarding geographical variation in life-forms. Darwin began writing what became the earliest draft of *On the Origin of Species* in the 1830s and refined his arguments and observations through further experiments in the 20 years leading up to its publication.

The Theory of Evolution

Evolution is a process, which over many generations, results in heritable changes in the gene pool of a population. In *On the Origin of Species*, Darwin suggests the mechanisms by which life diversifies. These can be reduced to five basic ideas:

1. The high rate of reproduction within a species makes it impossible for all individuals to survive, and therefore, it creates a struggle for resources both within and between populations.
2. Within a species, there is great variation in the traits represented, and within each specific environment, certain traits will enhance the chances an individual has of surviving and reproducing.
3. Variation in traits is heritable and can be passed down to offspring.
4. Individuals and their offspring with traits best allowing them to obtain resources are more likely to survive and be able to reproduce.
5. Over many generations, new species arise through the specific pressures in a certain environment acting on which traits are more advantageous for individuals to pass down.

Natural selection is the process by which advantageous traits become more represented in a population over generations, since individuals with these traits are better able to survive and reproduce.

Contemporaneous Reception of This Theory

Most scientists accepted Darwin's theory of evolution readily because of the thoroughness of Darwin's arguments. Darwin was aware of weaknesses in his ideas and active in seeking evidence opposed to his theory. Although scientists and the educated public became fast supporters of evolution, the reception in England's religious communities was divided. Some conservative Anglicans, including Samuel Wilberforce, the Bishop of Oxford, opposed evolution because it necessitated a change in the divine order. In contrast, many educated Christians, including more liberal Anglicans, embraced evolution as the blueprint of God's work in the world.

Early Controversy and Darwin's Response

The most famous manifestation of controversy immediately following the publication of *On the Origin of Species* involved Wilberforce arguing against evolution at a meeting for the British Association for the Advancement of Science in 1860. Botanist Joseph Hooker and physiologist Thomas Huxley debated as supporters for evolution. Following the debate, scholars noted that Darwinism was taken out of context by the public and articulations of dissenting views about this scientific theory were depicted as a war between science and religious faith. Although personally an agnostic, Darwin was sympathetic to those

with devout religious beliefs and was distressed at the confusion and dissent his theory caused. To make his theory more blatantly compatible with God-directed evolution, Darwin inserted the words "by the Creator" in the last sentence in the second edition of the *Origin of Species* published in 1860. Thus, the final sentence read,

There is grandeur in this view of life, with its several powers, having been originally breathed by the Creator into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved. (p. 490)

Although evolution was made more overtly palatable for those with religious beliefs with this inclusion, Darwin removed this reference to a creator in the third and subsequent editions. A small minority of conservative Christians in the 19th century and onward continued to oppose evolutionary theory (McCalla, 2007).

Modern Reception of This Theory

Since the 1860s, the theory of evolution has been almost universally accepted by academics and is now recognized as a unifying model for life on earth, from foundational to modern biology (Brooks & Wiley, 1988). Evolution is supported by overwhelming evidence from many diverse scientific disciplines (Bleckmann, 2006). It has become increasingly influential in all branches of scholarship, as details of its particulars have been refined through thousands of peer-reviewed publications, books, and complementary hypotheses and theories (Patterson, 1999). Evolution is supported by all known professional organizations of scientists, who perceive it as one of the most captivating theories of the modern day. A large group of fundamentalist Christians, primarily located in the United States, opposes evolutionary theory. They are called creationists.

Creationism

The Judeo-Christian Creation

Although there are myriad creation stories in various world religions, the creation story from the Judeo-Christian Bible is the specific account on which the vast majority of evolution/creation debates center. For this reason, this will be the only creation account presented in this chapter. The Judeo-Christian Bible asserts in Chapters 1 and 2 of *Genesis* that the world was created by God in 6 days and that God rested on the 7th day. According to this account, the Creation can be summarized as follows:

- *Day 1*: Light, day, and night were created.
- *Day 2*: Sky and water were created.

- *Day 3:* Land, seas, and all types of plants were created.
- *Day 4:* Stars, sun, and moon were created.
- *Day 5:* All sea life and all birds were created.
- *Day 6:* All terrestrial animals and humans were created.
- *Day 7:* God rested from his work, since all was complete.

Contemporaneous and Modern Theological Interpretations of the Creation Story

Creationism must be carefully differentiated from a belief in the Judeo-Christian God as the creator of life and the universe because the majority of Judeo-Christians maintain a belief in a Creator God that is consistent with evolutionary theory. Nineteenth-century theological scholarship suggested that the Bible's creation story should not be taken as scientific or historical truth but instead interpreted as a figurative, mythical account, which has religious but not literal meaning (McCalla, 2007). This type of biblical interpretation has been continued by most Christian groups today. Many Christian denominations, for example, may perceive the "days" of the creation myth as being much longer periods of time, such as ages of the world, or take nothing more literal from the story than the idea that God created the world. As numerous theologians note, Christian writers as far back as St. Augustine in the 5th century have approached the creation with great imagination at God's creative powers and the methods by which he executed this Creation (Van Till, 1998). Evolution is, according to this line of belief and many modern theologians, a reasonable mechanism through which the Judeo-Christian God created and complexified life by setting this macroevolutionary process in motion. However, these mainstream Christian beliefs about the origins of life contrast with varied origination beliefs held by many Americans and a minority of other fundamentalists worldwide who are termed creationists.

Old Earth Creationism

Old Earth creationism was one belief widely held by fundamentalist Christians before the 1960s and is still held by some today. According to various types of Old Earth creationism, life was created by the Judeo-Christian God in literal 24-hour days, as described in *Genesis*, although life was created recently on an old Earth. Fundamentalists with this belief saw the theory of evolution as incorrect because it contradicted a literal reading of the Bible. However, Old Earth creationists accepted the scientific consensus by geology and cosmology that Earth was billions of years old. Old Earth creationism is represented to the present day by major creationist organizations including Hugh Ross's Reasons to Believe (Pennock, 2003).

Young Earth Creationism

Young Earth creationism, a belief widely held by creationists since the 1960s (Pennock, 2003), can be summarized in the following beliefs:

1. The world was created in six literal 24-hour days.
2. The universe, matter, and life were created from nothing.
3. Earth is only around 10,000 to 12,000 years old.
4. A worldwide flood as described in *Genesis* happened around 6,000 to 12,000 years ago, creating modern geological features, such as mountains, canyons, and fossils.
5. A single-celled organism is not the ancestor of all living things. Organisms are not capable of developing this level of complexity through natural selection and mutation.
6. Plants and animals were created as types and can vary only within fixed limits.
7. Humans do not share a common ancestry with apes.

The Young Earth creationist belief perceives all scientific findings, which contradict these assertions—including evolutionary biology and modern geology—to be false science, since true science should confirm a literal biblical interpretation of the creation story. Young Earth creationism also views Old Earth creationism as an incorrect belief.

The majority of creationist lobbying since the 1960s has been done by Young Earth creationists. Two of the most active organizations supporting Young Earth creationism are Answers in Genesis (Pennock, 2003), led by Ken Ham and the Institute for Creation Research (McCalla, 2007; Scott & Branch, 2006), founded by Henry Morris and led by John Morris. The strength of their faction is evidenced in the number of organizations, Web sites, magazines, summer camps, and radio and television programs supporting them (McCalla, 2007).

Creation Science

Creation science is a manifestation of Young Earth creationism and the field of creationist inquiry, which was active from the 1960s to the 1980s (McCalla, 2007). It asserts that the Young Earth creationist account of the origins of life is more consistent with scientific facts than the evolutionary model of origins. Creation science presents evolutionary theory and the creation story as equivalent scientific models through which to perceive life and the universe but claim Young Earth creationism as the superior scientific model. They adhere to all beliefs held by Young Earth creationism. In addition, creation scientists argue that the evolutionary model is filled with inconsistencies and use four main claims to do so:

1. The second law of thermodynamics makes the theory of evolution impossible, since organisms cannot become increasingly complex.
2. Statistical probability suggests that the evolution of life by chance is astronomically unlikely.
3. Radiometric dating techniques giving an age of 13.5 to 14 billion years to the universe, around 4.5 billion years to Earth, and around 2.8 billion years to life are unreliable and no more than guesses.
4. Evolutionists commonly disagree amongst themselves, which shows that the field of evolutionary biology is not rooted in fact but belief.

Intelligent Design

Intelligent design is a field of creationist inquiry, which has been active since the 1980s. Intelligent design is creation science without the biblical foundation (McCalla, 2007). It asserts that life and the universe are better explained by an intelligent designer working in a directed fashion rather than by random processes, such as natural selection. Intelligent design is promoted as a scientific theory, not a religious belief system. This field of inquiry does not insist on a literal 6-day creation interpretation of *Genesis* but maintains the involvement of a supernatural being in all scientific events, particularly those that science cannot yet explain. In addition to the arguments against evolution put forward by creation science, some principal claims of intelligent design are as follows:

1. An intelligent designer exists who created life-forms.
2. This intelligent designer can be detected by looking for specified complexity in organisms.
3. Evolution cannot account for the great complexity of living cells. A cell's protein arrangements are so intricate and codependent that any change would render the entire mechanism useless. This necessitates entire complex mechanisms in living organisms originating at one time, which would not be possible without an intelligent designer to bring these into being. Biochemist Michael Behe originated this opinion (McCalla, 2007).
4. Certain mathematical theorems prove that evolutionary theory cannot account for the informational complexity of the DNA in living organisms. An intelligent designer must therefore have created DNA intact. Mathematician William Dembski originated this opinion (McCalla, 2007).
5. Evolutionists oppose intelligent design theory due to their own ideological biases, not based on valid scientific reason.

Non-Creationist Beliefs in the Evolution/Creation Debate

Theistic Evolution

Theistic or God-directed evolution is a commonly held Christian belief, which accepts all evidence related to evolution that is also accepted by the world's scientific community (Beverly, 2002). This belief is held by the Catholic Church, as well as most Protestant denominations. As well as supporting scientific findings, theistic evolutionists believe in the Judeo-Christian God as the sole creator of the universe and the initiator of the principles of nature such as scientific laws and evolution. In addition, they believe that humans are unique among all life-forms in having a spiritual nature, as well as a physical one, and are called to a special relationship with God. Theistic evolutionists are not creationists and generally oppose literal creationist beliefs and lobbying because they believe both

are incongruous with science and reason and therefore show Christianity in a negative light.

Evolutionary Naturalism

Evolutionary naturalism, a worldview present for hundreds of years, has become more prevalent since the publication of *On the Origin of Species* in 1859 (Van Till, 1998). Individuals with this perspective believe that nothing exists beyond the natural world and that there is no higher power. Seemingly inexplicable phenomena have a rational cause that will be discovered. In explaining a phenomenon, the principle of Occam's razor suggests that the explanation involving the fewest assumptions is the most likely one. Since there is a scientific explanation for every process and action in the universe, the existence of a higher power is an unnecessary assumption. Reason does not suggest that belief in a higher being is warranted.

Manifestations of the Evolution/Creation Debate in the United States

From 1859 and onward, a small group of conservative Protestants objected to evolutionary theory on the grounds that it contradicted a literal interpretation of scripture. They became known as fundamentalists based, in part, on their insistence on the literal, verbal inerrancy of scripture (McCalla, 2007). These fundamentalists viewed the creation story as both historic and scientific truth, with each "day" of creation lasting a literal 24 hours. By the 1920s, this group had banded together in a vocal minority within Protestant denominations in the United States, with some creating the World's Christian Fundamentals Association (WCFA) in 1918 to battle within the church against evolution and nonliteral theological interpretations.

Outside the church in the public education system, a text titled *Civic Biology* by George Hunter was widely used in science classes from 1914 to 1925. This text explained the theory of evolution, including human evolution. However, since the mid-1920s, there has been considerable legal controversy surrounding the teaching of evolution in public schools. Much of the evolution/creation controversy in the United States is centered around which origination "theories" are taught in the education system.

Legal Actions in the 1920s

In response to public demand by creationists, antievolution bills were introduced in Arkansas, Mississippi, and Tennessee in the 1920s. This bill was called the Butler Act in Tennessee (McCalla, 2007). Such bills were drafted and considered in at least 12 more states, including Louisiana. They made it illegal for human evolution to be taught in state-funded science classes at elementary and secondary schools and on university levels. It was not illegal to teach

evolutionary theory in general but only illegal to teach that part of evolutionary theory that suggested humans were descended from Primates.

The State of Tennessee v. John Thomas Scopes, Tennessee: 1925–1927

In 1925, the American Civil Liberties Union in conjunction with prosecutors from Dayton, Tennessee, wanted to test the constitutionality of Tennessee's new Butler Act (Larson, 1997). Local substitute high school teacher John Thomas Scopes agreed to act as defendant after teaching human evolution to a biology class. Scopes's supporters, with the exception of leading defense lawyer Clarence Darrow, were advocates of theistic evolution. The creationist prosecution, led by William Bryan, directed arguments not against unbelief but against other Christians who did not interpret the creation story literally. Despite favorable testimony from many distinguished scientists and widespread support from the public, Scopes was found guilty. The case was dismissed in 1927 on a technicality by the Tennessee Supreme court.

This trial and its appeal, despite being the most publicized evolution trial of the 20th century, did not accomplish the outcome that the American Civil Liberties Union had hoped for. Laws banning the teaching of human evolution in Tennessee, Mississippi, and Arkansas would remain the same for the next 40 years.

Evolution in the U.S. Education System: 1926–1960

The biologist Alfred Kinsey published the first U.S. high school science textbook in 1926, and this included clear and detailed sections on Charles Darwin and evolutionary theory. In the aftermath of the Scopes trial, subsequent editions of Kinsey's text reduced or eliminated these definitions, such that by the 1930s, this and other science texts used in U.S. schools presented little information on evolution (Bleckmann, 2006). Evolution was often not taught in school districts with a large proportion of creationists, although it continued to be taught in more liberal areas of the country. This persisted until the late 1950s, when Soviet scientific advances, such as the launch of *Sputnik I* in 1957, caused Americans to reexamine science education in the United States (Moore, 2001). New biological sciences curriculum textbooks were developed that outlined evolutionary theory explicitly. Use of this new textbook only prompted further resistance from creationists at the teaching of evolution (Moore, 2001).

The Advent of Young Earth Creationism and Creation Science: 1961–1968

In 1961, Young Earth creationism and creation science arose as the result of the publication of *The Genesis Flood*:

The Biblical Record and Its Scientific Implications by John Whitcomb and Henry Morris. This work was founded partly on the flood geology theories of Seventh Day Adventist George McCready Price, who argued that Earth is young and the flood was a worldwide event. This belief was called creation science in the hope that it would be accepted by the scientific community.

However, *The Genesis Flood* has been heavily criticized by scientists since publication (Moore, 2007). Since the early 1960s, scientists have perceived creation science as a misleading field of pseudo-science in which creationists disregard all research findings that contradict a Young Earth creationist belief. Many assertions made by creation science, including those regarding thermodynamics, radiometric dating, and statistical probability, have been exposed as either misinterpretations or unequivocal errors by scientists. Despite this widespread criticism from the scientific community, creation science gained a large public following.

Beginning in 1961 in California, Young Earth creationists, in conjunction with the Creation Research Society, took a new approach (Bleckmann, 2006). Instead of demanding that evolution be omitted from school curricula, creationists lobbied the state board of education to teach creation alongside evolution in science classes. They argued that equal time should be given to each origination model, that science texts be rewritten to include creationist "theories," and that a new textbook be adopted in California. Despite objections from their scientific advisors, California's state board of education implemented this change to the curriculum. Similar laws were proposed in 10 other states throughout the 1960s and passed in Louisiana and Arkansas while New Mexico passed a law requiring an evolutionary disclaimer sticker on textbooks. The most famous trial of this period was the Epperson trial in Arkansas.

Susan Epperson v. The State of Arkansas: 1968

At the urging of the Secretary of the Arkansas Education Association, high school biology teacher Susan Epperson challenged the Arkansas law making it illegal to teach human evolution in 1968. The U.S. Supreme Court overturned the law nationwide, ruling that the board of education must maintain religious neutrality and human evolution could be taught anywhere in the United States. This trial set an important precedent for future legal proceedings (Scott & Branch, 2006).

The Aftermath of the Epperson Trial: 1968–1981

Following the Epperson trial, creation science was the only creation model useful for further lobbying, since it was presented as a scientific model and not a religious belief. Many smaller lawsuits followed, which resulted in

further ground gained for the teaching of evolution in the United States (Moore & Miksch, 2003).

(Evolutionists have not lost any trials since the Scopes trial [Moore & Miksch, 2003], although they have lost ground through legislation.)

*William Willoughby v. H. Guyford Stever,
District of Columbia: 1972*

Creationist William Willoughby sued National Science Foundation director Guyford Stever in 1972 for using public funds to publish a textbook that included descriptions of evolution, which he deemed religious. This case ruled that the science textbooks were not religious material, and the textbooks were published. This verdict applied to the District of Columbia (Moore & Miksch, 2003).

*Wright v. Houston Independent
School District, Texas: 1973*

This case ruled in 1973 that teaching evolution is constitutional and does not promote a religious belief. This verdict applied to Louisiana, Mississippi, and Texas (Moore & Miksch, 2003).

Daniel v. Waters, Tennessee: 1975

This 1975 case overturned a Tennessee law requiring equal teaching time for creation and evolution in state public schools. The verdict (creation need not be taught alongside evolution) applied to Kentucky, Michigan, Ohio, and Tennessee (Moore & Miksch, 2003).

Hendren et al. v. Campbell et al., Indiana: 1977

This 1977 case ruled that the Creation Research Society's text *Biology: A Search for Order in Complexity* was religiously biased and therefore unconstitutional for use in public schools. The verdict applied to Marion County, Indiana (Moore & Miksch, 2003).

*Crowley v. Smithsonian Institute,
District of Columbia: 1980*

This 1980 case ruled that the government should give funds to promote evolutionary presentations in museum exhibits but should not give funds to promote creation science. The verdict applied to the District of Columbia (Moore & Miksch, 2003).

Kelly Seagraves v. The State of California: 1981

Creationist parent Kelly Seagraves charged the state of California in 1981 with violating her right to free exercise of religion due to the teaching of evolution to her children in public schools. The case was dismissed,

and evolution continued to be taught in California (http://ncse.com/webfm_send/60).

Creation Science Lobbying: 1981

Bills sponsored by creationist organizations, which demanded the balanced treatment of creation science and evolution in public schools, were passed in Louisiana and Arkansas in 1981. Equal amounts of classroom time were required for the presentation of each "theory." However, these bills were quickly challenged by scientists, human rights groups, and some members of the dissenting public. The challenge in Arkansas resulted in a well-publicized court case in 1981 (Nelkin, 1982).

Thus far, twenty years of litigation had provoked both camps, making the creation/evolution debate even more heated.

*William McLean v. The Arkansas
Board of Education: 1981–1982*

Judge William Overton ruled in 1982 that requirements to teach creation science alongside evolution advanced the claims of a particular religion. Creation science was declared a religious belief and could no longer be taught in science classes. This verdict applied to Arkansas alone but set a precedent for future trials (Moore & Miksch, 2003; Overton, 1982).

Edwards v. Aguillard, Louisiana: 1987

This 1987 case overturned laws nationwide requiring equal teaching time for creation science and evolution. Creation science was deemed a type of religion and could no longer be taught in public schools. Two federal Supreme Court judges dissented from this verdict, including Justice Scalia. Justice Scalia ruled that although creation science could not be taught in science classes in the United States, teaching the scientific evidence against evolution was admissible and could be considered a secular matter (Moore & Miksch, 2003; Pennock, 2003).

The Advent of Intelligent Design: 1987

Following the *Edwards v. Aguillard* trial, creationists changed their lobbying approaches, seizing on Justice Scalia's words and requesting the evidence against evolution rather than a literal 6-day creation be taught in science classes. The intelligent design (ID) movement emerged nationwide, continuing the creationist debate (Pennock, 2003). ID bypassed constitutional objections by eliminating all references to the Bible and the Judeo-Christian God from a creation science framework. ID creationism united Old Earth and Young Earth creationists, forcing them to suspend their differences in belief while opposing evolution as a unified force. Proponents have stated that through ID

they wish to reestablish Western culture's theistic basis and combat the materialist worldview promoted by evolution.

The ID movement was spearheaded by law professor Philip Johnson until the early 1990s, when members of Seattle's Center for Science and Culture at the Discovery Institute began acting as public spokespeople. Leaders are primarily politicians and philosophers such as Stephen Meyer, Bruce Chapman, and John West Jr., although some scientists, including biologists Dean Kenyon, Paul Chien, and Scott Minnich, molecular biologists Douglas Axe and Jonathan Wells, and biochemist Michael Behe are also involved.

The well-known ID textbook *Of Pandas and People* was written in 1989 by ID researchers Percival Davis and Dean Kenyon for use in public schools, and the influential *Icons of Evolution* by Jonathan Wells followed in 2000 (Pennock, 2003). Further textbooks and popular pseudo-scientific theological books advocating ID were published throughout the late 1980s to the early 2000s and widely read by creationists.

ID's influence has been far-reaching in the U.S. school system (Pennock, 2003). In 1999, the Kansas state board of education voted to de-emphasize evolutionary teaching in all public schools, including universities. Several other states, including Ohio, have incorporated critical analysis of evolutionary theory into the biology curriculum. A model lesson plan, eventually challenged and deemed inappropriate by the Ohio Board of Education in 2004, presented material from textbooks on ID.

ID has been subject to great criticism and thoroughly dismissed by scientists and most other scholars, who note that it is impossible to test using the methods of science and therefore cannot be science (Pennock, 2003). The scientific community has refuted all ID propagated criticisms of evolution, countering the claims of ID researchers.

The ID research program, although in existence for 20 years, has failed to produce a single peer-reviewed research publication in support of this theory. Mainstream scientists suggest that empirical evidence does not support a supernatural origin of life over a naturalistic one and that arguments against evolution are not proofs of ID. The legal battle in America has largely involved ID from 1987 onward (Pennock, 2003).

*Ray Webster v. New Lenox
School District, Illinois: 1990*

This 1990 case ruled that creationist teacher Ray Webster could not teach creation science to his classes. The verdict applied to Illinois, Indiana, and Wisconsin (Moore & Miksch, 2003).

Philip Bishop v. Aronov, Alabama: 1991

This 1991 case ruled that physiology professor Philip Bishop could not present ID material to his classes at the University of Alabama (Moore & Miksch, 2003).

*John Peloza v. Capistrano
Unified School District, California: 1994*

This 1994 case ruled that requirements to teach evolution did not violate a creationist teacher's right to free speech. The verdict applied to Alaska, Arizona, California, Hawai'i, Idaho, Montana, Nevada, Oregon, and Washington (Moore & Miksch, 2003).

This ruling encouraged ID advocates to present their arguments in a way that would avoid ID being regarded as a religious belief (DeWolf, Meyer, & DeForrest, 1999).

*Hellend v. South Bend
Community School Corporation: 1996*

This 1996 case ruled that schools must prevent teachers from teaching creationism in the classroom, since this is an expression of religion. The verdict applied to Illinois, Indiana, and Wisconsin (Moore & Miksch, 2003).

*Edwards v. California
University of Pennsylvania: 1998*

This 1998 case ruled that Professor Edwards could not present his religious beliefs in the classroom and was required to follow the curriculum decisions of the California University of Pennsylvania (<http://openjurist.org/156/f3d/488/edwards-v-california-university-of-pennsylvania>).

ID, The Wedge Document: 1998

In light of their lack of legal success, spokespeople for the ID movement announced in 1998 that their approach to realizing the goals of their organization would be termed the "wedge strategy" (Pennock, 2003). They released a document that, in addition to affirming their movement's fundamental ideological commitments, outlined their plan for the implementation of these in wider culture. This strategy can be summarized as follows:

- *Phase 1:* Scientific research, writing, and publication
- *Phase 2:* Publicity and opinion making
- *Phase 3:* Cultural confrontation and renewal

Although no refereed research publications have been produced, observers note that the ID movement has proceeded to phases 2 and 3. The lack of scientific support for ID has not prevented the gain of public success for the movement. ID has been widely publicized through popular books, debates, seminars, conferences, editorials, and favorable reports by conservative papers, such as the *Weekly Standard* and the *Washington Times*. As a result of the wedge strategy, ID is perceived by many Americans as a viable alternative to evolutionary

theory that should, in fairness, also be taught in public schools. A March 2007 poll found that 48% of the U.S. public agreed that “God created humans pretty much in the present form at one time within the last 10,000 years or so” (Kahle, 2008, p. 72), while a May 2007 poll found 60% of the respondents believed in a literal 6-day creation. In contrast, 95% of U.S. scientists polled in 1996 accepted human evolution (Bleckmann, 2006). Despite this strong scientific consensus, numerous members of the public have been influenced by ID marketing campaigns.

The notion behind the wedge strategy is to establish a minimal legal position, which can then be expanded through further court cases thus creating a wider wedge from a narrow crack. Some later court cases advanced the aims of ID, while most refuted it.

*Freiler v. Tangipahoa Parish
Board of Education, Louisiana: 1999*

This 1999 case ruled that when presenting evolution, teachers should not read a disclaimer saying that the school board did not specifically endorse evolution or oppose ID or biblical creation. The verdict applied to Louisiana, Mississippi, and Texas (Moore & Miksch, 2003).

*Rodney LeVake v. Independent
School District 656, Minnesota: 2000*

This 2000 case ruled that creationist teacher Rodney LeVake could not present the evidence against evolution to classes against his school board’s instructions. The verdict applied to Minnesota (Moore & Miksch, 2003).

Moeller v. Schrenko, Georgia: 2001

This 2001 case ruled that creationism is not science, and it is appropriate for public schools to use a biology textbook that states this. This verdict applied to Georgia (Moore & Miksch, 2003).

*Selman v. Cobb County
School District, Georgia: 2005*

This 2005 case ruled that stickers informing students that evolution is only a theory, not a fact, should be removed from all biology textbooks. The verdict applied to Cobb County School District, Georgia (<http://www.talkorigins.org/faqs/cobb/citizensforscience.html>).

*Tammy Kitzmiller v. Dover
Area School District, Pennsylvania: 2005*

This 2005 case ruled that ID should be removed from public school science curricula. The verdict applied to the Dover Area School District, Pennsylvania (McCalla, 2007).

The Continuing ID Controversy

The trials mentioned here are only a few of many trials on the evolution/creation controversy, the majority of which go unreported by the media. The National Center for Science Education reports that in a recent 2-year period, there were 143 different trials from 34 different states (Pennock, 2003).

In many of these recent court cases, ID advocates have used a number of arguments to implement the wedge strategy in public life (Pennock, 2003). They argue that students should be taught the controversy about evolution and presented with evidence against evolutionary theory to develop critical thinking. However, scientists feel that this would be an inaccurate presentation of current scholarship to students (Beverly, 2002). Accepted scientific theories, such as the theory of gravity, do not typically have evidence presented against them in classrooms. In addition evolution is not controversial within the scientific community; it is only politically and religiously controversial. Either ID-advocated inclusion would have implications for students about the validity of evolution. Despite continuous criticism from the scientific community and numerous legal verdicts against ID, the ID movement continues to be active and well supported by creationists to the present day.

Why Does the Evolution/Creation Controversy Continue?

A number of factors perpetuate the evolution/creation controversy in the United States. Some researchers suggest that although hierarchies based on power, money, and celebrity are supported in U.S. society, intellectual hierarchies based on specialist knowledge are not readily accepted (Pigliucci, 2003). In contrast with places such as Europe, the U.S. education system is, to some extent, seen as a democratic process in which different opinions should be taught for the sake of variety (Pigliucci, 2003). Scholars note that this mind-set has had disastrous consequences for science teaching. The best-accepted scientific theories about life have, for generations, not been presented clearly to students, and as a result, a number of common misconceptions persist about the theory of evolution (Pigliucci, 2003). These perpetuate the evolution/creation controversy.

Misconception #1: Argument That “Evolution Is Only a Theory”

One common misunderstanding is that the use of the term *evolution* as a theory means that it is no more than a guess or wild speculation. In science, a theory is a complex and well-conceived working hypothesis for how a given system functions. Many theories are accepted as well-established scientific principles. Science constructs working hypotheses

to ask and answer queries on a subject, which are tested in specifically designed experiments to yield clear results. These experiments and their results can be repeated and verified by other scientists. Evidence for or against a hypothesis is thus gathered through measurement, calculation, deduction, observation, and experimentation. This evidence can be presented to an international scientific community and can be assessed by all, and when a new discovery is made, theoretical explanations change. Scientific theory can thus be seen as the best explanation at a given time in history to account for the evidence available.

Misconception #2: Science “Contradicts” Religion

While science is based on testable, replicable methods, religion is a belief system through which the world is perceived, which comes from a different source of human experience. Many scholars note that science, in itself, does not support or refute religion. Rather, it is the worldview of the individual interpreting the science (Pennock, 2003; Van Till, 1998) that can make science seem for or against a particular religious belief. A scientist who does not believe in a higher power may reduce reality to the material, sensory world and may feel that understanding the mechanisms by which something works eliminates the need for any other types of explanations. In contrast, a scientist with theistic belief may see each new discovery as a testament to a higher being, with the mechanisms of this discovery revealing information about the way this power has worked in the universe. In this way, science and religion are capable of adding meaning to one another. A poll in the 1990s by the University of Georgia revealed that 40% of working physicists and biologists in the United States claim to have strong spiritual beliefs. This suggests that faith and science are, for many experts, not mutually exclusive.

Although religion and science are not intrinsically incompatible, this is one of the common misconceptions perpetuated by the evolution/creation controversy. Many scholars note that the notion that one must choose between believing in science or religion, evolution or creation, is false and even contradicts Darwin's own writings (Bleckmann, 2006; Pennock, 2003; Szebenyi, 2005; Van Till, 1998).

Misconception #3: Creationism Is as Scientifically Valid as Evolution

Although versions of creationism such as ID are still taught in U.S. schools, this does not mean they are valid scientific alternatives on par with evolutionary theory. There are many areas of active research in evolutionary biology and many disagreements among scientists on the specifics of the evolutionary mechanism; however, evolution has remained unchallenged in its main particulars for well over a century. There is no ongoing scientific debate about the

validity of evolutionary theory. Rather, the scientific community and numerous court hearings worldwide have declared that the theory of evolution is scientifically sound, while creationism is not.

Misconception #4: Scientists Think Evolutionary Theory Explains How Life Originated

A further misconception about evolution is that evolutionary theory has shown how life on Earth originated. Scholars note that this misconception inflames many creationists, who may otherwise be more open to evolutionary ideas. Although biological evolution is supported by the results of thousands of experiments, life's origins have not yet been determined. Darwin suggested in 1871 that life may have originated in some ancient pond, and biochemist Stanley Miller conducted famous “primordial soup” experiments in the 1950s. Miller found that in specific environmental conditions meant to mimic Earth's atmosphere billions of years ago, amino acids could be produced using a mixture of chemicals and adding electricity. Since proteins found in living organisms are made from amino acids, they were seen as a precursor to life. However, more recent researchers think that Earth's early atmosphere was unlike that simulated by Miller. New theories suggest that life may have originated on solid substrates and not in an aqueous environment at all. How life originated is currently an open area of scientific investigation.

The American public continues to see creationists pitted against modern evolutionary theory.

Manifestations of the Evolution/Creation Controversy in Other Countries Worldwide

Although the evolution/creation debate has had the most far-reaching influence in the United States, many other countries have been influenced by creationist teachings, and some smaller movements have emerged worldwide.

Australia

Australia has a growing fundamentalist Christian and creationist population. In 1980, the Queensland state government allowed creation science to be taught in schools. Since this time, the teaching of creationism alongside evolution has been a widespread problem in Australian schools, and some lawsuits have resulted (Beverley, 2002).

Europe

In Europe, there have been a few unsuccessful efforts by creationists to have forms of creationism, such as ID, taught in various European schools. Presentation of any form of creationism in schools was strongly opposed in 2007 by the

European council, who deem it a type of religion and not science (Feedback, November 2007).

Middle Eastern Countries

In some Islamic Middle Eastern countries, such as Saudi Arabia and Sudan, it is illegal to teach evolution in schools. Other countries such as Turkey and Egypt have much public support for creation science (Pitock, 2007).

Future Directions: Ways to Alleviate the Controversy

Experts suggest that the primary way to lessen the evolution/creation controversy worldwide is through improved science education (Beverley, 2002; Moore, 2007; Pennock, 2003).

Teach Evolution Clearly

The theory of evolution is considered the most plausible explanation for the diversification of life presently known to science; therefore, it has been suggested that evolutionary theory alone be taught in classrooms. It has also been suggested that teachers not present the controversy surrounding evolution or the evidence against evolution because these approaches mislead students about evolution's validity. Activities to educate students about the nature of science and to develop their scientific inquiry skills could be presented instead (Beverley, 2002; Moore, 2007; Pennock, 2003; Pigliucci, 2003; Moore, 2007).

Do Not Mix Science and Religion in the Classroom

Experts also suggest that science be taught in a religiously neutral way to avoid either misrepresenting the facts of science or offending individuals who are religious believers. Teachers might consider avoiding reference to their personal beliefs while in the classroom, since this may bias students and perpetuate the controversy (Beverley, 2002; Moore, 2007; Pennock, 2003).

Improve Teacher Education

Teacher training and continuing education could include training on how to teach evolutionary theory.

Scientists suggest that through these types of improved science education, the evolution/creation controversy can be alleviated (Moore, 2007; Pennock, 2003).

Conclusion

Despite the acceptance of evolutionary theory by the worldwide scientific community, the topic continues to be

controversial. Murray and Buffaloe noted that "the vast mainstream of theistic interpretation has long ago assimilated the concept of evolution into its faith perspective, along with modern astronomy, the atomic theory, and other scientific findings" (1983, p. 464). However, creationists from fundamentalist groups worldwide assert that no compromise is possible between evolution and religious faith. This extreme stance has also led some scientists to believe that evolution and spiritual belief are incompatible. The evolution/creation controversy has endured since 1859 and shows no sign of abating in the near future. Experts predict that this acrimonious debate will persist for some time to come.

PART X

PRIMATE RESEARCH

PRIMATE TAXONOMY

JOHN R. GREHAN

Buffalo Museum of Science

Primate taxonomy contributes to the science of anthropology by providing an evolutionary framework for the biological and cultural origins of human behavior. But taxonomy involves methods and principles that are not always readily accessible to the anthropologist who may depend upon the results of taxonomic research to interpret the evolution of human behavior. This juxtaposition of disciplines is particularly challenging for the anthropologist when taxonomic research either fails to provide a resolved classification for humans or other primate groups, or it requires the reevaluation and even falsification of long established units of classification. These taxonomic challenges are relevant to anthropological interpretation because the units of taxonomic classification are arranged to reflect hypotheses about evolutionary relationships. With these practical and conceptual challenges in mind, this review will examine the principal developments and issues of contention, as well as the main outlines of primate taxonomy at the beginning of the 21st century.

Taxonomy

The modern system of classification (the rules for naming and arranging taxa) is derived from the binomial system of Linnaeus who provided a genus and species epithet unique to each species and placed them within a hierarchal arrangement of successfully inclusive groups.

These units were proposed at a time when the similarities and differences among groups were seen to be the result of common design rather than shared descent. Following the publication of *On the Origin of Species* (Darwin, 1859), the widespread acceptance of evolution represented a major theoretical development where taxonomic units could now be seen to represent organisms sharing descent from a common ancestor. In practice, the process of classification was not radically altered as many approaches to recognizing groups or organisms were intuitive. Taxonomists often produced classifications based on characteristics that were thought to be particularly important for the evolution of a group or represented an amalgam of various characteristics to give some level of apparent coherence or stability in classification. Classifications also often emphasized overall similarity so that groups such as the reptiles and the great apes were each grouped together because they appeared to be more similar to each other than to other groups of species. As research into the theory and method of classification developed during the 20th century, there was an increasing awareness that similarity alone could not be assumed to indicate a close evolutionary relationship. The evolutionary challenge for taxonomists was to identify those similarities that provided evidence of common descent rather than those that may have evolved in different lineages or those that are misleading because they represent primitive retentions that have been lost in some

members of the group, so the remaining species are grouped together because they share ancestral characters.

Taxonomy and Systematics

A direct correspondence between evolutionary relationship and taxonomic classification was made possible through the development of *cladistic* methodology. The first detailed outlines of this method were made by Daniele Rosa (1918), but it did not become popular until after the English translation of Hennig's *Phylogenetic Systematics* (1966). Following a decade of sometimes contentious debate in the 1970s and early 1980s, cladistics became the standard methodology for reconstructing evolutionary relationships and identifying natural, or *monophyletic*, groups that include all descendants of a hypothesized common ancestor. Monophyletic groups are recognized by the shared presence of one or more unique features that are assumed to have been present in the common ancestor and therefore retained in all the descendants. As speciation occurs, each individual descendant may evolve further unique features that are in turn inherited by their descendants. This process results in a hierarchy of groups that are each characterized by uniquely shared features, or *synapomorphies*. Synapomorphies for a particular group represent ancestral features for member taxa. For example, the presence of at least one flat nail on the foot represents a primate synapomorphy, but within the primates, the presence of a flat nail on any individual primate species provides no information on their evolutionary relationships with other primate species. Similarly, the presence of body hair exemplifies modern mammals as a natural group but is uninformative about the evolutionary relationships of particular mammal groups or species with each other.

Perhaps the most fundamental consequence of cladistic reasoning for primate taxonomy was the requirement that all natural groups be monophyletic. The criterion for monophyly required that all members had to be not only descended from a unique common ancestor but also that *all* descendants were included in the group. In some non-cladistic classifications, there was an emphasis on separating out groups based on their sharing primitive features. This resulted in artificial, or *paraphyletic*, groups that failed to represent the actual pattern of evolutionary descent by leaving out taxa that had lost the primitive features due to the evolution of more derived features. Only by grouping organisms together according to their shared derived features is it possible to eliminate paraphyly. A classic example is the family Pongidae, which was originally designated to encompass all the great apes. But this group is paraphyletic because at least one great ape species is more closely related to humans than other great apes (see below under monophyly of hominoids).

Cladistic classification is always comparative. It is not sufficient, for example, to note that within the primates,

monkeys share with hominoids (apes and humans) the presence of a fused jaw. This comparison only indicates that they are similar to each other in this respect. What is necessary for understanding this similarity as evidence for an evolutionary relationship is that these two groups are more similar in sharing the presence of a fused jaw than a third group, such as the prosimians (that do not have a fused jaw). To have some confidence that the unique similarity of the monkey and hominid jaws is inherited from a unique common ancestor not shared with prosimians (these three taxa together representing the in-group), it is necessary to demonstrate that the feature is absent from a fourth, external out-group. Theoretically, all other life-forms comprise the out-group, but in practice, the out-group is more circumscribed. For example, comparison of Primates with an out-group comprising other mammal orders shows the presence of a fused jawbone to be relatively rare outside the Primates, being found in a few groups such as wombats, mystacinid bats, and pigs. This occasional occurrence in the out-group suggests that within Primates the fused jaw bone represents a separate development supporting the hypothesis that the fused jaw shared by monkeys and hominoids is the result of their being more closely related to each other than prosimians and that together (as anthropoids) they represent a natural phylogenetic group.

If the distribution of synapomorphies was consistent, then there would be only one hierarchical set of characters and only one classification. In practice, the distribution of unique features may indicate more than one possible set of evolutionary relationships and arrangement of taxa. Species A may share one or more unique characters with Species B but also share one or more unique characters with Species C. In this situation, systematists will choose the larger set of characters as being more likely to represent the correct evolutionary relationship because it minimizes the number of times it is necessary to explain the independent origin of false similarities originating in lineages that have already separated. There are also problems created by the loss of features—the Madagascan primate *Daubentonia* lacks a toothcomb, a feature that otherwise defines all prosimians, for example. If other features are consistent with *Daubentonia* being a prosimian, then this anomaly is viewed as the loss of a toothcomb rather than its never having been present (which would require that *Daubentonia* not be a prosimian as currently defined).

When a small number of taxa and characters are being analyzed, it may be a relatively simple procedure to sort out the best supported set of relationships. With larger numbers of taxa and characters supporting different relationships, the sorting procedure becomes much more complicated and requires computer algorithms to sort through the different possibilities. Even then, it may not be possible to find a consistent answer, especially where the numbers of characters supporting different evolutionary relationships are identical or nearly so. One confounding problem in primate

taxonomy is that some classifications that are characterized as being cladistic include analysis of features where some or all of the conditions of the in-group are also present in the out-group. This practice is not cladistic and may result in erroneous evolutionary relationships.

It is the nature of systematics that after years of comparative study, it may still be impossible to resolve the evolutionary relationships and classification of one or more taxa, and it is never possible to predict whether further study may not result in the discovery of other derived features that support an alternative to the accepted theory of relationship. It may not be possible for any one technique or only one aspect of an organism's biology to consistently and accurately reflect evolutionary relationships. It is probably a truism that organisms will always show features that could support more than one theory of relationship. In this respect, some taxonomic categories may always be ambiguous.

Molecular Taxonomy

The application of *molecular techniques* to primate classification is widely characterized as a powerful tool for resolving the classification of primates, particularly where morphology has previously given uncertain or ambiguous results. Molecular evidence is also widely seen to represent a better alternative to morphology because molecular techniques allow rapid comparison of many taxa without being confronted with the necessity of engaging in extensive and prolonged comparative analysis of individual characters to identify homologies as is the case for morphology. Instead, there is the apparent simplicity of analyzing the presence or absence of just four base pairs that may replace each other in different species. In the absence of each character being individually justified, the molecular technique is widely seen to be reliable because thousands of bases can be compared with the intuitive assumption that the sampling of large numbers increases the likelihood of finding a correct relationship.

The evolutionary problem for primate taxonomy represented by morphological and molecular techniques is that they do not always produce the same result. A widely accepted principle of molecular systematics is that strongly supported molecular similarities are correct even when they conflict with morphologically based classifications—although this determination is not always consistently applied—sometimes, molecular results are rejected when they conflict with strongly accepted morphologically based classifications. Molecular similarity was originally validated as evidence for evolutionary relationships by its general correspondence with well-established morphologically based classifications. Morphological evidence was later treated as suspect and usually rejected when not supported by molecular similarity. Currently unresolved

incongruities between molecular and morphological evidence include the monophyly of Madagascan lemurs, the relationships of tarsier and other primates, and the monophyly of great apes.

Although widely seen as a panacea for systematics and classification, molecular systematics lacks a comprehensive theory of homology (a principal of similarity that identifies a unique common ancestry). Evidence for molecular homology is limited to a set of four nucleotides and their relative position (sequence order). As in morphological data, shared similarity in DNA sequences can be due to primitive retention, reversal, or nonhomology (e.g., convergent). DNA sequences are further inherently ambiguous because substitutions leave no evidence of former replacement that would indicate whether matching base pairs represent primitive retention, convergence, or unique derivation. To match homologous base pairs shared between different primate species it is necessary to artificially make the genes the same length by creating changes to the relative positions by creating gaps between bases as inferring associated base substitutions. This alignment procedure requires mathematical models that generate a compromise fit to minimize gaps and substitutions. The resulting homology of each base is the product of the overall similarity created by the algorithms. In this procedure, there is no empirical evidence for the homology of individual bases and no way to know what bases represent primitive retentions or uniquely shared novelties, the latter being essential for cladistic analysis. Other potential problems include inadequate out-group sampling (often just a few species) in characters in the out-group being overlooked, the continued use of noncladistic techniques, such as distance measures that only measure overall similarity, and other methods such as maximum likelihood, which are based on theoretical models of what the correct phylogeny should be.

Taxonomic Categories

Taxonomic classification represents a list of named groups arranged in a hierarchical series of subordinating units based on the species, genus, family, order, and class categories along with various other intermediate or higher ranks. As monophyletic groups, these taxonomic labels may represent a natural classification for evolutionary relationships, but the number of groups, their scope, and their rank are entirely arbitrary. There is no necessary corresponding taxonomic significance for the same rank (e.g., family) compared between different lineages. For example, the family Hominidae may include only 1 (humans) or 6 species (humans and great apes) depending on how broadly the category may be applied. Similarly, the Hylobatidae (lesser apes) encompass a single genus and about 11 species. In contrast, the family Cercopithecidae (Old World monkeys) comprises at least 22 genera and

80 species. In some cases, restricted higher-level taxonomic categories are used to emphasize how particular primates are seen to be more different or more evolutionary significant than others. This has occurred with the use of Hominidae as a restricted family rank. Focusing on taxonomic ranks rather than evolutionary relationships can impede rather than advance the understanding of primate taxonomy.

The smallest evolutionary units of taxonomy represent a major area of research in primate taxonomy. Over the last century, there has been a continual expansion of the number of species with a concurrent debate over whether various subspecies represent geographic variants or distinct species in their own right. Naturally, the search for an objective and universal definition of a species has been a constant concern, not only for primate biologists but also for taxonomy in general. One criterion has been the absence of interbreeding, but this becomes problematic for taxa that are geographically isolated and do not interbreed simply as a geographic constraint. Some systematists favor the identification of the smallest cluster of monophyletic organisms that can be separated by a unique combination of character states. This approach has been extended to the use of DNA sequences such that any unique DNA sequence shared by some individual organisms may constitute a distinct species. In practice, primate species are identified with respect to particular places and times, and their resulting taxonomic status may or may not be controversial.

Defining Primates

Primate Characters

The modern concept of Primates has its origins with Karl Linnaeus's 1735 work *Systema Naturae*, where he proposed the group Anthropomorpha to include monkeys (*Simia*), sloths (*Bradypus*), and humans (*Homo*) based on their sharing the presence of a single pair of pectoral mammary glands. This classification was historically important for including humans within the taxonomy of other organisms for the first time. The name of the order was then changed to Primates in 1758 when Linnaeus also excluded sloths while also adding lemurs, bats (later removed by Johann Friedrich Blumenbach), and apes (the latter under *Simia*). A more extensive set of similarities was also identified to include the presence of four upper and four lower incisor teeth, parallel-sided lower anterior teeth, a pair of projecting canineline teeth in the upper and lower jaws, limbs terminating in hands or structures that functioned like hands, arms that were separated by clavicles, locomotion mostly on all four limbs, tree climbing, and fruit consumption. This new definition accommodated lemurs while excluding sloths, and it applied to bats if they were broadly viewed as having grasping feet.

Subsequent classifications frequently separated humans by placing them in their own group such as Bimanes, or Bimana, while the remaining four-handed primates were classified as Quadrumanes, or Quadrumana. Many early taxonomists regarded the possession of two hands in humans as sufficient justification to separate them from the rest of the animal kingdom. In 1811, Karl Illiger separated *Homo* from all other animals by their erect posture, and he also applied the term Prosimii for lemurs and lorises while *Tarsius* was placed in the Macrotarsi to emphasize their development of highly elongated tarsal bones. Separation of humans from other animals largely persisted until 1883 when William Henry Flower included the genus *Homo* in a classification that persisted into the 20th century. He also divided the primates into the suborders Lemuroidea (lemurs, lorises, tarsiers) and Anthropoidea (monkeys, apes, humans). The Lemuroidea was further subdivided into the families Lemuridae (lemurs, lorises, bush babies), Tarsiidae (tarsiers), and Chiromyidae (aye-aye). These primates came to be known as the "lower" or most primitive primates with lemurs being the most primitive of all. Tarsiers were initially grouped with galagos before being separated into their own group (Macrotarsi), leaving galagos, lemurs, and lorises in the Prosimii. As a separate family, tarsiers were then again grouped with lemurs, lorises, bush babies (Lemuridae), and the aye-aye (Chiromyidae) in the suborder Lemuroidea until this name was replaced by the Prosimii. Tarsiers were then separated from the prosimians by Pocock in 1918, who grouped them with anthropoids in a new suborder called Haplorrhini where the tarsiers were labeled the Tarsoidea and the anthropoids in the Pithecoidea (now Anthropoidea). The remaining prosimians were renamed the suborder Strepsirrhini. The haplorrhine classification was largely overlooked until the 1970s and 1980s when various features were widely seen to indicate a closer relationship between tarsiers and anthropoids than prosimians. Further support for the Haplorrhini was also found in various molecular comparisons of DNA although other studies continued to support the inclusion of tarsiers within the Prosimii.

Flower grouped the New and Old World monkeys, and hominoids (apes and humans) together under the Anthropoidea. The New World monkeys were further divided into the families Hapalidae (marmosets), and Cebidae (larger prehensile-tailed monkeys). The Old World monkeys were placed in the family Cercopithecidae comprising with two subfamilies, Cercopithecinae and Colobinae. Apes were initially assigned to the family Simiidae while humans were represented by the family Hominidae. The emphasis on distinguishing primitive taxa reflected a widely held notion that it was possible to line up lower primates in a sequence of increasing complexity leading to "higher" primates from prosimians to anthropoids.

The definition of primates also continued to evolve. In an effort to further clarify the primates definition, St. George Mirvart proposed a broad set of features in 1873: presence of nailed digits, clavicles, orbits encircled by bone, three types of teeth during the life of an individual, a brain with a posterior lobe and calcarine fissure, innermost digits opposable for at least one pair of limbs, a thumb with or without a flat nail, a well-developed cecum, and pendulous penis, scrotal testes, and two pectoral mammary glands. The possession of a thumblike digit to one part of limbs accommodated the inclusion of humans. These characters are all taxonomically problematic because they are not specific to primates and therefore not cladistically informative for understanding the monophyly of primates. The three teeth types also occur in some marsupials and placentals, such as pigs and bears. Most mammals also have a well-developed cecum and scrotal testes also occur in carnivores such as cats. Two pectoral mammary glands are present in sloths, bats, and flying lemurs, and a posterior cerebral lobe with calcarine fissure also occurs in tree shrews. The clavicle is found in other mammals and even reptiles. Possession of an opposable thumb or big toe is not restricted to primates, but it is rare in other mammals. Of these features, only the development of at least a flattened nail on the big toe is distinctive for extant primates.

Primates are often characterized as having thumbs and big toes that are divergent, flattened nails at least on the big toe and a postorbital bar behind the eye. These features are individually present (although rare) in some other extant mammals, but only primates have all. But all living primates (tarsiers, lemurs, anthropoids) share at least six unique characteristics of the cheek (molar) teeth: (1) low rounded cusps (bunodont) with the sides of the upper molars being filled out rather than concave, (2) anterior outer cusp (paraconid) of the first lower molar positioned more toward the cheek (buccal) than the anterior of the tooth, (3) upper molars with a shallow angle (entoflexus) between the protocone and metacone, (4) trigonid (anterior half of the lower molar) not much taller than the (posterior) talonid, (5) talonid at least as long and broad as the trigonid, and (6) an oblique crest between the hypoconid and metaconid (cristid obliqua). Since these are all hard tissue features, and teeth are often the only fossil remains of extinct primates, they can be used to determine whether various fossils fall within Primates as characterized by its living members.

Recognizing Fossil Primates

The primate fossil record often presents a taxonomic challenge because in the absence of soft tissue features, all taxonomic assignments must rely on the evidence of hard tissue features. The scope of evidence is further reduced

for many fossil taxa where skeletal material is incomplete and in some cases limited to a few bones or teeth. Some fossil taxa may remain chronically indeterminate until sufficiently complete samples are found. Integration of fossils within the taxonomy of living primates requires recognition of the same diagnostic features, but this is often lacking or is poorly documented for fossils, particularly those that are represented by only a few dental or other fragments. A recent example is the *Anthrasimias gujaratensis*, represented by three molars and one deciduous premolar. It was characterized as the earliest Asian fossil anthropoid recorded to date even though there were no diagnostic characters identified as being anthropoid or even primate. Efforts to classify fossils in relation to living taxa using parsimony or other computational methods may also be confounded by a prevalence of missing character states that contribute to poorly resolved phylogenies, even though the evolutionary relationships and taxonomic groupings may be unproblematic for the living taxa. Many fossil taxa remain, at this time, subject to future evaluation and the likelihood that the monophyly of some groups will be rejected and new taxonomic categories will be recognized. With this contingency in mind, the taxonomic arrangement of all fossil primate taxa must be regarded as subject to future revision.

A major question in primate classification has been the identification of its most primitive representatives in the fossil record that may not exhibit all features present in extant primates. This has been the situation for Plesiadapiformes, a group of fossils from the Paleocene, Eocene, and Oligocene of North America and Europe mostly represented by fragmentary jaws with teeth or isolated teeth. They conform to primates in their dental characteristics, but some skulls (such as for *Plesiadapis*) lack a postorbital bar. The typical primate's grasping hands and feet and flattened nails are also missing in *Plesiadapis*, but *Carpolestes* had a grasping foot with flattened nail as well as a grasping hand. This range of variation suggests that the defining features for all modern primates may have emerged at different times with mammals first evolving into primates in their dental characteristics and later in their skull, hands, and feet. This pattern of similarity may be interpreted taxonomically in two different ways. Either the definition of primates is limited to dental features in which case Plesiadapiformes are included within the primates, or the definition of primates is limited to the inclusion of all features found in modern primates in which case Plesiadapiformes may be considered an extinct primate relative but not a member of Primates as defined by the living taxa. Either way, the Plesiadapiformes represent the closest fossil primate relative, but this relationship may be represented by two different taxonomic arrangements according to whether the order Primates is defined to include or exclude the Plesiadapiformes (after Schwartz, 1986):

(a) *Inclusion within Primates***Order Primates**Suborder Plesiadapiformes
Suborders of living primates(b) *Exclusion from Primates***Order Plesiadapiformes**Order Primates
Suborders of living primates

The taxonomic status of other proposed primate fossils are more problematic. *Eosimias* and *Bahinia* have been identified as anthropoids even though they apparently lack dental features characteristic of living primates. Other fossils such as *Wailkia* and *Siamopithecus* are dentally primate, but their relationships within Primates are problematic because of inconsistencies between apparent similarities that would relate them either to anthropoids or prosimians.

Primate Classification

The living primates are represented by about 355 proposed or recognized species. The taxonomic composition of primates will continually be modified according to new interpretations of evidence about relationships, as well as new discoveries that alter the taxonomic position of known species or add new species and even genera. An increasing number of primatologists working in primate classification have rapidly increased the number of recognized species, although some may be poorly supported and possibly erroneous. There may also be differences over whether individual primate groups are recognized as species or subspecies, so the total number of primates will likely vary over time as well as between different classifications.

Primate classifications of living primates are represented by two alternative subordinal arrangements. The oldest classification divides Primates into the suborders Prosimii (lemurs, lorises, tarsiers) and Anthropoidea (monkeys, apes, humans). Prosimians were originally viewed as an assemblage of primitive primates in contrast to the more “advanced” simians (monkeys, apes, and humans). In this context, prosimians were a group by default—what was left over after exclusion from the anthropoids. Over the latter half of the 20th century, increasing interest has focused on an alternative division of the Primates into the suborders Strepsirrhini (prosimians without tarsiers) and Haplorrhini (tarsiers along with monkeys, apes, humans). Strepsirrhini refers to the presence of a nostril with a lateral slit or crease (*strepsis* means “twisting,” referring to the upward twist at the back end of the nostril slit), a primitive condition found in most mammals. Haplorrhini refers to a simple or unadorned (*haplos*) condition, although tarsiers and various New World monkeys are morphologically strepsirrhine in having laterally creased nostrils. The contrasting theories of relationship generate two possible classifications depending on whether tarsiers are more closely related to lemurs and lorises (Prosimii) or to the anthropoids (Haplorrhini). Table 61.1 illustrates alternatives with respect to the living Tarsiiformes represented by the single genus *Tarsier* with about seven species and Lorisiformes represented by the families Lorisidae (lorises of Africa, India, and Southeast Asia) and Galagonidae (galagos and bush babies of Africa). A third infraorder, Chiromyiformes, has also been proposed for the Strepsirrhini to represent the monotypic aye-aye, *Daubentonia madagascarensis*, which is otherwise usually placed within the Lemuriformes. The three main alternative classifications are illustrated below with example sources.

Table 61.1 Higher Classifications of the Primates

Suborder Prosimii (Martin, 1990)	Suborder Strepsirrhini (Shoshani et al., 1996)	Suborder Strepsirrhini (Groves, 2001)
Infraorder Tarsiiformes	Infraorder Lemuriformes	Infraorder Lemuriformes
Infraorder Lemuriformes	Infraorder Lorisiformes	Infraorder Lorisiformes
Infraorder Lorisiformes		Infraorder Chiromyiformes
Suborder Anthropoidea	Suborder Haplorrhini	Suborder Haplorrhini
	Semisuborder Tarsiiformes	Infraorder Tarsiiformes
	Semisuborder Anthropoidea	Infraorder Anthropoidea

SOURCES: Groves (2001); Martin (1990); Shoshani et al. (1996).

NOTE: Martin (1990) proposing two suborders with tarsiers grouped with lemurs and lorises; Shoshani, Groves, Simons, and Gunnell (1996) also proposing two suborders but with tarsiers grouped with anthropoids; and Groves (2001) with the same subordinal arrangement but separating the aye-aye (*Dubentoniidae*) of Madagascar as a distinct infraorder (*Chiromyiformes*).

Tarsier Relationships

Tarsiers are unique among primates in having scales around the nipples and under the tail, a tail that is longer than the body, a head that can turn 180 degrees in either direction, and a bulging, immobile eye larger than the brain. They also have sinus hairs outside the nasal cavity, hairs on upper and lower lips, the longest tarsal bones, and three fully developed cusps on the anterior part of each lower molar and pointed cusps on all teeth anterior to molars, and tarsiers are the only specialist primate carnivore. A principal question in prosimian classification concerns the relative position of *Tarsius*, a primate genus that has been controversial from the beginning of modern primate classification when it was at first not even recognized as a primate (Linnaeus later classified it as the primate *Simia syrichta* in 1758).

The distinctiveness of tarsiers has often represented a taxonomic distraction with the differences emphasized by its frequent allocation to a group of high taxonomic rank and uncertainty about its evolutionary relationships with other primates. Tarsiers have been closely identified with both prosimians and anthropoids. Their inclusion within prosimians was emphasized in earlier classifications, but current morphological evidence is limited to relatively few—but potentially significant—uniquely shared features. Tarsiers along with other prosimians have a clawlike nail (called a grooming claw in Lemuriformes and Lorisiformes) on the second toe of the foot (tarsiers are unique in also having a claw on the third toe). Tarsiers are unlike other prosimians in lacking a set of slender, elongate incisors (four or two) and canines that are either horizontal or upwardly tilted. Collectively, these teeth are characterized as a “toothcomb” used in grooming and sometimes feeding. Tarsiers have only two small, vertical anterior teeth, and in this respect, they do not have a toothcomb. One possibility is that tarsiers have lost the full set of anterior teeth found in other prosimians. This possibility is illustrated by the sifaka lemur where there are only four toothcomb teeth compared with six in other lemurs and loris. If tarsiers lost a further two teeth, then there would no longer be a recognizable toothcomb structure, and it has been suggested that the two anterior teeth of *Tarsius* show a similar transverse rounded shape with lateral borders to the outer anterior teeth of other prosimians.

In contrast to the few proposed uniquely shared similarities between tarsiers and prosimians, a relatively large number have been proposed for tarsiers and anthropoids. If all or most are correct, then they would provide less ambiguous evidence than molecular studies that have been divided between those that support a prosimian relationship and those that support an anthropoid relationship. Some of these features are problematic. Tarsier eyes lack a tapetum (a reflective layer of the retina) and in this respect are more like anthropoids than prosimians where a tapetum is said to be present, but several species of *Eulemur* and possibly *Varecia variegata* also lack a visible tapetum

(i.e., lack light reflection), although it is not known whether this indicates the absence of a tapetal layer. The completely fused upper lip of tarsiers is often characterized as an anthropoid trait, but it does not apply to various New World monkeys that have a groove (philtrum) down the midline of the upper lip indicating that fusion is not complete. Tarsiers and anthropoids have haemochorial placentation, but the similarity may be superficial, resulting from different developmental paths. The apparently short, anthropoid-like face of tarsiers (that is even shorter than some anthropoids) may be an artifact of enlarged eyeballs extending over the snout, and the partial postorbital closure in tarsiers and New World anthropoids involves different bones. In these and various other characteristics the correct homology and morphology is in dispute while some others such as the inability to manufacture vitamin C in tarsiers and anthropoids may be valid. In view of the morphological and molecular disagreements, the taxonomic position of tarsiers currently remains beyond consensus.

Fossil Prosimians

The fossil record is replete with many prosimian fossils that range from relatively complete skulls that are sometimes associated with postcranial remains and the many more largely fragmentary jaw fragments and isolated teeth. The absence of soft tissues that may otherwise provide critical evidence and the disparity of fossil representation render the accurate placement of many fossil taxa highly problematic, and many may remain irresolvable unless more complete fossils are found in the future. Some fossil prosimians are considered to lie outside the modern families and have been classified as members of families that are no longer extant, including the Protoadapinae, Omomyidae, Microchoeridae, and Adapidae. Membership within these families is sometimes problematic and influenced by assumptions about the relative size, location, and geological age of relevant fossils.

Monophyly of Lemuriformes

The lemurs of Madagascar comprise the families Cheirogaleidae (dwarf/mouse lemurs), Daubentoniidae (the aye-aye), Megaladapidae (Lepilemuridae; sportive lemurs), Lemuridae (lemurs), and Indriidae (indri). These families have traditionally been regarded as a monophyletic group called the Lemuriformes while the remaining prosimians were represented by the Lorisiformes (galagos and lorises). This monophyly has been challenged in some studies that support placement of the Cheirogaleidae within Lorisiformes and isolating the Daubentoniidae as a separate prosimian infraorder. These different systematic relationships may be represented by three principal alternative taxonomic arrangements (see Table 61.2).

Table 61.2 Alternative Classifications for Prosimian Primates

Suborder Prosimii (Schwartz, 1986)	Suborder Strepsirrhini (Shoshani et al., 1996)	Suborder Strepsirrhini (Groves, 2001)
Infraorder Lorisiformes	Infraorder Lorisiformes	Infraorder Loriformes
Family Cheirogaleidae	Family Lorisidae	Family Lorisidae
Family Lorisidae	Family Galagidae	Family Galagidae
Family Galagidae	Infraorder Lemuriformes	Infraorder Lemuriformes
Infraorder Lemuriformes	Family Cheirogaleidae	Family Cheirogaleidae
Family Lemuridae	Family Lemuridae	Family Lemuridae
Family Indriidae	Family Indriidae	Family Indriidae
Family Megaladapidae	Family Lepilemuridae	Family Lepilemuridae
Family Daubentoniidae	Family Daubentoniidae	Infraorder Chiromyiformes
Infraorder Tarsiiformes		Family Daubentoniidae

SOURCES: Groves (2001); Schwartz (1986); Shoshani et al. (1996).

NOTES: Schwartz (1986) with three infraorders to include tarsiers and the Madagascar Cheirogaleidae grouped with lorises rather than lemurs. Shoshani, Groves, Simons, and Gunnell (1996) with two infraorders to exclude tarsiers. Groves (2001) with three infraorders to separate the aye-aye (Daubentoniidae) from all other lemurs.

Taxonomy of the Anthropeidea

In anthropoids, olfaction is further diminished while vision becomes functionally dominant and the orbits are more consistently directed forward. Major defining features include postorbital closure of the postorbital bar; fusion of the lower jaws at birth or, as with the frontal bones, early in development; a single-chambered uterus (also in anteaters); hemochorial placentation characterized by concentration of blood vessels into at least one disklike structure; and development of the amniotic sac membranes by folding in and around the growing fetus in contrast to invagination as found in tarsiers. Molar cusps are relatively low in height, the number of premolars is reduced from four to three, the lower molars no longer have an anterior cusp, and a large cusp is consistently present on the posterior upper molars. The following taxonomic arrangement within the Anthropeidea (treated here as a suborder) is stable to the superfamily level:

Suborder Anthropeidea (after Groves, 2001)

Infraorder Platyrrhini (New World monkeys)

 Superfamily

 Family Cebidae

 Family Aotidae

 Family Atelidae

 Family Pitheciidae

Infraorder Catarrhini (Old World monkeys, apes, humans)

 Superfamily Cercopithecoidea

 Family Cercopithecoidea (Old World monkeys)

 Superfamily Hominoidea (apes and humans)

The New World monkeys are characterized by a platyrrhine nose where the nostrils are oriented laterally

and separated by a fleshy septum. Since this feature is also found in many other mammals, it does not constitute a character supporting platyrrhine monophyly. Monophyly of Platyrrhini is supported by several morphological features, including separation of the frontal bone from the sphenoid and the presence of an external auditory meatus. Monophyly of this group is also supported in molecular reconstructions. Old World monkeys and hominoids have a catarrhine nose with a narrow nasal septum separating nostrils that are closely adjacent and more forward directed. They also have only two premolars in the upper and lower jaws (compared with three in New World monkeys) and the possession of an ectotympanic tube forming the opening of the ear. Some Old World Oligocene fossils also have three premolars, and the Old World fossil monkey *Aegyptopithecus* lacks an ectotympanic tube like the New World monkeys. These fossil taxa may represent extinct taxa that do not lie within the Catarrhini but are nevertheless more closely related to the Catarrhini than Platyrrhini.

Fossil Anthropeidea

Most fossils characterized as anthropoids exhibit sufficient features to be recognized as primates with confidence. But the earliest claimed Asian anthropoid, *Anthrasimias gujaratensis* of India at 54.5 million years ago (mya), lacks any described anthropoid or even primate features, so uncertainties over the phylogenetic position and taxonomic identification of such fossils remain a persistent problem. Other fossils such as (*Branisella*) can be recognized as anthropoid but cannot

be placed within the two extant infraorders, while other fossils can be placed within one or the other but only as extinct families or superfamilies. Examples include Parapithecidae within the Platyrrhini and Pliopithecidae (east Asia, Europe) within the Catarrhini. A variety of extinct families has been proposed for the Hominoidea including Dendropithecidae, Dryopithecidae, Proconsulidae, Ramapithecidae, and Victoriapithecidae (Africa) with various levels of general acceptance.

Monophyly of Hominoids

Hominoids comprise humans, great apes, and lesser apes. Their monophyly appears to be well supported and the category is taxonomically stable for living taxa. Hominoids are most well known for the absence of an external tail in contrast to all other primate groups. Hominoids also exhibit major alternations of body shape including a thorax that is broader than deep, a dorsal position of the scapula, an elongate clavicle, a broad separation between the infra-orbital foramen and a suture between the zygomatic and maxillary bones, a variable articulation of the ulna and triquetral, and a postnatal ossification in the distal humeral and proximal radial epiphyses. The lesser apes represent a well-established and stable taxonomic category represented by a single family Hylobatidae (gibbons and siamangs) comprising about 15 species in Southeast Asia. The number of recognized genera varies from one (*Hylobates*) to four (*Hylobates*, *Hoolock*, *Nomascus*, *Symphangulus*) due to different perspectives over their overall divergence or phylogenetic age.

The taxonomic arrangement of the remaining hominoids is far less settled with respect to the relationship between humans and great apes. Great apes are represented by three genera, *Pongo* (one or two species of orangutan in Southeast Asia), *Gorilla* (two or three species of gorilla in Africa), and *Pan* (two species in Africa). From the early to mid-20th century, African apes were increasingly seen to be more closely related to humans than orangutans. Darwin had also expressed this view, although this was a speculation based on the presumption that Africa rather than Asia would provide the necessary selection pressures for the evolution of humans. Chimpanzees and gorillas are indeed more similar to humans than the long-armed orangutan, which also exhibits distinctive and unique features, such as cheek pads in males and large vocal sacs and having a much more specialized arboreal existence. In these respects, orangutans are widely seen to be much more distantly related to humans than African apes.

Morphologically, the African apes would seem to represent a natural group since chimpanzees and gorillas share a suite of uniquely shared features, including their specialized knuckle-walking anatomy. But in the 1960s,

another line of phylogenetic evidence has led to the now almost universal view that chimpanzees are more closely related to humans than gorillas. This evidence was principally in the form of shared similarities in biological molecules, beginning with protein and amino acid similarities supporting an African ape relationship and later DNA sequence similarities that are greatest between chimpanzees and humans. The chimpanzee relationship was at first rejected by primate morphologists but has since become so firmly accepted that it has become a fact of evolution that is beyond question. The only anomaly with this molecular theory is the lack of morphological features uniquely shared between humans and chimpanzees. A few such features have been proposed, but they have proven to be erroneous or lack verification. This lack of uniquely shared morphological similarity would not necessarily represent a problem as it could be attributed to a paucity of such features in the last common ancestor of humans and chimpanzees or a loss of those features subsequent to their respective divergence. This possibility is, however, confounded by the fact that humans do share a large and broad set of unique or specialized features with the orangutan.

The orangutan relationship was first identified by primate systematist Jeffrey Schwartz (2005) who found at least 40 features that were either uniquely shared or nearly so between humans and orangutans including several dental features, such as cusp configuration and thick molar enamel (African apes are like most other primates and mammals in having thin enamel), a single incisive foramen, a foramen lacerum, an anterior-posteriorly short scapula with a vertical vertebral boarder and a relatively small supraspinous fossa, the widest spaced mammary glands, highest estrus production, absence of tumescence of female genitalia during ovulation, greatest degree of cerebral and Sylvian sulcus asymmetry, beard and mustache in the male, forwardly directed cranial hair, receded hairline at birth, and absence of ischial callosities. For any other group, this preponderance of morphological evidence would be widely seen as critical if not conclusive. But this has been precluded by the majority of primate and evolutionary biologists because it conflicts with molecular evidence that has been already declared infallible. The morphological pattern may, however, suggest that in this case at least the pattern of molecular similarity is misleading, perhaps as the result of pervasive and unrecognized primitive retentions in the distribution of base pair sequences.

Molecular grouping of humans and chimpanzees is also problematic because it is incongruent with the hominid fossil record (hominid here referring to any fossil relatives more closely related to humans than the nearest living great ape). The earliest accepted hominids (*Australopithecus*) fail to exhibit uniquely chimpanzee features and instead show the same skeletal features as humans and orangutans. In addition,

they show typically orangutan features, such as large, vertically inclined cheekbones with anterior facing roots, and a posteriorly thickened posterior palate. Analysis of these and other morphological features suggests that australopiths along with humans and orangutans comprise a monophyletic group. This monophyletic group would include the hominids *Orrorin* and *Kenyanthropus* along with the extinct great ape genera *Hispanopithecus*, *Ouranopithecus*, *Ankarapithecus*, *Sivapithecus*, *Gigantopithecus*, *Lufengpithecus*, and *Koratpithecus*, while excluding the purported hominids *Ardipithecus* and *Sahelanthropus*. The taxonomic implications are listed in Table 61.3, although fossil taxa cannot be included in the molecular taxonomy since fossils cannot (with the exception of subfossils) provide evidence of molecular similarity.

Table 61.3 Contrasting Classifications of Apes and Humans Resulting From Morphological and Molecular Techniques

Morphological Taxonomy (Grehan & Schwartz, 2009)	Molecular Taxonomy (Shoshani et al., 1996)

SOURCES: Grehan and Schwartz (2009); Shoshani et al. (1996).

a. fossil taxa.

NOTES: Both approaches recognize the lesser apes (Hylobatidae) as a separate family. The morphological approach places the African apes, orangutans, and humans each in their own family, along with fossil forms where recognized. Humans and orangutans are also recognized as being more closely related to each other, but this is not formalized in the taxonomic arrangement. The molecular approach differs by grouping African apes and humans together in the same subfamily and chimpanzees and humans in the same tribe.

Humans and great apes together comprise the large bodied hominoids. Molecular reconstructions have popularized extending the family Hominidae to include this group, including their fossil relatives. In addition to those fossils listed below, the large bodied hominoids include the fossil genera *Afropithecus*, *Ardipithecus*, *Dryopithecus*, *Nacholapithecus*, *Oreopithecus*, *Otaviopithecus*, *Periopithecus*, *Kenyapithecus*, *Sahelanthropus*, and *Samburupithecus*.

Future Directions: Primate Taxonomy in the 21st Century

It is impossible to accurately predict the course of primate taxonomy and systematics further into the 21st century, but at the beginning of this century, several outstanding problems represent actual or potential challenges for the future.

Diagnostic Characters

Even though cladistic principles are now generally accepted as the current standard of systematic analysis and taxonomic classification, the specification of the unique features that place a fossil within a given taxon are often unclear. Fossil descriptions and analyses are frequently muddled without a focus on primitive states that obscures the presence of derived conditions that would link the fossil with other living or fossil taxa. This is particularly evident where new taxa may be distinguished (particularly in the fossil record) without reference to any uniquely derived features to define the taxon or without reference to synapomorphies that would place it within a higher taxon. A classic example is *Homo floresiensis*, which was first described as a member of the genus *Homo* related to *Homo erectus* without citation of supporting evidence. It was later stated that the generic name was selected as a rhetorical device to prevent the fossil falling into obscurity, and the relationship with *H. erectus* appears to have been determined by default since this was the only other known hominid in the same region at the same time. Subsequent morphological studies have reinforced the status of this fossil as a distinct species (as some argued it was the result of microcephally in a primitive human) while at the same time highlighting features that relate *H. floresiensis* more closely with australopiths or early *Homo*. Publications on new hominid or presumed hominid fossils are particularly prone to this kind of problem when there is a lack of subsequent detailed studies to follow the initial rapid and superficial announcements (although the study of *H. floresiensis* is proving to be a notable exception).

Holotype Access

The scientific foundation of taxonomy biological systematics is the ability to provide empirical verification. This

is the essence of testing in science. Without verification, scientific propositions lose their scientific status and instead become metaphysical abstractions supported entirely by faith. In the study of comparative biology, this pitfall can be avoided only through access to the original material on which theories about identity and relationships are made. In taxonomy and systematics, this is made possible through access to the type material, the specimens to which taxonomic names are attached and from which character similarities are generated. It is the *holotype* in particular that provides the critical verification as it is the reference specimen for each species identity and consequently for relating all additional specimens. For each species, there is only one holotype, and it is essential that there is open access as recognized in the International Rules for Zoological Nomenclature. This requirement by the systematics community is, however, all too often thwarted through the deliberate withholding of access to individual researchers. This practice represents a deviation from the principles of science, and for one primate group in particular—the hominids—it has become a pervasive and persistent problem that continues into the 21st century. Another problem in primate systematics is the use of pseudoholotypes in the form of photographs that cannot be subject to further testing or investigation. This practice reduces primate taxonomy and systematics to the level of stamp collecting as it removes access to the original material and therefore fails the scientific requirement of empirical corroboration.

Molecular Incongruence

This is probably the elephant in the room when it comes to primate taxonomy. There has been an increased focus on molecular similarity as the basis not only for classification but also for delineating the smallest taxonomic units, such as species. Some approaches attempt “total analysis” that treats morphological and molecular similarity as the same kind of data, but this overlooks the inherent problems of homology and similarity that have yet to be adequately addressed in molecular analysis. Emphasis on the same result from different genes or from large data sets may seem to further corroborate the molecular result, but if the molecular comparisons are not actually between homologous derived character states, then the large numbers of similarities may reflect a similar prevalence of primitive retentions in molecular similarity as is often found to be the case in demonstrations of overall morphological similarity. The alternative possibility is that robust morphological relationships may represent a viable falsifier of molecular similarity, particularly when the morphological evidence among living taxa is consistent with hypothesized phylogenetic relationships between fossil and living taxa. One possible resolution of incongruence between morphological and molecular similarity may come when the connection between uniquely shared morphological traits and their molecular position within DNA is understood. The current inclination for primatologists to focus on molecular

similarity to reconstruct primate relationships and delineate taxonomic categories at the expense of morphological incongruence may represent a critical future problem for primate taxonomy and systematics.

Taxonomic Labels

From Linnaeus to the present, primate taxonomy is represented by a hierarchical system of names. At the close of the 20th century, some systematists have argued for a system of names without rank called the *phylocode*. Each node on a *cladogram* could be named, but they would have no corresponding rank. There would also be no species and no binomials. The purpose of the phylocode was to introduce stability into taxonomy—given the constant flux in phylogenetic relationships that currently lead to new taxonomic arrangements. This goal may be problematic since the taxonomic meaning of any one node is still contingent upon its relative position on a phylogenetic tree, and if current Linnean names are incorporated, there is no necessary way to determine how their meaning may have changed. The incorporation of additional taxa within a given clade would also change the meaning of that node, requiring that the definition of the name would have to be changed, or the name would have to be redefined in reference to an entirely different node.

The actual and potential problems for the phylocode system appear, at this time, to present no necessary improvement over the problems confronting Linnean taxonomy against a background of uncertain phylogenetic reconstructions. In systematics, all relationships are relative when the primary question is whether any two taxa are more closely related to each other than either is to a third. In this phylogenetic context, taxonomic categories and classifications are irrelevant and unnecessary other than as convenient labels to designate particular groups of organisms. Whether the 21st century is witness to some other entirely novel solution remains to be seen by those fortunate to be around so long.

Conclusion: The Future Nature of Evidence

It is anticipated that the major contentious questions over evolutionary relationships among the primates will continue to dominate taxonomy and systematics into the 21st century, particularly where different sources of evidence continue to give contradictory or ambivalent results. In addition to those questions of classification within the primates, there will no doubt be further exploration of the interrelationships of modern primates to other mammalian groups.

The future status of morphological systematics represents a major future question. Morphology is problematic when different researchers use different characters, and this identifies a future need for comprehensive and illustrated comparative documentation of features used

to define clades (and in turn the taxonomic groups linked to those nodes). Detailed comparative morphology is probably better known for some obscure insect groups than many primates, especially not (and perhaps most surprising) for the great apes that have been of so much interest for theories of human origin. In some major respects, primate taxonomy and systematics during the last half of the 20th century exemplifies the severe decline in the science of comparative morphology as the inverse mirror image of the rapid expansion of molecular biology. This decline is often evident in the lack of knowledge on comparative primate anatomy and biology, often including some of the most basic elements of biology, such as reproduction. The foundering of comparative morphology may be inconsequential if the promotion of molecular similarity is justified as the final authority on evolutionary relationships. But this status has yet to be seriously evaluated, and it may yet be possible that the 21st century will take a new look at the role and importance of morphology in the reconstruction of primate relationships and classification.

PRIMATE LOCOMOTION

DAVID ALEXANDER LUKASZEK

University of Alaska Fairbanks

The family of primates, ranging from 13 to 16 separate families, includes over 200 individual species. Within these grouped species is our own species, *Homo sapiens*. In terms of *primate locomotion*, expressed forms of locomotion include various forms of quadrupedalism, tripedalism, vertical climbing, leaping, tail swinging, suspensory, and bipedalism, as discussed in John Fleagle's 1998 book *Primate Adaptation and Evolution* (see also Hunt et al., 1996). *Bipedalism* is a remarkable form of locomotion. Though many nonhuman primates occasionally use a form of bipedalism, humans are the only primate species that uses a distinct and obligate form of bipedalism as a primary form of locomotion.

Similarities among nonhuman primates, particularly the great apes and the human primate in terms of morphological, physiological, and social characteristics has confirmed many early naturalists' views of humankind's origin and relationships with extant primates. Such shared characteristics within an evolutionary framework affirmed Charles Darwin's view on humankind's "lowly origin" with his summation that humans differ only in degree but not in kind from the great apes. With the discovery of fossil hominins and hominids, the classically "human" distinguishing features become less pronounced. As more fossil evidence is recovered, the scientific community is faced with questions regarding the emergence of human bipedalism among various forms of primate locomotion within the fossil record. Though the fossil record is incomplete and

recovered fossils have blended ape and human characteristics, bipedalism (at least in some form) is suggested to have existed about 6 million years ago. If these dates and the interpretation of the fossil evidence are correct, a nonhuman form of primate bipedalism and quadrupedalism coexisted farther back than previously estimated. Primate locomotion, similar to morphology, becomes an interesting aspect of our evolutionary descent.

Types of Primate Locomotion

The geographic distribution of primates is limited to the tropical, temperate, subalpine, and alpine biomes of South America, Central America, Africa (including Madagascar), Asia, and the Oceania areas. Nonhuman primates can be found in rainforests, seasonal forests, woodlands, savannas, semideserts, evergreen forests, elfinwoods, and meadows. With the addition of the human species, primates can be found throughout the globe and in every habitat. Considering the totality of the nonhuman primate species, a particular mode of locomotion is not species specific. Rather, activity (e.g., being diurnal or nocturnal) and arboreal stratification and terrestrial territoriality foster evolutionary competition. The habitual modes of locomotion for arboreal primates primarily consist of branch quadrupedalism and/or bipedalism and brachiation. Vertical climbing and leaping are the second and third most common mode

of locomotion, respectively. Suspensory behavior, including arms, feet, and tail, are least common.

Primate locomotion, whether arboreal or terrestrial, is determined on the physical terrain and by the placement of the upper and lower limbs in relation to the adjacent limbs. While in motion, hand and foot configurations can be palmigrade, plantigrade, or digitigrade, and manifest as knuckle-walking, fist-walking, grasp-walking, serpentine grasp-walking, schizodactyl grasp-walking, or clawed quadrupedalism (Hunt et al., 1996; Vilensky & Larson, 1989). Consequently, locomotive gaits among primates could be either symmetrical or asymmetrical, for example, an evenly timed footfall pattern as opposed to an unevenly timed footfall pattern. In addition, gait sequence can be either a diagonal sequence (DS) and diagonal couplet (DSDC) or a lateral sequence (LS) and lateral couplet (LSLC). In a diagonal sequence, the placement of the forefoot is followed by the diagonal hindfoot. The lateral sequence has the forefoot following the ipsilateral hindfoot. It is interesting to note that the human primate develops along similar patterns. During the emerging human locomotive development, both types of gait sequence and variations in locomotive behavior are normally experienced (Higurashi, Hirasaki, & Kumakura, 2009; Shapiro & Raichlen, 2005; Vilensky & Larson, 1989). Although primates use both DS and LS gaits, recent research suggests that DS gaits are preferred over LS gaits. DS gaits are almost exclusively used (Cartmill, Lemelin, & Schmitt, 2007; Stevens, 2008).

The latest accepted theory as to why primates prefer DS gaits is related to an increase in neurological pathways and an increase in neurological motor control in order to have balance control while on branches or terminal supports; however, there is disagreement on the advantage of gait sequence or change of gait on stability (Davis, DeLuca, & Ounpuu, 2003; Higurashi et al., 2009; Stevens, 2008). Although there are disagreements regarding the advantages of gait sequence, branch diameter appears to have an effect on the speed of the gait cycle (Franz, Demes, & Carlson, 2005).

However, it should be noted that the observed type of locomotion and gait sequence can be problematic and can lead to erroneous statistical significance. The problem is method. Although the observations of primates in their natural habitats can be more realistic, controlled experiments that involve modified habitats—the use of re-created “trees” and obstacles, for example—may affect their natural forms of locomotion and gait preference. To this author, variations seen in those “branched trees” that are re-created for experimental purposes may alter natural primate behavior. This alteration may not be in purely psychological terms but rather a biomechanical response to an “unnatural” terrain.

Beyond gait sequence and mode of gait, primate locomotion as defined by this author is best described as that behavior consistent with the biomechanical limitations of the primate skeleton and neurological control within an ecological niche. The diagnostic skeletal features are critical

in both comparing and contrasting primates with the possibility of inferring a mode of locomotion. For example, consider the morphological differences that can be seen between arboreal and terrestrial quadrupeds. As detailed in Fleagle's 1998 book *Primate Adaptation and Evolution*, arboreal quadrupeds have distinct diagnostic features: similar lengths (usually short) of both forelimbs and hindlimbs; elliptically shaped glenoid fossa; a broad humeral head with a moderately robust shaft; medial epicondyle, which are oriented medially; a long olecranon process of the ulna; a broad hamate; a relatively high angled femoral shaft; an asymmetrical size of femoral condyles and articulating surfaces on the tibia; an asymmetrical tibiotalar joint; and a large hallux. Fleagle further reported that differing from their arboreal counterparts, terrestrial quadrupeds have limited anterior-posterior motion of the shoulder (scapula and humeral articulation), an olecranon process extending dorsally, a deep olecranon fossa, a short and posteriorly orientated medial epicondyle, a robust tarsal and robust metatarsals, and short and broad carpal bones.

Differences can also be seen among brachiating and leaping primates, as discussed in Fleagle's 1998 book *Primate Adaptation and Evolution: Leaping primates* have diagnostic features that include a deep femoral condyle, a narrow tibia, a short femoral neck, a slender fibula, a long calcaneus and navicular, and a long ischium. Brachiating and suspensory primates have narrow and dorsally orientated scapulas, a small and round glenoid fossa with a large humeral head, medially orientated medial epicondyle, a short olecranon process, curved phalanges, broad and a shallow femoral condyle, and a shallow patellar groove. Also, the ulna does not articulate with the carpals and the distal and proximal row of carpals via a ball and socket joint contribute to the range of movement.

Given the commonalities and diagnostic features among quadrupeds, brachiators, and leapers, as Esteban E. Sarmiento noted in his 1998 book *Generalized Quadrupeds, Committed Bipedes, and the Shift to Open Habitats: An Evolutionary Model of Hominid Divergence*, there is very little disagreement that the commonalities show a deep common evolutionary ancestry while the diagnostic features show evolutionary adaptation to various ecological niches. Species with overlapping modes of locomotion and morphological similarities have homologous and homoplasy issues regarding morphological traits. This issue can be problematic in determining the origin of human bipedality. Among the various traits attributed to our species (e.g., expansion of the human brain, tool use, and material culture), the emergence of obligate bipedalism preceded all other traits that are considered uniquely human.

Human Bipedal Locomotion

Human bipedalism can be defined as the constant utilization of alternating hindlimbs as a means for movement between

two points, according to Fleagle in his 1998 book *Primate Adaptation and Evolution*. The gait is a cycle (stride) that consists of a stance phase, midstance phase, and swing phase. The moment the heel strikes, the hip becomes flexed, and the knee is extended while the leg is laterally rotated. The adductor muscles then shift the body's weight over the supporting limb (midstance phase), and the opposite hip and knee are extended. During the increase in forward momentum, the ankle dorsiflexes, and the hip and knee pass the supporting leg. After toe-off, the weight passes the toe and hyperextends the hip joint. The swing phase completes the cycle, ending with the leg laterally rotated in preparation for another cycle, as noted by Leslie C. Aiello and Christopher Dean in their 2002 book *An Introduction to Human Evolutionary Anatomy*. This motion makes human bipedality different from the bipedalism of any nonhuman primate. For example, when a chimpanzee uses bipedalism, the cycle differs in its phases due to a lack of full hip and knee extension. In addition, the knee and ankle joints do not pass the hip joint, and the femur does not have a bicondylar angle. Aiello and Dean also noted the absence of abductor muscles and a reverse of the pelvic tilt during the stance phase as additional differences. Altogether, the differences between human bipedality and nonhuman primate bipedality are fourfold in (1) the degree of spinal curvature, (2) pelvic configuration, (3) foot morphology, and (4) biomechanical modifications in related muscles, tendons, and ligaments.

Evolutionary History of Human Primate Bipedality

As many previous primates throughout North America, Europe, and Asia went extinct during the Eocene to the middle Oligocene, the emergence of apes in Africa presented a unique evolutionary adaptation that would eventually be seen within our species in the form of bipedal locomotion. From its evolutionary ancestors, the African Miocene apes *Orrorin tugenensis* and *Sahelanthropus tchadensis* are considered the earliest bipeds. These specimens represent the earliest date for primate bipedalism—far earlier than the later genera of *Australopithecus* and early *Homo*.

Orrorin tugenensis, considered one of the oldest bipedal hominins, dated from 6 to 8.5 million years ago. The diagnostic features, which indicate bipedalism, include an anteriorly convex curvature of the femoral shaft, the blending of the tubercle into the greater trochanter, the presence of an intertrochanteric line (absent in other Miocene apes), a medially salient and well-developed lesser trochanter, elongation of the femoral neck (closer to the Australopithecines and humans), a proximo-distally elongated gluteal tuberosity with a distal leading crest, a marked pectineal line with a spiral line from below and medially orientated to the lesser trochanter and a linea aspera with mild cresting located below the trochanter, a right angled intertrochanteric crest,

an obturator groove originating from the fossa to the inferior margin of the femoral neck (indicating femoral hyperextension), and a developed but shallow hypotrochanteric fossa. *Orrorin*'s femoral neck is antero-posteriorly compressed, along with the presence of an obturator externus groove, which differs from both the Miocene and modern apes (Pickford, 2006; Pickford & Senut, 2001). Similarly, the asymmetrical distribution of the cortex, inferiorly thick and superiorly thin, suggests loading patterns or weight distribution that is indicative of having a degree of bipedalism and being orthograde (Galik et al., 2004).

Another Miocene hominin, *Sahelanthropus tchadensis*, dates back 6 to 7 million years ago. The diagnostic feature indicating bipedality, though controversial, revolves around a cranium (TM 266), which is partial and distorted. Through virtual reconstruction, the cranium depicts an orthognathic face, short premaxilla, a large foramen magnum (greater in length than breadth) that is positioned more anteriorly, and a short basioccipital. The orientation of the foramen magnum suggests bipedality. This is due to the relative angle of the foramen magnum to the orbital plane—103.2 degrees \pm 6.9 degrees for humans and 95 degrees for *Sahelanthropus*, for example, and the orientation of the flat nuchal plane being 36 degrees to the Frankfurt horizontal (Zollikofer et al., 2005). When these morphological features are compared among fossil apes, hominids, modern apes, and humans, *Sahelanthropus* is closer to both *Australopithecus* and modern *Homo*. Displaying morphological synapomorphines with other bipeds, bipedalism becomes the assumed form of locomotion (Guy et al., 2005).

The emergence of hominins in Africa provides the best evidence to date for the appearance of bipedalism. The subfamily Australopithecine consists of three genera: *Ardipithecus*, *Australopithecus*, and *Paranthropus* (previously robust australopithecines). For the *Ardipithecus* genera, *A. ramidus* and *A. kadabba* are suggested to be possibly bipedal and the beginning of the hominin line. This determination is based on the combined features of a short cranial base, an anteriorly positioned foramen magnum, and a strong plantar curvature of the proximal foot phalanx (Harcourt-Smith, 2007). Although *Ardipithecus*, as well as *Orrorin* and *Sahelanthropus*, is controversial regarding its bipedality, that the genus *Australopithecus* was bipedal is accepted with few reservations (e.g., the degree of bipedality Harcourt-Smith, 2007).

There are five species of *Australopithecus* located at sites in the southern, western, and central regions of Africa: *A. anamensis*, *A. afarensis*, *A. africanus*, *A. aethiopicus*, and *A. garhi*. *Australopithecus anamensis* (4.2 million years ago to 3.9 million years ago), though having blended human and ape characteristics, represents a more positive shift in hominin locomotion toward bipedalism. The locomotive indicators are limited. This hominin has a tibia shaft, which is oriented orthogonally to the talar joint surface; the metaphyses are flared both proximally and distally, which is

an indication of bipedal locomotion, as Glenn C. Conroy reported in his 2005 book titled *Reconstructing Human Origins* (see also Ward, 2007).

Australopithecus afarensis (3.6 million years ago to 2.9 million years ago), having similar qualities, presents the greatest blending of primitively derived traits from previous hominids with added humanlike characteristics. The lower limbs are typified by having major features, which include long and curved proximal phalanges with a circumferential trochlea, a navicular with a low dorsoplantar height and a large right-angled cuboid facet, a robust and triangular diaphysis of the first metatarsal, a calcaneus with a horizontal sustentacular shelf, a convergent hallux, a lateral cuneiform with plantar tuberosity, a proximal femur with a short neck relative to femoral length, a high bicondylar angle, an elliptical lateral condyle, a posterior angle of the distal tibia, and a distal fibula with a deep peroneal groove. In addition, the iliac blade faces posteriorly, including robust anterior and posterior superior iliac spines incorporating a sigmoid curve of the iliac crest, a thickened pubic symphysis (dorso-ventrally), and a short ischial shank (McHenry, 1991).

A. afarensis presents an interesting problem in its morphological interpretation. Bipedalism is cited as transpiring due to a lumbar lordosis, a high bicondylar angle, short and wide iliac blades, a prominent anterior inferior iliac spine, mediolateral orientation of the talar surface (distal tibia), a trochlear surface of the talus, and a lateral plantar process of the calcaneus. The dorsal orientation of the proximal articulating facets on the proximal pedal phalanges suggests dorsiflexion (needed during bipedal walking), but it falls outside the human range. Contrary to existing bipedal indicators, certain morphology indicating an arboreal nature and locomotion includes the curved and long proximal phalanges with flexor ridges, a medial cuneiform that is similar to apes (suggesting halluical opposability), a well-developed lateral trochlear crest of the distal humerus (prevents dislocation of the elbow joint during either climbing or suspension), and a cranially oriented glenoid, as discussed in Aiello and Dean's 2002 book *An Introduction to Human Evolutionary Anatomy* (see also Harcourt-Smith, 2007).

Australopithecus africanus (3 million years ago to 2.4 million years ago) shares many affinities with *A. afarensis*. Postcranial elements are fragmentary: capitate, scapula, proximal humerus, distal femora, pelvic blade, adolescent ischium, a fragmented piece of humeral shaft, vertebrae, left and right os coxae, fragmentary sacrum, and a left proximal femur without a head. Generally, *A. africanus* has wide and lateral flaring iliac blades and a small acetabulum and iliosacral joint. The proximal femur has a long neck with a small head. Similar to *A. afarensis*, the bicondylar angle is high (McHenry, 1986; Wood & Lonergan, 2008).

Paranthropus boisei (2.3 million years ago to 1.4 million years ago) and *Paranthropus robustus* (2 million years

ago to 1 million years ago) are suggested to be bipedal. The locomotion of *Paranthropus boisei* is uncertain due to the fragmentary nature of the recovered postcranial elements. Postcranial fragmentary elements attributed to this species include a clavicle, a distal humeral shaft, a proximal radius (left and right fragments), an ulna (proximal and shaft fragments), a distal femur, a tibia (left and fragments of the right), a distal fibula, and the right proximal third metatarsal (Wood & Constantino, 2007). However, the morphological similarities between recovered elements of *Paranthropus* and *Australopithecus*, especially the existence of an obturator externus groove, suggest a degree of bipedalism. *Paranthropus robustus* (2 million years ago to 1 million years ago) has femoral features, though fragmentary, that include the lack in the lateral expansion of the great trochanter, an absence of a trochanteric line and a femoral tubercle, and a deep trochanter fossa with an obturator externus groove (Wood & Richmond, 2000).

Although a degree of bipedality is assigned to *Australopithecus* and *Paranthropus*, the emergence of *Homo* is unequivocally bipedal. Included in the genus *Homo* (starting at 1.9 million years ago) are three early species that exhibit diagnostic features indicative of bipedality. They include *H. habilis*, *H. rudolfensis* (or *H. habilis*), and *H. erectus*. The major indicators include a large tibial tuberosity, an obturator externus groove located on the femoral neck, a bicondylar angle, the position of the foramen magnum, and pelvic and foot morphology. These features are discussed in Aiello and Dean's 2002 book *An Introduction to Human Evolutionary Anatomy* and in Fleagle's 1998 *Primate Adaptation and Evolution* (see also Wood & Richmond, 2000). However, it must be stressed that there remains a degree of morphological variation associated with bipedalism. Today, as in the past, this variation can be found within and among bipedal species.

Today, many researchers conclude that bipedalism could have evolved multiple times in primate history. Given the incompleteness of the fossil record and no definitive relationships among hominin and hominid genera, there is the possibility that multiple lines of bipedal apes could have evolved separately from the direct ancestral descent of the *Homo* line. The committed time to bipedality, even among *Australopithecus* morphology and the associated Laetoli footprints, is unknown and very controversial. This is primarily due to the blended characteristics associated with an arboreal setting. Given that Plesiadapiforms, Adapoidea, and Omomyoidea were arboreal and assumed quadrupeds, the question remains: What eventually prompted the emergence of bipedality as early as the Miocene? Assuming bipedality was established during the Miocene, what major influences would cause the greater diversity of hominins to develop this bipedal characteristic? Finally, what evolutionary pressures between the Miocene and Pliocene could account for the morphological differences seen among bipedal primates? The theoretical answers are far from being conclusive. In terms of evolution, it is very probable

that natural selection is responsible for the divergence from quadrupedalism to a form of bipedality.

Theories on the Origin of Human Bipedalism

The environment, serving as a selective force, may explain the diversity of primates within various biomes and consequently the various modes of locomotion exhibited by primate species, as Alison F. Richard suggested in 1985 in *Primates in Nature*. The role of the environment acting as a selective pressure is widely recognized as a major factor (Kingston, 2007). Based on multiple analyses of marine isotopes, ice cores, sediments, loess sequences, pollen sequences, and stable isotopes, environmental conditions have varied throughout the world, including in Africa. Locations at hominin and hominid sites in Africa indicate a mixture of open woodlands, wooded savannas, grassy plains, and closed vegetation. Fluctuations in aridity and environmental changes during the Miocene to the Pleistocene are caused by various factors. Milankovitch cycling, plate tectonics, glacial and interglacial periods, the Messinian salinity crisis, and Walker circulation patterns reshaped the African coastline and the African Rift Valley. However, re-creation of the hominin and hominid environment is far from complete. Yet interestingly enough, extinct bipedal primates are found in various terrestrial settings and are not limited to one type of environment—the savanna, for example. The importance of the environment on the interpretation of hominin and hominid evolution poses critical questions. If hominids and hominins evolved a form of bipedalism independently from either wooded savannas or closed vegetation, then what was the driving force for the development of bipedalism? And what implications does this have on this “unique” trait that is considered a hallmark of being human? Various hypotheses are proposed to answer such questions.

Scientific consensus on the origin of human bipedalism is not conclusive. However, some theories are more acceptable than others. Some of the more accepted hypotheses include the knuckle-walking hypothesis, the brachiation hypothesis, the climbing hypothesis, the energetic hypothesis, and the thermal regulation hypothesis. The foci of these hypotheses are dependent on models established on extant primate behavior. Two major models include the *hylobatian model* and *trogloidytian model*. In the *hylobatian model*, it is suggested that a small brachiating and tailless gibbonlike primate made the transition to become a terrestrial biped. It is suggested that the bipedal precursor would have entailed a combination of arm hanging and arboreal branch bipedalism. The characteristics included long forelimbs, mobile shoulder and wrist joints, broad and coronally orientated iliac blades, a laterally facing scapula, long and curved fingers, and highly developed thumbs and first toes. Although the

arboreal setting deep within human evolution is widely accepted, the *hylobatian model* and the *brachiation hypothesis* have very little evidence for their support (Crompton, Vereecke, & Thorpe, 2008).

The *trogloidytian model* suggests that knuckle-walking was the precursor to human bipedalism. Proponents for the knuckle-walking theory have a focus on the morphological features of the shoulder, arm (forelimbs), and the wrist and hand in terms of functionality. Functional morphology becomes the critical factor in discriminating between apes in Africa and apes in Asia and hence the locomotive difference that is seen between knuckle-walkers and brachiators (Begun, 2004). The wrist and hand have many shared features between African apes and humans that are indicative of a knuckle-walking origin. The main morphological features include an early fusion of the os centrale, or central portion, to the scaphoid; the size and facet orientation of the scaphoid; a dorsally orientated scaphoid notch; a broad capitate and hamate with dorsal ridges; an enlarged trapezoid; a small triquetrum; and a palmer and proximal pisiform. The articulation of the scaphoid with the lunate, trapezium, trapezoid, and capitates, along with the articulation of the trapezoid with the capitate (which articulates with the second and third metacarpals and the hamate, which articulates with both the fourth and fifth metacarpals) and the second metacarpal, have biomechanical implications for knuckle-walking. During knuckle-walking, compression and shear stress are placed on the hands and wrists. Shear stress is placed on the carpals when the weight is transferred in a rolling manner from the fourth digit to the second digit, although sometimes to the fifth digit during locomotion (Richmond, Begun, & Strait, 2001).

Among these models, the *climbing hypothesis* for the origin of human bipedalism is based on both the morphological features and limb patterns involving muscle movements. The humeral shaft profile, the scapula orientation, and the position of the vertebral column, together with the perspective of the center of gravity, have many similarities with humans. Although human hand and wrist morphology have suggested an affinity with knuckle-walkers, evidence from hominid morphology has implied an “intermediate” form of an arboreal existence with adaptive bipedal traits. The climbing behavior of great apes, as with other primates, closely approximated human bipedalism more than any other mode of locomotion, including nonhuman primate bipedalism. This is based on both kinematic and electromyographic studies of monkeys and apes that showed that limb patterns and muscle movements (*latissimus dorsi*, *caudal serratus anterior*, *deltoid*, *pectoralis major*, and *biceps brachii*) during climbing were similar to human locomotion, as reported by Fleagle in *Primate Adaptation and Evolution* (1998). The climbing hypothesis is recognized as a possibility for the origin of bipedality.

Energy efficiency, or *energetics*, is another theory considered as the origin for human bipedality. When looking at extant primates as possible models, energetics among

primates vary according to species and gait velocity. For example, the amount of energy expenditures of chimpanzees and gorillas are not significant when either walking bipedal or quadrupedal (Okada, 2006). Yet Japanese macaques spend more energy walking bipedal than quadrupedal, and spider monkeys and lorises have lower energy costs for suspended walking than for either brachiation or quadrupedalism (Nakatsukasa, Hirasaki, & Ogihara, 2006). For humans, energy expenditure is greater during running than walking, but walking has slightly greater efficiency than quadrupedalism. Tied in with environmental conditions, it is suggested that this new form of locomotion was necessary for hominins to travel between wooded patches among the savannas, as Conroy explained in 2005 in *Reconstructing Human Origins*.

Associated with energy efficiency, the *thermal regulation hypothesis* states that bipedality is a regulatory process between the environment and the body's thermal regulation. The combination of an upright stance with the reduction of body hair, water retention rate, and energy efficiency, or metabolism, would reduce the amount of heat stress experienced. An increase in diurnal water consumption between a naked biped and a fully haired biped at 30 degrees Celsius with the same metabolic expenditure (2.0 BMR) increases from 0.62 kg/12hr to 0.82 kg/12hr. This water consumption is lower than both a naked and fully haired quadruped at the same temperature and metabolic rate, which is 1.16 kg/12hr and 1.11 kg/12hr, respectively (Amarl, 1996; Wheller, 1991). Even though the evidence on environmental re-creation and the emergence of bipedality can be contradictory, the energetics and thermal regulation remain strong possibilities.

There are several other hypotheses that are known but not widely accepted among members of the scientific community. These hypotheses include migration, food transport, posture, reproduction, birthing, and the aquatic ape. Although these hypotheses do not rely on extensive morphological or primate behavior data, many of the conclusions are based on assumptions and possible scenarios that fit a preconceived conclusion. Nevertheless, each of these hypotheses remains as possible but improbable explanations for the origin of bipedalism.

The *migration hypothesis* suggests that the development of bipedalism occurred during long distance scavenging. Any mutation(s) that furthered the development of bipedality would increase the amount of food found over greater distances. This adaptation would favor bipedalism over quadrupedalism. Furthermore, the freeing of the hands would allow for tool usage designed for the quicker butchering of carcasses (Sinclair, Leakey, & Norton-Griffiths, 1986).

Similar to the migration hypothesis, the *food transport hypothesis* states that erect posture and habitual bipedalism allowed for the freeing of hands in order to carry scavenged food. The combination of body size, distance between food sources, predation, and competition could have favored a

greater degree of bipedality (Hewes, 1961). This view is similar to the tripedal hypotheses where objects are carried either close to the abdomen or slightly behind the back. The key to the transport model is based on the efficiency of the transportation of objects. However, relatively recent research in body proportions and biomechanics, which would include gait, shows an increase in efficiency in carrying goods (while walking) in modern humans as opposed to nonhuman primates with an inference to our hominid ancestors (Wang & Crompton, 2004). Though efficiency in carrying loads among hominids may differ in degree, the morphological changes that result in a greater degree of bipedalism would have a greater biomechanical advantage over less efficient hominids.

Stemming from the migration and food carrying hypotheses, *hominid posture* is considered as another possible explanation for the origin of bipedalism. The upright posture is suggested to allow the ability to evade predators and for displays of aggression. Aggressive displays, along with the ability to exploit new food sources, would have conveyed a greater advantage to a hominid that had both a larger body size and a more erect posture. Research has shown that the stance of *Pan troglodytes* during defensive displays were either primary or secondary (passive and aggressive, respectively). Depending on the circumstance and the presence and distance of predators or competition, the display or postural stance would have changed with every situation. An upright posture would have allowed not only for a greater amount of time for the flight versus fight response and/or cost benefit analysis but also the possibility of intimidation with or without physical contact. In any terms, the speed of a quadrupedal gait versus the benefits of an upright posture was unquestionable during defensive displays. An erect posture would have allowed for a greater line of sight and a greater awareness of the surrounding environment (Walter, 2004).

The *reproductive hypothesis* suggests that human upright posture and bipedal gait are conducive for reproductive efficiency. Unlike the nonhuman primate counterpart, human sexual adaptations for efficiency were seen in a copulation position (ventral-ventral) that would have allowed the female reproductive tract (vaginal angle) to be parallel with gravity, resulting in a greater sperm retention around the cervix. Additional adaptations to increase sperm retention included the sedative effect of an orgasm, females capable of multiple orgasms, the dominance of nocturnal copulation, and a pair-bond sleeping arrangement (Gallup & Suarez, 1983).

As for the final product of copulation, the *birthing hypothesis* suggests that bipedalism transformed the birthing process from an individual experience to a social experience. For example, in the position of the female reproductive tract in a nonhuman primate, an infant emerges from the birth canal facing the female without the necessity of rotating the infant. This differs from the human primate. Due to the human infant head and shoulder dimensions, as

compared to the dimensional opening of the human female birth canal, human infants typically need to be rotated to ensure that they emerge facing away from the female. The vulnerability of females during the birthing process has made assistance a necessity. In terms of hominid evolution, the emergence of complex social systems aided not only in the birthing process, but also provided vigilance against predation during this process (Trevathan, 1996).

The *aquatic ape hypothesis* suggests an aquatic phase during human evolution with implications for bipedalism. This explanation points to humankind's untraditional features, such as the great ability to swim, a reduction of body hair, hair tracking toward the midline of the body, subcutaneous fat, and unspecialized hands. Additional features such as body odor, a voluntary control of respiration, a pronounced bradycardia, salt tears, round female breasts, ventro-ventral mating, and dilute urine are suggested by some researchers as evidence for an aquatic phase in human evolution. It is claimed that our early bipedal ancestors existed in a semiaquatic state within the tropical rainforests. These early ancestors are depicted as "advancing" in a linear progression. At first, these ancestral descendants lived an idyllic life feasting on plants, and then later, they consumed shellfish, and finally, they became terrestrial hunters of game with a spoken language, according to Elaine Morgan in her 1997 book titled *The Aquatic Ape Hypothesis: Most Credible Theory of Human Evolution* (see also Verhaegen, 1985). It may be concluded, based on this theory, that bipedality would have an advantage in the water. However, the efficiency of humans compared to other aquatic mammals within water may suggest otherwise.

Future Areas of Research

While comparing and contrasting the morphology between humans and nonhuman primates can give clues to the relationship among primate taxa, other areas of research are shedding light on the nature of locomotion. The area of biomechanics can aid in the development of new models of origin by understanding the interaction and relationship between bones and muscles. Even the influence of stress and shear on bone morphology can aid in the understanding of locomotive behavior. In addition, contributions made in the area of robotics can also further the understanding of the mind's (computer's) control over multiple mechanical systems. The future development and advancement in understanding locomotion could be within these areas of research and development.

One of the best areas for future research is genetics. Since the developmental basis of vertebral morphology and sequences are the same for all human and nonhuman primates, the differences reflected in both posture and mode of locomotion are suggested to reside in the genetic controls, particularly *homeobox genes*. Homeobox genes (ranging from 100 to 1,000 in number) are a set of DNA

sequences involved in regulating embryonic development (Gehring, 1994). As for humans, there are four Hox gene (39 genes) sequences that control vertebral segmentation: Hox A, Hox B, Hox C, and Hox D. These gene sequences are located in various chromosomes and are expressed in the cells of both the mesoderm and ectoderm (body axis). Research has suggested that changes in the Hox gene code depend on the timed introduction of retinoic acid by means of binding to the transcription regulatory sites and the naturally timed introduction of a teratogen that is controlled by retinoic acid receptor genes. Thus, a change in the timing of the introduction of retinoic acid will change vertebral morphology. For example, inactivation of the RAR- γ changes the anterior formation of the vertebrae and Pax genes (a binding protein) that control sclerotome differentiation (Dietrich & Kessel, 1997).

While humans and pongids differ in their number of chromosomes, 46 and 48 chromosomes respectively, the changes in Hox genes could contribute to the "sudden" emergence and continuing development of the erect posture and bipedal locomotion of hominids. Research has suggested that changes in the distal sequence of the Hox D gene (located on the second chromosome) are responsible for the junction between the lumbar and sacral vertebral region. These changes are suggested to be a product of a mutation, which resulted in the chromosomal fusion of panine chromosomes 12 and 13 into hominine chromosome two. This structural alteration would have changed the rate of protein "evolution" and would have allowed for a high rate of protein change. This change in the rate of protein evolution is suggested to account for the sudden emergence of bipedalism via vertebral morphology. The control of Hox genes on axial morphology and comparative chromosomes among primates are supported by other research (Bowers, 2006; Chimpanzee Sequencing and Analysis Consortium, 2005; Navarro & Barton, 2003). In addition to modifications of the vertebral region, other research determined that Hox b9, Hox c9, and Hox d9 were responsible for limb structure and placement in relation to the axial skeleton during application of fibroblast growth factors (chick embryos). Interestingly, any changes in Hox genes resulted in appendicular skeletal placement with no changes in the axial morphology (Cohn et al., 1997; Muragaki, Mundlos, Upton, & Olsen, 1996).

Conclusion

When evaluating primate locomotion, opinions vary across the scientific community. Nonhuman primates use many forms of locomotion. From quadrupedalism to bipedalism, nonhuman primates exhibit these forms of locomotion depending on the environment (e.g., arboreal or terrestrial) and their biomechanical limitations. The expansion of the neural complexity within primate evolution can explain gait sequence (LS or DS) and limb preference. This is not

to say that the neural complexity is near that of humans; rather, the complexity of the human brain far exceeds the complexity of any nonhuman primate. In terms of locomotion, neural complexity may contribute to limb movement and propulsion, but complexity may not have any influence on posture or preference for a mode of locomotion.

Humans provide an interesting inquiry on the evolution of bipedality. As depicted within the fossil record, forms of bipedalism have evolved multiple times, stretching back to 6 million years ago. Since these hominins and hominids probably did not have the complexity of the modern human brain, what prompted these individuals to stand erect or semierect and walk bipedal is still unknown. However, bipedalism was well established within the Australopithecines. The reason for the emergence of bipedalism from the Miocene apes is still unknown.

Today, hypotheses on the origin of bipedalism and the relationship to the locomotion of extant primates express various opinions. No researcher has complete answers to the many questions posed by human evolution. Morphologically, humans have many shared characteristics with nonhuman primates. However, do these shared evolutionary characteristics show the origin of bipedalism? The presented hypothetical descriptions have attempted to illustrate the deep philosophical problem when attempting to tie shared morphological characteristics with a particular behavior. Experience and probability define the validity in any of these explanations. Through future research, greater light will be shed on the origin of bipedalism, echoing Darwin's words that our species differs in degree and not in kind from the great apes.

PRIMATE BEHAVIOR STUDIES

RYAN J. TRUBITS

Lancaster, New York

Our species' existence is an enigma that intrigues both scientists and the average human. The reason that we are even able to scratch the surface about this complex question is due to our ability to think critically, maintain culture, and articulate in a manner that has allowed other humans to understand. Humans are able to achieve success based on the ability to express their thoughts in written language, making use of semiotic systems. Scholars for the past 2 centuries have laid the bedrock of knowledge about our close biological and behavioral ties to the primates of this world. This evidence has provided the scientific community and the average human being an understanding of primate behavior as well as the opportunity for future advances. Despite their understanding of the primates, there are many individuals in our world who are still not convinced that humankind spawned from a fossil apelike form. Even so, it is hard to deny organic evolution as a convincing scientific theory. Humans cannot be the only exception to a theory that applies to the emergence of all other species on this planet.

Aristotle was the first of many naturalists to inquire about human existence. For centuries, Aristotle's ideas of a static nature were the doctrine, despite an ever-changing world. Aristotle believed that species are eternally fixed on this planet. This claim rests on his belief that those species that are living on this planet at this moment have always been here and will always be living on earth. Many naturalists attempted to prove that Aristotle's claims were

outdated and dogmatized, but most failed to prove to the masses that the Aristotelian and later Christian view of life was wrong. Charles Darwin, the "father of evolution," is one of the greatest naturalists to have lived. His comprehensive view of organic evolution provided the scientific world with a theory that incorporated not only biology but also geology, paleontology, and anthropology. His empirical arguments challenged old dogmatic ideas that spanned back to the insights of the ancient Greek philosophers.

When Darwin (2007) made his voyage on the HMS *Beagle*, he discovered that organisms that live in different environments acquire certain physical traits and behavioral patterns to adapt and survive. He also came across the idea that if identical species are isolated for long periods from one another, then these identical species will eventually radiate into different varieties and perhaps, given enough time, even into new species. Darwin extended this evolutionary framework to also include our own species, stating that human fossil remains would be found in rock strata and that these specimens would help scientists connect our lineage to the two living pongids on this planet. This idea was known as the pithecometra hypothesis, first presented by Thomas Huxley and Ernst Haeckel. This hypothesis argued the idea that our species is closer to the great apes or pongids (orangutan, gorilla, and chimpanzee) than they are to the lesser apes (gibbon and siamang). While Darwin was correct about the fossil evidence, today we have discovered a total of four living

pongids (which now includes the bonobo), which are all arguably our closest living relatives.

The discovery of the DNA molecule in 1953 by James Watson and Francis Crick helped open the world's eyes to the scientific truth of organic evolution. The molecular evidence that was discovered has shown that humans are biologically closer to the pongids than Huxley of England, Haeckel of Germany, or even Darwin himself could have imagined in the 19th century. These pioneers in human evolution studies had sparked interest around the world, and their influence contributed to the emergence of the discipline of anthropology. The theory that anthropologists follow in their search for knowledge about our past is based on the ideas of evolutionary thought. Many of our speculations may be incorrect, but the truth is that the fossil and artifact evidence found in the rock strata of our planet provides us with the opportunity to pose questions in a logical manner.

Anthropology covers many areas of science such as biology, archaeology, societies and cultures, linguistics, and applied anthropology. The study of primatology, while being a specific focus in biological anthropology, is itself comprehensive in that it attempts to compare and contrast both the similarities and differences in the human species with the other living primates on this planet. In the four pongids (orangutans, gorillas, chimpanzees, and bonobos), we have a window into our past. These complex and self-aware species are the only creatures on this planet, besides humans, which are able to think critically above the rest of the animal kingdom. In our modern world, we have obtained a significant amount of empirical evidence about our biological similarities to the other primates on this earth. These findings have allowed anthropologists to make substantial claims about our behavioral similarities to the other primates.

Studying the behavior of our closest living ancestors is important to advance anthropology because with this information, we can attempt to understand and appreciate how our fossil ancestors developed into the complex human creature of today. Unfortunately, the four pongids and the two hylobates are facing extinction. This is largely due to the environmental changes and human interventions they are trying to endure. At this time, it is crucial for scientists to study these primate species. To truly understand our complex relatives, we must be able to do extensive research on wild apes in their natural habitats. While research in zoos and labs allow scientists to determine these species' intelligence and natural behavior, the only place where we can understand the life processes of these wild organisms in a nonintrusive matter is in their wild habitats.

What is the proof that we actually split from the pongids? While our species did not split from one of the living pongids, it is known that our existence arose from the time period that gave rise to the Dryopithecinae complex of fossil apelike species. During the Miocene epoch, hominids emerged in many different varieties. By the end of the

Pliocene epoch, around 3 million years ago, the environment changed. As a result of this climate change, the tropical jungles of Africa started to vanish causing scattered open woodlands and grassy savannas. This caused a rift in the way fossil apes lived and the way fossil hominids lived. Some species remained arboreal (dryopithecines) while others become terrestrial (kenyapithecines). Fossil evidence demonstrates that the split happened in the Pliocene period, roughly 6 million years ago. Those species that were able to adapt and survive as terrestrial forms (kenyapithecines) evolved to become our more recent ancestors. Bipedality is the trait that first separated the hominid-like hominoids from the pongidlike hominoids. Later developments such as toolmaking, articulate speech, and a complex brain emerged in hominids during the last 3 million years. The living pongids are those great ape species that remained in the rain forests of the Eastern Hemisphere. In this long evolutionary experiment, only those species that were able to adapt to their ever-changing environments survived and reproduced.

Emergence of Primate Behavior Studies

The ability to think critically in terms of science and reason is what separates humans from the rest of the organisms on this planet. Our large cranial capacity and specialized brain have given us the ability to trace our historical lineage. While our species is by far more advanced in many functions of the brain, it is remarkable to see the striking similarities to us that the great apes and hylobates demonstrate. Evidence in behavioral studies clearly shows that we are not the only species to show the ability to think abstractly and articulate our emotions. Scientists accept the fact that we differ only in degree rather than in kind from nonhuman primates. We must not forget to study these species from an objective perspective, not form a bias that humans are far superior to their primate counterparts.

How primate behavior became of interest is a relatively new focus, only originating in the 1960s. This does not mean that there were not studies before this time. Research studies were carried out from 1800 to 1960 and the results analyzed but not with the rigorous discipline that is seen in the 20th and 21st centuries. The study of primates was in many cases secondary to the general mission of these studies. Some early naturalists avoided the behavior studies of wild apes in their natural habitats because these researchers accepted preconceived notions of the large primates, especially ideas about the "violent" gorillas. The fear that these savage creatures would cause harm to individuals set back intensive research studies in Africa.

The first major and groundbreaking study was not in Africa but in the New World, by Raymond Carpenter (1964), who studied the Howler monkeys and later the gibbons in Asia during the 1930s. One may claim this was prior to the 1960s, and they would be correct. But the

progress made by Carpenter would be forgotten until after World War II. Primate field research was not a priority when the world was at war. Carpenter and other rising anthropologists, such as Louis Leakey in the 1950s, paved the way for future researchers and also provided an opportunity for individuals to actually go and study wild primate species in their natural habitats. The passion, which was missing from past studies, was instilled into a new generation of scientists who strove to further our understanding of humans by studying the nonhuman primates of our world. Through extensive investigation and comprehensive research on these close primate relatives, scientists hoped to open doors into our past. The 1970s and 1980s were a period in primate behavioral studies when research was done from a quantitative viewpoint. The goal of these missions was to obtain as much information as possible about the primate species of our planet. However, there has been a shift in emphasis from quantitative to qualitative studies, which forces scientists to refine their research methods. While it is important to learn the scientific specifics about a particular species, we must not forget that comprehensive studies should not be abandoned without constantly revisiting the main facts about a species, lest we dogmatize facts about our closest relatives. The more interpretations we have about a subject, the more valid our generalizations will be. While not intentionally disposing quantitative studies, scientists in many cases have been pressured by both government and private organizations to stray away from large ethological studies because they are not being funded. This can be seen even most recently in the rediscovery of the pygmy tarsier (*Tarsius pumilus*) of Indonesia. This species was believed to be extinct in the 1920s, but scientists fortunately discovered that this species still exists.

My argument is that we cannot allow for the slow removal of large comprehensive studies, especially when we have not truly learned everything there is to know about each species. In the case of the pygmy tarsier, we did not even know that it still existed. The truth is that our closest living species are vanishing before our eyes. If we do not obtain as much information as possible now and take serious steps to save primate species, then they could eventually disappear forever.

Prosimians

To truly understand what are primates, one must understand the criteria that we share with the other species of this planet. The morphological attributes that taxonomists use to determine what is a primate are ones that set it above and beyond other mammals. Species in this group are ones with grasping hands and feet, larger brains, shorter jaws, and a flat face in comparison to other living mammals on earth. The eyes of these organisms are close together and on the front of their faces; these species also have digits with nails rather than claws.

The two subgroups of primates are the Prosimii and Anthropoidea. Prosimian means “premonkey,” and the prosimians of today are believed to be living representations of the early arboreal primates. Prosimians are located in the rain forests of Africa and south Asia.

The earliest and least complex primates are represented several living forms, as the tree shrew, loris, lemur, indri, and tarsier. Tree shrews are found in India, Burma, Sumatra, Java, and the Philippines. The tree shrew is a solitary and asocial creature by nature; the tree shrew will be seen in pairs only in time of mating, but this is the only period where pair-bonding is present. Males are aggressive and will defend their territory. They do so by marking trees with a fluid excreted from the chest.

Prosimians are arboreal and insectivorous, and many taxonomists still classify them with the insectivores. But their complex brain, emphasis on vision rather than smell, and digital flexibility place them in the higher suborder Prosimii. Many believe that the tree shrew is a biological and social link between insectivores and the more evolved prosimians.

Lorisiformes are located in Africa and Asia; they are characterized for their nocturnal lifestyles and for dwelling in trees. Lorisiformes are found normally as individuals or in pairs. Grooming plays a large role in their lives, and it is seen as a form of communication and the creating of relationships between individuals. Lorises feed mostly on insects and supplement their diet with a source of fruits. All members of this subfamily are nocturnal, and they hunt their prey by proceeding quadrupedally through the trees.

The Lemuriformes of Madagascar and the Comoro Islands in the Indian Ocean are composed of lemurs, the aye-aye, and the indri. The species of the Lemuriformes vary in size from the tiny mouse lemur to the largest species, the ring-tailed lemur. Smaller species are nocturnal in behavior, but the larger members of this family are diurnal. These groups, depending on the species, live as individuals or in social groups. These prosimians, especially the lemurs of Madagascar, have prospered on the island due to its being an environment with little to no predators. The only species who threaten this arboreal creature are the hawks, eagles, and humans, who have placed the lemur on the endangered species list because we have infringed on their environment with logging.

Lemurs, due to natural selection, have favored vision over smell and have also created tight social groups to survive against predators. This can be compared to humans in the sense that we adapted to a lifestyle that has been dependent on sight and working together to survive in our ever-changing world. Lemurs are a very social group that play and groom one another; lemurs live in groups of about 24 individuals. They form close relationships with other lemurs due to this nonverbal communication with one another. Like humans, lemurs share a sense of pride in protecting their territory but do so by marking their territory. Lemurs mark their surroundings by urinating or releasing hormones from a gland in the forearm and inner side of

the upper arm; they rub their scents onto trees by scratching. In lemur society, males have a hierarchy that is determined by which males are able to distinguish themselves from the others in the form of vocalization.

Tarsiers are found in Borneo, Sumatra, and parts of the Philippines. They are a small species with very specialized traits. Its large eyes and large ears allow for an ideal adaptation to nocturnal behavior. The Tarsiiformes are usually considered the highest form of Prosimians because of the emphasis on vision, the flexibility in its digits, and also the specialization in the brain found in the tarsiers. Tarsiers are unable to rotate their eyes, but they compensate for this by being able to rotate their head 180 degrees. The species is dependent on being able to leap from tree to tree in search of insects and small vertebrates for its strictly carnivorous diet.

New World Monkeys

The anthropoids of the world consist of monkeys, apes, and humans; this grouping is supported by the close genetic similarities among the anthropoid species, as well as the fossil evidence found in China in the rock strata of the mid-Eocene, which is about 45 million years old. This fossil evidence led people to support the separation of two subgroups of primates, the prosimians and the anthropoids. However, the fossil evidence of some anthropoids is anatomically similar to the modern tarsiers, which allows science to claim that the tarsier is the most related prosimian to the anthropoids of the planet.

The fossil record proves that 40 million years ago, both New World monkeys and Old World monkeys shared a similar genetic relative. By this time, the planet had already shifted into the current geological makeup of our modern world. The science community is still unaware of how the forming of New World monkeys occurred, but it is believed that New World monkeys evolved in the Old World and reached South America via rafting on logs. After this time, the New World monkeys of our planet evolved independently from the Old World monkeys. They now live in the tropical forests of the Western Hemisphere. New World monkeys are known as platyrrhines, a term that comes from the characterization of each species having a broad, flat nose. Due to the geographic isolation of the two groups of monkeys, they diverged in characteristics but in similar ways because of their common evolutionary ancestry.

New World monkeys are found in Central and South America. The species are all classified under the superfamily of Callitrichidae, which is broken up into two subfamilies (Callithricidae and Cebidae). Dependency on the trees as a form of protection, the adaptation of a prehensile tail, and dermal ridges on their tails have allowed these species to live for the most part without fear of predators.

The Callitrichidae includes marmosets and tamarins. Marmosets are found only in southern areas around the

Amazon River. Tamarins are found only in areas north and west of the Amazon River. Marmosets inhabit most types of forests. They feed on insects and fruit. Marmosets move quadrupedally, leaping and climbing from tree to tree. This New World monkey lives in family units consisting of a mother, father, and offspring. The major anatomical differences between the two species (the marmosets and the tamarins) is the structural makeup of the lower jaw. Marmosets have a V-shaped mouth, while tamarins have a U-shaped mouth. Tamarins are dependent on a stable diet of fruit, with insects being a supplement, and like their counterparts live in family groups (mother, father, and offspring) that move together from place to place.

The Cebidae group, the larger of these two families, is a subfamily in which most members are diurnal. This family consists of the capuchins, who live in very social communities of 10 to 30 members. They feed on whatever is available to them such as fruit, flowers, leaves, invertebrates, and birds.

The most extensive study performed to this day was done by C. R. Carpenter (1964), who did field studies on the free-ranging red howler monkey. This isolated primate was ideal for studies because it helped not only the study of this primate but also the study of interactions between other groups, as well as the howler's own ecological territory. His study helped uncover information about the size, movements, age and sex distribution, sexual behavior, and forms of communication. Howlers belong to a subfamily of the Cebidae family called the Alouattinae, which has six species that cover a region from Mexico to Argentina.

Howler monkeys, the largest New World monkey, can reach 6 feet in size from nose to tail. They are entirely arboreal, living in the highest branches of the tallest trees. They travel in small bands of 10 individuals. Howlers have good color vision but a poor sense of smell. They eat leaves, fruits, and flowers. The adult male howlers bellow a roar, which is possible because of the bone at the base of their tongue known as the hyoid bone. This hollow bone allows for a large powerful bellow. Bellowing may be used to express an emotion or defend a territory. Adult males gather for social roaring in the early morning or early evening; their howling carries through the jungle for almost 2 miles.

Sexual dimorphism is very present in all six howler species; females are three quarters the size of males. Howler monkeys are also dichromatic as males and females have different color coats. The howler monkey, in comparison to other New World monkeys, does not venture far from its territory. A howler society consists of a multimale group, which ranges in size from just 3 to 20 members. It covers a small radius of land. The howler diet is primarily of leaves, so the howler is a slow moving monkey.

The spider monkey is a New World monkey. It is part of the Atelidae group and is structurally similar to the howler with a difference only in the size; the howler monkey is significantly larger. The spider monkey is a sexually monomorphic species, which means that males and females

are almost identical in size. The only major difference between the sexes is the length in the canines of the males, which are longer. The long and narrow hands of the spider monkey allow it to move swiftly through the trees; this differs from the slow moving howler monkey. Like the howler monkey, the spider monkey has a long prehensile tail that is used like a fifth appendage. This tail shapes the behavior of the species, as it is used to make the balance and adaptability of an arboreal lifestyle possible.

Females play a dominant role in a spider monkey society. This species lives in groups of 15 to 25 members, making it a very social group. Females decide when the group will move from one place to the next, when they will search for food, and when the group eats. Unlike the howler monkey, who lives primarily on leaves, the spider monkey has a staple diet of fruit. Since ripe fruit is difficult to find, spider monkeys break up into small foraging groups of 2 to 8 individuals to reduce competition among members. The female leaders know where all the great feeding paths are, so they are more likely to receive the ripest fruit. Unlike most primate groups, spider monkeys do not really see a great importance in grooming. However, grooming is usually present in most of the primate species that live in a complex social group.

Old World Monkeys

The Old World monkeys of this planet are found in Africa, Europe, and Asia. These species of monkeys are roughly 30 million years removed from humans and the great apes. The superfamily in which these species are classified is known as the Cercopithecoidea and is divided into the two subfamilies of Colobinae and Cercopithecinae. The Old World monkeys are arboreal and terrestrial species that live off a diet of vegetation or fruits. The communities in which they live vary in size from 8 to 200 members.

The Colobinae are leaf-eating insectivorous monkeys that are represented by the colobus monkeys of Africa or the langurs of Asia. This species, in contrast to the cercopithecinines, are vegetarian. Other factors that distinguish them from the adjacent subfamily are that they lack cheek pouches, and they have a complex digestive system, which divides their stomachs into multiple chambers. Unlike the terrestrial Cercopithecinae species, these species are dependent on living an arboreal lifestyle. They nourish themselves with fruits, leaves, and flowers. To collect food, a group forms a party to forage for these necessities. The group consists of a single dominant male and a number of females and their offspring.

Langurs, unlike the colobus monkeys, live in groups of one or more males with the company of females and their young. They go out and forage in groups to obtain food. The langurs are located in the regions from India to China and Southeast Asia. While the colobus monkey shows a behavior of using semibrachiation, langurs are very

specialized in their hands, which allow them to move from tree to tree with precision. The fingers of the langur are very long, and its thumb is reduced in size to allow for an easy ability to cling to trees.

The Cercopithecinae include the baboons, mandrill, drill, galeda, macaques, and vervets. These species are found throughout Africa and parts of Asia. The species of this sub-group are both arboreal and terrestrial, compared to their counterparts, the arboreal Colobinae Old World monkeys.

Based on their well-adapted life on the grassy savannas, baboons are of special interest to anthropologists. The baboon is the largest of the Old World monkeys. The social behavior and structure of this Old World monkey has become of much interest. The baboons' ability to live in large societies and cooperate to survive in an environment where they are the prey of many larger animals (cheetahs, lions, hyenas, hippos, leopards, water buffalo, and crocodile) is crucial to understanding the evolutionary past of early humans who lived in a similar climate and environment and faced the same obstacles. The recognition that the baboon is an intelligent species, not strictly relying on instinct, dates back to Charles Darwin. In the 18th century, prior to Darwin, it was believed that intelligence rested in the mind of humans who were able to separate their natural instinctive urges and live in a world of strictly rational thought. This was changed with Darwin's claim that humans are like all animals that are able to learn from experiences as well as from instinctive ingrained memory. Darwin believed that instinct is a product of our evolution. Metaphysics is the understanding of existence. To understand how humans evolved into the species it is today, we must uncover fossil evidence to study our closest relatives so that we can envision how we once lived.

While Old World monkeys are roughly 30 million years removed from us, their social network is of major importance because it helps to point out the fact that before tool use and language, social networks must have formed first to promote the survival of species that were limited to smaller cranial capacities. Having large brains has many evolutionary risks. Complex brains need lots of caloric energy to run efficiently. As a result, to reduce the need for larger brains, other animals become specialized in specific skills and in specific brain tissue.

In central East Africa, olive baboons (*Papop anubis*) use their social skills to ban together to avoid becoming killed by other species. While collectively this allows for a better opportunity to survive, it also becomes difficult when resources are limited. The social order of a baboon society revolves around a static matrilineal and an unpredictable male social hierarchy. The dominant male is constantly threatened by new immigrant males and younger males, who challenge the alpha male with their larger and stronger physical makeup. As the alpha male, the leader must make decisions for the entire baboon colony, and he is allowed the first right to impregnate females that are in periods of ovulation. Maintaining a status of alpha male is

difficult due to constant attempts by other males for this position. The average control of this position by one male rarely is longer than 7 to 8 months. To determine one's dominance over another male, males challenge other males by chasing one another. Physical fights are rare to nonexistent. However, if males are unable to determine if one male is stronger than another, they display wahoo calls (loud, low-pitched calls) to indicate who is the strongest. Wahoo calls take a lot of energy, so many males become exhausted after the challenge. While the dominant male is provided the first chance to impregnate the female members of the group, he will not necessarily be successful in the monopolization of all the offspring of all the women. Alpha males achieve success through reproduction and also by the killing of infants that are not their own. Infanticide is not just a process done by baboons; it is performed by many species in the animal kingdom. Infanticide is a way for males to eliminate competition from the gene pool. Since alpha males have a period of only 8 months to monopolize the mating of an entire baboon society, males try to eliminate any infants that are not their offspring. Infanticide is a sexually selected trait that enhances a male's fitness. Infanticide in the animal kingdom happens in primarily polygynous species where competition is intense and females are unable to organize and protect themselves from male attacks. Unlike females, males rarely live past 15 years because they are unable to live longer in such a stressful world. The constant threat of losing one's alpha status is a constant risk as a male becomes older and fears that immigrant males will be able to enter a group and dominate.

Reproductive success and becoming the alpha male are the two most important instinctive goals of all males. While this attitude appears to be selfish, it is one of many variables that disturb the balance of a community. Grooming is another behavior that allows for communication and a sense of security. This practice is not only just a way to relieve stress within a group, but also a practical way to remove salt, dirt, and parasites from the skin of fellow baboons. Grooming is a large part of the social life of this Old World monkey; they spend over 4 hours a day grooming.

The nuclear family is nonexistent in baboon culture. Friendships and alliances between males and females are only for short amounts of time. These truces are a way of handling business. Females appreciate protection from outside immigrant males who may kill their children, and males are willing to protect these infants because they have a vested interest in protecting their offspring. Infants are completely dependent on their mothers for over a year. Female baboons' aspirations are to protect their children and to live a long life. Unlike males, females are seen as a large social unit because females with genetic ties will protect each other. It is common for females to form ties outside of their genetic group; this is established through grooming. Matrilineal society is linear in which one family is dominant over all other natal groups. This hierarchy is

transitive in which natal Group A is dominant over B, and natal Group A is dominant over C. The female hierarchy, unlike in males, is not dependent on being able to physically dominant other members of the society. Rank is determined by age (the youngest sister is the highest ranking of the family members), a baboon's association with natal relatives, and alliances with other females. The female caste system is very rigid. While it is possible that one could fall from status, it is almost impossible to achieve alpha status overnight. Low-ranking females are unable to achieve higher status because the association of lower-ranking kin affects their status. Without the alliances of fellow kin, a female is unable to ever achieve higher status because she is unable to protect herself against other kin groups. A comparison to human social life is the belief that poor people have high stress in their lives because of low income, but the fact is that without a social support system, they are never comfortable because of the lack of control in their lives. When disputes happen between a higher and a lower female baboon, it is engrained in the inferior female that she will have to back down from the dispute. High-ranking females have a regal allure that is unquestioned by lower-ranking females. As a result, when a dispute ends, there is no direct reconciliation. One may ask how society ever functions if there is never a resolution to an argument. The answer is that other family members confront the victim of the aggressor. The reason higher-ranking families stay in power is their ability to remain unified. Unlike males, who are constantly trying to obtain alpha male status, females live a life that is less stressful when social movement is not present. It is equally stressful when they are going up or down on the social spectrum. The only true downside to being a lower-ranking female is the fact that protection of infanticide is lower because high-ranking males see no reason to protect socially weaker females. Protection is vital to a family's ability to live a long life and allow for a safe environment for its offspring.

The reason that baboons are known for having an extensive social network is the fact that all baboons in a society must be able to adapt to ever-changing demographics. As scientists learn more about this species, they realize that baboons live traumatic lives, which have directly resulted in a short life span. With limited cranial capacity, baboons are unable to alter their environment to their needs. This sets humans and baboons apart. It affects not only the immune system of the baboon but also causes major damage to the mind of the baboon. In a life span, an individual must be constantly aware of its surroundings (such as births, deaths, immigrations, emigrations, sexual courtships, and fights). How is this physically possible? For baboons, it is an unconscious function. Baboons are able to determine social relationships and kinship ties based on the ability to recognize individuals in their group through smell and vocalization. While self-recognition is present in baboons and other Old World monkeys, it is difficult for scientists to prove that these species can empathize with other members of their

community. Even though humans are more suited to perform this task, it seems the development of this function in our brains is grounded in symbolic language as articulate speech rather than merely in social observations. The baboons' ability to unconsciously determine the rank of an individual is a skill that must have been favored by natural selection for this species. Baboons that are able to effectively determine their social network are able to live in a large, governed social structure. This allows for baboons to live on the open savannas where they are physically less dominant than other species. The ability to make quick judgments allows for a simplified method for running a social organization. Simplifying social life is a process that is unconscious and can be compared to humans when our species tries to make tasks easier by creating new methods or tools to allow our life to function more efficiently. The evolutionary history of baboons favored the social function, so baboons became more efficient at living in large groups. As stated before, bigger brains result in the need for more energy, and as a result, instead of bigger brains, the social specialization of the baboon species has resulted in a less solitary life, whereas a baboon with an individual lifestyle would be dependent only on its own ability. Having social skills is a trait that allows for baboons to survive not just in their harsh environment but also for being able to observe the unpredictable social world of baboon culture. In comparison to humans, the baboon is a very introverted species. Understanding the internal thoughts of an individual is difficult. Vocalization is limited to grunts that express a very general idea. This struggle to express information highlights the ability to observe the world as a necessity.

The day-to-day ability to plan for future events is not possible for a baboon. The brain of Old World monkeys is not as developed in comparison to the brain of pongids and humans. Baboons live in the moment, unable to sort information to help make their lives easier. Baboons are a diurnal species like humans. A baboon sleeps in the trees at night and hunts by day with an entire group. When traveling through the forest, baboons make loud noises to scare off predators. To achieve success in fighting off large animals like water buffalo, leopards, and hyenas, baboons mob up against the predator. Baboons are vegetarians, so fighting off large animals is only to prevent traumatic attacks.

The other *Papio* species of baboon (*Papio hamadryas*) is found in the deserts of northeastern Africa. Unlike the large groups of eastern Africa, the baboons of the desert are forced to live in small units because of the scarcity of food. Feeding units consist of a single alpha male and 1 to 4 females who also bring along their offspring. This baboon spends the night in large groups of hundreds of individuals on rock strata to protect themselves from larger predators, but during the day, a large group disperses into family units. A group forages with a single adult male accompanied by his females and their offspring. There is significant sexual dimorphism and sexual dichromatism in

the baboons of East Africa. The adult male hamadryas baboon clearly distinguishes itself from its female counterparts. With large canines, caped hair, and a dominating size almost double that of females, males clearly have an upper hand at maintaining control in the baboon world.

Studying the Old World monkeys of Africa and southern Asia has provided a scientific insight on how proto-hominids and early hominids may have existed before the emergence of our own species. The ability of baboons to work with one another in communities led to their success in surviving on the unforgiving savannas.

Hylobates

Gibbons are members of the Hylobatidae family. They are most notably known for their long arms and unique vocalization. Gibbons are very nimble in their arboreal setting, using their long slender fingers as hooks, allowing them to swing from tree branch to tree branch efficiently. The type of locomotion that hylobates perform is known as brachiation. Based on the anatomical ball and socket design, the gibbons' locomotion style is an arm over arm movement. Gibbons are known as lesser apes in comparison to their counterparts, the pongids or great apes. While they share similar characteristics such as an absence of tails, broad chests, and an upright posture, the lesser apes are unlike the great apes due to having a smaller cranial capacity and body size. The Hylobatidae family consists of 11 species that are recognized. These species are divided into four subgenera based on their different characteristics.

Gibbons live in moist rain-forest-like settings, where they spend the majority of their time, living in the high canopy of the forest. This allows for hylobates to look over the entire forest, helping them to avoid conflict with larger predators like leopards and pythons that live less than 10 meters from the ground. This is another behavioral trait that separates hylobates from the great apes, as the great apes are more prone to a terrestrial life. The lesser apes of Southeast Asia are similar to monkeys anatomically in size and their dental makeup. However, they are also similar to the great apes because they do not have tails.

Their diet consists mainly of fruits but also includes leaves, flowers, and small invertebrates, such as bugs. Monogamy is present in gibbon behavior. It is believed to be an ingrained practice, due to the social need and time spent in raising offspring. Forming strong bonds with its mother or father plays a direct role in the health of gibbon offspring. If the male is not present to protect and provide resources for the family, the species would have never survived as long as it has. Around the age of 10 years, an offspring leaves the comfort of its parents and ventures off to find a mate. Vocalization plays a pivotal role in the pair bonding of mates. Duets in the morning and evening between males and females allow for an understanding of the other ape before they meet. This form of communication

is not only important for a baboon in meeting its future mate but also is important in the guarding of its territory. The species is able to perform these melodic sounds due to a throat sac that lies below the chin.

Due to the gibbon's dependence on living in trees, researchers are still attempting to understand this hylobate. Since the species is isolated up in the canopies of the forest, it is difficult to understand the lives of this creature after the sun has set. The gibbon, unlike any other tree-dwelling ape, does not build a nest in the trees. This is due to the adaptation of its callused hindquarters.

The time is now right for scientists to uncover as much information about the gibbon species as possible. As the environment of these species becomes increasingly threatened by humans in the forms of logging and agriculture, the species are more and more at risk of extinction.

Pongids

Orangutans, known as the men of the forest, are seen as the most antisocial of the four pongids. While this species is more introverted, it does not mean that there is not much to learn about this behaviorally and genetically great ape similar to our own species. Researchers such as Birute Galdikas (1996, 2005) and even the pioneer of orangutan studies, the late Alfred Russel Wallace, claimed that this animal in its natural environment of Sumatra and Borneo is not challenged to outwit other animals on these secluded islands. The only true threat to this species is human intervention. Hunters steal infants and sell them on the black market or to zoos. Adult males, in response to these attempts to steal the babies, attack poachers and are killed as a result. Human intervention does not just stop there. Deforestation is also a part of the orangutan's struggle for survival and reproduction. Logging companies use the precious timber of these islands for carpentry and use the leveled land for farming and/or ranching.

As stated before, the orangutan is a very introverted primate. The only ties that are shared between adult males and females are for procreation. Large males attempt to monopolize the gene pool of their area. They perform this by spreading their genes to as many females as physically possible. The reason it is impossible for this feat to occur is due to the size of an adult orangutan. They vary in size from 110 to 198 pounds, which makes it difficult to travel efficiently. While this task may be impossible, it does not stop the males from wanting to achieve this goal. Female orangutans have a slow reproductive cycle; the opportunity to conceive is only every 10 years. The long gestation period has its benefits and its drawbacks, as it gives the females the responsibility to choose the most suitable mate. But the survival rate of the species is dwindling because it takes so much time to conceive only one child.

Compassion is rare; it is displayed only between a mother and her offspring. While genetically 97% similar to

the human species, orangutans are seen as not being our closet living relative. However, there are many who believe that anatomy and social behavior should be enough evidence to outweigh the DNA difference. The argument is somewhat valid due to the genetic difference. However, there are still many examples that show similarities to us such as intelligence. Orangutans understand the importance of protecting themselves from the elements. They do this by building huts for themselves. They create a nestlike structure with a roof to protect them from rain.

The prehistoric human's diet was once similar to the pongid's of our world. But due to environmental pressures, we changed our diet for a better opportunity for survival. An orangutan's diet consists primarily of fruits, leaves, flowers, bark, honey, termites, bird eggs, insects, buds, shoots, and seeds. This diet can make it quite difficult for this pongid to survive because of the unpredictable occurrences that happen to the environment. When their environment is being deforested and the climate causes long spells of drought, hostility reigns over the islands. Since orangutans are anti-social, cooperation is not present. When resources are scarce, males fight over the resources. Orangutans obtain most of their caloric value from fruits, and it takes a lot of fruits to achieve their desired caloric intake.

While scientists believe that humans are not closest to the orangutan, there are alarming characteristics that prove otherwise. Like humans, orangutans are susceptible to human diseases like malaria and the common cold. Other remarkable physical characteristics that single out this great ape from the other pongids are its sexual dimorphism between males and females. Facial hair, cheek pads, long hair, and a throat sac (male traits) show the complexity between the male and female development. Humans show a large spectrum of diversity in their physical characteristics. This difference occasionally results in males and females being unable to show physical differences or result in a human being sterile. Male orangutans have this shared similarity, known as bimaturism. These males are unable to grow long hair and lack cheek pads or a throat sac, but surprisingly they are able to mate. Even though it is difficult for these males to attract the opposite sex, they are still able and willing to mate.

The debate about genetic similarities is always contradicted by unique similarities; scientists can make assumptions about the bonobo and chimpanzee because they are more extroverted pongids than the orangutans and gorillas. The gorilla is seen by scientists as the pongid with untapped potential to be our closest relative. It is hard to judge this large and peaceful species because scientists are still trying to study these primates within their remote locations.

The shy, gentle, curious gorilla is seen as a species that has the most potential for scientists to discover more about ourselves. The gorilla has shown proof of its ability to solve complex problems in tests performed in labs and zoos. However, in the isolated mountains of Rwanda and

northern Congo, it is a different story. Like the orangutans, gorillas do not have predators that challenge their well-being for survival and reproduction. Without any animal forcing them to critically think about how to obtain the resources they need for survival, the gorilla does not show objective signs of great intelligence, and therefore, it is stereotyped as unintelligent. The gorilla is a more social creature in comparison to the orangutan. Gorillas groom and play with other members of their communities. These small societies in which they live are very important for the development of the members of the community. Male gorillas take pride in the protection of their territory from other predators. Mountain gorillas live in small groups of approximately 10 individuals. One silverback male gorilla rules over adult blackback males, adult females, and juveniles.

Males are the dominant figures in a gorilla society. The functions of the entire community revolve around the silverback male. Some extreme cases of inability to accomplish tasks occur when a silverback male dies. The entire group can dissolve because the female's only bonding is between her child and significant other. As a result of this situation, females will leave to join other groups in order to mate. Mature silverbacks can weigh up to 450 pounds; unlike any other pongid, blackback gorilla males must assert themselves into a role in their group. When males reach a certain age, they are forced to decide if they are going to leave the group to start their own clan or remain as a part of their initial clan and hope the adult silverback will share his females. Leaving a group is difficult because it takes a long time to be accepted by another group—males may spend from months to years wandering in hopes of being accepted.

Like humans, gorillas are unique. All individuals have their own personality, distinct nose print, and voice pitch. This shy species, like humans, also appreciates its privacy. In cases of mating, males and females will find hideaways to share time alone. These intelligent creatures show signs of compassion toward one another. Dian Fossey (2000) depicted a moment from her long list of encounters where an elder male tickled a child with a flower and other moments at times when gorillas have encountered the death of loved ones. The first findings of the mountain gorilla, depicted first by George B. Schaller's (1997, 2003) studies, helped eliminate the generalizations about this shy and timid species.

This gorilla was once known as a savage animal, but now we see the mountain gorilla as comparable to cattle. The diet of the gorilla is poor, forcing the species to live a slow, uneventful life. With a diet consisting of insects and grasses, the gorilla has no leisure time because it is constantly foraging for food. This type of diet is unknown to humans, who are primarily omnivorous, which allows us the best chance for survival. Diet is very important to the chimpanzee and is similar to that of humans. Scientists have much knowledge about this extroverted primate, and evidence suggests that this great ape is our closest living relative.

The knowledge that we have obtained about the chimpanzee can be credited primarily to Jane Goodall (1990, 2000). Influenced by the late Louis S. B. Leakey, Goodall has studied chimpanzees in the Gombe area of Africa for over 45 years. The research about the chimpanzee's social interactions with others has shown the intelligence and the shocking acts that make the chimpanzee debatably the pongid most similar to *Homo sapiens sapiens*.

Unlike the gorillas and orangutans, chimpanzees are known for their tool usage and their ability to solve problems. This pongid has shown countless examples of its methods of outwitting its environment. Chimpanzees use twigs to extract termites from logs and pipelike sticks to hunt for fish and to extract honey from hives. Another intriguing behavior is the chimpanzee's ability to use leaves as a sponge to soak up water from streams and puddles. While tool usage varies, there is evidence that proves that this great ape critically thinks to solve problems. These techniques are learned from an individual of the group and learned from others through observation. The most important development in a young infant chimpanzee's life is the time spent with its mother.

Chimpanzees live in groups of 25 to 125 individuals. Chimpanzees in a society like humankind's is very community oriented. Chimpanzees work together because everyone has a vested interest in survival and prosperity. The males of the community share a sense of pride toward their territory. This land has specific boundaries that are constantly being fought over for its resources. The borders are defended by males who fight against neighboring communities. It is important to the success of the chimpanzee groups that males become a cohesive unit "army" because it plays a direct role in the survival of the community. Males never leave their communities, which allows for this cohesive bonding among other male chimps. The males of a society are very social with one another. They spend lots of time grooming, hunting, and protecting their territory.

Females, on the other hand, are by far not as sociable as males. Females spend most of their time raising their offspring, which is their primary goal in life. Outside of taking care of their children, females are solely interested in being around males. The female's menstrual cycle, unlike the orangutan's, is a 37-day cycle that every 9 to 10 days is evident by sexual swelling on the female's hindquarters. This swelling is appealing to males. This pink football sized sac shows the sexual availability of the female. This swelling is believed to be an adaptation to promote reproductive success and also competition among males. The sac is the body's physical reaction to the time when conception is optimum in an adult female. The membrane inflates from an increase in hormones. Scientists believe that females are the key to the success of the chimpanzee population because females hold the key to selecting the most fit among the males. Female chimps, like gorillas, are free to leave societies and join other groups; this is acceptable based on the fact that sexual swelling is a "passport"

into other communities. This is not the case for males, which are tied to their community.

Territory, while not clearly marked, is one of the sole reasons for violence in chimpanzee society. Like humans, chimps are very emotional creatures; Jane Goodall (1990, 2000) has reported cannibalism and murder in chimp behavior. These brutal displays are shown when males stray from their group. As a result, males that stray away from a group are usually killed and eaten. Warfare between groups is never a battle of epic proportions. The only time groups will even attack is when they know they outnumber another group.

Chimpanzees, like humans, understand that territory expansion is important to increase their resources. Males see the importance of reproductive gain in finding new females. By extending their borders, they are able to take resources such as fruit trees, sources of water, and termite hills. Cooperation between chimpanzees is vital to achieve a successful hunt; most nonhuman primates do not eat vertebrates. Only a few higher primates, such as chimpanzees and humans, eat other mammals. Chimps prey on a variety of mammals of at least 35 known species. Of the prey that chimpanzees hunt, 80% is the red colobus monkey. Meat accounts only for 3% of their diet, though. Hunting is primarily a male role in society. Tracking for prey is a bonding experience that promotes cooperation among males. Having a large group improves the chances of success. The reason scientists think that the chimpanzees may be our closest living relative is due to our strikingly similar diets. Their diet is comparable to the diet of past hunters and gatherers.

On the other side of the Congo River, another extroverted species known as the bonobo is a species that is only now being studied. DNA analysis shows that we share over 98% of our genetic matter with both the chimpanzee and bonobo. This arboreal pongid found in central Africa is known for being less aggressive than its strikingly similar counterpart, the chimpanzee. The bonobo (*Pan paniscus*) forms a female-centered egalitarian society. Their social order is run by an adult alpha female. The extroverted bonobo is seen as one of the closer links to our existence. With its ability to use tools, stand erect most of the time, and express a wide range of emotions, this great ape makes a case for being the closest living relative to us. Primarily frugivorous, scientists believe that this harmonious species lives in peace. This is because the species' environment has an abundance of vegetation, allowing them to live in large groups without fear of competition.

The discovery of this species was first documented by Belgian hunters, who brought back to Belgium their carcasses and skeletons from the Congo in the 1920s during the age of colonialism. Bonobos were first claimed to be a subspecies of the chimpanzee up until the 1980s. The distinction was finally made in 1982 by Harold Coolidge, an American anatomist, who claimed that the species was structurally different from the chimpanzee. The major

anatomical differences between chimps and bonobos are that bonobos have a slender frame and bonobo males are only slightly larger than females. Both bonobo and chimpanzee males are more robust than females. From the neck up, bonobos resemble chimpanzees: Males are more robust than females, with larger canine teeth. From the neck down, bonobo males and females are almost identical. Due to isolation, these species eventually specialized to form the modern chimpanzee and bonobo. Chimpanzees, unlike the bonobos, live in an environment that is half savanna and half forest, while bonobos live strictly in a tropical rain forest climate.

Anatomical differences are not the only significant distinction between these two species. The social behavior of these two pongids are polar opposites. The first major study that helped shed light on these behavioral disparities was performed in the 1930s by Eduard Tratz and Heinz Heck at the Hellabrunn Zoo in Munich. Their template provided evidence of the major differences between the two great apes. The eight point behavioral study emphasizes sexual behavior, intensity of aggression, and vocal expression. This study was sadly disrupted when World War II broke out. This setback is just one of many in the search to understand this forgotten ape. The bonobo has been the most difficult ape to study for a multitude of factors—for example, the shy and timid species takes time to open up to humans. The successful studies at the Wamba site were due to the use of sugarcane to entice bonobos to approach and accept humans. The bonobos' environment is another reason why this species is difficult to study. It lives in a thick and isolated rain forest, which covers 80% of the country. The Democratic Republic of the Congo is much larger than a map truly portrays. The Democratic Republic of the Congo's rain forest is the second largest after the Amazon rain forest. To access this remote land, one must hike through the rain forest or paddle along rivers. To add more difficulties to the search for knowledge, the Democratic Republic of Congo since the 1960s has been in political upheaval.

The endangered bonobo species is an important subject to study because it will allow us to come to an understanding of how our species survived and how we developed into the species we are today. The bonobo is an example of a species in which the environment has played a significant role in shaping its social and emotional patterns. In this tranquil land, the female bonobo, unlike in any primate species, creates alliances with other females. This is unique because in other species females migrate to other communities. This static unity among bonobo females allows for unity among the females. With this close social bonding, females are able to control bonobo society through the regulation of food and the protection of infants. Bonobos provide for an alternative view of what is natural in society. This species shows that evolution does not consistently promote the development of a patriarchal society. The common scientific belief has been that polygyny has been the reason

why *Homo sapiens sapiens* survived. This theory was based on the fact that males naturally felt it necessary to protect their offspring to help promote the passing of their genetic traits. As a result of this fear, males would form close ties with their female counterparts. This close tie led to the creation of the nuclear family in which a male, female, and child live as a cohesive unit.

This contradicts the argument that society revolves around the belief in a nuclear family as the ideal way of life. Based on limited information, scientists are unable to prove that there is a social model that demonstrates whether humans are closer to the chimpanzee or the bonobo. The bonobo is a species that allows anthropologists to glimpse another way of living in a society. This difference in perspective prevents humans from making universal assumptions about the past. For humans to truly understand where we have come from, we must be able to learn not only about our evolutionary history, but also a vast amount about the social and evolutionary history of our closest relatives, the chimpanzee and the bonobo. Bonobos are the contradiction to the argument that a formation of a nuclear family was present because their environment does not force them to constantly fight for resources. Another reason why there is more cooperation within their large communities is due to males and females being unable to determine who the genetic father of an offspring is. This allows for a society in which everyone collectively takes care of one another.

Bonobo males, unlike those in the other three great apes, migrate to other bonobo groups after they become old enough to leave their mother's care. Gorillas, orangutans, and chimpanzees all revolve around a patriarchal society. The reason the bonobo species is remarkable is that females—which are 85% anatomically identical to males—are able to run society based on cooperation with other females. Sexual dimorphism is a driving force for why the majority of males in the animal kingdom function as the dominate gender.

While both chimpanzees and bonobos have policies regarding how a society should function, both are dramatically different. Chimpanzees follow a method of knowing what they want, when they will get it, and how they will get it. Bonobos are not less intelligent, but they simply use different methods to obtain what they want. Chimps resort to violence or power to obtain what they want, while bonobos use sex to solve problems. As previously stated, bonobos and chimps are specialized for behaving in different ways. Chimps function with the method of working together to use violence to obtain power. Bonobos are more in touch with placing themselves in the “shoes” of another bonobo's needs and desires. With this awareness, bonobos are able to share an understanding without becoming consumed with their own needs and desires.

Making other individuals in a community comfortable is done by forming close bonds with other members. When competition for resources is at hand, tension is

released through the rubbing of genital areas. With the use of sex as a method to relieve aggression, bonobos are able to be at peace with not just individuals in their community but also with complete strangers. This rubbing is not exclusive to females; both males and females use it as a form of resolving conflict. Bonobos engage in sex with every partner combination: male-male, male-female, female-female, male-juvenile, and female-juvenile. Despite all this sexual activity, the species' rate of reproduction is low (single births in 5-year intervals), and to prevent incest, adult females instinctively leave their communities in search for new mates. This happens when females migrate in their adolescent years, leaving their homes around the age of 7, when they develop the first signs of sexual swelling. In bonobo societies, since adult females retain their sexual swelling when pregnant, it becomes impossible for males to determine whether a child is theirs. This ambiguous pregnancy, while making it difficult for females to find a dependable father figure, allows for the community to remain unified because males are not at constant odds with other males over females or killing infants. To show another behavioral difference from other animals on this planet, bonobos understand the importance of procreation, but like humans, they believe sex is an act of pleasure. Sex, in many cases among humans, is seen to be simply an act of procreation because it forces them to accept the fact that humans are just like every other animal on this planet.

The use of tools has always been an indicator of intelligence. However, there are not many cases in which bonobos have been prone to tool usage. Frans de Waal (1998) argued that this does not prove that bonobos are more or less intelligent than their counterparts, the chimpanzees. He argues that bonobos have provided only a few cases because they are not challenged to think critically to obtain food in their environment. Tool use in most cases is a method used to collect objects that pongids cannot obtain without the advantage of tools. While the bonobo has shown rare cases of tool use in the wild, Kanzi, a bonobo at the San Diego Zoo, was able to create Oldowan tools by cracking stones together to make flakes. The reason Kanzi actually created the flakes was based on her desire to acquire food.

Tool use is not a standard that all individual pongids can achieve: Some individuals are more intelligent than others. It is debated if culture is present in other primates. Culture will never be present if one generation is unable to teach another generation a skill. Humans are able to perform this task through many methods such as literature, oral traditions, and events. But for apes, it varies based on the community's ability to transmit information. While it may seem difficult for people to picture a society such as the bonobos, we can truly learn something about ourselves from watching the social behaviors of this close relative. Roughly around 5 to 6 million years ago, we shared the same common ancestor. Through observations, we are able

to glimpse a picture of this past if bonobos have retained traits similar to those of our ancestors.

Language

Communication is a function that allows all living animals the ability to transmit ideas and feelings to one another. Conversing is what separates the living from the nonliving. Each organism on this planet achieves this process in many different ways. The study of linguistics is a comprehensive field that does not study just language in humans; it also has incorporated an extensive study on animals to determine if language is uniquely human. While studies have varied among different animal species, the main focus has centered around our closest ancestors, the primates, and more specifically the four pongids. From the study of our closest living relatives, the science community hopes to discover the true definition of what language is, and it also hopes to shed light on the evolution of human social and cognitive abilities.

As scientists learn more about the hominoids, they will uncover the properties of acquiring language and also the ability for language comprehension. In the early history of studying our closest relatives, most research was performed in labs to test the limits of the human mind. As time passed, a debate arose over which direction science should turn in decoding the answers to the origins of language. In the natural world, we can truly see these species in an unaltered state. However, many of our closest relatives, the pongids, use only a fraction of their intellect. The reason for this is that their environment does not demand that they develop communication beyond only their need to survive and reproduce.

The great apes in their natural habitat dominate their living space. The only true threat to their existence is human intervention. Without their environment challenging them to alter their lives, there is no need for these species to create stronger social relations with one another. Researchers argue that what truly separates the pongids from other primates is that their cranial capacity has allowed them to think on an individual level. As a result, this has not led to the forming of strong community ties. Sharing information with one another does not need to be as specialized as compared to that among members of the human species. In our recent evolutionary past, selective pressures must have forced humans to work together in a cohesive society in order to adapt, survive, and reproduce.

The specialization as stated previously in nonhuman primates is less sophisticated. Most primates use communication as a method of warning other individuals that there are predators. For example, chimpanzees vocalize in as many as 34 distinct calls. Though these rough grunts form a method of greeting, it can also be a form of expression such as excitement toward food or a feeling of compassion when a mother embraces an infant. Recognizing that these four relatives closest to humans are a key to understanding language,

scientists are in the process of uncovering evidence about these primates and if they are, in fact, deliberately vocalizing to one another. It is important for scientists to know if these species understand the meaning of calls because it would demonstrate the complexity of their minds. This will help scientists understand if these species have the cognitive ability to understand commands given by humans, which will allow us to test their intellect. While pongids are anatomically unable to articulate all the sounds of our universal grammar, it is more important to focus on their ability to understand what we are trying to convey. It is important to figure out if this is possible because it would show the complexity of their brain, which allows them to adapt to the world around them.

A shift is taking place in the way we study primates. Placing them in a world of human interaction will allow scientists to see their ability to adapt to a different social environment. While determining if other species are able to comprehend our communication system, we must keep in mind the fact that while this communication system works for us, it is evident that it does not mean that we are living an ideal way of life.

To understand species such as the chimpanzee, one must be informed about not just the biological and psychological makeup but also about the behavior of our complex relative. The anatomical makeup of our supposedly closest living ancestor, the chimpanzee, shows that the vocal folds in chimps are too fatty and less muscular than those of humans, and therefore, the chimpanzees cannot create sounds necessary for language. The larynx plays a large role in humankind's ability to articulate effectively; in chimpanzees, the epiglottis extends well higher in the throat, lessening the range of sounds it can produce. This evidence proves that our closest ancestors are physically unable to pronounce all the sounds capable of human language. Due to the chimps inability to speak with our capacity, scientists are divided on what research approach should be followed to test chimpanzees potential limits. The major division in the science community is between two methods: the use of pictograms, which allows primates to create simple symbolic syntax, or the use of ASL (American Sign Language).

The history of using ASL as a form of communication was first studied in 1965 by Allen and Beatrice Gardener. In their experiment, which lasted from 1965 to 1972, they raised a chimp as if it were a human child. Washoe, the chimp, was able to form simple syntax through the use of sign language in an intelligent and creative matter. Within 3 years, Washoe was able to learn 130 signs. This experiment was the first of many experiments that shed light on the capabilities of chimpanzees and led to the pursuit of studying other primates.

Modern studies pertaining to our closest living relatives have revolved around the alteration of an environment. One variable is selected in which the pongid studied is forced to think critically, forcing it to test its social limits. In 1999, the University of Georgia conducted an experiment that entrenched two apes in a human atmosphere. Panzee, a

chimpanzee (*Pan troglodytes*), and Panbanisha, a bonobo (*Pan piniscus*), were raised from 6 weeks of age and fixed in human society. The study's focus was to see the capacity of these species through the use of lexigrams and to see if these pongids could comprehend human speech.

Experiments that proved the complexity of the two pongids were performed by forcing the apes to use their social skills to get what they wanted. The most well-known and successful study was a double study in which a scientist would place a fruit outside of Panzee's reach. Another scientist would go near Panzee, and she would make the scientist aware of the location of the fruit. The forms of communication that Panzee used were initially displaying her hindquarters as a greeting, and after this greeting, pointing to a picture on a computer screen that displayed the item hidden. After she received the attention of the scientist, she would go outside in her play area and attempt to direct the researcher to the location. This test did not involve just a unique event; this study was practiced multiple times with the use of different locations and items. Usually, Panzee would inform someone of the fruit or image within a 24-hour time span, and in rare cases, within a few days. Behaviorally, the primates do not have the same complexity as humans do in speech, complex learning, or invention, but these behaviors are present to some degree. How will scientists uncover the mysteries of our closest relatives? The truth is that we can truly understand by simply forming a relationship with them, as well as observing them.

Every unexplainable event causes humans to consider the possibility that we are not the only species to actually have a complex brain. The social phenomenon of this world has played a direct role in the shift in our mentality and our understanding of behavior. The consensus since the late 20th century has been the belief that all animals were simple, walking biological machines having no feelings or compassion toward other organisms. Even the father of evolution, Charles Darwin, believed that all organisms follow the practice of survival of the fittest in which all animals are completely fueled by their primordial nonrational instincts, which drive them with any means possible to survive. Each species on this planet is unique and diverse, but this does not mean that we are not all connected through organic evolution. We all experience and react to stimuli to survive. Behavioral science is still flourishing because there is still much to learn about the primates of this world. Understanding and observing the day-to-day experiences of these species will allow us to see how their brain functions and also how our early hominid ancestors once lived.

Future of Primate Behavior Studies

Primate behavior has endless possibilities and many directions in which the field can go; but we must not forget our history and also allow for no "stone to be unturned." In order for primatology to achieve its goal in the understanding

of nonhuman primates, we must exhaust all options in all fields. While research has been seen as a highly competitive and an individualistic practice, it seems all the more logical for anthropologists and other scientists to band together to accomplish our goals. The reason we are motivated to study primate behavior is to learn more about ourselves and the other primates. To allow for the discipline to flourish, we must spark interest not only in our community of researchers but also in the general population. By providing information for people to learn, we allow individuals the opportunity to understand anthropology by creating the means to understand. We are providing readers with the sources, which will hopefully enlighten those who have questions.

Technology has affected all aspects of our lives. This is not contrary to the field of anthropology and the study of primate behavior. The ability to test the genome of individual primates is one of many fields that allow researchers the opportunity to become more attuned with evolutionary research. Knowing which offspring is whose is especially important in bonobos; this allows scientists the ability to create elaborate data, such as the family trees of individual groups. Other studies that have allowed scientists a greater insight into the understanding of our primate relatives are the testing of hormonal levels within species. This has given researchers the ability to gain insight into the reproductive cycles, ovulation cycles, male testosterone levels, and stress levels of the species studied. This is especially important in the study of baboons, which was addressed in *Baboon Metaphysics* by Dorothy L. Cheney (2008). While new advances in technology are costly, especially for large studies, their availability furthers the understanding of primates. As time progresses and technology becomes more efficient, these products will become obtainable to all.

Technology allows primatologists to obtain information on a more consistent and less invasive basis. In particular, by using radio collars to track species, scientists will not have to be constantly on the move for fear of losing the group being studied. The great benefit of these forms of monitoring groups is that scientists can watch over multiple colonies, which allows for cross-cultural studies. While advances in technology allow humans to study our closest ancestors with more efficiency, we must not forget that even though technology has allowed humans to achieve many goals, we have also caused great harm to our world. We must remember that humans have been in interaction with other nonhuman primates for millions of years, and for us to keep this possible in the future, we must be responsible and environmentally friendly.

While the scientific community knows there is evidence to prove this fact, the difficulty of trying to get into the minds of our closest living relatives remains. Do the great apes and the lesser apes have the rational faculty to understand the reasoning behind their actions, or is it simply that they are performing a task through mimicking? Are primates able to

create and maintain culture, and are primates restricted to only nonsymbolic language? Can these animals understand abstract thought by referring to symbols that are not physically present? In many cases, these questions cannot be addressed in the natural environments of these species because their environments do not demand that they use their complex brains in this fashion. This is why it is important to not only study primates in their natural environments but also to incorporate these animals into human social contexts.

Conclusion

The future of primatology has endless possibilities. What makes primatology such a unique focus is its ability to cover many areas of specialization. A comprehensive study has foundations in genetics, zoology, anatomy, veterinary medicine, behavioral ecology, anthropology, sociology, psychology, and linguistics. Since the 1950s, people have been curious to not only learn about our closest living relatives but also through learning about these species to learn something about ourselves and where we have come from. The major reason why primatology has been able to make the progress it has made is because in the science community, people treat the field and subject with utmost respect and have decided they will devote their lives to this field. Without scientists who truly love what they are doing, primatology would never achieve its goal in understanding the nonhuman primates of the world. As in any subject, the only way for us to continuously expand our knowledge is to establish the general descriptions of the subject in order to create a meaningful framework. The focus of broad general and quantitative studies during the 1970s and 1980s allowed for future studies to achieve the success we have today. In our focus to find the specifics of our study, we must not forget our history and how to perform broad studies. Every day, we are uncovering new species, and while it is necessary to obtain more and more information about primates, we know we must also create a comprehensive view of the new species in the taxonomic kingdom. As species are being discovered, we must remember that as more and more human contact takes place among the primates, the more likely that our chances to study these species will begin to dwindle. As much as we as humans have created and discovered remarkable things, we intentionally and unintentionally have the ability to alter not only our own lives but also the lives of other organisms around us. To discover the information we need, primatologists must work together in the effort to enlighten not just the science community but also the human world.

PRIMATE EXTINCTION AND CONSERVATION

ANDREA PATRICIA BIRKBY

Fort Lewis College

Nonhuman primates offer tremendous value for many different reasons. Being humankind's closest living relatives, they can teach us a great deal about ourselves in terms of understanding our own cognitive abilities including behavior, health, language and development, and, importantly, evolution. They also play a significant role in habitat biodiversity, which is of tremendous importance to overall health of the world's fragile ecosystem. In terms of biological diversity, primates are both seed dispersers and seed predators, occupying specific niches throughout tropical rain forests. Some of the world's richest and most diverse ecosystems also have the largest and most diverse primate populations.

The Issue

Many primates live in tropical, developing countries and compete with humans for valuable resources, such as food and habitat. In various parts of the world, they are exploited for consumption either directly as food or indirectly for medicinal value and also commercial trade. Primates that raid crops, like other animals around the world, are sometimes shot as pests or poisoned. Their forest habitat is being logged and cleared at an alarming rate by commercial loggers and subsistence farmers for land use, such as plantations for cash crops and even firewood. Finally, since endangered primates live in primary rain forests, which

often have the most valuable wood, their conservation is directly tied to the protection of their habitats.

Background

Within the animal kingdom is the order of primates, a group comprising more than 230 different genera. Groupings within the order are either classified into prosimians (smaller bodied and often nocturnal insectivores, with claws instead of nails) and anthropoids (larger bodied, diurnal, often frugivorous, with female reproductive cycles similar to that found in humans) or strepsirrhines or haplorrhines. For example, lorises and lemurs are considered prosimians and strepsirrhines, whereas all monkeys and apes are anthropoids and haplorrhines. Perhaps the most unique primate is the only one that shares characteristics with prosimians and anthropoids and maintains characteristics unique to itself—the tarsier. It has been the subject of controversy for some time and because of its unique combination of traits looks to remain that way.

Nearly each species found within this distinct order possesses physical qualities that separate them from other mammals and other animals. Primates, including humans, share a variety of characteristics not necessarily unique in and of themselves. However, it is the combination of these traits that make them unique. Some of the specific traits

that certain primates have include a complex stomach (sometimes sacculated in colobines species), flexible shoulder girdle (to allow for the greatest range in motion between arms and shoulders), toilet claw (used for extraction of food), dental comb (to scrape bark and gum off trees), prehensile tail with a skinlike undersurface (often used as another limb as well as for balance), postorbital bar (how the eyes are situated in the skull), ischial callosities (sitting pads found on monkeys but greatly reduced in gibbons and siamangs), and cheek pads (food storage).

General traits include lengthy gestation, grasping hands and feet with an opposable thumb, a generalized skeleton, stereoscopic and binocular vision, and a large brain. In particular, the lengthy gestation makes primates particularly vulnerable to extinction. Apes on average reproduce only every 5 to 9 years in the wild (depending on the species). The grasping hand and opposable thumb allow for dexterity and manipulation of objects other animals are not capable of. The thumb has been perhaps one of our greatest evolutionary biological developments, as it allows for a specialized manipulation of objects and tools, which ultimately aids in our survival. Of all of our fingers (and toes), it is the thumb that allows for the greatest range of object manipulation. A generalized skeleton allows the primate to move through its environment in a variety of ways while also allowing an existence in a variety of habitats. Rather than only flying through the air to get from one point to another or slithering from Point A to Point B, a primate can walk, run, jump, climb, swing, brachiate, hop, leap—to move from place to place. Binocular and stereoscopic vision give the primate an ability to have overlapping fields of sight which provide a three-dimensional “(3-D)” view as a result of the eyes being on the front of the face rather than at the sides of the head. This allows for a depth in vision not all animals are afforded. The shape (and relative size) of the brain is similar between humans and non-human primates. The great apes have the most similar brain in structure and size compared to humans, with lesser apes closely behind. Monkeys have a similar brain structure but notably smaller.

Finally, the brain, nature’s most dangerous product (as some would say) happens to be relatively large in all primates. Big brainedness has many benefits not the least of which is an increased cognitive ability often associated with survival.

Intelligence and Cognition

Primate intelligence is a much studied area. Primates are able to demonstrate intelligence in numerous ways including via language, culture, tool use and innovation, and, perhaps most important, survival.

For example, each great ape species has several members that live in captivity and are capable of language in various capacities. Kanzi, a bonobo, uses a symbolic communication

board called the lexigram and is capable of understanding spoken language. Koko (perhaps the most famous signing gorilla) has a vocabulary of over 1,000 signs, and she understands approximately 2,000 words of spoken English. There are also examples from the orangutan and chimpanzee families.

Another example of primate intelligence is found in cultural behavior. Jane Goodall’s (1990) long-term field research has revealed that chimpanzees not only use tools but also make them. Chimpanzee tool use occurs for a variety of reasons including extraction of ants and termites, extraction of certain nuts with anvil and hammer types of tools, and even for symbolic gestures, such as bluff charges to intimidate rivals.

Primate self-medication is another area demonstrating cognitive abilities among primates. Many use plants to treat a variety of parasitic infections. Chimpanzee expert Toshisada Nishida’s studies have shown that out of nearly 200 native plant species eaten by Mahale Mountain chimpanzees, one fourth are used by natives to treat gastrointestinal disorders or parasite disease. In addition, monkeys and prosimians have been seen using millipede and ants as appropriate material for an anointment as protection from insects.

Social Structure/Food/Locomotion

Primate behavior is centered around group living in most cases. In fact, all but one species of Primates is considered social. The orangutan is semisolitary. This is believed to be because their primary food source, fruit, is only found sporadically; therefore, orangutans cannot afford to be social. While many primates eat fruit, the orangutan is a super-specialist of fruit and relies on it for over 90% of its diet.

Most primates live in groups from just several members (as in the case of monogamous species, such as gibbons) to large groups, numbering into the hundreds—hamadryas baboons live in groups as large as 700, for example; that, however, is extremely rare. Most primates live in smaller groups of less than 100 members. They are most often classified as diurnal (day living) or nocturnal, though some forms of lemurs are more crepuscular.

Nonhuman primates like their human relatives are heavily dependent on learned behavior. They learn what they need for survival from their mothers and also other group members. Alloparenting (care of infant by a group member not necessarily related to the individual but often is) is an important part of primate living, and thereby, only primates living in groups benefit from this behavior while raising their offspring. This has serious implications for long-term survival and conservation for different species of primates.

Many perform a variety of locomotion (with their generalized skeletons) and can brachiate through trees as well as walk quadrupedally on the ground and in the branches. Some

even walk bipedally (though rare). The bonobo is our most adapted primate for this type of specialized locomotion.

Primates eat an array of food especially fruit, leaves, other plant material, insects, and even meat. Some are highly specialized, such as the orangutan and gorilla, while others such as certain types of baboons are considered more omnivorous (like humans). Perhaps one of the most “vegetarian” species, the mountain gorilla has an herbaceous diet, with very little fruit and no meat other than insects. Proboscis and other colobus monkeys have sacculated stomachs (chambered) to aid in digestion of (often bitter) plant material, such as leaves.

In a general sense, most primates are found in tropical areas, with just a few genera found in more temperate climates. In fact, the generalized primate (one who can live in numerous ecological niches and eat a more general omnivorous diet) is rare. This includes some macaques, baboons, and of course humans. Thus, unsurprisingly, change in climate reasonably explains the extinction of numerous species of primates.

Wild primate populations are currently found in fairly specific regions and climates in almost 100 different countries throughout the world. They are found throughout Africa and Asia (Old World) and in both Central and South America (New World). Most primates live on or near the equator in tropical areas or rain forests. In fact, more than 90% of all primate species today live in tropical areas, and their fate is directly linked to the places in which they call home, forests. One species in particular, however, does live in northern Japan (Japanese macaques). There is only one species of primate found in Europe—the Barbary ape. The name is somewhat of a misnomer because the Barbary ape is actually a monkey but has no tail, and that may be the reason it was given the name.

Around the time dinosaurs went extinct, the fossil record reveals the first true primates. These ancestors of modern primates were small in size, active at night (nocturnal), and moved through their environments on all four limbs, quadrupedally. They were mainly in the form of lemur and lorislke creatures, smaller forms dating back to older epochs. The earliest known primate (ancestor) was around in the Paleocene or Cretaceous period. It was a tiny, insect-eating fossil mammal not unlike a tree shrew called *Purgatorius*. Then the rise and increase in numbers and diversity of primates was seen in the Miocene epoch. Around 30 million years ago (mya), monkey and apelike primates surfaced. Approximately 4 mya, hominids began to appear, and with this new species of primate came the adaptation to ground living and walking, or bipedalism. The Pleistocene is the epoch in which we currently find 234 (plus or minus) different types of primates. As each radiation of different primates occurs with each epoch, we also see the extinction of particular species.

Human evolution and adaptation expert John Fleagle (1988) stated, “The extinction of plesiadapiforms, for example, coincides roughly with the radiation of both

rodents and early prosimians, and the decline of proconsulids in the middle and late Miocene of Africa is associated with an increased abundance of cercopithecoid monkeys” (p. 460).

The record indicates that first rodents extinguished smaller forms of primates, and then later, larger forms of primates extinguished smaller forms of primates. This demonstrates a pattern of one animal form eradicating another. Humans, being one of the larger forms of primate species and undoubtedly the most prolific, also apparently display the same tendency.

Predation is one explanation for the disappearance of large numbers of primates (and other animals). It is known that humans have been hunting primates into endangerment and even extinction for hundreds of thousands of years. It is thought that during the Pleistocene in East Africa human predation was also responsible for annihilation of many large monkeys. Some 2,000 years ago (indicated by fossil data) with the arrival of *Homo sapiens* to Madagascar, we see numerous primate species driven into extinction. *Archaeoindri*, a gorilla sized lemur became extinct at this point. Today, many of the remaining species of lemurs found on Madagascar are also considered highly endangered—the main reason, human.

Extinction

As nature specialist David Quammen (1998) stated, “The concept of mass extinction implies a biological crisis that spanned large parts of the planet and, in a relatively short time, eradicated a sizable number of species from a variety of groups” (p. 58). Once this point is reached, viable populations no longer exist and so vanishes the goal of each biological organism perpetuation of self into the next generation. Specifically, Quammen (1996) added,

The crux of the matter of extinction . . . is not who or what kills the last individual. The final death reflects only a proximate cause. The ultimate cause or causes, may be quite different. By the time the death of its last individual becomes imminent, a species has already lost too many battles in the war for survival. . . . Its evolutionary adaptability is largely gone. Ecologically, it has become moribund. (p. 77)

It is well-known that human activity is changing weather patterns and ultimately the climate. In addition, competition from other primates (humans) coupled with destruction of natural habitats now accounts for the largest extinction seen in history. Comparatively, recent historical times have shown extinction on a small scale. As Quammen (1998) told it, “Between 1600 and 1900, by his tally, it is believed that humans caused the extinction of about 75 known species, almost all of them mammals and birds. Between 1900 and 1979, humans had extinguished about another 75 known species” (p. 59). Obviously, unrecorded and unknown extinctions are not factored into

these numbers. This rate is well above rates of known loss during the Cretaceous extinction (the most recent and perhaps most famous of all extinctions, extinction of dinosaurs). Mathematical calculations can be done estimating current rates of destruction and the number of species that will therefore become extinct. As an example, it has been estimated by W. V. Reid of the World Resources Institute that before 2040 up to one third of tropical forest species will either be extinct or doomed to extinction unless drastic change occurs. This has grave implications for a slow-reproducing, long-living animal, such as a primate.

Some argue that extinctions (in mass scale) are natural—having occurred at least 5 other times in history. The difference this time is what makes the current situation most alarming, the rapid degree at which it is occurring, as well as the cause. Smaller extinctions were thought to take only one species per major group per million years according to experts such as Quammen. It is believed that this background rate was counterbalanced by the evolution of new species. Mass extinction tells a different story.

Endangerment

Primates are vulnerable to extinction for several reasons. Lengthy interbirth intervals coupled with long lives are characteristics often associated with primates. With that, comes grave conservation implications for both individuals as well as species, not to mention overall ecological diversity.

In a general sense, primates are considered slow breeders compared to other animals. While some are capable of producing offspring up to twice a year, that is rare. As an example, for each of the ape species, the time between births (interbirth interval) varies from up to 2 years in gibbons to up to 9 years for orangutans. Chimpanzees, bonobos, and gorillas all have approximately 4 to 6 years between births. For a species that only gives birth normally once every 9 years, vulnerability to extinction looms closely.

However, there are additional reasons, which make the issue more complex. Proboscis monkeys are currently found in the wild only in Borneo and are at great risk. Their numbers are estimated at less than 10,000. They have very specialized diets, including certain leaves, which require the unique digestion that only a sacculated stomach can provide, and do not do well in captivity. Proboscis monkeys seem to have a rather calm and sensitive temperament in contrast to, say, a macaque or baboon. It is for these reasons that these culturally distinct monkeys are some of our most vulnerable to extinction.

Another example provided, this time on the African continent, is found only in the Democratic Republic of Congo—the bonobo. These great apes are genetically 98.5% plus similar to humans and considered to be temperamentally sensitive and also culturally unique. According to bonobo and chimpanzee expert Frans B. M. de Waal, during

World War II bombings near the Hellabrunn zoo, captive bonobos died of fright in zoos, while their chimpanzee cousins remained seemingly “unaffected.” Bonobos have proven to be one of the most intelligent (in human measured terms) species ever documented, with capabilities for language, tool use and innovation, and other various attributes. Thus far, bonobos are the only known species to use sex for more than pleasure and reproduction. It has been widely researched that they rely on sex to diffuse aggression.

Both bonobos and proboscis monkeys are two diverse species found within this particular order in the animal kingdom. Yet sadly, we as humans risk their very existence at the hands of our own ignorance and greed.

Human overpopulation is one reason for endangerment of other species. Even though a few countries and states have declining population growth, overall world population continues to grow at an alarming rate. This compounds an already bad situation by putting enormous pressure on available land (and therefore biodiversity).

Destruction of habitat comes in a variety of packages, most often for the reason of land conversion for resource exploitation. For example, in Indonesian rain forests (home to many different species of plant and animal) wood is harvested for several reasons. These include use for plywood, furniture, homes, fuel, knickknacks, and even toothpicks. As Franke Wilmer (1993) articulated in *In the Indigenous Voice in World Politics Since Time Immemorial*, “The international demand for hardwood between 1950 and 1985 increased from four to seventy million cubic meters. Japan and the United States are the primary consumers. The Philippines, Malaysia, and Indonesia are the primary suppliers” (p. 17). It seems our insatiable desire for wood may doom our closest living relatives.

Land conversion (for profit) is another reason why primate habitat is disappearing. This includes logging, overgrazing cattle for human consumption, and converting natural, undisturbed areas to cash-bearing profit crops (such as rain forest to palm plantation or small-scale forest to tourist destination). Plantations for coconut, palm, rubber, sugar, and so on are also devastating the natural environment including many forested regions in tropical places, such as Asia and Africa. Palm oil is the chosen oil used in almost every household throughout Southeast Asia. Indonesia, home to the endangered orangutan, is the largest producer of the plant. It is used locally, as well as exported to countries throughout the world. It is found in numerous consumable products sold in the United States, including cakes, cookies, candy, crackers, soap, and so on. In fact, some believe that palm plantations have replaced the frenzied logging industry because the rate of destruction is even greater for this type of land conversion than simply taking product out of the forest.

Another threat to primates is the transmission of disease between animal and human (zoonosis). Numerous viruses and parasites can pass between humans and nonhuman primates. These include the common cold viruses, malaria,

tuberculosis (TB), herpes, scabies, Ebola, HIV (which in primates is a form called SIV), and so on. Because of the genetic similarity between primates and humans (up to 98.5% between chimpanzees, bonobos, and humans) justification for medical testing on primates is not uncommon. Ironically, however, often the disease affects the given primate differently than it does in the human counterpart. It is believed that HIV originated from the blood and butchering of a chimpanzee in Africa in the 1950s; however, HIV is not fatal to chimpanzees. Unfortunately, medical testing and the infection of HIV in chimpanzees has resulted in a captive ape population, which is now lethally dangerous to humans but didn't further knowledge and understanding of the disease in humans. The care for infected individuals (that often live lengthy lives and cannot be afforded exposure to others of its kind) is yet another ethical (and financial) concern born of this type of situation.

Primates are also poached out of the wild to be used for medical research testing. Yerkes Regional Primate Research Center regularly imports primates to be used in medical experiments. At one time, the center had one of the largest populations of captive orangutans originally intended for biological warfare experimentation. Currently, macaques seem to have been deemed to be experimented on for diseases ranging from TB to HIV (or SIV in the primate form). In addition, international demands for biomedical testing on primates have had serious effects on certain populations such as rhesus macaques. In India, they nearly became extinct from "overharvesting." Until recently, conservational status has rarely been a concern. There are numerous considerations to this issue, in particular the ethics of capturing and holding primates for human experimentation is of grave ethical concern.

Nearly universally, primates are soft, cuddly, charming, and intelligent, exuding great appeal to humans. Therefore, capturing primates to be used as pets is another factor affecting their conservational status. People see them used for entertainment on TV or in movies, performing at circuses and at zoos, and people think they might make good pets. Primates are often willful and, particularly great apes, are at least 5 times stronger than most humans. They also bite and can carry diseases.

And while difficult to obtain a primate for a pet in the United States, that's not always the case with other countries. For example, in Taiwan until it became a member of Convention on International Trade in Endangered Species (CITES) (in 1990), it was considered fairly easy to obtain a primate such as an orangutan for private homes. C. Martin and E. Martin stated,

In the period 1987–1990 the demand was so great that more than a thousand (and possibly as many as two thousand) orangutan youngsters were smuggled out of Indonesia to supply a private market which was reportedly prepared to pay anything between US\$ 11,000 and 20,000 for an individual ape. While to some it may seem a high financial price to bear for humans, for primates, the cost is far greater. (cited in Rijkse and Meijaard, 1999, p. 121).

Capture for any animal is disruptive to say the least and traumatizing, often fatally so. There is no way to obtain an infant primate in the wild without killing its mother and often the entire family unit. There are numerous estimates on how taking one primate member out of its natural group in the wild negatively affects not just the individual but also its entire family and sometimes community. For example, experts such as Dian Fossey (1983), Geza Teleki (chimpanzee expert), and Herman Rijkse (1982; orangutan expert) approximate that for every infant ape captured at least 5 adults were killed; in another estimation, only 1 in 5 captives may survive long enough to reach its destination.

Primates are very dependent on their mothers for information critical to survival in the wild. Therefore, it is biological instinct for a mother to protect her infant at any cost. Further, in the case of mountain gorillas, the silverback will protect any member of his group and fight to his own death in the effort to protect them from humans or other dangers. Since gorilla groups can be as large as 20 members, this can mean a severe depletion in population when people hunt primates for pets or entertainment.

Hunting primates for food is another threat to them. Some local human populations throughout Africa have hunted animals in the forest for hundreds of years. Prior to the globalization of forest products, such as mahogany wood used for furniture, remote hunting was much more difficult. In more recent times, infrastructure provided by logging companies now contributes to access of previously restricted areas. The logger then subsidizes the hunter by providing weapons and guns and also provides free transportation into the forest, home to so many different species of primates. As authors Dale Peterson and Karl Ammann (2003) depicted, "It is possible to imagine that the loggers and the hunters and the meat traders are working side by side in a single coordinated and continuous activity: the industrialized extraction of valuable resources from a great forest" (p. 116). Companies bring in large numbers of nonnatives (and their families) and thereby stimulate the bushmeat business by supplying new consumers. It is said that typically these workers can afford more meat than people living locally. The authors also talk about studies in which wood workers were consuming bushmeat 2 to 3 times as often as natives in nearby villages. Employment for hunters is also provided by logging companies that may depend on them to eat. So here lies the connection between demand for wood, habitat destruction, bushmeat, and the endangerment of primates.

Unlike more natural causes for extinctions (such as effects from weather or other natural catastrophe), hunting has a greater influence on overall species numbers. In nature, the weaker, smaller, or diseased members are usually most affected. Hunters, on the other hand, will look for the largest animals available, females with dependent offspring (in the case of hunting for the pet trade), or even hunt indiscriminately. Chronic pressure

on primate populations by hunters is a further effect negatively affecting conservational status. The extinction (or near extinction) of certain monkeys is believed to be a direct result of bushmeat. It's difficult to know for certain because one of the ways in which conservationists know a primate female has been killed is in encountering her infant in captivity. For the hunted male, no such immediate record exists, though his body parts may wind up in commercial trade as relics intended for selling to tourists. For example, decorated, adult male orangutan skulls or even gorilla hands used for ashtrays are sometimes found intended for sale. Obviously, losing reproductive age females has significant implications in the overall conservation of the species.

Further compounding the issue is the fact that certain consumers have developed a cultural preference for bushmeat, such as gorilla. Primatologist Craig Stanford (2001) described it this way:

At an open air market in Yaounde, capital of Cameroon, a brand-new sports utility vehicle sweeps past a row of rusting tin-roofed shacks, stops in a cloud of dust, and disgorges a pair of Cameroonian yuppies in white tennis whites. They bargain briefly with a vendor seated behind wicker baskets piled with slabs of smoked meats and climb back into the SUV with the hand of a gorilla, the leg of a chimpanzee. Two hundred miles away, a logging truck rumbles along a rutted dirt road cut through the forest the previous year. Tethered to various parts of the truck are more animal parts, mainly duiker antelope but also gorilla. The meat, the surplus of what the logging crews have for their table, is being shipped via the forest road out to the towns for commercial sale. Along the way the truckers stop at settlements where more parcels of bushmeat are loaded on. The logging truck works for more than the loggers; it is the flagship of the ape bushmeat industry. The logging crew employs hunters at its camp to supplement the starchy diet the company provides. The company, a French-based conglomerate, knows this; in fact they have supplied the logging crew with big-barreled guns, intended to kill anything from gorilla size on down. (pp. 192–193)

Also, the role the government plays in this economic and global issue must be examined. It has been said that some officials not only condone consumption of bushmeat but will also serve and eat it themselves. In some central African countries, gorilla meat has been served at state dinners as well as found in metropolitan cities, such as Paris and London. This implies some sort of preference for bushmeat by the cultural elite. In addition, it has been found in areas where there are migrant populations of central Africans. Each species of great ape (as well as many monkey species) is potentially affected by this. The International Primate Protection League (2008) reported infant victims of the bushmeat trade ending up at a bonobo sanctuary in the Democratic Republic of Congo. These infants' mothers have been killed by hunters and poachers. Primates including chimpanzees, gorillas, and even slow lorises are also hunted for medicinal use.

Orangutans are not exempt from this threat either. Though shocking to learn, orangutan meat is said to be available for sale in local markets in Indonesia. According to orangutan experts Rijksen and Meijaard (1999), it is believed that at least two restaurants in Jakarta and even perhaps in other Southeast Asian cities orangutan and gibbon organs and meat are available at extraordinarily high prices, subject to availability. In addition, it's rumored that wealthy, east Asian customers place advance orders and on special occasion indulge in "primitive substitution cannibalism." It is this idea that then begs the question—though bushmeat hunting has gone on for generations—is the degree to which we currently see it occur sustainable, ethical, or even necessary.

Over on the Asian continent, primates are also hunted for consumption by humans but on a smaller and less direct scale. For example, orangutans, which have been hunted by local populations of Dayaks for centuries, are also at great risk but not due to overhunting and bushmeat, as seen in Africa. It is anticipated that the overall population in Indonesia will surpass 250 million people by the year 2020. The consequences of this growth will be perhaps most felt by biological organisms such as the slow-breeding orangutan. The ever-growing, insatiable quest for commodities by humans will present a sobering picture: the pushing of our primate cousin toward the edge of extinction.

Orangutans are therefore moving rapidly toward the edge of extinction. They are suffering mostly due to habitat loss as their forest homes turn into palm plantations for human consumption. So while they aren't directly hunted as often as African primates, they are as vulnerable due to the same global forces that are driving our African relatives into extinction.

Primates, especially the charismatic apes, are also exploited for entertainment in the media. Again according to experts Rijksen and Meijaard (1999), a Taiwanese television sequel (also featuring an adolescent male orangutan) called "The Naughty Family" ignited a "booming demand" for pet orangutans. It continues here in the United States as well. 1996 brought another star to American film: *Dunston Checks in Again* features another male orangutan, igniting an inappropriate interest in keeping primates as pets.

The American film *Any Which Way You Can*, starring Clint Eastwood and a subadult male orangutan, ignited an interest in keeping apes for pets. Most people don't realize that training an animal up to 8 times as strong as an adult human male, with keen cognitive abilities, often requires brute force. Many viewers may also be unaware that according to Peterson and Goodall (2000), authors of *Visions of Caliban*, the original orangutan "Clyde" was trained with a

can of mace and a pipe wrapped in newspaper. He was viciously beaten the day before filming started to make him more docile. Near the end of filming the sequel *Any Which Way You Can*, the orangutan was caught stealing doughnuts on the set, brought back to the training facility and beaten for 20 minutes with a

3 1/2-foot ax handle. He died sometime soon after of a cerebral hemorrhage” (pp. 145–146).

Future Directions: Conservation

The goal of conservation in general is to limit loss wherever possible. In the words of conservationist Russell Mittermeier (1996), a broad approach includes the following:

- (1) protecting areas for particularly endangered and vulnerable species; (2) creating large national parks and reserves in areas of high primate diversity or abundance; (3) maintaining parks and reserves that already exist and enforcing protective legislature in them; (4) creating public awareness of the need for primate conservation and the importance of primates as both a national heritage and a resource; . . . (5) determining ways in which people and other primates can coexist in multiple-use areas. (p. 1)

These efforts will help ensure that future generations understand and appreciate what has taken 65 million years in evolution and adaptation to create.

CITES (initiated in the 1970s) has helped the conservation of plants and animals by ranking just how threatened, endangered, and vulnerable each is to extinction. With more than 160 participating countries, laws have become more strictly enforced in hopes of saving and preserving the biodiversity still found in today’s modern world.

The idea of sustainable development is often used in association with conservation and globalization today. It looks at efficient management of resources and production levels, which increase or maintain productivity while causing minimum (or preferably no) damage to the environment. Specifically, too, sustainable development must be economically viable, ecologically sound, and culturally acceptable. It’s often a high order for a sometimes theoretic idea.

Protection plays a significant role in the conservation of primates. It is necessary that this occurs on several levels. Individual primates, entire species, as well as their habitat must all be protected. The rain forest is a biological system, which produces valuable product. When trees are cut unsustainably, precious nutrients are depleted, exacerbated by processes such as farming and cultivation. People must understand this connection between rain forest products and balance within a natural system. It requires awareness and recognition of the value of living primates. This occurs through education of not just values but also important factors, such as evolution, disease transmission, primate cognition, and general biodiversity. Primates must then be protected by laws, and those must be enforced rather than risk more theoretic conservation and less applied protection of them.

Establishing wildlife or habitat corridors has the potential to also aid greatly in the conservation of many different

primate species. This enables animals to move safely from one area to another, allowing important processes to occur, such as seed dispersal and gene flow. Seed dispersal contributes to overall biodiversity of all life. Evolutionarily speaking, gene flow is critical for reducing risk of inbreeding for smaller populations of primates.

Captive breeding and reintroduction plans offer some hope toward the preservation of certain primate species. The species most often highlighted as successful is the golden lion tamarin. It is an example of a species successfully brought back from the brink of extinction. Native to Brazil, these tiny primates had become incredibly endangered. Golden lion tamarin experts D. G. Kleiman and A. B. Rylands stated,

By 1975, fewer than 200 golden lion tamarins were estimated to survive in just a few small patches of Atlantic Forest in the state of Rio de Janeiro; but by 2000, their numbers in the wild were estimated at about 1000, with another 500 or so housed in zoos. (Campbell, Fuentes, MacKinnon, Panger, & Bearder, 2007, p. 505)

Also, incredibly, as many as 40% of golden lion tamarins found in the wild today were either born in captivity and reintroduced into the wild or are descendants of these captive born animals. Part of the success of the golden lion tamarin conservation program is attributed to small size and high reproductive rates of these monkeys (weighing approximately only 4–5 ounces and reproducing up to every 160 days or so). Also, protected habitats still available contribute greatly to the conservation success seen with golden lion tamarins.

Well-regulated ecotourism is another avenue that can lead toward the conservation of primates. As an example, both orangutans and mountain gorillas are species that interact with ecotourists. Through education and awareness to the public, the plight of the given species becomes more real to the visitor through a hands-on rather than theoretic understanding of issues these primates are facing today. Ideally, this can lead to behavior that is more globally responsible in educating the consumer on how consumptive choices may or may not affect a given species. It also brings employment and money into local populations who then take part in the caring for the apes or the parks in which they are found.

Another avenue of conservation in effort toward overall protection and prevention of extinction is rehabilitation. Dr. Carey Yeager (1996) defined rehabilitation in this way: “Rehabilitation implies a process in which animals in captivity are given medical treatment, protective care, and experience or training necessary for successful life in the wild” (p. 10). In addition, skills such as foraging, finding appropriate food sources, climbing, nest building, and even social interaction between conspecifics are developed and nurtured.

It is a difficult and time-consuming process, further complicated by financial challenges. Most agree that this wildlife management tool should be used only as, in the

words of orangutan experts H. D. Rijksen and E. Meijaard (1999), a “temporary measure to remedy a weakness in the legal framework concerning the conservation of protected species” (p. 154), as opposed to using it as an end all solution toward combating global issues surrounding endangerment. In other words, if the legal framework were enough, rehabilitation would be unnecessary. The goal of returning to a life in the wild though sometimes lofty is critical to those providing rehabilitative care for endangered primates. There are numerous rehabilitation projects located throughout the world. In particular, the island of Borneo, home to most of the remaining world population of orangutans, has several orangutan rehabilitation projects. Examples include Sepilok, located in Malaysian Borneo, which is known for its educational center and strict adherence to quarantine procedures. Semengok is also located in Malaysian Borneo and is locally known as an orangutan rehabilitation center. Wanariset (Indonesian Borneo) adheres to strict quarantine and release procedures for animals entering into the center. Nyaru Menting is the newest orangutan rehabilitation center and has been featured on Animal Planet’s “Orangutan Island” series. It is fastidiously run, and care for individual orangutans, as well as the overall species, is quite apparent. Camp Leakey, now a destination for tourists, is home to ex-captive orangutans, as well as wild ones. These are just some examples of orangutan rehabilitation in one geographic area of the world. When done well, it can serve as a model for other species in other parts of the world, facing similar challenges.

Additional efforts focus on providing sanctuary for endangered primates. Different than rehabilitation, a sanctuary does not have the goal of returning the individual to the wild. A prime example located within the United States is a sanctuary for lesser apes located in South Carolina. The International Primate Protection League (or IPPL) cares for 30 some gibbons rescued from biomedical labs, zoos, and even the homes of people who once had them as pets.

Many Western-living people have first come to know primates in zoos. Historically, however, most animals came from the wild, and those that survived often ended up in zoos. In *Our Vanishing Relative*, authors Rijksen and Meijaard (1999) depicted a Dutch animal collector named van Goens who was rumored to specialize in hunting adult orangutans rather than juveniles, arriving in Amsterdam with a reported 25 (sold for 25,000 German marks per pair). Then, for the Ringling Brothers Circus, he imported 33 more orangutans. Not one year later, the Dutchman returned to Amsterdam with another 44 orangutans, all from Sumatra. Based on records from zoos, at least 218 orangutans were exported from Indonesia between 1924 and 1943.

Modern-day zoos house many animals who have been born in captivity (to parents and grandparents caught in the wild). They are now considered another vehicle used in the

conservation of those very species. Within some zoos and aquariums, the Species Survival Program was developed in an effort to help certain species deemed most endangered. Its focus is on select animals that are in danger of becoming extinct in the wild. The program was developed with the idea that zoos and other captive breeding programs may be these species best chance to survive. By maintaining a healthy and genetically diverse population, these management programs offer some hope as more and more habitat is destroyed, fragmenting larger populations of animals, which large-bodied, slow-breeding primates are especially vulnerable to. Ideally, those rescued from poachers and pet traffickers should be the only members held captive and on display, in hopes of furthering education about the plight so many primates face today. As ambassadors for their species, these individuals carry significant educational and awareness messages for their closest living relatives to those who have put them in the greatest danger of potential extinction.

Conservational efforts focus on megafauna or flagship species (charismatic animals attracting attention to the plight of the given species). Primates, especially the great apes, certainly hold such appeal. For example, the Great Ape Project founded in 1993 by Paola Cavalieri and Peter Singer (1993) is an international organization of experts from a range of fields including primatologists, psychologists, and ethicists. The UN declaration of the Rights of Great Apes would confer basic legal rights on nonhuman great apes: chimpanzees, bonobos, orangutans, and gorillas. Specifically, of the rights suggested, the first is the right to life. Individuals are to be protected and not killed, except in self-defense. Protection of individual liberty, essentially the right to not be imprisoned or held captive is the second right. The right to be free from infliction of pain (torture) either wantonly or for alleged benefit of others is considered basic. This has obvious positive conservation implications for at least these four species.

All hope is not lost. At the turn of this century, estimates for lowland gorilla populations were around 100,000. In July 2008, a population was discovered in the Democratic Republic of Congo at 125,000—upping the overall total to more than 200,000 gorillas today. Also, since Dian Fossey’s time (late 1960s through mid 1980s), mountain gorilla populations have tripled, though with still just over 700, they are still considered critically endangered.

Another hopeful example as of late 2008 was reported on the Tonkin snub-nosed monkey. A small population of this extremely rare monkey, with its distinctive upturned nose, has recently been discovered in a remote forest in northern Vietnam.

As reported in *Science Daily* in late 2008, the monkeys were believed to be extinct until the late 1980s, with only approximately 200 Tonkin monkeys remaining in the wild. In April of 2008, biologists managed to observe 15 to 20 individuals (including 3 infants). This exciting discovery offers hope for the snub-nosed monkey’s future.

The past includes very little known information on primates in general. The last 30 to 40 years have brought a wealth of information about primate behavior to the forefront, crucial to understanding conservation issues. Presently, we are at what many experts consider to be the “11th Hour” in terms of understanding enough of the complexities involved in primate conservation and endangerment to prevent extinction. The future, while bleak in some ways, also offers increasing hope. As the human population expands so does our understanding of our kin. We have been endowed with tremendous cognitive abilities, and it is my hope that we will put those abilities toward great use in the preservation of our closest living relatives—the primates.

PART XI

CULTURE STUDIES

AMAZONIA

CARLOS ANTONIO MARTIN SORIA

Instituto del Bien Común Peru

The Amazon is the second-largest river in the world, with a basin that encompasses nine countries and is known as *Amazonia*. Amazonia, or Amazon rain forest, is one of the largest remaining forests of the world. It is home to indigenous peoples, both noncontacted and settled, mestizos, and European immigrants' descendants. A home to megabiodiversity, Amazonia contains plenty of natural resources—not only land but also timber, gold, oil, and gas. Amazonia is largely a remote rural area with people living in subsistence economies, but it is also a network of vibrant and chaotic urban centers and towns that have been supplying natural resources to the world market since as early as the 16th century. The export of mahogany, rubber, quinine, fauna, and many other products has always influenced the region's economy with a boom and bust cycle. The trail of natural products leaving the region serves as a channel through the subsistence economy, the mercantilist economy, and the free market economy. The fate of the forest is very much related to the demands of the world market and the unwillingness of national governments to invest government resources in an area already ruled by local economies supplying the world market through the export network.

The Amazon rain forest is divided into upper and lower sections of the Amazon River basin. The first one lies between 800 and 3,400 meters above sea level while the second area lies at an altitude below 800 meters. As many other tropical rain forests, Amazonia hosts a trilogy of

human and natural resources that constitutes not only its main value but also the fate of its destruction, indigenous peoples, biodiversity, and natural resources, such as gold and oil. Wood, medicinal plants, food, and firewood are some of the direct uses of forests. These forests provide for the survival of a number of rural populations, including indigenous peoples and resource-poor farmers. The standard of living of these populations depends largely on maintaining rain forest vitality, diversity, and coverage. The extraction of oil and mineral resources has fueled only economies foreign to the Amazon, which usually invest little in the areas where they mine or extract oil.

Settled Indigenous Peoples

The early works of Meggers and Evans (1957, p. 598) suggested that the first Amazonian settlers initiated a slow process of “filtration” through the main course of the Amazon River and its tributaries. Other works (Roosevelt, 1991) showed that the area in the Island of Marajo and in the main stream of the Amazon River hosted large, sedentary societies capable of military chiefdoms. The presence of these societies forced less complex societies to leave the *terra firme* and move to the 5,000 smaller Amazon tributaries and its headwaters. At the time of the European contact around 1542, when Orellana descended through the Napo River into the Amazon, some 5 to 6 million

Amerindian peoples lived in Amazonia (Denevan, 1976, 2003; Newson, 1996). Since early contact with the Europeans, the indigenous peoples' population rapidly decreased by epidemics and forced labor.

The Web page of the Red Amazónica De Información Socioambiental Georreferenciada (<http://www.raisg.socioambiental.org/node/106>) gives an overall estimate of more than 370 Amazonian indigenous peoples with a total population of 1.6 million people living in 2,200 territories. Additional to this population are the urban indigenous peoples and the noncontacted indigenous peoples. Bearing in mind that all estimates are gross, we can say that Bolivia has 31 indigenous peoples with 172,000 individuals, Brazil has 200 indigenous peoples with 213,000 individuals, Colombia has 52 indigenous peoples with 70,000 individuals, Ecuador has 6 indigenous peoples with 95,000 individuals, Guyana has 9 indigenous peoples with 40,000 individuals, Peru has 60 indigenous peoples with 400,000 individuals, Surinam has 5 indigenous peoples with 7,000 individuals, and Venezuela has 16 indigenous peoples with 39,000 individuals. Our comparison of these estimates with others cited below suggests a margin of error between 10% and 15%. Now, probably around 1.6 million indigenous peoples live in Amazonia.

Brazil's almost 200 indigenous peoples involve the Apalaí, Apinayé, Apurinã, Arára do Pará, Asurini do Tocantins, Asurini do Xingu, Atroari, Banawá, Bororo, Caiuá, Canela, Cinta-Larga, Deni, Fulniô, Guajajara, Guarani Mbyá, Hixkaryana, Hupda, Ikpeng, Jamamadi, Jarawara, Juma, Kaapor, Kadiwéu, Kaingáng, Kamayurá, Karajá, Karipuna do Amapá, Karitiana, Kaxarari, Kayabi, Kayapó, Krahô, Kuikuro, Kurá-Bakairi, Mamaindé, Maxakalí, Mundurukú, Nadëb, Nambikuára, Palikúr, Parakanã, Paresi, Paumari, Pirahã, Rikbaktsa, Sateré-Mawé, Suruí do Pará, Suruí de Rondônia, Suyá, Tenharim, Terena, Waiãpi, Waurá, Xavante, Xokleng, Yanomámi Waicá Central, and Yuhup, among others.

The large extension of the Brazilian Amazonia and different stages of development among these areas has meant diverse organizational processes for Brazil's Amazonian indigenous peoples. Since the arrival of Europeans to Brazil, the indigenous population that inhabited the main river areas was the first to succumb to the European expansion and to move westward. During the first centuries of contact, the indigenous peoples' population dropped nearly to extinction. The manhunt was carried out by means of the sword or the crucifix. Many early attempts at evangelization were resisted by indigenous warfare; however, evangelization gave way to settlements where indigenous peoples were forced to live and work. The benefits of evangelization are still being debated with the evidence provided by the cases of various indigenous peoples in initial contact. By the beginning of the 20th century, the ongoing manhunting for indigenous peoples was continuing in the hands of the "professional killers" (*bugreiros* in Portuguese) that cleared the land. At the

same time, the evangelization of indigenous peoples had not achieved full results. In the early 20th century, there were indigenous uprisings outside of Amazonia in Sao Paulo state, Espirito Santo, Minas Gerais, Santa Catarina, and Parana that brought the issue of manhunts to national attention through the media. Internationally, the 1908 16th International Congress of Americanists held in Vienna, Austria, received complaints that Brazil was enforcing a national policy of eliminating indigenous peoples. This bad reputation forced the Brazilian government to act in order to protect indigenous peoples through the 1910 creation of the state agency Service to Protect Indigenous Peoples (SPI by its acronym in Portuguese). The man picked as chief of the organization was Candido Mariano Da Silva, who later changed his surname to Rondon. He was a descendant of Terena, Bororo, and Guana indigenous peoples. From 1889, he helped set up thousands of kilometers of telegraphic lines—peacefully—in indigenous peoples' lands; that service led the government to nominate him as the first director of the SPI.

In the 1940s, the Ronçador-Xingu Expedition was in charge of pacifying indigenous peoples, opening roads, and setting up emergency camps. The brothers Orlando, Claudio, and Leonardo Villas Boas took part in this expedition. In 1944, the expedition was successful in pacifying the Xavante and 2 years later, 14 other indigenous peoples of the Xingu. It was not until 1961 that the Xingu Indigenous Peoples National Park was set up in support of these 15 indigenous peoples.

The agency decayed by the 1950s and was finally closed and replaced by a new National Foundation for Indigenous Peoples (FUNAI by its acronym in Portuguese) in 1967. This has meant a different organizational process from those experienced by their Andean Amazonian neighbors.

In Ecuador, the Amazonian rural population outnumbered the urban population. The Amazonian rural population has been growing since 1950 when it represented only 1.68% of the national rural population (Ecuador's National Institute For Statistics and Census [INEC], 1951). In 1990, it was 285,728 and represented 6.35% of the national rural population (INEC, 1991). In 1990, the Amazonian urban population was 102,215 people and represented 1.86% of the national urban population (INEC, 1991). In 2001, the Amazonian urban population was 129,861 people while the rural population had reached 233,379 people, for a total Ecuadorian-Amazonian population of 363,240, representing 2.98% of the national population. This was the result of both migration and colonization.

According to the Confederation of Indigenous Peoples Nationalities of Ecuador (Confederación de Nacionalidades Indígenas del Ecuador [CONAIE], 1989), the region was inhabited by several indigenous groups: 60,000 Amazonian Quichuas in the provinces of Pastaza, Napo, and part of Sucumbios; around 600 Sionas Secoyas; 700 Cofan; 600 Huaoranis; 40,000 Shuars in the provinces of Morona Santiago, Zamora Chinchipe, and part of Pastaza; and

2,400 Achuars for a total of 104,060 people (CONAIE, 1989; Hicks, 1990, p. 6; Ruiz, 1993, p. 641).

Until 1974, Ecuadorian-Amazonian indigenous peoples represented 40% of the Amazonian population, but by 1990, they represented only 28% of the regional population (INEC, 1975, 1991). The process of colonization of the Amazon region pushed indigenous populations toward more remote areas. The indigenous population had to confront integration or resort to isolation in the forests. Migration to the Amazonian region grew steadily, threatening indigenous survival. The use of indigenous peoples as a labor force also affected their pattern of settlement and their cultural survival. Since the 1960s, the indigenous population has initiated a process of organization and has demanded land rights. Until 1979, indigenous peoples did not vote in Ecuador. It was only then that the literacy test was cancelled and indigenous peoples were eligible to vote and to be elected (Mumme & Korzetz, 1997, p. 49). Mumme and Korzetz point out that Ecuador's indigenous peoples have defended their environmental interests through the representation offered by CONAIE rather than through "electorally based representation" (p. 49). The organizational process gradually expanded throughout the Amazonian region. In 1992, 2,000 Amazonian Indians marched to Quito and demanded land rights; as a result, outgoing President Rodrigo Borja (1988–1992) awarded land rights to an extent that surpassed the land titles given by all previous governments together (Rainforest Action Network, 1997; Sawyer, 1997). These Ecuadorian-Amazonian indigenous peoples' organizations were part of the social movements' uprisings that removed Presidents Bucaram, Mahuad, and Gutierrez.

In Peru, there is a broad estimate of around 48 to 65 ethnic groups belonging to 12 to 14 indigenous language groups, with an estimated population of approximately 300,000 inhabitants in the Amazon region (Comisión Amazónica de Medio Ambiente y Desarrollo [CAMAD], 1992, p. 34; Dandler et al., 1998, p. 9; Instituto Nacional de Recursos Naturales [INRENA], 1999, p. 3); Yañez, Noewjovich, & Tobin, 1998, p. 40). The Instituto del Bien Común, a non-profit organization that has mapped 80% of Peruvian indigenous lands, registers in its Amazonian Indigenous Communities Information System 59 ethnic groups belonging to 15 indigenous language groups. In 2008, this population was still grossly estimated around 300,000 people who in fact could be probably closer to 400,000.

In 1969, three indigenous peoples' organizations were born in the Peruvian Amazon. After 3 years of intense efforts, the Amuesha people from the central Peruvian Amazon created the Congress of Amuesha Communities (Brysk, 1996, p. 40). In the northern Peruvian Amazon, two indigenous peoples' organizations were created by the Aguaruna people from the Potro and Manseriche rivers and by the Achuar people from the Huitoyacu, Manchari, and Shintusi rivers (Dandler et al., 1998, p. 12). Since then, a large number of indigenous peoples' organizations have been created.

Ten years later, the first regional and interethnic indigenous peoples' organization was born: the Aguaruna and Huambisa Council. That same year, the first national organization was born with the creation of the Coordinator of the Native Communities of the Peruvian Jungle, which in 1980 changed its name to Interethnic Association for the Development of the Peruvian Jungle (AIDSESEP). In 1984, AIDSESEP led the process of creating the only pan-Amazon organization representing the eight countries of the basin, the Coordinator of Indigenous Peoples Organizations of the Amazon Basin (COICA). In 1987, a second national organization was born with the creation of the Confederation of Amazonian Nationalities of Peru (CONAP). AIDSESEP has been active in defending the land, opposing mining and oil prospecting in their territories and in protected areas, and organizing the grassroots to plan and implement education, health, and production projects (Varese, 1996). CONAP, which initially had the same view, at some point changed and decided to sign a deal with Perupetro in 2007, but this stance has a longer history and has marked the division between the indigenous peoples' organizations, their nongovernmental organizations (NGOs) of support, and is influencing many of the organizations of the Peruvian environmental movement.

Perupetro (Petróleos del Perú), Peru's state corporation in charge of managing oil concessions, differs from Petroperu, Peru's first state oil company and manager of oil resources, which is currently only in charge of commercializing some oil products in Peru.

The recognition of indigenous peoples' lands has had diverse historical processes, legislation, and institutions involved. In Brazil, after initial eviction and relocation, larger territories were awarded to indigenous peoples as in the case of the Yanomami. In Ecuador, government had granted small concessions until the government of Rodrigo Borja when the government granted an amount of land similar to all that had been granted before in all republican history and introduced the legal concept of "indigenous peoples' territory." In Peru, small land holdings have been granted for approximately 1,500 native communities totaling over 12 million hectares of forests. Only the Matses and a few other peoples have been able to secure larger territories while most have been titled and surrounded with colonists who are mainly from the Andean highlands and fewer from the coast.

During the 1990s, the United States Agency for International Development (USAID) promoted Latin America land liberalization under the principles of promoting democratic values and free market principles and thereby created a land market. Thus, counterreform in México, Perú, and Honduras, for example, proposed to generate employment, promote environmentally and socially sound economic growth, and political freedom and governance. Land liberalization involved changing the legal framework to support private sector access to the land market. These reforms affected the most vulnerable, who

had previously benefited by the agrarian reform (Van Dam, 1999, p. 16). During 2008, the Garcia government (2006–2011) in Peru was aiming to promote investment in Amazonian lands for biofuels, soy, and timber. These intentions caused major concern among the indigenous peoples and nonindigenous peoples of the Peruvian-Amazonian region who went on strike demanding the nullification of this legislation. After many days of revolt, the Garcia government overruled two decrees modifying access to indigenous peoples' lands by third parties. Similar protests had been occurring in Colombia in 2008 where the indigenous peoples went on a national march to the national capital, Bogota, to press the government for land rights and to denounce violence.

All Amazonian national governments declare respect for indigenous peoples' rights and the commitments of international legislation protecting their rights, while regional and local authorities want to prevent the enforcement of these rights. World Bank-funded programs have favored individual land titling for colonists over communal land titling for indigenous peoples. But now with the impulse of a second wave of privatization, governments of Colombia and Peru are calling for the small land holders to leave the land. In the case of Colombia, the rural populations are in the midst of the violence that has long affected this country. Indigenous peoples are easy targets for any of the contending forces involved. The governments of Ecuador and Bolivia may be more open to listening to the demand for land rights. The former has been increasing protection to noncontacted indigenous peoples, while the latter has offered to continue land titling. However, the same offer has been made to colonists by Evo Morales, who emerged from the Bolivian electorate. Both governments have indigenous peoples as public officials and involve the participation of indigenous peoples' political organizations among other social sectors.

The Noncontacted Indigenous Peoples

Of the world's 100 noncontacted indigenous peoples, some 85 of these remain noncontacted in the Amazonian countries. There are 67 noncontacted indigenous peoples in Brazil, 14 of them in Peru, and at least one each of them in Bolivia, Colombia, and Ecuador.

The noncontacted indigenous peoples inhabit headwaters, ranges, and other higher ground available to them. Many remain in cloud forests where fauna is more abundant. They live off hunting, fishing, gathering, and incipient agriculture. Reports coincide on their seasonal migration along riverbanks to gather turtle eggs on which occasions they move in family groups of around 25 people, usually with some domesticated huanganas that they breed as dogs, and set camp every 5 kilometers after a 1-day walking journey. In these cases, they have been spotted from air while reports by park guards along riverbanks

show huts made of palm leaves, some of them big enough to provide cover for 5 to 6 people.

The noncontacted indigenous peoples bravely enforce, with spears and arrows, their right to remain without contact. When their possibilities of avoiding contact are reduced by external actors, their alternative is to move to remote areas where this is possible. Their decision to remain noncontacted is evidence of their strong pursuit of their right to be protected from development ensuring their hunter-gatherer lifestyle. In fact, these people try to avoid contact, but when possible and necessary, they aim to scare us out of their land to protect it. They are no more nomadic than many other populations that seasonally adapt to climate change and availability of resources.

The existence of the last remaining indigenous peoples is denied by those interested in their lands, namely loggers, cattle ranchers, and oil companies. Those denying the existence of these peoples usually argue their "absence" in the literature, the fact that the area has been intervened in the last decades, and the fact that there are no scientific reports stating so. Those affirming the existence of these peoples rely on local informants, artifacts found in the field such as stone axes, pottery, wooden containers, bags, or signs or marks on trees, as well as trails and stories of encounters and sightings, human calls in the night imitating animals, and some spearheaded animals appearing at their campsites. Thus, the matter of probing the existence of these peoples in a given area is a much debated issue.

Activities by loggers, cattle ranchers, and oil companies can affect the forest where the noncontacted indigenous peoples live through deforestation and clear-cutting, forest fragmentation and biodiversity loss, negative effects on the wildlife and protected areas, and ecosystem fragmentation. The presence of teams of workers, equipment, and tools will produce solid and liquid waste that will be eliminated in the forests without any more treatment than burying solid waste in the ground. These activities usually include the arrival of airplanes and helicopters flying over the area. In the case of oil, seismic lines will cut usually a few 100 kilometers through the forests. These risks altogether represent a serious threat to the health and wealth of these populations by affecting their integrity, their access to food, and by their lethal exposure to disease.

Over the last decades, Brazil has developed a policy on demarcating and protecting noncontacted indigenous peoples' territories. Although not all efforts were successful, they did contribute to the process of understanding the need to not contact these peoples and respect their right to their land. Since the creation of FUNAI, 13 million hectares of land have been set aside as protected areas for noncontacted indigenous peoples. Protecting their land is a first priority and should be done taking into account the need to contain human pressure and to provide buffer zones to avoid destruction and disappearance of these peoples. Since 1987, FUNAI has focused its work on noncontacted indigenous peoples through seven teams operating

in the states of Amazonas, Pará, Acre, Mato Grosso, Rondônia, and Goiás. In Acre, there are 10 indigenous lands, 5 of which belong to noncontacted indigenous peoples. In Brazil, there is an estimate of around 40 noncontacted indigenous peoples that have been verified and another 27 nonverified, which accounts for a total of 67 noncontacted indigenous peoples.

In the case of Peru, five territorial reserves have been created over 2,812,000 hectares. These are the Murunahua Territorial Reserve and the Mashco Piro Territorial Reserve in the Ucayali Region (1997), the Isconahua Territorial Reserve in the Ucayali Region (1998), the Madre de Dios Territorial Reserve for the Mashco Piro peoples in Madre de Dios (2002), and the Kugapakori Nahua Nanti Territorial Reserve in the Ucayali and Cuzco Regions (2003). However, another five proposed territorial reserves have been awaiting government approval, some of them since 1999. These are the Yavari Tapiche, Yavari Mirim, the Napo Tigre Curaray in Loreto, the Kapanawa in Loreto and Ucayali, and the Cacataibo in Loreto and Ucayali. In Peru, the government department responsible for noncontacted indigenous peoples and the territorial reserves is the National Institute for Andean, Amazonian and Afro-Peruvian Peoples (Instituto Nacional de Pueblos Andinos, Amazonicos y Afroperuanos [INDEPA]). The executive had reorganized and reassigned INDEPA between different ministries during 2006 and 2008 until Congress passed a law restoring the institution's autonomy. However, it still lacks financial and technical resources to carry its duties adequately.

In Bolivia in 2006, the government set up the Intangible Zone for Integral Protection and Absolute Reserve of the Toromona peoples in the Madidi National Park, which is also inhabited by the Ese Ejja and the Kapuibo peoples. The Sinabo, who live between the lower Beni and Yata rivers, are also considered to be in a situation of noncontact; however, another indigenous peoples, the Warasug'we, live in the Noel Kempff National Park in a situation of initial contact. In both cases, these indigenous peoples inhabit a national park, a strict protection area with a ban on resource use.

In Ecuador, although there is no general legislation covering this matter, in 1999, the Ecuadorian government passed an Executive decree (a Presidential decree) creating the Tagaeri Taromenani Intangible Zone. Since then, the Ecuadorean government has failed to delimit the boundaries of the area. After some Ecuadorean campaigners lodged a request for precautionary measures to protect the Tagaeri Taromenani, the Inter American Commission on Human Rights requested the Ecuadorean government "to protect the life and integrity of the Tagaeri Taromenani, adopting the necessary measure to protect the territory that they inhabit, including measures to prevent access" particularly from illegal loggers (see Oilwatch report at http://www.oilwatch.org/reparacion/index.php?option=com_content&task=view&id=62&Itemid=56). The delimitation of the Tagaeri Taromenani Intangible Zone is still pending. Instead, the Correa government proposed in

October 2008 a code of conduct to be followed by the oil companies operating in the area.

In 2002, the Colombian government set up the 999.880 hectares of the Pure River Natural National Park to protect the Aroje, Yuri, and Caraballo peoples, respecting their right to remain noncontacted and allowing them to settle in the future and turn the national park into a communally titled, indigenous-peoples' land. The National Park has among its usual conservation objectives a first and primary goal to protect the territory of the noncontacted, ensuring their survival and their decision not to be contacted.

Migrants

Migration is always in vogue in Amazonia. It was so in the 1950s when Brazil aimed to relocate landless people from outside the Amazon, and it is so today when Andean populations are still moving every day to live in the Amazonian lowlands. These Andean indigenous peoples move to live in Amazonia to practice agriculture, cattle ranching, and commerce. These people usually overvalue their own culture in comparison with that of the Amazonian indigenous peoples.' The more commercially oriented Andean peoples are usually non-Catholic Christians, whereas the Catholic are less organized and lack the organizational skills and group support of non-Catholic Christians. Other migrants include coastal and European settlers.

It usually takes 30 years for many newcomers to understand that agricultural production in tropical lands is quite different from irrigated-land agriculture. In some cases, the migrant population of a rural area has been there for enough time to have integrated traditional knowledge with the exploitation of the Amazonian environment. After one or more generations, this mixture has produced a Creole-Amazonian culture of extractive and "riparian peoples" (*riberenos* in Spanish, *ribeirinhos* in Portuguese)—descendants of migrants who over generations had adapted to indigenous peoples' use of resources—who are partly a mixture of beliefs involving traditional knowledge on how to harvest the environment. While Brazil has granted land rights to these populations, other countries such as Peru have not recognized land rights for these "migrant" peoples and their descendants, despite the fact that many of them live on the forest and feed on it.

Forced labor is still a common situation in Bolivia and Peru both in artisan gold mining and in forest extraction. Andean laborers are hired in their towns and sent to the lower Amazonian forests and rivers to extract resources with a mixture of 15th-century labor conditions and 15th-century cheap, Chinese equipment to dig for oil in Amazonian riverbeds. A small investor usually holds a mining permit that is not supervised on-site. This means miners usually forcefully enforce their limits with their neighbors, feeding conflict with agriculturalists and other resource users. A laborer is hired for a 2-year period to

work 6 days a week, with no holidays and a credit account that can extend its contract.

Urban Centers and Towns

Amazonian societies at some point generated larger sedentary societies along the main Amazon River and its main tributaries, such as in Marajo Island. Many other smaller, nonmilitary chiefdom societies also coexisted in the smaller tributaries and biggest cities. The arrival of missionaries, soldiers, and all sorts of fortune seekers changed the Amazonian landscape. Since then, the region has been exporting natural resources to the world market. The boom and bust cycle has characterized the export of Amazonian products, such as timber, gold, leather, pets, and all sorts of products from biodiversity. All those resource cycles developed a network of rural towns, small cities, and large capitals, such as Manaus and Iquitos. The rubber boom cycle was the most important of these boom cycles. Between 1865 and 1920, Manaus was Brazil's most developed city with electric lighting, piped water, and opera theaters.

Since then, a lot has changed in Amazonia and its cities. Some approximate numbers for current urban Amazonian populations are as follows: Bolivia (Trinidad 89,613; Cobija 32,200), Brazil (Belén 1,912,600; Manaus 1,524,600; Boa Vista 300,000), Colombia (Florencia 150,000; Mocoa 31,000; Leticia 29,666), Ecuador (Lago Agrio 81,918; Puyo 24,881), Peru (Iquitos 396,615; Pucallpa 204,772; Yurimaguas 41,827; Oxapampa 7,743), and Venezuela (Puerto Ayacucho 52,526). These urban centers supply smaller towns that are at the forefront of frontier expansion. They serve as networks for the natural resources flowing to the regional, national, and international markets. Thus, large catfish from Peru goes to the Colombian market, while Brazil nuts and some Amazonian leathers are commercialized in the world market.

Outside most of these Amazonian cities and towns remains the rural landscape, more so up the tributaries. Grasslands and pastures dominate many eastern Amazonian river areas, while in the Brazilian Amazon, the expansion of a network of roads initiated in the 1950s has given space to modern soy crops that dominate the landscape. In the Peruvian Central Amazon, for instance, an area colonized 150 years ago, the descendants of European settlers have forced the Yaneshá indigenous peoples to the fringes of the valleys now occupied by pastures, grasslands, and European-looking urban settlements. Similar phenomena have occurred with other European settlers in different areas of the Amazon. Beyond these areas, the subsistence economies of small colonists and indigenous peoples occupy the smaller tributaries with their family settlements. In the upper section of some of the less occupied headwaters, some noncontacted indigenous peoples still remain. That is the case of the Peruvian–Brazilian border where the national societies stopped their search for rubber at the edge of the rubber forests leaving the hills untouched by the rubber trade. In the

western Amazon, many indigenous peoples living in the upper section of tributaries retain their traditional costumes, language, and organization, while those indigenous peoples of the lower lands are commercial, riparian societies open to commerce and trade since very early times. Traditional Amazonian trade involves coca, salt, stones for knives and axes, cotton, and fauna among other products.

The Effect of the Timber Trade

In the last two decades, efforts to produce a tropical forest reform sprouted in the Amazonian countries. Bolivia, Brazil, and Peru passed new legislation to move away from the mismanagement and forest mining into sustainable forest management. Forest certification schemes and the support of USAID helped Bolivia experiment with forest reform in the 1990s. Peru took until 2002 to start granting forest concessions. However, corruption, mismanagement, and short-term policies favored reform that did not change the relevance and priority of illegal logging, which feeds the national and international markets.

In Peru, between 2002 and 2004, approximately 7.8 million hectares of forests were granted in forest concessions that struggled to comply with the prices offered in the auction and the poorly enforced management plans. Although forest concessions are the official main source for timber production, permissions to agricultural producers for habitat conversion also allow them to sell timber, while another 12 million hectares of forestlands are in the hands of indigenous peoples and sought by loggers aiming to set up contracts with these communities to access the timber. Protected areas are an important source of illegal timber as much as they are territorial reserves for noncontacted indigenous peoples.

Indigenous peoples are the most deeply affected by the timber trade that drains their forests and many times their organizations and trust, too. Indigenous peoples are affected by the forest reform through the overlapping of forest concessions with indigenous lands, particularly, land that is not yet registered; the lack of an adequate process of consultation prior to the awarding of all forest management categories; the invasion of communal land and territorial reserves for noncontacted indigenous peoples; and the government's failure to meet its offers of technical advice in support of communal forest management. At the same time, these indigenous peoples can be affected by corruption from the illegal logging market.

Recent progress in decentralization does not offer much hope for the forests. Regional and national politicians in Madre de Dios, Loreto, and other Amazonian regions are proud representatives of illegal timber interests. The regional president of Loreto announced in 2008 at an international conference attended by the minister of the environment of Brazil that Loreto will not grant 1 square meter to protected areas or indigenous lands, in accordance with the demands of loggers and other extractive industries.

Regional political leadership is very much influenced by the regional economic forces, which in many cases are also strong, local political actors.

To strengthen compliance with forestry legislation, a possible innovation could be the requirement to use the global positioning system (GPS) to link a forest production area with a log going to the market. This would trace the route of a legally harvested log instead of supporting a timber market characterized by wood coming from illegal logging. These actions coupled with a sound database that discounts the timber harvested can be a useful tool for tracing the origin of legally harvested timber.

Megadevelopments

The asymmetry between the actors involved in land use and extractive industries is a central issue in socioenvironmental conflicts occurring in the region. The opening of roads and the paving of the already existing ones will foster the arrival of new populations demanding land and resources and expelling the old population without land titles or capital to new deforestation areas. When looking at socioenvironmental conflict around natural resource policies, we find a divorce between the discourse of the legislation and of the public officials and the implementation at all levels. The assumptions of the legal framework have very little relevance to resource users making decisions in the forests about how to manage resources, how to solve conflicts, and how to compensate for damages. Under these circumstances, the opening of new areas by the South American Regional Integration initiative (IIRSA by its Spanish acronym) suggests the intensification of conflicts affecting indigenous peoples, colonists, peasants, and riparian populations due to the increase in the demand for land, forests, minerals, oil and gas, and illicit crops.

Until the financial crisis of October 2008, a wealth of financial resources from the international financial institutions set up the conditions to carry out large-scale projects, such as IIRSA. IIRSA aims to develop road and communications infrastructure to favor trade and economic development. Geopolitically, it is the affirmation of the continental role of the Brazilian State in the South American region. IIRSA is a proposal to build not only roads coming out of Brazil to connect with its neighbors but also roads among Brazil's neighbors, as well as ports in the Amazon and in both oceans and communications networks.

The Inter-American Development Bank (IADB), whose social and environmental policies are below the standards of the World Bank, plays an important role in the region financing corporations, governments, and megaprojects, such as the components of IIRSA. Another important player is Brazil's National Development Bank that will invest \$220,000 million as part of a plan to accelerate growth (PAC by its acronym in Portuguese) by developing infrastructure, telecommunications, and

energy lines between 2007 and 2010. IIRSA is one of the projects funded by PAC.

Many Amazonian countries lack adequate environmental and social management of infrastructure development. Some of the international financial institutions that are financing these projects also lack these adequate standards. Some governments see these standards as a hindrance to development preferring, though, to avoid the introduction of necessary reforms or proposing to weaken the mechanisms already in place.

In Peru, IIRSA is building the Northern (Paita-Yurimaguas-Huallaga-Amazon River) and Southern (Ilo-Cusco/Puno-Madre de Dios-Assis) Interoceanic Highways while a Central Interoceanic Highway from Pucallpa to Cruzeiro do Sul with connection to Lima has been proposed. In addition, at least two proposals have been mentioned in regard to trains. The social and environmental effects of this expansion to the last frontier in South America will disproportionately affect the most vulnerable populations in these areas, the indigenous populations, both noncontacted and settled and other rural populations. For instance, the current proposed design for the Pucallpa to Cruzeiro do Sul highway aims to cross over a proposed Sierra Del Divisor National Park and over the Isonahua Territorial Reserve in Peru for noncontacted indigenous peoples. The reserve is set up for the noncontacted indigenous peoples, and the crossover is going to negatively affect them by providing open access to the area.

The implementation of IIRSA will only contribute to accelerating the processes already affecting Amazonian peoples and their forests. Protected areas and forest production areas will be crossed by new lines of flow of mahogany and other forest products. At the same time, the national government transfers few responsibilities to regional and local governments, mainly responsibilities in areas in which the national government finds no profit such as artisan gold mining, whereas the profitable concessions of gas, oil, and timber remain in the hands of the national government.

Brazil's Amazonia can be seen as a showcase of the risks posed by current development as usual to the region's rich biological and social diversity. In the 1950s, Brazil decided to open two main roads into the Amazon (one south to north, and another east to west). Along with the road came the settlers into the newly opened areas. Since then, deforestation has had a significant effect in modeling future climate change in the region with an expected increase between 2.3 °C and 5.5 °C for the next 100 years. Similarly, other models predict a rainfall reduction around 20% for the same period. This reality is particularly harsh when we look at the development of urban centers and towns in the Amazon. A study by the Brazilian-based Instituto Socioambiental of seven Amazonian tributaries (Jurua, Purus Madeira, Tapajos, Xingu, Araguaia, and Tocantins) showed that unplanned settlement is creating a network of deforested urban centers that lack recreational

areas and tend to elevate temperatures at the local level thus building islands of deforestation in the Amazonian forest with a tendency to more deforestation.

Oil and Gas

In 1867, only 4 years after the first pioneer oil well was drilled in Titusville, Pennsylvania, a well was drilled in Zorritos on the northwest Peruvian Pacific coast. Peru started production in La Brea and Pariñas oil fields in 1905 (PetroPeru, 1995, p. 5). The first exploration for oil in the Peruvian Amazon occurred in 1911 on Ashaninka land in the central Peruvian Amazon (Dandler et al., 1998, p. 32).

In 1962, Peru started to import oil (PetroPeru, 1995, p. 5). The military junta led by General Juan Velasco Alvarado (1969–1974), following the nationalistic trend of developing countries at the time, decided to expropriate International Petroleum Company, a subsidiary of Standard Oil of New Jersey, ESSO. As a result of this, the government created the Peruvian state oil corporation (PetroPeru) on July 24, 1969 (PetroPeru, 1995, p. 12). The aim was to develop a national state-oil-corporation able to explore and produce oil. The junta also decided to build an 854 km-long pipeline from the Marañon river town of San Jose de Saramuro to the port of Bayovar on the Peruvian north coast. This pipeline has a capacity of 200,000 barrels per day (bbl/d), but it carried only 75,000 bbl/d of crude oil during the 1990s (Ministerio de Energia y Minas, 1999, p. 50).

In the 1960s, Ecuador and Peru initiated the development of oil resources with the collaboration of foreign corporations; however, these countries had no environmental regulations or any concern for environmental matters. By the end of the millennium, both countries had started to develop environmental regulations and set up standards to manage the social and environmental effect of oil activities. However, the transition from discourse into action was and still is slow. This was a particularly difficult issue for Amazonian populations, particularly indigenous peoples.

During the 1980s and early 1990s, Peru's oil production had a downward trend. In 1985, PetroPeru produced 188.5 bbl/d, and in 1992, oil production was 115.6 bbl/d (PetroPeru, 1993, p. 7). From 1990 to 1992, the oil sector was affected by the economic and political crisis left by the Garcia administration (1985–1990). The Fujimori government (1990–2001) was confronted by lack of investment because the country had been declared ineligible by many international financial organizations. Economically, the country was hit by unusually high rates of inflation and devaluation, while politically, drug traffickers and two terrorist organizations were in control of some areas of the country. This economic and political environment had an effect on an already declining trend in foreign investment in the oil sector. In this context, in 1989, PetroPeru shared the market with one operation of Oxi-Bridas (joint oil venture) in oil block 11 in the northwest and an operation

of Occidental Oil Company in block 1-AB (Ministerio de Energia y Minas, 1999, p. 49).

In the case of the environmental and social effects of energy development, the case studies from my dissertation looking into the 1990s showed how the process of development of the legal framework evidenced some tension between the text of the law and enforcement of the social fact (Habermas, 1997, pp. 1–9). On one hand, there is the normative text, the letter of the law, expressing the results of the political debate, and parallel to it runs the social interpretation of the facts, the interpretation done by politicians, the private sector, NGOs, and the general public. In the Ecuadorian case, there was tension between the legislation that forbade oil pollution in protected areas and the final interpretation made by President Durán Ballén (1992–1996) allowing oil activities in the Cuyabeno Wildlife Production Reserve. In the middle, lay a number of diverse interpretations of the law made by oil companies operating in the Ecuadorian Amazon. In the Peruvian case, this tension resulted in the modification and overruling of one third of the environmental code in order to favor foreign investment at the beginning of the 1990s. However, in early 1999, the Peruvian government approved the National Strategy for Natural Protected Areas by Supreme Decree 10–99-AG. This decree stated that non-renewable resources could be exploited only in protected areas where direct use of resources is allowed, a policy still in force today.

Since 2004, a second oil and gas boom fed by the growing economies of the United States, Europe, China, and India and a price hike that reached \$140 per barrel in 2008 expanded oil activities in Peru from 13% of the Peruvian Amazon to 75% of this region. This occurred amidst poor enforcement in environmental management and lack of resources to operate at an adequate level while maintaining very low legal standards. Political pressure on technical officers caused the Camisea pipeline to fail so bad that it broke down five times in its inaugural year—amid claims of human rights violations over the lack of adequate compensation to local peoples and over its effect on noncontacted indigenous peoples and indigenous peoples in initial contact. The Peruvian ombudsman's office produced a report in 2005 based on citizens' complaints citing environmental impact assessment infractions. Political pressure came directly from President Alejandro Toledo who stated that the gas had to arrive in Lima at the city gate on August 9, 2004. The Ministry of Environment was created in 2008 by the Garcia administration only as a requisite for a free trade agreement with the United States and also by the pressure of the IADB involved in financing a second Camisea gas pipeline. This new ministry does not oversee oil, gas, electricity, or piped water. Today, oil activities affect two territorial reserves for noncontacted indigenous peoples and many reserves. A second pipeline adjacent to Camisea, which has changed 50% of its original route, is being built with plans to build a third one. Despite 500 years

of European activity and despite current disturbing and threatening oil exploration, noncontacted indigenous peoples still remain in the forests in three other proposed territorial reserves.

In Brazil, oil activities occurred mainly on the coast. In the 1990s, an oil spill in Rio de Janeiro forced a change in support of the environmental policies of Petrobras, Brazil's state-owned oil corporation. Later on, when Petrobras went into the Urucu oil fields, it had already improved its environmental and social standards; however, the local populations near the pipeline to Manaus still had to make demands to obtain gas and other benefits with a \$20 million environmental management plan and a \$20 million social management plan package. Petrobras is now expanding activities in Peru in areas involving noncontacted indigenous peoples while some Brazilian politicians are aiming to mirror such policies in their own side of Amazonia.

Future Directions

The expansion of extractive industries and the development of road and energy infrastructure are the main threats to the health of the Amazonian rainforests and ecosystems and its inhabitants. Particularly, the very vulnerable noncontacted indigenous peoples in Ecuador and Peru are facing the pressure of oil activities and loggers, while cattle ranchers are the main threat on the Brazilian's side of the Amazon. This is an example of a human rights catastrophe that goes unaccounted by regional politicians interested in accessing natural resources not only at the cost of lives but also at aiming to end a lifestyle that has kept a healthy forest and ecosystems. Development at the hands of individual interests fails to address the broader issues of resilience, sustainability, and governance. These latter issues are central considerations in the planning of a sustainable future for Amazonia. Some Amazonian regional and local governments, civil society, and social movements are demanding accountability in the land-use allocation process; the overlapping of multiple uses has long been a tradition in the Amazonian rainforests. However, when one of these uses forbids the possibility of the other uses—as in the case of extractive industries—the recipe for social conflict is ready, as the processes of social unrest show in Colombia, Ecuador, and Peru. In the short term, the need for prior informed consent by indigenous peoples appears to be the key to finally developing indigenous peoples' public policies. In the long term, the process of urbanization and its rate of growth suggest that unplanned development will continue to deplete the forest, affecting the water rainfall and the climate.

AUSTRALIAN ABORIGINES

SUSANNA SERVELLO

Cremona, Italy

The native people of Australia are commonly called *Aborigines*, a much discussed term that comes from the Latin expression *ab origine* whose meaning is “from the beginning.” Even though nowadays this definition is mostly accepted, many members of the local populations dislike it as they perceive it as synonymous with oppression and as a stereotyped and discriminating way of distinguishing them from others. For this reason, they usually prefer to call each other by using hundreds of local expressions, such as *alaua*, *nmattjera*, or *tagoman*, which are some of the names used in the Northern Territory, or *gingai*, *gringai*, *wiljagali*, or *illawarra* used in the New South Wales state. These terms generally mean “person.”

Controversial Definition

In the linguistic anthropology field, the identification issue is a very important aspect as it conveys a meaningful message: the fact that their wise ancient culture conceives all the people to be the same, without any classification—simply anyone belonging to the human species. In order to respect their culture and their point of view, the adjective *Aboriginal* and the noun *Aborigine* will be used in this chapter simply as conventional.

Past and Present

Torres Strait islanders also belong to the indigenous population of Australia, but due to the peculiar features of their culture, which include some Papuan and Austronesian elements, they are generally referred to separately from the populations living on the continent.

The precise timing of the beginning of the human occupation on the mainland is still a controversial topic. Aborigines immigrated to the land we now call Australia from Southeast Asia between 70,000 and 40,000 years ago. Relative to the results of thermoluminescence dating, most archaeologists agree with the hypothesis of Aborigine arrival as 50,000 years ago, while radiocarbon testing places that epoch as 40,000 years ago.

An extraordinary discovery in 2003 has brought to light more than 400 Pleistocene-era human footprints together with some animal imprints (those of a kangaroo, an emu, and a big bird) in a desert area of southeastern Australia near the World Heritage Site of the Willandra Lakes Region. The researchers think that those prints can be dated to 20,000 years ago and describe the movement of women, men, and children through a humid area that could have provided them with food. Nowadays, Australian Aborigines embody the most ancient living culture in the world even though colonialism inflicted severe pain on them, bringing drastic changes to their lifestyle. Before colonialism's

beginning in the 18th century, Aborigines numbered much higher than today, but their numbers decreased enormously due to the killings the foreign settlers carried out against them, to scarcity of food and water caused by land deprivation, and last but not least to new illnesses (such as influenza, measles, smallpox, and venereal diseases) brought by the European conquerors for which Aborigines did not have any immune defense. Most of the local populations used to live near the coastline where they could fish and gather crustaceans while others obtained sustenance from the bush where they could find fruits, leaves, berries, and roots, or they could hunt in the desert areas. Nowadays, some communities that are still independent live especially in certain areas of Arnhem Land and in the dry regions of central and west Australia, but most of the natives live in the metropolis suburbs, generally in conditions of poverty and homelessness and often victims of alcoholism and social prejudices. That has caused the extinction of many traditional groups. Their life expectancy is 15 or 20 years lower in comparison with that of the white Australian population, and the infant mortality rate is nearly triple. As far as job opportunities are concerned, their unemployment rate is high, while salaries are definitely low.

Aboriginal ethnicities are estimated to be around 2% of the total population of the continent, which amounts to 22,156,867 inhabitants in early 2010 (Australian Bureau of Statistics, <http://www.abs.gov.au/>). They live both on the mainland and on many islands such as Groote Eylandt, Mornington Island, Palm Island, Fraser Island, and Tasmania and are organized as more than 500 tribal groups.

The Effects of Colonialism

As underlined before, life for the Aborigines became extremely difficult and troublesome when the first European settlers arrived in Australia claiming to have “discovered” a new continent and considering its inhabitants to be simply cumbersome objects to get rid of: The serious consequences of those treatments of the native people’s life cannot be ignored or denied as they are historically documented.

The fact that the indigenous people did not consider the territory as property and that they did not use to mark out the lands made it possible for the foreigners to claim that the wide Australian continent belonged to no one. Consequently, the rights that the Aborigines had had on their land for 1,000s of years were ignored, whereas the *terra nullius* (“land belonging to no one,” or “empty land”) principle was applied by the English who could take possession of the Australian regions in the name of the British Crown.

Even though the indigenous people often behaved defenseless in the face of the invasion, their attempts at rebellion caused the colonial government to reach the decision to use extreme clamping down to suppress rioting. In an instrumental way, massacres and individual killings

perpetrated against Aborigines were made and believed to be supported by Charles Darwin’s theory of natural selection, that is, that some races (such as Aborigines, who were considered to be inferior in comparison with the other ethnic groups) are destined for extinction. Therefore, the colonizers tried to pretend that Aborigines’ deaths were natural events. The government also tried to denigrate their adversaries by describing them as drones and inclined to alcoholism.

Notwithstanding, protests against violence arose and public opinion started to acknowledge how atrocious and unequal was the attitude of the members of the political power toward the natives.

For these reasons, the British chiefs felt compelled to change their strategy and to adopt an only apparently different approach to the Aborigines. The real aim of what was officially presented as “protection policy” was to “hide” native people through severe racial segregations and keep control over them. Indigenous communities were controlled by Western religious missions and forced to follow new cultural models.

However, the Aborigines were still a problem for the white Australians who decided then to start a new form of dominance by “assimilating” the native peoples into the European civilization and trying to make their 1,000-year culture disappear. Their traditional social structure was dismantled, and people were forced to follow the Western model of life. Moreover, since the second half of the 19th century and for 100 years, a new plan was undertaken by the political institutions: Thousands of children (above all, those who had a white parent and who are now known as the *stolen generation*) were systematically removed from their families and constrained to live in religious structures or orphanages or with white families where they were educated according to European principles so that they would pursue the ideal of totally transforming their population and purifying their race through eugenics. Those practices are now considered to have been real cultural genocide.

The shocking results of that policy are still visible today as many Aborigines now live excluded from both societies: oblivious of their traditional culture and languages and marginalized by the well-off Australians whose system they are dependent on. Real integration seems to be still a mirage.

In February 2008, the Prime Minister of Australia Kevin Rudd offered in parliament what many observers have defined as “historical” apologies for “the laws and policies that have inflicted profound grief, suffering and loss” (British Broadcasting Corporation [BBC] News, February 13, 2008).

Social Structure

In Aboriginal culture, social organization is very complex as group life is considered to be more important than individuality.

The language groups (i.e., the various groups that differentiate themselves from the others as far as their spoken idiom is concerned) are based on several clans, which have their links with the territories they live in and with certain animals or plants or other natural elements venerated as totems. Each clan is divided into 2, 4, or even 8 “skin groups” (also called *moiety*s).

The kinship system is a fundamental concept. It establishes the roles, the duties, and the display of manners of every member as it regulates every kind of relationship. According to its laws, for instance, members belonging to the same clan are forbidden to marry one another.

The way people address the other members is also extremely interesting but really very difficult to be understood by an outsider’s point of view. *Mother* and *father*, for example, are names that also refer to aunts and uncles, while *aunt* and *uncle* are terms used for older people; *sister* and *brother* are used not only for someone with whom a person shares his or her own biological parents but also for close relatives of the same generation. These examples make clear the meaning of *family* in Aboriginal culture, that is, a group that configures itself as “extended.”

If a person lives in harmony with an Aboriginal clan for a relatively long period, he or she is adopted by the group in the sense that he or she receives a kin name and, consequently, becomes aware of his or her particular role in that society.

On the other hand, strict social rules regarding external interactions are in force within each clan. Some individuals cannot, for instance, attend certain meetings or communicate with certain clan members. In such cases, communication may take place through the mediation of a third person or by using nonverbal means, such as signs and gestures.

The status of children and aged people is peculiar. As told before, from the end of the 19th century until the second half of the 20th century, Aboriginal children suffered psychological violence when fiercely taken away from their families by the government. They grew up without knowing anything about their origins or their family background, forgetting their names, and being taught to disregard the culture of their ancestors. Young boys were made to work for many hours every day, especially as farmhands, and they were often beaten if they did not obey the orders; in contrast, girls were indoctrinated to become docile wives for white men and to pursue through interethnic marriages the aim to make the white race prevail on the others.

Within indigenous societies, on the contrary, children are taken care of not only by their own parents but also by everyone within the group. The education they get causes them to approach the beauties of nature. Through storytelling, they learn how to go hunting, how to find fruits in the forest, and how to discern good food from dangerous ones or, more generally, they learn how to correctly behave toward the other members of the group; some knowledge is not revealed until the child has reached a suitable level of understanding.

When boys and girls are considered ready to become real men and women, their initiation takes place. Those rites will symbolize the death of their childhood and their passage into the world of adulthood. This can usually happen when the child is between 10 and 16 years old.

Non-Aboriginal people are forbidden to attend those ceremonies; the indigenous people describe these initiation ceremonies as particularly intense. The young protagonists wear ornaments or have their bodies painted and also have to endure painful experiences, such as having cuts made on their skin or having their noses and ears pierced; the teachings they receive will be precious in their lives.

Contemporary elders are highly respected for their wisdom and their role as moral guides, for they pass on their knowledge and experiences: The elders are, in fact, extremely important figures in the cultural Aboriginal panorama as they represent a symbolic link between the past and the future.

A central role in the community is assumed by shamans, too; their importance within the society will be described on the following pages.

Languages

Many years of colonial dominion have also caused severe loss as far as the cultural, Aboriginal heritage is concerned, considering, for instance, that more than 300 local idioms have disappeared since its beginning. Nowadays, 200 original “dialects” remain: *Aranda*, *Wati*, *Walmatjari*, and *Tiwi* are some of the most well known.

Aboriginal culture has essentially been spread orally, and only in recent times the languages of central Australia have started to be written down. The overall linguistic panorama is much diversified in northern Australia, while it is more homogeneous in other areas of the country.

Many pidgins (also called Aboriginal English) have developed from the contact between English and the huge variety of local dialects. They are a sort of English whose structure and vocabulary have been changed by the influence of local idioms: Some of them are very close to Standard English and are spoken in nearby cities, whereas others are more different from it and are mainly used in isolated regions. They are very important in communication between indigenous groups who did not share a common language and whose peculiar mother tongues could otherwise be an obstacle for relationship with each other. White Australians, however, generally still ignore both the traditional languages and the modern forms of pidgins, but in some schools of the continent, bilingual education is now an opportunity for Aboriginal students.

Australian native languages can be divided into two main families: the Pama-Nyungan and the Gunwinyguan languages. The first group is the more diffused one. Its name derives from the Pama idioms spoken in the northeast and the Nyungan, which are from the southwest; the

Gunwinyguan languages, on the contrary, are spoken in the northeastern area of the Northern Territory.

Apart from these two principal linguistic families, there are many other languages and also isolated idioms. Generally, most Australian languages share several phonological or lexical elements. Different speech styles are interesting aspects of their features. For instance, avoidance speech, also called by the colorful expression “mother-in-law language,” is a particular type of speaking that involves the use of synonyms when some relatives are present and everyday words that could be perceived as taboos. In some cases, certain words are even replaced by signs. This happens, above all, in some central and southern desert areas or near the Gulf of Carpentaria. In Aboriginal culture, silence is also an important strategy of communication.

Some languages, then, have unique characteristics, such as the use of certain words only by men or only by women; on the other hand, lexicon can also differ if the language is spoken on the mainland or on islands.

In contrast with the commonly accepted theory that native idioms derive from an older language that spread through Australia 5,000 or 6,000 years ago, the linguistic anthropologist Mark Clendon has recently hypothesized that current Aboriginal languages might have more ancient origins as they could have come from the period of the last Ice Age (approximately 13,000 years ago) when a narrow strip of land united Australia to New Guinea in an area that was as densely populated as the eastern coastline of what is now the Australian continent (American Broadcasting Company [ABC] Science Online, December 13, 2006).

The Dreaming

At the end of the 19th century, the British-Australian anthropologist Sir Walter Baldwin Spencer (1860–1929), who was also one of the earliest filmmakers in the history of anthropology, and his Australian colleague, the anthropologist and ethnologist Francis Gillen (1855–1912), used for the very first time the word *Dreamtime*, referring to one of the essential beliefs in indigenous culture. They spent several months working and studying together, participating in expeditions, and trying to understand the Aboriginal way of thinking. The results of their research were collected in books such as *Native Tribes of Central Australia*, which appeared in 1899, *The Northern Tribes of Central Australia*, published 5 years later, and *The Arunta: A Study of a Stone Age People*, which appeared in 1927 (Spencer & Gillen, 1966, 1969, 2000).

Some years later, the Australian anthropologist William Edward Hanley Stanner (1905–1981) was listening to a native who was speaking about Dreamtime and who explained to him that the white man does not know the real meaning of *Dreaming*. Stanner (1972) preferred this last

word for referring to what the Aborigines believe to have been the “time of the creation”: A gerund verbal form could, in fact, better give the idea of the continuous presence of the time of the creation in the present moment. According to Aboriginal philosophy, Dreamtime, or Dreaming, is a timeless dimension that is not relegated to the past; on the contrary, it is a concept that is actual in every epoch, just as creation is an uninterrupted process.

Sometime later, Stanner (1972) also coined the expression *everywhen* thinking that this term could be more appropriate to define the concept of Dreaming that was so distant from the Western way of thinking.

On the other hand, Theodor George Henry Strehlow (1908–1978), an Australian anthropologist who dedicated himself to studying the Aranda group in particular, defined this idea by the terms *uncreated* and *eternal*, underlying in this way the fact that the Dreaming does not know any human-limited temporal dimension in its essence.

However, the most meaningful definition of this concept is the one that comes directly from the voice of the natives: It is *all-at-once* and underlines the particular role that time and no-time play in their cosmogony.

The indigenous people believe that when the *primordial beings*—that are now considered to be their “totemic ancestors”—came out from earth, time started to exist on our planet, which was featureless, bare, and dipped in silence and in darkness. The ancestors emerged from the crust and began to travel: They made the humans and the animals as well as the sun, the moon, and the planets, and they woke up the various forms of living beings that were asleep, hidden under the surface of the land. Ancestral Spirits deposited the seed of life and shaped the world through their actions (Dreamings), their will, and their imagination by following the Dream of the creation. They also created the *unchangeable law* (i.e., the “lifestyle and rules” every native Australian should follow even today) that also encompasses every legend and every ceremony. Several interesting tales are related to Aboriginal cosmogony: Some of them such as the one about “Rainbow Serpent” (also named “Rainbow Snake”) will be reported in the following pages.

The Dreamtime beliefs were much more vivid before the arrival of the first colonizers: Europeans found the Aboriginal beliefs very complex at first but later simplistic. At that point, to the European mentality, the natives were often considered to be similar to children who live in the Dreaming world created by their imagination. Past anthropological studies implied, in this sense, that the wisdom of an ancient culture was instead rather childish.

At the beginning of the 20th century, the French anthropologist and ethnologist Lucien Lévy-Bruhl (1857–1939) in his studies on the mental processes of Aboriginal populations theorized that they owned a “primitive” sort of mind as they were unable to use logic and that they experienced a sort of mystical involvement in the reality shown by the myths.

The Rainbow Serpent

The so-called Rainbow Serpent (or Rainbow Snake) is one of the greatest and most important Aboriginal spiritual symbols.

The legend of this mythical creature probably originated in northern Australia near the area where nowadays the Kakadu National Park is located. However, due to its unlimited value, it is obviously known everywhere on the continent where it is also called by other names depending on different tribes: *Ungur*, *Taipan*, *Yero*, *Ngalyod*, *Wonambi*, *Langal*, *Almudj*, *Borlung*, *Wonungur*, *Yurlunggur*, *Galeru*, *Wollunqua*, *Muit*, and others.

The Rainbow essence of this mythical creature is energy and light. Its dualistic nature allows it to not only create life but also to destroy it: It represents both creation and destruction, good and evil, masculine and feminine powers. Generally, it is believed to be a female being. Like women, she is related to natural cycles: She generated life on our planet, gave nourishment, took care of all creatures, and represents the feminine power on earth. Women belong to this mythical creature, and when women pass away, they return to her cycle of life-death-rebirthing. She regulates fertility, menstrual cycles, and blood circulation as well as the rhythm of the seasons and of other natural elements, such as tidal phenomena and wind flow. Her relation to weather phenomena is especially believed in Australia's monsoon area. Rainbow Serpent is also associated with the sun that gives us warmth and nutrition but can also make hot and sultry weather that causes the scarce and precious water resources of the desert to evaporate: In this case, its noxious and destructive energy is associated with male nature.

There are various stories related to this mythic being. One of the most famous legends tells us that the Rainbow Serpent came from the deepness of the earth when the world was still in a state of sleep, and it felt lonely. It started its journey on the ground and it created mountains, plains, gorges, hills, and all landscapes while crawling and slithering on the soil. Through its interaction with sunlight and wind, it provoked rain that created lakes and rivers. Even today, rainmakers and healers ask for its help through giving gifts of shells and quartz crystals. When Rainbow Serpent wanted to rest, it coiled up and slept without turning into any other element of the landscape or modifying its original nature. Australian Aborigines believe that it still hides in water holes or in a canyon formed by erosion near a waterfall in central Australia (but according to Gagudju people, it precisely lives in a place called Djuwarr) and that it does not allow people to disturb its quiet.

Male adolescents are said to risk being kidnapped by Rainbow Serpent—who would eat them and vomit them—to let them enter the adult age, while pregnant women are forbidden to touch the water it drinks. Legends said that the Serpent swallowed two young boys and transformed them into two iridescent parrots as colorful as the rainbow. That mythical event was a rite of passage that allowed them

to obtain awareness and power. Nowadays, during ceremonies, people still primp with multicolored feathers to look like the Snake. Women, on the contrary, do not need such rites to get its power: They already own it, and they become adults with the onset of menarche.

People cannot see the Serpent except when it rises, arches its huge body, and shows itself in the semblance of a rainbow in the sky.

The intelligence of the Serpent is said to give to shamans the powers of healing and of traveling beneath the earth, flying through the air, and breathing underwater.

The Land

The bond between Aborigines and their land has always been very strong. In fact, land is an important element both as a fundamental source of sustenance and as a deep spiritual significance.

The indigenous people are very respectful toward the environment and know how to use its resources without damaging it. They do not overexploit it but try to maintain its delicate equilibrium and do not compromise its natural cycles that balance and regulate it. Taking care of it is a preeminent moral duty for them. For this reason above all in the past, people did not live at the same place too long and were careful not to hunt or fish too intensively in order to preserve different species and their reproductive rhythms so that the people could have enough food for themselves in the following seasons.

It is clear how the contemporary biodiversity loss caused by pollution and excessive use of natural resources could have a devastating affect on their lives and menace their own survival.

Their wisdom has allowed them to live in harmony with nature since the oldest time up to now. This symbiotic relationship derives from their animistic perspective that makes them feel devotion and respect toward all the elements. In this sense, land holds particular religious significance.

Moreover, according to their moral principles, land cannot be owned or traded: Those actions would be sacrilegious toward their ancestors who are believed to have roamed through the continent giving shape to it.

The native people do not fence in the land, and the concept of *border* is very different from that of the Western culture in the sense that it does not imply the concept of private ownership.

In the 1970s, Aboriginal human rights movements started as demonstrations to obtain justice against unequal laws and to claim rights to lands founded on the Aboriginal's 1,000-year occupation. Since the beginning of the colonial dominion, in fact, local populations had been deprived of their richest soil and had not been able to gain any economic benefits from the natural resources that had been found in their territories. One of the most important results in the fight for equal rights was obtained in 1994 when the

High Court of Australia declared that the concept of terra nullius, or land belonging to no one—that the English had applied to take possession of land—should be considered illegal and that the presence of the Aboriginal populations on the Australian continent before the arrival of the first settlers should be admitted.

Magical Elements

The land and its beauties (shells, minerals, and precious stones) represent a world of magic power. *Jakuli* or *riji*, for example, are traditional male ornaments (pubic covers or necklaces) typical of the northern area of the continent that are worn by men who have reached the main level as far as initiation degree is concerned. Those pearl shells are decorated with tribal motifs and are believed to be linked to the spiritual energies of water that let shamans own the power of healing people. On the other hand, the mother-of-pearl glow reminds us of the Rainbow Serpent descriptions that are deeply connected to water power as underlined before.

As far as Queensland's local culture is concerned, opals (Australia owns very important quantities of this mineral) also own their beautiful, iridescent colors because of the fact that they had been touched by the Snake; on the contrary, according to some tribes living in New South Wales, opals originated in water that a pelican was carrying in its beak.

Mabain (or maban) is a material associated with quartz crystals and other elements such as mother-of-pearl, iron, and desert rose, or ochre, and it is considered to give magic powers. It is used during ceremonies and rites of passage when parts of it are inserted into the initiate's body to symbolize the link between the human status and the spiritual one: the bond between the present time and the eternal time of the Dreaming. Also, red ochre has intense significance in Aboriginal rites; related to the color of blood, it is used as a pigment for decorations and rubbed over naked bodies.

As it has been shown, the land and its elements transcend their material concreteness to reach deeper meanings. In local languages, shamans, who are the ones who succeed in completing all initiation levels, are called by terms that mean "clever men" or "powerful men." The first anthropologists who visited Aboriginal tribes described them as people with extraordinary powers, such as clairvoyance or telepathy. Among them are the so-called medicine men, that is, men who are able to heal people by using natural remedies and giving energy. They are said to get this power from the cosmic harmony that created everything; this happens through symbolic death and rebirth. The ancestral spirits, in fact, are believed to come and bring the new shaman to the netherworld where they introduce magic shining quartz into his body. After acquiring its vital energy (as light possesses healing and regenerating virtues), the shaman can reach the world of the Spirits and meet his totemic guide. According to the tradition, those

powerful stones could also come from water holes where the Rainbow Serpent lived.

There are also women who become shamans: Their secrets can be known only by other women or by men of high degrees.

Mythical Geography

Australian natives are bound to their land above all through a deep feeling of affection and filial love: Earth is like a mother, and they feel part of her. Damaging her means making unacceptable violence, and depriving them of her causes them to lose their own identity. As the anthropologist Theodor Strehlow (1947) underlined, the territory is like a giant *genealogical tree* as past and present are written on it.

The term *songlines* refers to a series of songs related to those trails that describe the mythical journey of the sacred Spirits of the Dreaming throughout the continent. In fact, as told before, the ancestors are believed to have awoken the different forms of life and shaped the countryside by distributing plants and animals, by making rivers and streams flow, or by relating one place to another. While doing that, they left their marks such as footprints or incisions on the land giving in this way significance to every natural element; according to the Aboriginal animistic view, whatever exists (rocks, plants, stars, water, etc.) has its own soul. The mythical trails of their passage trace a sort of labyrinth all over Australia and are said to be still visible as impressed upon its landscape features. Because of them, many places acquire a fundamental spiritual value and become a source of "law"; in this sense, Aborigines prefer to call the songlines by the phrase "way of the ancestral law." These sites are considered to be sacred, and the natives keep them secret. The sites are said to own particular energy that lets people reconnect with the Dreaming dimension. Only a few people are allowed to visit them, and tourists or companies involved in economic businesses that do not respect this moral prohibition outrage the Aboriginal people and offend their sensitivity.

Aborigines, who identify their origins with a particular Ancestral Spirit, keep an extraordinary relationship to the characteristics of the landscape that are associated with it: In this sense, we can refer to the Aboriginal spatial view as a totemic one.

We can consider the concept of songlines as a principle of mythical geography, giving symbolic interpretation to some particular sites that are perceived as backgrounds to mythical events. In fact, this complex system of songs gives significance to the geographical features of the landscape and suggests mythical explanations of those natural phenomena that can infuse the territory with special value.

The Rainbow Serpent is considered to have created a song describing its own actions on the land surface. Aboriginal people still sing it, particularly when they have to travel from one place to another: It can help them to face

difficulties in daily life as it offers indications of how to get understanding of the secrets of the territory. In arid desert areas, for instance, its spirit can guide them to find precious fresh water to drink.

Uluru

Mount Uluru (called Ayers Rock by the white explorers at the end of the 19th century in honor of Sir Henry Ayers, who was premier of South Australia) is a huge rock formation set in central Australia and also one of the most famous sacred sites in Aboriginal mythology that is considered to be still inhabited by many Ancestral Spirits. According to the Australian ethnologist Cyril Havecker (1988), it is one of the symbols of the Rainbow Snake, which originated life. Aborigines consider it an emblem of fertility.

There are so many legends related to it. One of them tells that Tatji, the small red lizard, lived on the plains near Uluru and came to the rock where it threw and lost its curved stick (a sort of boomerang). Trying to find it, Tatji started to dig the soil and scar the rock causing those cracks and hollows that are still visible today. Another story tells that the Bell-Bird (typical Australian birds belonging to the sparrow family) brothers were hunting an emu, which ran away toward the big rock. Two fantastic creatures, the Blue-Tongued Lizard men, caught it and killed it. When the Bell-Birds arrived, the lizards had already eaten the emu, so the birds took their revenge by burning the lizard men's shelter. The lizards tried to escape the flames by climbing the rock, but they fell and burned. Gray lichens on the surface of the rock still remind us of the smoke of that fire, and two boulders are seen as the two dead lizard men.

These examples show us how in Aboriginal culture mythological tales are useful to explain natural phenomena, such as erosion or the presence of a certain type of flora and fauna.

Even more significant is the legend that tells us about the origins of Uluru. At the "out-of-time epoch" of creation, two local ancestral tribes did not participate in a feast as they stayed gazing at the wonderful Sleepy Lizard women. The hosts got so furious because of the attitude of the tribes that in order to kill the leaders of both groups, they gave life to a mud sculpture that became a dingo. Earth was so desperate because of that tragic event that it rose up and originated Uluru, whose splendid tones remind us of red blood.

Many examples of cave art, illustrating both mythological scenes and daily life events, are there to remind us of the richness of this culture that has never broken its deep bond to the past.

There are still many secrets concerning the magic charm of Uluru, which are inaccessible to non-Aboriginal people. Visitors are strongly asked to not damage the rock or climb over it as a sign of respect for its sacred value. Unluckily,

too often this request goes unheard. The mount is still an attraction for thousands of tourists who visit it every year.

Art and Musical Traditions

Art is a really important way of expression in Aboriginal culture as it is bound to nature, mythology, and rituals. As far as painting is concerned, many different types of surfaces are used to decorate (rock, barks, objects such as boomerangs, etc.), and there are also various styles to realize it, in particular, the so-called X-ray art (in which people and animals are portrayed and their skeletons and organs can be seen), the "stencil art" made by using, for example, leaves or hands as templates, and the "dot painting" originally made with sand, stones, seed, or other natural elements and nowadays by using dots of color. Drawings were originally realized through natural pigments, such as ochre and crushed rocks mixed with water or spittle. Those colors were also used for body painting on particular occasions such as initiation ceremonies, funerals, and ritual dances, whose decorations own a social and spiritual meaning.

Recently, thousands of extraordinary pictographs and petroglyphs (that date from 15,000 years ago to the middle of last century) have been found in Arnhem Land, northern Australia, arousing enthusiasm in the archaeologists for the exceptionally long period of time they cover.

Also, the role of music and of sounding expression in Australian traditional culture is highly significant. Dreaming Spirits are said to have created everything by "singing" life into the world, and even nowadays, during ceremonies (called by the indigenous *caribberie* but known by the English as *corroborees*), people chant the ancient songs of their mythical origins. Some of the songs are widespread, but many others are kept secret to preserve their evocative and magic power from corruption.

According to Aboriginal philosophy, whatever exists needs a name in order to be identified through a series of letters that can be pronounced: That allows the primordial energy of creation, which is the essence of every being, to materialize in tangible forms of life. Through the cultural concept of the songlines, music joins the surrounding environment and generates the peculiar, mythical meaning of geography that has been previously illustrated.

There are various sorts of instruments played during ceremonies. One of the most famous is what non-Aboriginal people know as *didgeridoo*, which is called in local languages by many different names such as *ganbag*, *yirdaki*, *maluk*, and *yigi yigi*. It is a natural musical instrument made not by humans but created by termites that feed on wood and consequently create hollows in tree trunks.

Its employment is very ancient, and it is traditionally known as a *eucalyptus trunk* or *bamboo* that Aborigines decorate with totemic drawings. Two ancient legends explain its accidental discovery by human beings.

According to the Northern Queensland's tribal culture, it once happened that some women went to get firewood, and

while going back to their villages, they heard an unknown but enchanting sort of deep sound coming from one of the trunks they were carrying. The wind blowing into it was letting them discover what can be considered one of the most fascinating types of natural music in worldwide cultures. On the contrary, as far as the traditions of the North Territory are concerned, not women but men were involved in the discovery of didgeridoo. They were roaming through the woods to find some food when they noticed that animals used to find their hiding places in excavated trunks. When one of those hunters tried to blow into one of the trees, it unexpectedly uttered a sound. Since that day, those trunks have been used to create music.

Conclusion

The description of the Aboriginal world that has been presented in this chapter has essentially aimed to be an invitation for the reader to reflect on the importance that indigenous cultures still have in the contemporary world.

History teaches us that too many arbitrary clichés and subtle interests have tried to persuade us that many local and often marginalized populations live in a sort of “prehistorical era.” The indisputable fact is, however, that they actually live in the same time as we do.

The different sectors in which anthropology structures itself can offer a valuable contribution: to make evident that there is not a unique way but different ways to live in the present. For this reason, the approach to the Australian indigenous people that has been illustrated could have important applications in future research. Their ancestral and modern holistic view of the world—instead of appearing as separated from the current temporal context—may offer a chance to rethink our own present. The richness of their culture and their unconditional respect for nature can help us to think over an idea of progress that should not imply indiscriminate growth to the detriment of emarginated populations. In the intercultural dialogue that should animate the contemporary globalized world, the deep study of their artistic richness, of their sensitiveness as far as ecological lifestyles are concerned, and of their precious, orally transmitted knowledge heritage could contribute to letting us better know our own identity. Thinking of ourselves as members of the great *natural family*, rediscovering sounds and silences, and considering the immense value of biodiversity and not running the risk of losing it forever can give us the force of constantly creating and improving our world in a modern Dreaming.

INUIT

PAMELA RAE HUTESON

Edmonds, Washington

Bands of Paleo-Eskimos migrated into the New World near the conclusion of the Beringia, or Land Bridge era; it is inconclusive, though, whether they traveled by land or water. Initial theories of origin suggested derivation from areas such as Mongolia, Japan, and Korea to circumscribe on a more generic area of Asia. The evolution from “Paleo-Eskimo” into *Inuit* occurred after arriving at the tip of the northeastern Siberian area around 8000 BCE. It was once believed that the Inuit migration initiated from the west end of the volcanic Aleutian Islands, progressed eastward toward the Alaska mainland, and then continued northerly; fieldwork reveals that the ancient encampments appear increasingly antiquated on the islands closest to the Alaska mainland and less aged on each successive island. Therefore, it is the nomadic and seasonal journeys of certain bands that initiated relocations farther south (after departing Siberia) to the Aleutian Archipelago, or “the birthplace of the winds,” as it is called by its inhabitants. These journeys resulted in the continuous occupancy at Nikolski Bay, which was established around 6700 BCE. From approximately 4000 to 1000 BCE, these Aleutian Island dwellers evolved into the *Unangan* people (more popularly known as “Aleut”). That the Unangan are related to the Inuit will be recognized in this chapter.

The *Tuniiit*, a name derived from the Canadian Inuit oral history, made an epic eastward migration into Canada; by 2500 BCE to 800 BCE, Inuit settlements were maintained

in Greenland (the ancestors of the modern Greenland Inuit arrived around CE 1250). A division of the Eastern Inuit returned to the northern area of Alaska. Similarities have been noted in the stone-wall habitations found in two opposite locations of the North American continent: on the Diomed Islands in the Bering Sea and in Greenland.

Inuit Seasons

The Inuit’s hunting/fishing/gathering economy transpired in an apparent two-season (summer and winter) location, although the Canadian Inuit observe six seasons:

- Upingaassak—the material for spring (early spring)
- Upingaak—spring
- Aujak—summer
- Ukiassak—the material for a small winter (early fall)
- Ukiak—small winter (fall)
- Ukiuk—winter

These isolated Inuit communities, which resided on the continuous terrain of permafrost, cultivated a distinctive society that is congruous with their environment and effectually capable of thriving in the Far North. An example of evolutionary adaptation is the Inuit’s physical structure, which reduces heat loss with a shorter, stockier body, as opposed to a taller, more slender body that would dissipate heat faster. The Inuit’s survival-appropriate technology

meant that hunting provided material for their primary source of provisions as there was relatively little waste, for example, material for clothing such as the waterproof coats fashioned from mammal intestines (e.g., from walrus, seal, sea lion, and bear) and whalebone for housing support and various hunting and fishing implements (e.g., hooks and spears). Marine mammals and fish were subsistence staples, although from Alaska to Greenland caribou and other land mammals were also hunted, while in Siberia the reindeer was important. For the most part, the meat of fish and mammals was consumed raw. In this land that lacks vegetation (save for the summer), the nutrition that was needed to avoid scurvy was provided within the uncooked meat. Clothing such as pants could be worn with the fur on the outside, or “inside out,” with the fur next to the skin. The severe winters required two layers of clothing to be worn with the inner layer designed with the fur side facing the skin for increased insulation. The Inuit mode of land transportation consisted of dogsleds or sledges. On water, the Inuit and Unangan are experts in maneuvering their kayaks (the Unangan name for kayak is *iqax*); these slender and complex vessels were originally fashioned from driftwood, bone, and mammal skin, with Inuit blood for glue (some kayaks even had joints of bone or stone).

The traditional kayak is a single-person closed vessel. Russian Orthodox priest Ioann Veniaminov (Durham, 1960) noted how a cord secured within the hem of the hatch and tied around the body and under the armpits prohibited water from entering the kayak. Captain Cook (Durham, 1960) documented his ship’s sailing speed at approximately 7 to 10 miles per hour as the kayaks (or *bidarka*) held their pace with his ship. The Umiak (also *baidar*) is a wide and spacious

Traditional Inuit kayaks were constructed from bone, driftwood, and skins. This modern version is constructed from a design similar to the traditional one, but it is made with new wood and canvas.

vessel (more similar to a rowboat) that transported groups of people and cargo.

The continuity of the Inuit family was fortified through the belief in reincarnation. For example, after a death in the camp, the first child born is bestowed with the deceased’s name (from either gender). Moreover, the child is then entitled to the respect due to the former person (e.g., a child named after a mother may be endeared as “little mother”). The Inuit’s oral history occurred throughout the child’s life, with family stories and the reenactment of the family’s songs and dances. The Inuit believed in spirit entities that held power over their world. Inuit mythology reveals the entity Sedna (a half-human, half-creature being) who is credited with creating sea mammals (Paskievich, Van Raalte, Pratt, Pitsiulak, & Zemma Pictures, 1992), as well as controlling the harvest (bestowing the harvest only on those truly worthy). Consequently, the Inuit observed a myriad of rules and taboos and the belief in amulet charms. Amulets have been worn by both the hunters and their kayakers (a kayak was considered a living vessel and therefore required the protection of amulet charms). Because of the conviction that charms increase in power with each passing year, a female child would be adorned with the amulets intended for her future sons. Animal life was respected, too; when a seal was taken, freshwater was poured into its mouth so that it would let the other seals know how well it was treated. The shaman was relied on to heal the sick and to contact the esoteric world concerning issues pertaining to societal matters, hunting, and weather predictions. A majority of the seasons (from spring to fall) were spent in hunting, fishing, and harvesting in order to store for the winter. The winter was a time of festivals, drumming, singing, dancing, wearing masks, storytelling, giving gifts, and having feasts.

First Contacts

The expansive, primal attributes of the Arctic are experienced as a territory of harsh and unmitigated challenges for those unaccustomed to this harsh environment. This region has also inspired presentiment tales of early explorer adventurers who “expanded the frontier” and documented a people from a primitive social structure living within the Arctic Circle:

- 14th century: The Norse Vikings became the first European contact and bestowed on the Inuit the nomenclature of *skraelings*, or screamers (Fitzhugh, Ward, & National Museum of Natural History, 2000). Their depictions of *skraelings* resembled dwarfs.
- Mid-1500s: The Basque from Spain arrived with fishing and hunting parties, establishing a camp at Labrador that resulted in the first illustration of an Inuit camp (Proulx & Canadian Parks Service, 1993).

- 1570s: The British aspiration for a Northwest Passage brought the first voyage with Martin Frobisher, in 1576, to Baffin Island and returned with documentation of the Inuit peoples (Williams, 2003). Inuit were also brought back to England in some of the British voyages.
- 1648: The Russian explorer Semyon Dezhnev documented the people he called *Chukchi* at the Diomed Islands between Russia and Alaska (Berg, 1949).
- 1741: Dane navigator Vitus Jonassen Bering, employed by the Russian Navy, arrived at the Aleutian Archipelagos (Miller & Urness, 1986). The Unangan population drastically declined during Russian occupancy.
- 1700s: Moravian missionaries began evangelical work in Greenland and Labrador (Nowak, 1999).
- 1800s: European and American whalers occupied both the Atlantic and Pacific sides of the Arctic until 1918 (Spence, 1980).
- 1825: The first English explorer in Alaska, Sir John Franklin, documented a trading system between the Inuit and the “Indians” (Simmonds, 2005).

Methods

Adaptation to Inuit Technology

The risk of early scientific expeditions lay in the paucity of available knowledge concerning preparations for an Arctic expedition, such as the inadequacy of European clothing to buffer the frigid Arctic conditions, overland travel that entailed human power to haul barges across the terrain of ice and snow, and so on. In the 19th century, Arctic explorers broke from convention. They marked the inaugural adaptation of integrating Inuit apparel and transportation into their expeditions, initiating with Charles Francis Hall (Hall, Davis, & U.S. Navy Department, 1876) in his 1860 to 1862 exploration to search for the lost Franklin expedition. Those who followed suit were Robert E. Peary, Knud Rasmussen, and Vilhjalmur Stefansson (while a minority, they also assimilated Inuit victuals into their provisions, e.g., raw meat).

Fieldwork

Early fieldwork preparations relied on procuring a local guide, usually Inuit, for equipping an entourage for a successful Arctic journey. Charles Brower (Brower, Farrelly, & Anson, 1942), whaler/trader/census taker/postman/novice archaeologist of Barrow, was indispensable for equipping explorers such as Diamond Jenness, Rasmussen, and Stefansson for an Alaskan Arctic exploration. Between the field expeditions, Brower also coordinated with the explorers and museums in order to supply them with shipments of artifacts, which he received from the local Inupiaqs.

Rasmussen’s amulet-artifact gathering once developed into creative negotiations. He declared that the protection

constituent of the amulets—for the original owners—would hold steadfast (as Rasmussen was not from that region, he therefore should be denied benefit from an amulet’s influence). Trading resumed as a consequence of his hypothesis, although with a stipulation insisted on by the Inuit that locks of Rasmussen’s hair be a necessary condition of the trade to ensure the extension of the amulets’ charms.

Language

The acquisition and mastery of the Inuit language, standardizing a writing system for the “Eskimo-Aleut” (also known as *Eskaleut*, *Eskimoan*) linguistic stock, aided essential cultural decoding and the comprehension of the embedded histories, belief systems, and allegories within the Inuit traditions. Rasmussen (1999) held an advantageous position over his colleagues because he was part Greenland Inuit and spoke Kalaallisut (Greenlandic Inuit language) fluently.

Major Dialects Within Each Region

- Siberia: Yup’ik
- Alaska: Inupiat, Yup’ik, Alutiiq, Unangam Tunuu (Aleut)
- Canada: Inuktitut
- Greenland: Kalaallisut (Greenlander)

Notably commented on are the Alaskan dialects, for although in relative proximity, they are virtually different languages. Comparably, the Alaskan northern Inupiat dialect (i.e., the Point Barrow area) resembles that of the Greenland Kalaallisut dialect. It was initially observed by Rasmussen during the Danish Fifth Thule expedition that the Greenland Inuit accompanying him were able to comprehend the American Inuit, from the Naujat (Repulse Bay) to the Netsilik Inuit (Rasmussen, 1927) to the Point Barrow Inupiaq (Brower, Farrelly, & Anson, 1942). Concerning the retention of the native languages, the Inuit, due to their locale, have retained their language, although in Siberia, the Sirenik dialect from the Chukotka Peninsula is extinct. Also, the Inuit who have relocated to metropolitan areas are witnessing the disintegration of their language in younger generations.

Inuit oration contains valuable information concerning their cultures and traditions and represents insights into the Inuit psyche. In her research, Margaret Lantis (1952, 1953) ascertained that the Inuit mythology includes clues into the Inuit cognitive processes (e.g., fear, coping strategies, behaviors, etc.). Within Inuit oral history, early European contact has also been discovered (Seidelman & Turner, 1994). Rasmussen documented Inuit stories of the lost Franklin expedition, which occurred nearly 75 years prior, as well as the John Ross expedition of approximately 90 years prior. Archibald Fleming documented Inuit oral history concerning the winter encampment of the

Martin Frobisher's expedition at Baffin Island, which occurred nearly 350 years prior to documentation.

Cartography on Baffin Island

The 1883 to 1884 groundbreaking research and cultural interaction by "the father of North American anthropology" Franz Boas for his publication *The Central Eskimo* originated as a by-product of his unique cartographic project on Baffin Island. Boas maintained the significance of recording Inuit place names (as opposed to affixing early explorers' names to that region). He also launched an unprecedented collaboration with the Inuit by respecting the distinction of their geographical wisdom and by encouraging both genders to illustrate maps and identify the areas. Boas therefore illustrated not only the Inuit's technical skills and ability in creating accurate maps but also the Inuit's personal relationship with their land as well.

Art Comparison in Origin Theory

Prior Inuit origin theories once focused on the Paleo-Eskimo emergence from Europe as claimed by British archaeologist Sir W. Boyd Dawkins (1886), who asserted that the Inuit descended from the Magdalenian/reindeer hunters of Western Europe. This theory originated from prevalent parallelisms in lifestyles of the Inuit and Magdalenian population. The theory of the Paleo-Eskimo's originating in Europe appeared to coordinate with the "follow-the-reindeer" theory, that is, the reindeer hunters who followed their game northeasterly as the weather warmed. This concept attained popularity in 1899 when Frenchman L. Testut (Bandi, 1969) interpreted the Magdalenian skeletons from the Chancelade area to have an Eskimoid resemblance. However, in the early 1930s, Frederica de Laguna (Bandi, 1969) challenged this speculation in her article "A Comparison of Eskimo and Palaeolithic Art," which indicated that when juxtaposed, there was an absence in the accordance of artistic expressions concerning the two cultures, albeit with similarities in the materials used (i.e., ivory, bone, etc.).

Acculturation in the Arctic

The intervals of benign and incursive contact from the Euro-American cultures established a governmental authority on the indigenous people who were unfamiliar with a conspicuous, consumptive culture. Sociologist Peter Usher (Creery, 1983) revealed that the usurpations from traditional hunting lifestyle to a trapping economy at the Arctic Hudson Bay post in 1901 was effectively realized in approximately a decade. In addition, the conventional demarcation of the Arctic region, with the consequential aggression of division and relocations of

the Inuit families into countries and settlements, contributed to impairing the Inuit social organizations. The Russian and Alaskan Inuit families (e.g., the families between the Diomed Islands) though only 20 miles apart were not allowed to visit. Also, the Pribilof Islands in Alaska were inhabited by the Unangan who were subjects of Russia for the seal trade. When the Americans "took over" Alaska, the Pribilof Unangans became American wards (as opposed to the Unangans who lived on the Aleutian Islands who were not wards). The Pribilof Unangans/Aleuts did not obtain emancipation until after World War II. Meanwhile, in Canada, the separation of young Inuit couples and their children from their immediate families took place as they were shipped to mining camps. And in Russia in the 1920s, the communist Soviet Union relocated the Siberian Yup'iks from their ancestral lands and assigned them to units known as collectives for laboring at manufacturing.

In the early 20th century, the accession of ramifications concerning this unprecedented acculturation event within the Arctic imposed insurmountable digressions within the Inuit communities. The sovereign and independent Inuit had become reliant on the Euro-American cultures that projected their standpoints as benefactors, "improving" the Inuit's circumstances. These "improvements" facilitated a cultural genocide and social alienation (i.e., the interference with the Inuit by separating them from their traditional culture that through centuries of vicissitudinous change had adapted them to their Arctic environment).

The periodic establishments of the new lifestyles became noticeably evident at the earlier stages of Euro-American contact; the Inuit felt that they had lived a healthier lifestyle prior to the "modern" standard of living conversions. Those who still lived off the land commented on how the village dwellers had lacked color and vigor.

Sample Chain Effect in the Arctic

What follows is a small sampling of certain Canadian villages that experienced a drastic change in their way of life, which started with the removal or tying of their dogs, and the progression of "civilization" (Huteson, 2007b):

- Some "civilized" villages required that dogs be restrained to their owners' property in lieu of the freedom the dogs once enjoyed (in certain villages, the slaughtering of dogs immobilized the Inuit families and prohibited seasonal movements). The restraint of dogs resulted in the consequential incapacity of their canines to pull their sleds for an extended traditional hunting trip (due to lack of adequate exercise).
- The Inuit were then unable to hunt for their families or travel (this impediment produced hardships).
- The inability to hunt forced a need to purchase food, thereby establishing the necessity for employment and solidifying dietary changes (e.g., sugars, flour, fatty acids, etc.).

- The endorsement of gas-powered snow sleds replaced the custom of dog sledges. These modern sleds were prone to breaking down, thereby facilitating the Inuit's mechanical knowledge (a marketable skill for employment).
- Therefore, the Inuit, who from time immemorial had maintained a self-sufficient and active life (i.e., running alongside the dogsleds and subsistence hunting and gathering), transitioned toward a sedentary lifestyle of riding "skidoos" and retaining steady employment to purchase hunting gear and provisions.
- And finally, the reliance on Western medicine counteracted the emergence of physiological issues (i.e., excess weight gain, diabetes, heart disease, cancer, etc.).

Alcohol has brought devastating consequences on the indigenous peoples. In Alaska, for instance, it interrupted the food gathering activities of the Inupiaq villages, which brought starvation in numerous camps. Violence increased within the villages, and camps of these Arctic peoples, who were attempting to adapt to their new way of life, spent monies acquired through fur trade on inebriations. In the early 1900s, George Gordon (1906) witnessed the deterioration in the Arctic due to Euro-American contact—the amalgamation of rampant diseases, the Inuit's traditional food sources substantially hunted out by nonnatives, coupled with a drastic dietary change—which prompted Gordon to warn of the impending extinction of the Inuit.

Additional preeminent advocacies of lifestyle conversions came from churches and schools; both disrupted the Inuit's hunting and gathering practices. The church forbade hunting on Sundays, while stipulating a necessitation to attend various worship practices throughout the week. In addition, the traditional Inuit ceremonies were forbidden; in their stead, Christian holidays were enforced. Other non-Christian activities, for example, tattoos, labrets, and wife exchanges, were outlawed. The schools imposed an allocated academic schedule, which held precedence over the Inuit's traditional mobile lifestyle. Also, children were flown to larger towns for education; some Inuit families followed their children to the new locations. The children's relocating for school from fall to spring also created hardships for their families who relied on them to assist during the hunting season. Another hardship ensued when the children brought back diseases of smallpox, measles, and so on.

In Alaska, the excessively consuming whaling industry and growing dependence on mercantilism resulted in a cessation of the seasonal trade route traditions of the Inuit from coastal to inland bands (Brower, Farrelly, & Anson, 1942). In addition, throughout the Arctic, the Inuit people gave up their traditional semisubmerged residences, the accustomed abode of separate men and women houses, to

drafty, wooden houses where families were expected to live together (prior to this, Inuit families lived together only when in camp). These drafty wood-constructed buildings augmented illnesses among the children as well as the elders. Following the adaptation to "white man" products, these single-room houses required oil for heating and induced both sewage concerns and garbage dilemmas. Becoming permanent village dwellers as opposed to living a seminomadic to nomadic lifestyle required permanent employment; having a "9 to 5" schedule was difficult to adhere to, especially during subsistence seasons. In addition, the devastating European diseases could not be cured by their shaman, which prompted the Inuit toward use of Western medicine. The combined circumstances served to reinforce assimilation and the adherence to earning wages.

Enculturation, or the integration of elements from the Euro-American customs into the Inuit culture, has also served as an alliance to augment the Inuit culture in some positive outgrowths. For instance, as sailors began frequenting Nome, assiduous carver Angokwazhuk (known as "Happy Jack") became exposed to scrimshaw and cultivated a new art form of engraving ivory with fine needles, integrating Inuit and American art and thereby inventing a new trade. Carving pervaded the North to become either the main source of income in the Arctic villages or at least a supplement to it. The 1960s witnessed the increase of Inuit artists as Inuit prints and sculptures (i.e., soapstone, ivory, and bone) of modern Inuit art began emerging in fine art galleries. Also, the publications of anthropological monographs and biographies on Inuit lives began to reveal the Inuit's personal perspective on history, for example, Margaret B. Blackman's *Sadie Brower Neakok: An Inupiaq Woman*. The Inuit grassroots movement has also endeavored to capture the culture in documenting autobiographies and personal documentaries. Edna Wider's *Once Upon an Eskimo Time*, which represents a year's span of Inuit lifestyle prior to Euro-American contact, is an excellent example. Another illustration of nontraditional integration is with the drum songs. Originally, drum songs were performed at gatherings, especially during the winter festivals. When the missionaries became established in the Arctic, the drum songs were prohibited. Today, drum songs are once again performed at special gatherings although in addition to traditional or ancient songs, songs are also sung in English and tell stories about contemporary topics.

Arctic Politics

The rich resources in the Arctic appeared to be available for acquisition for the edacious industrial cities to the south, regardless of established Inuit hunting, gathering, and seasonal encampments. This hegemonic perspective

concerning the Arctic has consequently brought the administrations of governments, their policies, and laws within this region. The executions of these policies were alien to the Inuit, which gave the semblance of subterfuge to these northern people, which in turn provoked fear and confusion within the villages. These strange and foreign policies of obtrusive coercion were also enforced to maintain “civilization” in the indigenous settlements and/or subsistence areas, for example, the establishment of the Royal Canadian Mounted Police (RCMP) to oversee the indigenous populations.

The Arctic people were attacked on various levels. These attacks were insurmountable and collapsed the very core of the Inuit lifestyle. First, the deluge of Old World epidemics initiated Arctic-wide relocations as deaths ensued, and the unforeseen accumulation of Inuit orphans was assimilated into Christian boarding schools. Then, the collapse of the whale and fur trade induced poverty throughout the Arctic; the Inuit had come to rely on a monetary system for food and warmth for their new lifestyle. A reindeer industry, imported from Siberia and attempted in Alaska in the late 1800s, deteriorated from enumerable complications such as an ill-managed reindeer association, wolf attacks, and a weak market for reindeer meat. The Canadian Inuit, in addition, experienced unforeseen alterations in the migrations of vital subsistence game, such as the caribou. Starvation ensued as game failed to appear in the accustomed hunting areas. The Inuit were no longer a nomadic people but affixed to villages, and so they could not relocate to better hunting areas. RCMP Henry Larsen (Marcus, 1995) reported on how the self-sufficiency of the Inuit communities was reduced to “starvation camps.” During Rasmussen’s fifth expedition, he assured RCMP inspector Stuart T. Wood with the highly controversial statement that he would “not make public the starving conditions” (Treude, 2004).

In 1952, nearly 30 years later, a highly controversial book, *People of the Deer*, was published by author Farley Mowat, who passionately revealed the Inuit hardships and mean standard of living that had occurred in the Canadian Arctic during his occupancy among the Inuit. The book’s agenda accomplished the awakening of the sensibilities of the southern communities of North America and Europe to the afflictions experienced by the Inuit peoples. The “Eskimo problem” became an insurmountable international discussion (Marcus, 1995), which compelled the Canadian government to appropriate, committed attention. This developed into an experiment of misadventure, involving the perilous relocation of a community of 34 Inuit “volunteers” (both adults and children) into the high Arctic on August 25, 1953. Death, starvation, a lack of mates, and a murder trial are samples of the consequences from this endeavor.

From the mid-20th century, an alternate approach began to be voiced by scholars such as M. Lantis

(1952, 1953), James Van Stone (Van Stone & Oswalt, 1959), and Wendall Oswalt (1990), who recommended assisting the Inuit in the community to accomplish a constructive means toward their achievement of social advancement and leadership. Also, education and training the Inuit in employable skills had been suggested by scholars at that time. The combined suggestions would constructively attend to the aforementioned dependency. Furthermore, scholars such as Van Stone and Alice Wilson would advocate for bilingual Inuit teacher’s and teachers’ aides to enhance the success of Inuit children within the school system. These suggestions are comparably similar to the Danish mode of management toward the Greenland Inuit; the Danish system protects the Inuit culture, designing curriculums translated into Kalaallisut, and are significant to the Inuit lifestyle (as opposed to an urban-focused curriculum).

Contemporary Inuit

Inuit Ethnogenesis

The traditional way of life for the Inuit endured in some areas into the 1960s; nevertheless, as contemporaneous changes were established within the villages, the changes gradually altered their worldview. An Inuit ethnogenesis evolved and disseminated throughout the Arctic (Burch, 2005; Cowan, 1976; Hensel, 1996; Morgan, 1988; Oakes & Riew, 1996; Stern & Stevenson, 2006; Young, 1992). This outgrowth derived from the very challenging circumstances that were experienced that thereby contributed to the impetus of a political consciousness. The institution of this monumental Inuit political consciousness manifested itself as the Inuit began insisting on their inviolable rights as human beings. This consciousness ranged from the humble rebellion of Inupiaq teens in Alaska, who obtained a cessation from the illicit advancements from their teachers at White Mountain School in 1929 (Morgan, 1988), to the Eskimo dancing ban—which had been imposed upon Inuit residents of Noorvik, Alaska, by Quaker missionaries in 1914—lifted in celebration of being the first community to be counted in the 2010 U.S. Census, to the unprecedented first Inuit representatives who in 1959 attended the 10th Eskimo Affairs Committee (with the intention to give their own position and perspective on the Eskimo problem). In addition, a united Arctic-wide Inuit culture was strengthened with the expansion of radio programs (e.g., CBC North Nunavut) and publications in Inuktitut. During the 1960s, there was a launching of new Inuit organizations (Huteson, 2007b): Committee for Original Peoples Entitlement, Inuit Tapirisat (Inuit Brotherhood) of Canada, Alaskan Eskimo Whaling Commission (AEW), and the first Inuit newspaper, the *Tundra Times*, in the fall of 1962 (Morgan, 1988).

There was a reclaiming and redefining of the Inuit culture within new political fields associated with the rights to their culture and subsistence and a response to the encroachment of government and “big business” on their land. For instance, in 1975, the Alaska Department of Fish and Game announced the reduction in the numbers of caribou and endeavored to initiate a regulation on the harvest (concentrating on the Inupiaqs). In the countercase, the Inupiaqs proclaimed that the “lower herd numbers” (that they debated was higher) was symptomatic of the expanding industrial occupation within the caribou’s terrain. In 1978, the establishment of the AEWG ensued in response to the International Whaling Commission’s (IWC) announcement 2 years prior of a reduction in its count of the bowhead whales and an imposed regulation on the harvest. In resolution, the count on whales is now a collaborative effort conducted by a representative of both the AEWG and the IWC.

Inuit representatives maintain dedicated, committed participation in the political achievements of the 1971 Land Claims Act in Alaska and the 1999 Nunavut Territory establishment in Canada. In 1979, Greenland obtained the status of home rule but with limited sovereignty. The next phase toward their independence from Denmark came as a result of the granting of a self-rule government on June 21, 2009. This new government will generate focused attention foremost on the educational and social issues of Greenland prior to the “primary objective” of sovereign independence, as stated by Greenland’s president, Olafur Ragnar Grimsson.

Nomenclature

Of late, the indigenous peoples’ aversion to the ambiguous nomenclature labels (assigned to them by early explorers) has initiated the reclamation of their indigenous identities, while symbolically casting off the collective misrepresentations and discriminations. The Inuit therefore are discarding the label *Eskimo* (Huteson, 2007b), an act comparable to that of the Kwakwaka’wakw of British Columbia who relinquished the name *Kwakiutl*. The Unangan have also renounced their title (Huteson, 2008); they no longer want to be referred to as *Aleut* (a name acquired from the Russians). The term *Eskimo* is credited to origination from an Algonquin expression of a much debatable translation; suggested translations were “to eat it raw,” “speakers of a foreign language,” and also “netter of snow shoes.” In Canada, the name Inuit is accepted as the generic term for their people; however, in Alaska, there is poignancy on being “correctly” identified as either Inupiat/Inupiaq or Yup’ik, while adamant that the Inuit are from Canada (although in Alaska, *Eskimo* is still in usage). In Siberian, the Yuits have become more popularly known as the Yup’iks. Comparatively, within the anthropological

profession, the implementation of Inuit has occurred as an alternative to *Eskimo*; until the mid-1970s, *Eskimology* was the title for the study of the Inuit.

Future Directions in Inuit Anthropology

Comprehensive Versus Regional Focus

The expansive Inuit culture is comprised of socially isolated communities, which are geographically extended throughout four countries. Considering the immensity of the Arctic and the former difficulties of researching in Russia, Inuit researchers have developed a tendency to focus on regional areas or countries as isolated cases rather than on the completeness of a comprehensive study. Ethnologist Pamela Sterns has advocated for the research of a cultural accumulation concerning the Inuit communities from the northeastern coast of Russia to Greenland such as the method described in Charles C. Hughes’s article (1965) “Under Four Flags: Recent Culture Change Among the Eskimos.” Inuit studies would undoubtedly benefit from disembarking from the practice of regional focus and adopting the expansiveness of a comprehensive comparative method.

Underwater Archaeology

Excavating relics concealed below the eustatic rise of the Bering Sea (with the shorelines modified and submerged at the conclusion of the land bridge) can now be explored through underwater archaeology. The 10,300-year-old “Prince-of-Wales-Man” discovered in the On-Your-Knees cave in southeastern Alaska (in an area once presumed to be inaccessible due to glacier coverage) strengthened the discussion of an Inuit littoral migration advancing along the glacier-lined coasts. The ancient shoreline of the land bridge, with the submerged encampments, suggests that underwater archaeology is an important addition to Inuit anthropology.

Arctic Climate Change

Arctic warming has been creating longer summers and shorter winters, which has caused a pertinent and unavoidable concern for the preservation of the tundra biome, which from time immemorial had remained largely reliable throughout the Inuit’s occupancy in the Arctic. The Inuit way of life has become endangered as their source of sustenance is principally derived from a subsistence diet. The safeguarding of the wildlife habitats has become a primary focus, such as the dilemma concerning polar bears that are starving and being reduced in numbers as a result of the latest unfolding conditions. Of late, some Inuit communities have also become compromised due to Arctic warming. In Alaska,

Inuit villages, beginning with Newtok, Shismaref, and Kivalina, have initiated the planning process of expensive relocations caused by permafrost crumbling within the villages and sliding into the ocean or nearby rivers. At the rate of this occurrence, the impending danger may occur to more Inuit villages. The surrounding Greenland coastlines are experiencing new satellite islands as apparent ice bridges melt and break away. The reduction and thinning of Greenland's sea ice has caused dangerous conditions for dog teams on this island, which lacks interconnecting roads between villages; an increased usage of boats and planes for intervillage travel has also resulted from unsafe ice conditions. On a positive note, Greenland's agrarian industries are on the rise, with a burgeoning tourist trade, in addition to the potentialities of oil and other mineral discoveries being made as the ice recedes.

Ecology

The critical awareness of global climate change has confirmed the imperativeness in the 21st century to research the effect on human settlements. In studies of limnology by researcher Marianne S. V. Douglas et al. of the University of Toronto, pond core samples from adjacent encampments of the ancient Inuit whalers were analyzed, and the researchers discovered that these ponds became enriched with nutrients subsequent to the Inuit's arrival due to decomposing whale remains; seemingly, these ponds endured at higher nutrient levels thereafter.

Politically Correct (PC)

A reformation of the *modus operandi* has occurred concerning the research ethics in combination with indigenous rights, concentrating on the reexamination of the standard protocol during bush work (also known as northern field-work). Previous uninhibited research methods involved acquiring information and artifacts (at times) by questionable means to secure intended data from "primitive people." For example, several Northwest tribes experienced the removal of an entire totem pole from their winter villages unbeknownst to them while the community was at its summer fishing camps at the Tongass village in southeast Alaska; Boas and George Thornton Emmons participated in the ransacking of shamans' graves for artifacts; and in 1987, anthropologist Carol Zane Jolles became apprehensive about the encouragement of her professors (prior to her first field experience) to tape-record Yup'iks incognito if necessary. The latter 20th century to early 21st century witnessed a metamorphosis within the anthropological realm concerning PC awareness. As a result, the past methods of biases of the *other* have been transmuted as literary works became decolonized, and Inuit are now welcomed as "part of the team."

DNA

The study of mitochondrial DNA (mtDNA) has broadened the comprehension in researching the bloodlines of the Inuit peoples and has offered near-definitive evidence or lack thereof concerning ancestry. For example, the Norse occupied Greenland settlements from CE mid-980 to the end of the 15th century, with exploration activities in the surrounding territories. An urban legend of "blond Inuits" surfaced following Captain "Charlie" Klengenbergo who informed explorer Stefansson about a "tribe" of Inuit with "European features" although that band of Inuit asserted no prior European contact. In turn, Stefansson observed and proclaimed that the Copper Inuit of northern Canada indeed appeared to have European features, although this declaration was seriously debated. In 2003, Icelandic scientists Agnar Helgason and Gisli Palsson (Steckley, 2008) conducted DNA research on a sample group of both Inuit and Norse descendants, without demonstrating a successful link to either ancestry. DNA research in the Aleutians has been conducted by Dr. Michael Crawford and Rohina Rubicz (Rubicz, Schurr, & Crawford, 2003) from the University of Kansas. Through their research, it was discovered that the Unangan DNA has an extant closer relationship with the Siberian Yup'iks and the Chukchi People.

Inuit Community and Anthropology Cooperation

Although the examination and sampling of prehistoric skeletal remains has aroused concerns by the *Lower-48* (an Alaskan term for mainland America) natives, the Inuit, Unangan, and northern indigenous tribes, in comparison, have been supportive of cooperation with those in the anthropological field and with the inclusion of the determining of genetic similarities between the prehistoric skeletal discoveries and the contemporary native population. In Alaska, the Tlingit and Haida tribal corporations on Prince of Wales Island joined in cooperation with Washington State molecular anthropologist Brian Kemp (Kemp et al., 2007), concerning the remains of the Prince-of-Wales-Man, which were discovered mere weeks prior to the unearthing of the controversial Kennewick man discovered on the banks of the Columbia River. Sealaska Corporation included a volunteer DNA sampling from their members during their 2008 biannual cultural festival, *Celebration*, to ascertain the tribal identity and moreover to discover the possibility of existing relations. The research conclusion noted no direct lineage from the limited sampling; the DNA from the skeletal remains was of the D mutation, which is found among some Unangans in addition to certain tribes in Southern California and farther south. The remains of this ancient person were returned to the tribes on Prince of Wales Island after Kemp's research conclusion. At the burial,

the name of *Shuka Kaa* (Man-Ahead-of-Us) was given to this ancestor of the indigenous peoples of the North American continent.

The dynamics of cooperation within the Arctic have cultivated a collaborative enterprise of both Inuit and non-Inuit scholars. In the beginning, unexpected and favorable developments resulted from addressing the mounting concerns that had culminated from the years of research in the Inuit communities. Examples of problematic concerns are as follows: A range of years may be required for scientists to publish their research reports; in addition, there is an apparent rarity of follow-up from the researchers to the participating communities; also, certain communities had felt the weight from years of study endured and concluded to suspend further research on their people. Addressing the concerns of the Inuit population created partnerships to integrate an agenda to benefit the Inuit communities.

Sample of Mutual Negotiations

The Inuit Heritage Trust of Nunavut is a model of this investiture concerning its cooperation and alliance with academic research in regard to the prehistoric skeletal remains inventoried at the Museum of Civilization:

1. A substantial quantity of skeletal material was allowed (more than researcher Dennis O'Rourke requested).
2. Copies of documentations, published or unpublished, are to be submitted to the Inuit Heritage Trust.
3. A nontechnical report translated into Inuktitut will also be submitted.

This progressive level of cooperation addresses the obvious—research will continue in the Arctic and mutual collaboration can accommodate both researchers and communities.

Conclusion

The practices and methods of Inuit study have become comparably altered and sophisticated since those early expeditions to the Northern Hemisphere. New technology, such as DNA research, has significantly broadened and enhanced anthropological research from the Inuit's epic journey from their traditional way of life, through their many challenges to learn a whole new lifestyle, and to their cultural culmination back to sovereignty, which has been actuated within their cultural arts, education, research, and politics. The Inuit have tenaciously demonstrated the incentive for the reestablishment of their autonomy and inviolate rights pertaining to their accurate representation in research, their rights as hunters/fishermen/gatherers, and their right to speak their own language and govern

their own education, and to establish the direction of growth in their communities. The Inuit's aspiration to study their own culture and direct their own destiny has, indeed, broadened the 21st-century Inuit community and fundamentally established their political stance and desire to enrich their culture.

This 21st-century Inuit anthropological focus will ultimately continue to benefit the expansion of DNA research with the Inuit, the Unangans, and the North coastal tribes. They have been exemplars in forming cooperations with the scientific community to allow DNA sampling, which is increasing the knowledge and appreciation of the family of *Shuka Kaa*, the people who have arrived ahead of us!

IROQUOIAN PEOPLES

NEIL PATRICK O'DONNELL

Canisius College

Iroquoian communities have long been the subject of anthropological discourse. Exemplified by Morgan's *League of the Ho-De-No-Sau-Nee or Iroquois* (1851/1901), initial inquiries and theses served as little more than compilations of technologies, rituals, and myths attributed to only a fraction of all Iroquoian-speaking peoples. By the end of the 20th century, however, Iroquoian-centered research expanded to include analyses of Iroquoian political developments, the effect of European contact on Iroquoian peoples, and the progression of Iroquoian nations through the centuries. This long history of research has resulted in the preservation and knowledge of Iroquoian history and development, providing sound direction for anthropologists throughout the 21st century.

The Iroquoian Language Family

The *Haudenosaunee Confederacy*, its members commonly referred to as "the Iroquois," is only part of the family of Native American nations that speak (or spoke) an Iroquoian language. Member nations of the Haudenosaunee Confederacy initially included the Seneca, Cayuga, Onondaga, Oneida, and Mohawk and were among the first Native American populations Europeans encountered. All speakers of an Iroquoian dialect, the Haudenosaunee nations occupied territory that covered most of present-day New York State. Additional Iroquoian-speaking peoples inhabited areas

north and west of the Haudenosaunee Confederacy, with the Erie, Wenro, and Neutral nations occupying much of the Niagara Frontier and the Huron and Petun settling in portions of present-day Ontario.

South of the Haudenosaunee Confederacy's territory dwelled other Iroquoian-speaking populations. In the areas now recognized as southern New York State and Pennsylvania, the Susquehannock were the dominant Iroquoian nation. Further south, in the region of the Carolinas, other Iroquoian-speaking nations lived, which included the Tuscarora and the Cherokee. Collectively, Iroquoian nations occupied territory covering much of eastern North America.

Early Surveys of Iroquoian Peoples

Champlain, La Salle, and Cartier, among other explorers, provided the first written accounts regarding Iroquoian peoples. Far from the detailed research and texts generated by anthropologists during the late 19th century and onward, their writings relayed details of Iroquoian combat tactics, horticultural techniques, food processing and storage methods, religious beliefs, and architecture. Explorers also recorded the interactions between Iroquoians and neighboring nations, friendly or otherwise, which helped Europeans gauge the extent of Iroquoian territories and how to best manage relations with them. The latter proved

beneficial in both maintaining peaceful coexistence at times and exploiting ties with Iroquoians to acquire resources, land, and allies as European conflicts played out in the New World.

Missionaries interacted with and recorded information regarding Iroquoians not long after explorers penetrated Iroquoian territories. While their journals and correspondence detailed similar events and customs as reported by explorers, Jesuits and other missionaries commented heavily on intersocietal relations and supplied translations of Iroquoian dialects, which added a linguistics component to the Jesuits' efforts. Collectively, these firsthand accounts secured knowledge of Iroquoian cultures while simultaneously providing a foundation for early anthropological research of Iroquoians.

The conflicts, languages, relocation, treaties, and traditions of Iroquoian nations remained the subject of miscellaneous historical accounts. Yet it was not until the late 19th century that recognized anthropologists studied and documented Iroquoian lifestyles, activities, and history. Lewis Henry Morgan's (1851/1901) *League of the Ho-De-No-Sau-Nee or Iroquois* was the most comprehensive such work, and it remains one of the foremost anthropological studies of Iroquoian society to date.

Morgan, an attorney from Rochester, New York, remains prominent among early anthropologists, particularly for his work *Ancient Society* (1877), which promoted and enhanced the idea of cultural evolution. Today, Morgan's ideas regarding cultural evolution are generally rejected. Yet *League of the Ho-De-No-Sau-Nee or Iroquois* (1851/1901), a work he completed earlier in life, still maintains a prominence unmatched by most later anthropological publications.

Living in New York, Morgan was often in contact with members of Haudenosaunee Confederacy nations, commonly referred to as *the Iroquois*. Working in cooperation with Ely Parker, a Seneca and Civil War brigadier general, Morgan studied Iroquoian culture, his focus placed on the Seneca, Cayuga, Onondaga, Oneida, Mohawk, and Tuscarora. The prominence of Morgan's work was due to his providing more than just a simple historical account of the Haudenosaunee Confederacy's formation and interaction with Europeans during the protohistoric period. Morgan's in-depth research, coupled with his reliance on archaeological remains, oral tradition, and collaboration with Iroquoians themselves helped him construct a thorough relation of Iroquoian traditions, language patterns, political structure, religious beliefs, technological advancements, and architecture. Arguably, Morgan, beyond his work in cultural anthropological and archaeological research, also made strides in applied anthropology as he used his legal background and knowledge of Iroquoian history and customs to aid Haudenosaunee members in legal battles. Collectively, Lewis Henry Morgan's efforts provided a foundation for both Iroquoian studies/knowledge and anthropological research; few anthropologists have made as lasting an effect in either regard.

Iroquoian Studies in the 20th Century

Archaeologists, both professional and amateur, provided a new impetus for Iroquoian research during the late 19th and early 20th centuries. Highlighted by the work of Frederick Houghton (1927) and Arthur Parker (1916), the latter being an archaeologist of Iroquoian descent, such research initiatives, while often lacking any definitive scientific framework, helped uncover prehistoric Iroquoian sites and massive assemblages of ceramics, lithic, archaeological features, and faunal remains. The artifact assemblages alone were of monumental importance to anthropologists attempting to understand technological advancements in projectile points, pots, pipes, beadwork, and architecture. While much of this material culture resides in museum storage facilities, unanalyzed, the lithic, ceramic, and bone artifacts studied thus far provided insight into prehistoric Iroquoian communities as well as other northeastern Native American nations. The discovery of prehistoric and historic sites by anthropologists and anthropology enthusiasts of the time was equally important to current knowledge of Iroquoian nations and their societal development.

A. L. Benedict, a medical doctor/Iroquoian specialist from Buffalo, New York, traveled throughout western New York State throughout the late 19th and early 20th centuries, looking for prehistoric Iroquoian sites. Ultimately, Benedict provided thousands of artifacts from Iroquoian sites. Specifically speaking, Benedict recorded the location of the sites he excavated and collected everything from projectile points and pottery shards to net sinkers and faunal remains. While Benedict's notes lacked substantial provenience data, he provided the only evidence for many Iroquoian sites as parking lots and buildings now cover where the prehistoric sites once stood. Today, much of Benedict's Iroquoian collections and notes are contained at museums and colleges throughout the western New York region.

Along with the massive assemblages of Iroquoian artifacts collected during this period, anthropologists also dedicated time to theorizing as to the origins of Iroquoian culture. Guided by archaeological investigations, oral traditions, and historical documentation, early 20th-century anthropologists reasoned that Iroquoian nations migrated into the northeastern regions of North America, replacing other native populations, including Algonquian-speaking nations. This migration hypothesis would dominate Iroquoian studies for decades until additional anthropological research redirected our understanding of Iroquoian origins.

In Situ Hypothesis: Pursuit of Iroquoian Origins

While the focus of cultural anthropologists on Iroquoian peoples comparatively diminished during the early

20th century, archaeologists provided an influx of data to our understanding of Iroquoian culture. With emphasis placed both on single, prehistoric Iroquoian populations/sites as well as regional development of Iroquoian culture, archaeologists, including William Ritchie, Alfred Guthe, Richard MacNeish, Marian White, and James Wright, excavated for, analyzed, and secured Iroquoian material culture from Erie, Huron, Haudenosaunee, and Neutral sites. Anthropologists acquired an improved knowledge of Iroquoian technologies during this time, which is to be expected. Yet a greater understanding of the development of Iroquoian culture(s) was arguably the greater achievement during this period. Archaeologists, most notably MacNeish and Ritchie, uncovered evidence of cultural connections between earlier Owasco societies and proto-Iroquoians via ceramic assemblages and architectural evidence causing some to argue that instead of the hypothesis of Iroquoians migrating into the northeast, it was likely that Iroquoian traditions developed *in situ*, or rather from earlier traditions long established in the region. A radical change in direction from earlier migration theories, the *in situ* hypothesis quickly became the dominant theory regarding Iroquoian origins in the northeast.

Sociocultural Investigations of Iroquoians

Aside from archaeological pursuits, sociocultural research did continue throughout the 20th century. Whereas archaeologists primarily sought to understand Iroquoian origins and the effect of European contact on Iroquoian societies, cultural anthropological interests, as with other indigenous populations throughout the world, focused on recording as much data on current Iroquoian traditions as possible *before* Iroquoians disappeared altogether. Obviously, such fears regarding the disappearance of Iroquoian populations did not come to full fruition. Yet such concerns did help salvage an understanding of Iroquoian culture that likely would have been lost otherwise. That said, these cultural investigations, including those of William Fenton (1951, 1978) and Martha Champion Randle (1951), concentrated on issues from land and nation rights to the contemporary roles of men and women within Iroquoian society. Reflective of the research methodology of Lewis Henry Morgan, these anthropologists ushered in a new wave of ethnological inquiries that accentuated the facts that Iroquoians were living societies, cognizant of their heritage and ceaselessly adapting and contributing to contemporary circumstances.

Given anthropology's dependence on a multidisciplinary approach to the study of humanity, it is fitting that historians were markedly influential to anthropologists' understanding of contemporary Iroquoian culture. While anthropologists long focused on Iroquoian *prehistory*, historians, including Barbara Graymont, Laurence Hauptman, and Daniel Richter, led efforts to record and

interpret the recent history of Iroquoians, particularly that of Haudenosaunee nations. Though historians acknowledged the longevity of Iroquoian culture, their focus was on the effect that contact with non-Iroquoians continued to have on the lives and traditions of Iroquoian people. From the first arrival of missionaries and explorers up to 20th-century events, such as the building of the Kinzua Dam and its effect on Iroquoian societies, historians helped ensure the recording of Iroquoian adaptations to the ever-growing world population, a task anthropologists would have struggled to do alone. Together, anthropologists and historians ensured the preservation of Iroquoian history and traditions while simultaneously reminding the world that Iroquoian societies still existed. Evidence of such collaboration appeared in school textbooks, documentaries, and museum exhibit scripts where Iroquoianists attempted to explain that the Haudenosaunee were not the only Iroquoian-speaking nations and that there was more to *Iroquoian* culture than corn, beans, and squash.

20th-Century Anthropology: Forgotten Studies of Iroquoian Peoples

The aforementioned mid- to late 20th-century anthropological studies often overshadow other pivotal research centered on Iroquoian societies. Specifically speaking, non-Iroquoianists fail to realize that migration theories for Iroquoian origins are still supported, that settlement pattern analyses of prehistoric/early historic Iroquoian populations were prominent throughout the 20th century, and that the last decade of the century was dominated by efforts to inventory Iroquoian collections throughout the country.

Migration Versus In Situ Development

Anthropologists did not simply abandon migration theories once *in situ* hypotheses surfaced. While most anthropologists today still favor the latter category of hypotheses, arguments in support of the migration of established Iroquoian societies to the northeast (as opposed to Iroquoian culture developing in the northeast) remain. Adherents to migration hypotheses, Dean Snow (1996) most prominent among them, cite matrilineal-societal constructs and linguistic similarities between Iroquoian language families and populations outside the northeastern cultural area as evidence suggesting that Iroquoian culture is not indigenous to the northeast.

Debates regarding the origins of Iroquoian culture are not likely to end anytime soon. While *in situ* hypotheses remain more widely accepted, Snow and other migration theorists have raised important issues worth considering, particularly given the fact that so much information is still lacking with which to verify either argument.

Iroquoian Settlement Patterns

The settlement patterns of Iroquoian nations have long been the subject of narratives and anthropological studies, the former including the earliest known written accounts of Iroquoian peoples recorded by European missionaries and explorers circa CE 1600. Initially, such studies were quite basic in detail, providing rough dimensions for longhouses, population estimates for Iroquoians living within household and village boundaries, and analyses of household dispersal patterns relative to matrilineal residency. While this information was useful in early historic period military campaigns on the part of Europeans and non-Iroquoian, indigenous populations likely benefited the most from these rudimentary accounts; the information gathered reflected the fundamental understanding of Iroquoian settlement patterns well into the 20th century.

Between 1920 and 1970, a large quantity of archaeological reconnaissance, tempered by a thorough analysis of features, ecofacts, and artifacts collected, led anthropologists toward a more comprehensive understanding of Iroquoian settlement patterns. The culmination of anthropological understanding of this settlement data was evident in Ritchie and Funk's publication, *Aboriginal Settlement Patterns in the Northeast* (1973). After centuries of studying and interacting with Iroquoians, anthropologists affirmed the general layout of Iroquoian communities up to early historic times, common elements being the presence of multiple longhouses located on an elevated plane or knoll, which were often surrounded by a palisade. In addition, anthropologists, mostly through the recovery and investigation of archaeological features (postmolds, hearths, and storage pits in particular), discerned that villages were composed of multiple clans, each of which maintained one or more longhouses. Residency was matrilineal; husbands moved in with their wives' extended family. Within the longhouse, an additional breakdown of households occurred, each nuclear family maintaining their own apartment area where they slept, ate, and stored personal possessions.

Additional archaeological excavations of Iroquoian sites, particularly the large-scale excavations conducted on Huron sites in southeastern Ontario, further emphasized this understanding. With the addition of historical research and accounts, anthropologists and historians alike have determined that villages were occupied for up to 30 years before natural resources and soil nutrients were depleted, making a village occupation zone inefficient for Iroquoian needs. Furthermore, archaeologists, once again dependent on archaeological features recovered, determined that the architecture of longhouses (and overall village design) was relatively constant throughout northern Iroquoian nations well into protohistoric times, a point most effectively made by Mima Kapches (1993a, 1993b) during the late 20th century. All knowledge considered, including accounts of the assimilation of captured peoples into other Iroquoian

nations, settlement patterns for Iroquoian societies remained relatively constant for a considerable length of time.

Turning attention toward historically recent and contemporary Iroquoian societies, anthropologists, once again, had the benefit of historical documents and field observations with which to determine settlement patterns. As the United States of America expanded, Iroquoian communities were continually forced westward onto reservations. During the 19th century, a series of questionable transactions between Iroquoian nations and North American governments further depleted Iroquoian territories, including arable land suitable for farming. Iroquoians, as with many Native American nations, were compelled to live in cities in order to obtain work and a means to survive. Consequently, Iroquoian household structures increasingly reflected the nuclear family residences. Further erosion of Iroquoian lands continued into the 20th century as state and national infrastructure projects, most notably the Kinzua Dam, claimed thousands of acres of reservation land. Such action further influenced Iroquoians to leave reservations to secure work and resources. Today, individuals of Iroquoian descent live throughout North America, both on reservations in the United States and Canada as well as in cities and towns throughout the continent. As for household structure, nuclear families commonly make up domestic residences. Yet the extended family cohesion still exists as clans maintain political rights and control of property and natural resources.

Native American Graves Protection and Repatriation Act (NAGPRA)

NAGPRA legislation, passed in the United States in 1990, provided a significant opportunity for anthropologists interested in Iroquoian studies. This act required any federal institution or institution receiving federal funding to document all Native American objects and/or remains held and return human remains, sacred artifacts, and objects of cultural patrimony to respective Native American nations. Faced with the prospect of loss of federal funds, museums, libraries, and similar repositories sought archaeologists and cultural anthropologists to help identify and analyze Native American material in exhibits and storage. With the help of federal, state, and local grants, these cultural institutions provided an impetus for research on native cultures including Iroquoians.

From the start, NAGPRA brought together anthropologists and Iroquoians, which helped open a series of dialogues regarding Iroquoian rights, beliefs, and concerns over the preservation of Iroquoian heritage. The resultant dialogue also allowed Iroquoians to provide greater insight into their traditions, political endeavors, and educational efforts. Essentially, anthropologists started placing greater emphasis on contemporary Iroquoian societies, people who were often ignored as opposed to the early historic

populations depicted in narratives and archaeological research. The resultant information, collected quickly, found its way into museum scripts, miscellaneous texts, and educational programming, which helped strengthen a long heeded axiom: Iroquoians still exist.

In addition to the increased interaction between anthropologists and Iroquoians after the inception of NAGPRA, the resulting analyses of collected artifacts and human remains helped validate and disprove long-held beliefs regarding Iroquoian culture. For instance, with so much archaeological material collected and unanalyzed during the late 19th and early 20th centuries, the evaluations initiated through NAGPRA uncovered evidence of European trade goods, including glass beads and metal tools, at Iroquoian sites where previously such evidence was not recovered. In some cases, Iroquoian material stored in the collections of cultural institutions provided evidence of Iroquoian occupations occupying territories longer than previously believed. Ultimately, NAGPRA provided anthropologists with an opportunity to check their findings and correct our knowledge and understanding of Iroquoian societies.

21st-Century Anthropology: Iroquoian Research

Iroquoian studies remain an important part of anthropology. To an extent, the interests of anthropologists, including cultural anthropologists and archaeologists, revolve around long-standing debates, which have yet to be sorted out. Yet new avenues of anthropological research have begun, which are clarifying the resilience and adaptability of Iroquoians to their constantly changing circumstances.

Iroquoian Culture and Societies: Updating the Masses

The arrival of the new millennium and the 21st century brought with it a reconsideration of our knowledge of Iroquoian societies as well as the commitment to rectify the shortcomings of museum exhibits and miscellaneous texts used to educate students of all ages. Such purpose and obligation is by no means innovative since every generation (of anthropologists or otherwise) seemingly renews its pursuit of *truth*. Yet as the first decade of the 21st century draws to a close, evidence of anthropologists rectifying misinterpretations of Iroquoian culture, history, and action is already apparent. In New York State, archaeologists and cultural anthropologists have been enlisted by schools to educate teachers about Iroquoian culture and societies so that school curriculums are accurate. For too long, Iroquoian (and other Native American) peoples remained relegated to a general “native” status with little recognition for the ingenuity of and differences among Iroquoian societies. The input of anthropologists specialized in Iroquoian

studies (including many of Iroquoian descent) has and will continue to rectify such shortsightedness.

Museums, likewise, have hired anthropologists specialized in Iroquoian studies to update exhibits and educational programming. Given the prominence of member nations of the Haudenosaunee Confederacy in recent years, particularly with regards to treaty rights, casino gambling, and taxation enforcement for nonnatives on reservation land, it is becoming harder to ignore the fact that Iroquoian peoples are not locked in a vacuum where bark-covered longhouses are still the preferred form of dwelling. Unfortunately, many museum exhibits and lecture series continue to promote a basic *corn, beans, and squash approach*, which focuses on early historic Iroquoian cultures. There is generally little or no mention of Iroquoian involvement in military campaigns of the United States, the seizure of Iroquoian land via eminent domain on the part of the United States, or the current living conditions for Iroquoians on reservation land. Within the last decade alone, anthropologists as well as historians and Iroquoians themselves have helped rectify such misunderstanding on the part of cultural institutions.

As for general references (encyclopedias, dictionaries, etc.) and textbooks, anthropologists specialized in Iroquoian studies have generated entries regarding Iroquoian culture and societies that have corrected misunderstandings long held by students and teachers alike. Admittedly, with the far-reaching capabilities of the Internet and the volume of incorrect information available therein, questions could be and have been raised as to the benefit of many references available. However, given the rise in Web use by cultural institutions with Iroquoian specialists on staff, the ability of anthropologists to provide verifiable data regarding Iroquoians is certainly greater than in the past. As with the aforementioned feedback, instruction and direction provided by anthropologists, the continued monitoring and adjustment of what is taught to students and the community at large, is a responsibility to all of us Iroquoianists.

NAGPRA Enforcement: An Ongoing Research Project

The effect of NAGPRA has certainly been influential on Iroquoian studies and the development of anthropology in general. For the foreseeable future, NAGPRA will continue to require cultural institutions and staff anthropologists to unbox collections that have remained hidden and unanalyzed for, in some instances, over a century. While these collections rarely are associated with any detailed records—their collectors usually more interested in the object rather than its overall context within Iroquoian culture—the records that still exist could help anthropologists to better understand issues ranging from the origins of Iroquoian culture (migration vs. in situ) to the birth of the Haudenosaunee

(Iroquois) Confederacy. Consequently, anthropologists should remain mindful of the fact that museums, libraries, and historical societies likely contain artifacts, narratives, and correspondence that could enhance our understanding of Iroquoian societies and culture.

Contact and Disease: Population Decline in Iroquoian Societies

The crippling impact of European-borne diseases on Native American communities has long been documented and discussed, such discourse present even in the earliest journals of explorers and missionaries who first entered North America. Yet, detailed and specific understanding of how, when, and through what conditions such diseases became virulent among Iroquoian societies did not surface until the late 20th century as highlighted by the work of Snow and Starna (1989). Part of the interest in the effect of diseases is related to attempts to ascertain the size of Native American populations *before* contact with Europeans. Anthropologists, long concerned with the validity of population estimates of Native Americans relayed in historical documents written in the late 16th and early 17th centuries, questioned if the spread of European diseases outpaced the actual rate of contact between Europeans and Native American societies. This interest has carried over into the 21st century, as evidenced by the work of Warrick (2003), which focused on the depopulation of Huron and Petun Iroquoians due to European diseases. Such recent investigations suggest that European-borne diseases would not have decimated Native American populations until greater concentrations of Europeans, including families, arrived in the New World. Consequently, there is evidence that initial population estimates for Iroquoian nations provided by missionaries and explorers were relatively accurate.

Rise of the League of the Haudenosaunee

The story of Hiawatha and the formation of the Haudenosaunee Confederacy is a staple of school textbooks and museum scripts throughout the northeast. It also remains the focus of anthropological research, discourse, and conjecture. As for the actual date of when the Haudenosaunee Confederacy formed, estimates have ranged from centuries before Europeans first entered North America to years after contact between Europeans and Iroquoians, the confederacy's formation resulting from Iroquoian reacting to European conquest. As for data used to calculate the Haudenosaunee Confederacy's formation, everything from oral tradition to historical records and archaeological remains have been cited, the more distant dates often related to oral tradition. Disagreements over *when* the Seneca, Cayuga, Onondaga, Oneida, and Mohawk nations first united long remained heated, and no

consensus appears likely as anthropologists continue to search for an answer.

As for recent anthropological approaches to determining the confederacy's formation, including that of Kuhn and Sempowski (2001), emphasis has been placed on the examination of related artifact assemblages, the argument being that emergence of similarities in ceramic patterning among Haudenosaunee nations reflects the confederacy's formation or, at the very least, growing contact between the respective Haudenosaunee member nations. Kuhn and Sempowski's research, which linked their findings to some oral traditions, focused attention on the Seneca and Mohawk nations, an understandable data set given that these two Native American nations were the respective western and eastern geographical extremes (doorways) of the Haudenosaunee Confederacy. The results of their comparison of Seneca and Mohawk (pipe) ceramics indicated the confederacy formed circa CE 1600. While these results will not likely end the debate as to when the Haudenosaunee Confederacy formed, the methodology certainly provided guidance for further investigations.

The Forgotten Iroquoians

The Haudenosaunee Confederacy (including the Seneca, Cayuga, Onondaga, Oneida, Mohawk, and Tuscarora), the Huron, and to a lesser extent, the Erie, Neutral, and Wenro are arguably the most noted of the northern Iroquoian populations. What is generally unknown is that additional Iroquoian-speaking populations occupied territories peripheral to these Iroquoian nations, including territory along the St. Lawrence River and in Jefferson County, New York State. History books, not to mention museum exhibits and multiple media outlets, rarely include text, artifacts, diagrams, or maps referring to these populations nor did many manuscripts completed by anthropologists until the mid to late 20th century. Within the first decade of the 21st century, however, research and publications have already devoted more attention to these Iroquoians including research by Engelbrecht (2003) and Morin (2001). While these forgotten Iroquoian populations remain a mystery to anthropologists and other research, continued focus on them will hopefully add to our understanding on the development of Iroquoian culture.

Warfare and Iroquoian Societies

The term "Iroquois" has long stirred fear in the hearts of Europeans and Native Americans, the term itself becoming synonymous with war. Even the earliest historical accounts written by missionaries and explorers seemed to equate the Iroquois, or rather the Haudenosaunee Confederacy with the marked conflicts that seemed almost commonplace throughout the New World. Yet though most Native American

societies were seen as militant and “savage” to Europeans, the Iroquois seemed especially feared and respected, akin to the fiercest of foes one could ever imagine encountering. During the concluding decades of the 20th century, anthropologists endeavored to dispel such sweeping generalizations, arguing that the Haudenosaunee were no more invested in warfare than most societies, turning toward conflict only when pressed by need. Work completed during the early 21st century has already focused on clarifying and supporting this argument.

William Engelbrecht, a leading anthropologist among Iroquoian specialists, provided one of the first such studies, which included data he collected over a long career studying Iroquoian culture. In his book, titled *Iroquoia: The Development of a Native World* (2003), Engelbrecht provided insight into the Haudenosaunee nations and the prevalence war and conflict played in their society. From the construction of village fortifications, such as palisades, to the purposes linked to conflict, ranging from economic concerns to revenge, all Iroquoian nations, as have many societies through time, relied on warfare for protection and acquisition. Engelbrecht’s work, published in the early years of the 21st century, was a major first step in clarifying the context in which warfare arises among Iroquoian societies. His work also helps anthropologists recognize areas of their objectives, theories, and methodologies that still need work.

Iroquoian Societies Today

Iroquoian studies, particularly as presented in museum exhibit scripts and school textbooks, often focused on historical events or changes to Iroquoian societies during the past. Today, while anthropological research continues to emphasize Iroquoians in a historical context, more anthropologists are examining contemporary Iroquoian societies and their effect locally, nationally, and internationally. As previously mentioned, NAGPRA legislation certainly influenced this change in research focus by bringing anthropologists and Iroquoians together. Consequently, anthropologists interacted with Iroquoians in the real world, learning firsthand how Iroquoians were coping in the contemporary world. Now, Iroquoians are more colleagues than subjects being observed from a distance, often collaborating with anthropologists in the development of educational programming for schools, exhibits for cultural institutions, and manuscripts for both academic and general public venues.

Admittedly, anthropologists remain predominately interested in the prehistoric development of Iroquoian societies as well as in the effect of Iroquoians on formation and historical transformation of North America in general. Yet contemporary actions on the part of Iroquoian communities throughout North America, particularly in New York State, increasingly drive anthropologists to examine

Iroquoian actions of today. Furthermore, where anthropologists have long examined Iroquoian societies from a distance, now a growing number of Iroquoians have assumed the role of anthropologist, providing internal viewpoints with extraordinary insight. All things considered, anthropological studies of Iroquoian societies should provide valuable and interesting insight during the next century.

What’s Good for the 20th Century

Anthropological research objectives and activities of the 20th century should not be completely discarded simply because *times have changed*. Much of the work conducted by anthropologists regarding Iroquoian societies during the last 50 years alone remains unfinished as related artifacts in the collections of museums and other repositories have yet to be examined and analyzed within the context of Iroquoian knowledge thus far obtained. In addition, as land is continually developed and Iroquoian sites are uncovered through archaeological reconnaissance, careful excavation and analysis of recovered material remains a priority as the destructive nature of excavation provides only one chance to get our observations right. Consequently, there needs to be a continuation of the analysis of collected Iroquoian material culture, as well as the incorporation of newly acquired artifacts, oral tradition, and historical documentation. Cultural Resource Management efforts, in particular, will undoubtedly serve as a major source of new artifacts and feature analyses. However, NAGPRA-generated research of repository collections will also need to continue as artifacts and records collected by anthropologists during the 20th century may still provide vital information in the effort to better understand Iroquoian societies, then and now.

Future Directions

Iroquoian societies were among the first indigenous populations European explorers and missionaries encountered and extensively interacted with on setting foot on North American soil. With Lewis Henry Morgan leading the way, Iroquoians were also among the first Native Americans thoroughly studied by anthropologists. Now, as the 21st century rapidly approaches its 2nd decade, Iroquoians, fittingly, remain a major focus of anthropological inquiry: not only because Iroquoians have long been a source of interest but also because there is still so much anthropologists still do not understand about the development and histories of these Native American nations. As for the direction of Iroquoian studies for the duration of the 21st century, specific research questions to consider, given the knowledge thus far acquired, include inquiries regarding government structure, Iroquoian diversity, and the ingenuity of Iroquoian peoples through history.

Iroquoian Governments: Beyond the Haudenosaunee

The structure of the Haudenosaunee Confederacy, which still exists, is well documented in historical manuscripts dating back as far as the 17th century. This includes governmental structure at the village, tribe, and national level. The governmental structure of other northern Iroquoian nations, particularly that of the Erie, Neutral, and Wenro nations, is relatively nonexistent. While scholars from multiple fields have hypothesized that the Erie, Neutral, and Wenro confederacies were possibly structured in a similar fashion to that of the Haudenosaunee, extensive research has yet to be devoted to such inquiries. The author (O'Donnell, 2003) opened the door for comparisons between the Haudenosaunee and those Iroquoian confederacies aforementioned. With focus placed on differences in longhouse architectural patterns, it was hypothesized that stark differences did exist between Iroquoian nations at least at the village level. With only a small sample of longhouse patterns to include in the study, there are obvious limitations to what can be determined with regards to the differences among the Iroquoian nations. Yet this initial work provides, at the minimum, direction for future research.

The Depopulation of Iroquoia

Warrick's (2003) examination into the depopulation of Huron and Petun territories/villages offered valuable insight, not only into the effect of contact of Native American peoples but also into the errors of long-held assumptions on the part of anthropologists and historians alike. The belief that diseases spread quicker than the rate of actual contact between Iroquoians and Europeans is certainly in doubt, as discussed earlier. Admittedly, such examinations were limited to only a portion of the northern Iroquoian nations that occupied portions of northeastern North America at the time of contact. Yet the methodology that Warrick implemented as well as his findings certainly provide anthropologists with a direction and a tool set with which to determine if all Iroquoian peoples were affected similarly by European-borne diseases. The methodology may also serve as a guide for the study of other indigenous populations as well since the Iroquoians were not the only societies occupying North America when Europeans first arrived.

To Preserve, Record, and Defend

Too many archaeological sites have been destroyed or rendered inaccessible due to construction activities during the 20th century. As more records recorded by archaeologists during the early 20th century surface, anthropologists learn of more sites discovered. Yet when visiting the site

locations described by these early Iroquoian enthusiasts, all too often we discover that the area of the site is now home to a building, golf course, or parking lot, which leaves little chance for recovery of additional material culture or relevant features. As collections continue to surface, anthropologists must pay heed to documentation of sites uncovered during the recent and distant past. Any site described should be photographed and examined, with current conditions of the area recorded. A lack of trained anthropologists for this initiative certainly limits the volume of records that can be examined and respective sites that can be recorded. However, as more development continues, more Iroquoian sites are at risk to bulldozers and suburban sprawl. This leaves anthropologists with an added burden of excavating sites at danger of destruction through construction and/or preserving sites until such time that they can be examined by properly trained anthropologists. While it is likely not every site will be sampled through fieldwork or protected to any extent, we have to try.

Conclusion

Mima Kapches's (1993a, 1993b) work has certainly provided valuable insight into the complexities of Iroquoian engineering as well as the spatial contexts within Iroquoian villages. The implications of Kapches's discoveries are too important to ignore. Already, other anthropologists have received direction from Kapches's research (Engelbrecht, 2003; O'Donnell, 2003; Williams-Shuker & Allen, 1997), with special interest focused on Kapches's findings and their implications regarding societal differences between Haudenosaunee peoples and other Iroquoian nations. Guiding questions with regard to these findings include inquiries into the power of clans within the various Iroquoian nations and the alliances that may have existed among Iroquoian societies. Ultimately, given our lack of understanding with regard to non-Haudenosaunee Iroquoians, Mima Kapches's (1993a, 1993b) research can only help in providing anthropologists with a course in our research.

Looking to the Future of Iroquoian Research

Anthropologists' understanding of Iroquoian societies has certainly progressed significantly during the last century. From a larger vantage point, it could be argued that Iroquoians are even one of the most studied and understood Native American cultures to date. Yet the work is not finished. From an archaeological standpoint, many sites have yet to be fully excavated and/or discovered, limiting anthropological understanding of how Iroquoian culture formed and the differences that developed between the various Iroquoian nations. From a cultural anthropology standpoint, too little emphasis has been directed toward living Iroquoian communities and the continuing

development of their societies both on reservations and within urban spaces. Also, collaboration with Iroquoian peoples today needs to be expanded as oral tradition and private collections could provide additional information pertinent to anthropological inquiries. The reality of what still needs to be studied and accomplished is not meant to discourage anthropologists or to critique the research currently underway by anthropologists. The points highlighted throughout this article are simply meant to remind anthropologists and Iroquoian enthusiasts that we all have our work cut out for us in the 21st century. Given what we learned about Iroquoians during the last century, it seems fair to say that the next century should provide some interesting insight into Iroquoian culture.

PART XII

CULTURE AREAS

AFRICA

Past and Present

BELETE K. MEBRATU

Medaille College

This chapter presents the study of Africa from historical and contemporary perspectives and considers its future prospects. It discusses Africa as the origin of humankind, where prehistoric and modern human societies have lived since the remote past. The chapter throws light on the ancient civilizations of Africa and African kingdoms. It outlines briefly the history of European contacts with Africa, first through exploration, then trade, and recently in the form of colonization. Other topics of interest in African studies are also part of this chapter, including the peoples, landscapes, regions, and countries of the continent, as well as the independence movement, postcolonial Africa, disillusionment, and modern challenges, hopes, and prospects. It ends with a summary and conclusion and suggests issues for continued inquiries into the study of Africa. Further readings are provided to enrich the understanding of the African continent and its peoples within the global village of our world.

Ancient Civilizations

Africa is believed to be the cradle of humankind. This belief is becoming even stronger with the recent findings of evidence of our distant roots, such as the remains of “Lucy” (*Australopithecus afarensis*), and more recently “Ardi” (*Ardipithecus ramidus*) in Ethiopia—remains that date our connections to the remote past of 4.4 million years ago.

According to R. Hunt Davis (1998), advanced primates of hominids called *Homo erectus* moved out of Africa to Europe and Asia some 800,000 years ago. Molefi Asante (2007), among many, argued that the source of prehistoric evidence about the origin of humankind is found in Africa. Africans began farming and domestication of animals as early as 5000 BCE. They used iron to enhance their means of production. Trade brought about wealth that added sophistication to the political and economic changes in African society. Continued migration led to social expansion and the introduction of iron-based technology and agricultural skills to wider parts of Africa. These developments helped the emergence of cities and states that later evolved into kingdoms. Davis noted that a massive migration enabled Bantu-speaking people to introduce their agricultural skills widely and dominate large areas of Africa south of the Sahara.

Advanced civilizations in places like Egypt enjoyed the benefits of the invention of written language, which goes back to 3200 BCE and is also part of the history of Africa. Egyptian civilizations along the course of the Nile River reached south to the kingdoms of Nubia and Kush of today's Sudan. The kingdom of Axum in Ethiopia was one of the advanced civilizations of the ancient world. Axum had contacts with Rome, Arabia, and India for trade and commerce. Famous for its carved monuments, Axum formed the foundation of the Ethiopian Empire, which is still a center of tourist attraction and a source of pride for Ethiopia as a reminder of its ancient African civilization.

Major global events have had great impacts on Africa. The expansion of the Roman Empire reached Africa and took control over the northern part, including Egypt and Morocco, at the onset of the first millennium CE. The Romans' conquest was preceded by the Greeks' dynasty in Egypt, one that lasted from 332 to 30 BCE. Toyin Falola (2002) emphasized that Egypt was a center of trade, intellectual discussion, and culture. Likewise, Christianity was introduced to Africa through Egypt, and Alexandria has been the home of theologians who laid the foundations of a new religion. Ethiopia also was one of the earliest countries to be converted to Christianity, beginning in the 4th century CE during the time of King Ezana. Similarly, the rise of Islam had a major effect on Africa. Arabs conquered Egypt in 640 CE, and by the end of the 7th century CE, the followers of Islam controlled most of North Africa. This part of Africa remains predominantly inhabited by Muslim populations. Islam gradually expanded from North Africa to West and East Africa. According to Asante, Africa as we know it today was both influenced and shaped by these two major events, the introduction of Christianity and Islam.

Falola (2002) wrote that contacts with Europeans, beginning from the 15th century CE onward, left enduring impacts on the African continent. The first contact occurred on the coasts, and it was only later that Europeans had access to the interior part of Africa. M. Alpha Bah (1998) noted that the Portuguese were the first Europeans to have encounters with African people when they gained control of the fortress of Ceuta from the Moroccans in 1415. Later, the British, Dutch, French, Swedes, and Spanish joined the Portuguese in the exploration of the African continent for trade. The contacts gradually led to the transatlantic slave trade and then to the colonization of Africa under European rule. By 1885, most African countries were under colonial rule. This development brought with it a major cultural influx. Western traditions and practices were introduced to the African soil, and they have enduring influences to this day. Following independence in the 1950s and 1960s, African states struggled to build nations with stronger links to the outside world. Subsequently, Africa showed progress in many areas while also facing daunting challenges of political instability, civil war, dictatorship, and poverty.

African Kingdoms

Africa enjoyed being the home of famous and expansive kingdoms from the earliest days until the medieval period. According to Asante (2007), Africa was the home of many kingdoms and empires known to be the earliest in the world. One of the kingdoms that developed during the Middle Ages was the Kingdom of Ghana. This kingdom later declined with the attack that came from the north in the 11th century. Another kingdom emerged in Southwest Nigeria, centering in the city of Ife. Ife declined during the 16th century. Benin was the other rich and powerful

African kingdom. The Kingdom of Mali was founded in the 13th century and was known for its famous city of Timbuktu, a city well known for trade in salt, horses, gold, and slaves. This kingdom, which developed during the 14th century, was later destroyed by the Songhai Kingdom in the 16th century. The Songhai Kingdom was also a Mali kingdom, on the Niger River, that developed in the 14th century and was doomed to destruction toward the end of the 16th century by the invasion of the Moroccans. The Kingdom of Kanem-Bornu developed near Lake Chad; it became strong and remained independent until the 19th century. On the coast of East Africa, Arabs founded the states of Mogadishu and Zanzibar. In the south, other kingdoms were organized in Zimbabwe in 1430. The existence of these kingdoms, Davis (1998) argued, demonstrates the ability of the African people to master their environment and develop a political system indigenous to their culture.

Ethiopia maintained its kingdoms throughout the Middle Ages. The Axum kingdom was one of its well-known kingdoms; it dated back to 730 BCE. Later, it transferred its political power to another Ethiopian kingdom called the Zagua Dynasty, with a shift of power from the north toward the center and south. During the 13th century, according to the account of Tadesse Tamrat (1972), the Zagua Dynasty constructed complex monolith churches out of rocks; these churches remain standing today as one of the wonders of global heritage. King Lalibela, who was very religious himself, mobilized his people to construct churches using their remarkable engineering talent. This was a show to make Lalibela the center of politics and religious worship, thus claiming his legitimacy to the throne. Power was later shifted from the Zagua Dynasty to a new dynasty called the Solomonic Dynasty, which established a political theory that Ethiopian kings have their root in King Solomon of Jerusalem. This explanation for the source of their power continued to be used by Ethiopian kings from then until 1974, when the last emperor of Ethiopia, Haile Selassie, was dethroned.

People, Landscapes, Regions, and Countries

Africa is characterized by the diversity of its geography. It is known for its forests, savannahs, deserts, mountains, rivers, lakes, and varied weather. The equator and the Great Rift Valley are part of the geographic features of Africa. The equator divides the continent, and its latitude has a major impact on its climate. The huge water bodies of the Atlantic and Indian oceans, as well as the Mediterranean and Red seas, surround the African continent. Famous rivers such as the Nile, Congo, and Zambezi are part of the African natural makeup. The Sahara Desert, the most massive desert in the world, is also found in Africa. The savannah, an extensive grassland that covers a large area, is the other wonder of the physical landscape of the continent. Also,

Africa is not deprived of forests; it has one of the largest rainforests in the world. According to Davis (1998), 90% of the continent is over 500 feet above sea level. Mt. Kilimanjaro, which is 19,340 feet above sea level, is among the tallest mountains of the high terrain landscape of this continent. Falola (2002) wrote that diversity is one of the characteristics of the African continent that makes up its richness and beauty.

Thousands of languages are spoken in Africa. Contacts with other cultures have also brought to Africa languages from Europeans and other peoples. English, French, Arabic, Portuguese, and other European languages are spoken in Africa. Proverbs and storytelling are among the prominent parts of the traditions of maintaining and passing heritages and wisdom in African societies. An extended family structure, kinship support, cooperation, and respect for elders are some of the common values and traditions upheld among African peoples. Christianity, Islam, and traditional indigenous beliefs are forms of worship and religiosity among African peoples. J. Peter Schraeder (2004) observed that Africa is a mosaic of different languages, cultures, traditions, peoples, countries, and beliefs.

Africa is made up of 53 countries. Davis (1998) wrote that Africa is more than 3 times the size of the United States. The African continent is so vast that it is divided into regions. These regions are east, west, north, south, and central. In the north, one finds the countries of Egypt, Algeria, Tunisia, Libya, and Morocco. These are countries inhabited predominantly by Arabic-speaking Muslim populations. West Africa consists of 16 countries: Benin, Burkina Faso, Cape Verde, Cote d'Ivoire, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mauritania, Niger, Nigeria, Senegal, Sierra Leone, Western Sahara, and Togo. Countries in the east African region are Kenya, the Sudan, Uganda, Tanzania, Rwanda, Burundi, Ethiopia, Djibouti, Eritrea, the Comoros, Madagascar, Mauritius, and Seychelles. Central African countries include Cameroon, Chad, Congo, the Democratic Republic of Congo, Equatorial Guinea, Gabon, Sao Tome, and Principe. These countries are historically connected to French colonial rule; thus, the French language is common in the region. In the southern part of Africa are the countries of Angola, Botswana, Lesotho, Malawi, Mozambique, Namibia, South Africa, Swaziland, Zambia, and Zimbabwe.

African literature is characterized by both indigenous oral and written literatures. It is reflective of African traditions, religion, philosophy, culture, and livelihood. African literature has depicted the indigenous heritage of oral traditions before the advent of European colonization and cultural influx. In Africa, literature has also been part of the struggle and movement for independence. Poetry, drama, short stories, and larger prose writings were at the center of the pan-African movement and the Negritude activism to mobilize Africans for independence and to express the pains of colonialism. African literature is written in both African and European

languages. Among the notable European languages are English, French, and Portuguese.

During the colonial period, literature was part of the effort to define and demonstrate African identity, culture, and history to the outer world. The postcolonial African literature has, however, turned to look inward in addressing African challenges and issues. The change in trend is also reflected in the use of African languages, instead of European languages, for literature. African writers have been focusing on political distaste by exposing corruption, dictatorship, and inept leadership on the continent, and writers have become victims of intimidation, harassment, imprisonment, disappearance, and executions. Naguib Mahfouz (Egypt), Wole Soyinka (Nigeria), Nadine Gordimer (South Africa), and J. M. Coetzee (South Africa) are four African writers who received the Nobel Prize in literature. Joseph (2007), however, argued that even though these writers are from Africa, they represent divergent literary backgrounds reflecting Arab-Islamic traditions, conditions of European settlers in Africa, and indigenous African traditions. This is an indication of the great extent of diversity within the African continent and its societies.

European Interests in Africa: From Exploration to Colonialism

Early European knowledge of Africa came from the exploration of European expeditions, which required a series of efforts with challenges and difficulties. The European explorers made continuous efforts to uncover the African continent beginning in the 15th century. Such efforts began with some knowledge about the coastal part of Africa. European explorers first came in contact with places such as Timbuktu, Gambia, Senegal, Tripoli, and Cairo. According to Ieuan Griffiths (1995), Europeans had been familiar with coastal Africa for a long time before discovering the interior of Africa; this took so long because many voyages ended in vain due to the difficulties of surviving diseases, traversing the terrain of deserts, and overcoming the challenges of following the courses of rivers, such as the Niger, to their roots. European explorers were mainly from Portugal, Britain, and France. Griffiths notes that the European interest in Africa was motivated by religious missions, trade, and the intellectual curiosity for explorations. In that process, the Portuguese took the lead and reached the Azores in 1431, the mouth of Congo River in 1445, and the Cape of Good Hope in 1488.

Europeans started to transport slaves from Africa across the Atlantic in the 16th century. The trade transaction followed a triangular route, in which manufactured goods were taken from Europe to Africa and, in return, the ships took slaves from Africa to the West Indies, and finally they took sugar and other products from the colonial plantations to Europe. This was called the triangular trade route. Even though the slave trade was neither new nor limited to the

one that was carried out by Europeans, Schraeder (2004) shared what many believe, which is that the transatlantic route was the one used for the most trade.

Part of the horror of the slave trade was that the slaves were captured in raids and as war captives before they were brought to the coast. Africans took part and became rich out of the business of supplying slaves for European merchants at the coast. Slavery was one of the most horrifying experiences of Africans and humanity at large in terms of its immediate and long-term impact. Slavery brought about cultural shock, humiliation, and exploitation. Thomas O'Toole (2007) wrote that slavery, among other impacts, has overshadowed the glory of the history and civilizations of Africa that stretch as far back as to ancient Egypt. With Great Britain's decision to abolish the slave trade, it became illegal in 1807. Despite the decision, Schraeder (2004) indicated that thousands of slaves continued to be smuggled illegally into the United States throughout the first half of the 19th century.

Another shocking experience for Africa was the advent of colonialism. European countries substituted slavery for an alternative grip on the African soul through a rule commonly called colonialism. Among the notable European powers to rule Africa through colonialism were Great Britain, France, Portugal, Italy, Belgium, Germany, and the Netherlands. According to Griffiths (1995), the colonial powers made Africa virtually their private property, and they scrambled the continent with no restrictions or limitations except the rivalry and competition among themselves. Falola (2002) outlined the timeline in the processes of the scrambling of the continent among the European powers. The Portuguese settled in Angola and Mozambique in the 16th century. The Dutch founded a colony in South Africa. In 1814, the British took the Dutch colony in South Africa. The French invaded and colonized Algeria in 1830. Germany took control of Namibia, Togo, and Cameroon in 1884 and took Tanzania in 1885. The Belgians colonized what is known today as the Democratic Republic of Congo in 1885. The French took Madagascar in 1896 and Morocco in 1912. In the early 20th century, the British added to their stock Egypt, Zimbabwe, Zambia, Malawi, Uganda, and Kenya. The Italians had a colony in Libya, and they also made an attempt to colonize Ethiopia during World War II but failed after five years of occupation. By the middle of the 20th century, nearly all of the African countries had fallen under the colonial rule of the Europeans. Exceptions to this were Liberia and Ethiopia, the only African countries that remained uncolonized.

According to Falola (2002), Europeans were successful in colonizing Africa for many reasons. Africans were not one single force; rather, they were in many separate entities. Europeans took one place at a time, sometimes with assistance from African leaders. With regard to technology and resources, Europeans had professional armies equipped with better firearms and resources than the natives had. In terms of resistance against European invasions, however,

one of the most successful cases in the history of the continent was the victory of Emperor Menelik II of Ethiopia over the Italian colonial army at the battle of Adwa in 1896. Asante (2007) referred to this victory as decisive and monumental in a movement for the liberation and freedom of African peoples.

The Independence Movement

Africans resisted European invasion and colonial rule from the outset. European colonial ambition was not without challenges and resistances from the natives of Africa. In fact, Europeans had to win a number of battles to overcome the resistance. Rebellion movements against the European colonial rule became common throughout Africa in the 20th century. Pan-Africanism, the African National Congress, Negritude, and the Mau Mau movements were among the well-known forms of struggle and movement for independence. Many African countries became independent in the 1950s and 1960s. Some remained under colonial rule until the 1970s and 1980s. Zimbabwe got its independence in 1980. The last country to attain its independence from colonial rule was Zambia in 1990. The independence movement was not only a drive to become free from foreign rule; it also represented a hope for prosperity and development under the rule of Africa's new leaders. Africans hoped for a better life under the leadership of their own children free from the rule by Europeans.

One of the nationalist political movements during the colonial period was the Mau Mau uprising in Kenya. The Mau Mau movement was much more forceful than the forms of struggle in other parts of Africa. According to Falola (2002), factors such as land scarcity and grievance against the British rule led to a more violent form of resistance, which later became guerilla warfare against the government. The movement accelerated Kenyan independence, which was made possible in 1963. One of the leaders of the movements, Jomo Kenyatta, became the first president of an independent Kenya.

The armed struggle resistance in Algeria was part of the struggle for independence in Africa. France had a stronghold in Algeria, claiming that Algeria was a part of France. Despite the various attempts made by the French to ease the colonial rule for appeasement, armed struggle became inevitable. This war became the bloodiest form of struggle in Africa, and it cost the lives of thousands on both sides. After this devastating war that lasted nearly a decade, Algeria became independent in 1962 following a referendum both in France and Algeria. One of the leaders of this armed struggle, Ahmed Ben Bella, became the first president of independent Algeria.

Pan-Africanism was a movement for the independence of Africa from colonial rule. It was a movement aimed at mobilizing the black people in Africa and all over the world against colonial rule. The movement initiated awareness

and unity among black people in the United States, the Caribbean, Europe, and Africa for the end of exploitation and oppression and for the freedom of the African people from European rule. Kwame Nkrumah, who was among the notable activists of the Pan-African movement, became the first president of Ghana after independence.

World War II had its own consequences for strengthening the movement toward the end of colonialism in Africa. Many colonies of the European countries that were participants in World War II used Africans as the source of human power required by the war. Many served in the British and French armies as fighters. Basil Davidson (1994) highlighted what Africa paid for the war with its children. Returnees from the war later became well aware and conscious of their conditions at home and began to join the resistance movement against colonial rule. Opinions also began to change, even in Europe, about colonial rule in Africa. The outcome of World War II brought about a change in the balance of power on the world stage. It also had an impact on the conditions and opinions in Europe that contributed to the changes made in the Europeans' colonial policy in Africa.

The Italian invasion of Ethiopia in 1935 antagonized many independence activists all over the world. Ethiopia remained independent for centuries and has been an example of an independent black nation not colonized by European powers. It was a big surprise when the League of Nations remained silent and did not protect its own member nation, Ethiopia, from being attacked by another member nation, Italy. This contributed to the League of Nations' demise and subsequent replacement with the United Nations right after World War II. Nationalists and Pan-African leaders and supporters were radicalized and made every effort to call for an end to colonial rule in Africa. According to Davidson (1994), the Italian invasion of Ethiopia created outrage among many in Africa and beyond, and it helped to strengthen the Pan-African movement. The effect of this event was clearly seen in British West Africa, with its renewal of commitment and spirit to stand not only against the Italian invasion of Ethiopia, but also the entire imperialist colonial rule in Africa.

International developments have had their contribution to the strengthening of the movement for independence in Africa. The independence of India from British colonial rule in 1947 was a good model to imitate, and it became an example for a peaceful resistance struggle on the African continent. Schraeder (2004) stressed that Asian nationalism provided an impetus for Africa's demand for independence. Internally, politicians were also very committed to the independence movement in anticipation of leadership positions in the new independent Africa. To that end, many political parties were formed and mobilized millions of people in the struggle for the end of colonial rule. Workers established unions and organizations. Students in higher education institutions also joined the movement by becoming activists for liberation. The African-educated elites

took a critical role in exposing the hidden interest of the colonial powers and agitating the African people for resistance. The media also played a part through its publication of materials that challenged the European colonization. Peaceful struggles in the form of demonstrations, mass strikes, boycotts, publications of literary materials and political writings, and armed struggles were coupled with developments from the outside world in Europe, North America, and the Caribbean, bringing to an end European rule over the African continent that had lasted for more than a century.

Postcolonial Africa

The outcomes of independence from colonial subjugation were immense. Achieving independence was significant to the emotional and psychological makeup of the African people. Africans who had been under European rule—deprived of so much with so many restrictions, limits, and indignity—rejoiced in their freedom with the onset of independence. Independence brought about the feeling of freedom, respect, and dignity. The educated Africans, elites, and politicians came to be at the helm of the society and assumed leadership roles. They formulated policies and started the work needed to make changes in the lives of millions of people. Continental associations were also formed in order to unite the entire African continent to move forward. One such entity was the Organization of African Unity (OAU), which was formed in 1961 with headquarters in Addis Ababa, Ethiopia. Following independence, many African countries also joined the United Nations. New businesses and enterprises also began to emerge with the leadership and ownership by Africans themselves.

Expansion in the service sectors was another task of building nations in Africa after independence. Building schools to serve students at both lower and higher levels was a priority for the new African leaders. Education was thought to be the key for development, and much hope for prosperity was put into the schools. The concept of access for all, including girls, was among the new academic policies. Changing the contents of the curriculum, from a focus on European studies to the concerns of African societies, was part of the reform effort in the education system. Education received significant attention among the new leaders as a vital tool for nation building across independent Africa.

Africans began to use their native languages. Cultures and traditions that are indigenous to the African people began to be revived for full use with pride and dignity among African people. Following independence, the publication of literary works grew significantly. Many African writers have produced novels that have a wide readership beyond Africa. These writers include Nobel Prize laureate Wole Soyinka of Nigeria and others such as Ngugi Wa Thingo and Chinua Achebe. Their works of literature reflected on life under

colonial rule, the movement for independence, the hopes and prospects of independent Africa, and the celebration of African traditions and cultures.

In the aftermath of their independence, African countries began to restore their cultural heritages, while they also lived with the carryover effects of the colonial past. European modernity and bureaucracy, which left footprints on the African soul, continued to influence the organization of governments, businesses, and other sectors among African countries. In many sectors, including the education sector, there has been a significant introduction of European culture into the African traditions. Africans have had to make great efforts to regain the cultural identities, traditions, and customs that they sacrificed during the colonial period. Thus, Africa struggled to maintain an equilibrium between retrieving its lost indigenous cultural heritages and the cultural influx it received from European traditions.

Disillusionment

There were many promises that were made during the independence movement concerning Africa once it was back in the hands of the African people. Equally, the African people developed high expectations for a better life after independence. However, these expectations were not met as the years went by with the new leaders in power. Unfulfilled dreams of prosperity began to build up dissatisfaction and doubt toward the new leaders on the part of the people. Many started to believe that the change was only in the leadership, that is, African elites had replaced European rulers. The new leaders became the new elite class in the African society, and not much change was delivered to the population. Louis Serapiao (1998) noted that liberation from colonial rule was perceived as a solution to Africa's problems. Contrary to the expectations, however, limited resources, power struggles, ethnic conflicts, coups, the use of politics as a source of business and wealth, one-party rule, military rule, lack of strong foundations for economic infrastructures, and limited exports all created complications in Africa following its independence. According to Serapiao, some of the roots of these problems are the legacy of colonialism, the global economy and market systems, environmental challenges, and the problems caused by the leadership of the new African leaders.

In an unfortunate way, Africans never realized the dreams of prosperity, freedom, and peaceful livelihood after independence as they had hoped they would during their struggle for independence. For the most part, Africa became a center of political unrest, civil wars, dictatorship, military coups, poverty, and disease. The state of Africa became one of disillusionment for its children, as many became confused by being oppressed by their own so-called liberators. African leaders deprived their own people of political as well as economic freedom. Many were infected with

corruption and diverted state resources to benefit their family members. Africa came to be known for challenges such as coups in Nigeria, Algeria, Togo, Libya, and the Sudan; human suffering in Darfur; genocide in Rwanda and Burundi; civil wars in the Congo and Sierra Leone; and the protracted destabilization of Somalia. According to Falola (2002), there were 21 countries under military rule and 70 cases of military coups on the African continent between 1960 and 1992.

Military regimes that are the outcomes of coups often end up in disaster and further dissatisfaction. Lacking the skill for civilian leadership in matters of economic and social development, military personnel never succeeded in bringing about the desired changes in the lives of millions of Africans. Military regimes have contributed to instability and economic underdevelopment in Africa. These regimes abandoned democratic institutions and multiparty political practices, and they ruined economies through corruption and mismanagement. Poverty has remained an overwhelming challenge for most of the African continent. Fundamental needs for clean water, food, and health services are not met well in the 21st century. The low economic growth rate and unemployment are aggravated by political instability, power struggles, tyrannical leadership, mismanagement, and the embezzlement of resources.

The political ideologies of socialism and communism did not solve the challenges of African people. In the aftermath of the Cold War, since the early 1990s, many of the African countries that had been allies of the former Soviet Union abandoned the communist ideology and began to embrace Western democratic liberalization policies. The reform efforts included the institution of free markets, privatization of state businesses, elections, and multiparty political systems. Despite some success stories, elections have turned out to be less encouraging, having been marred by fraud and voter intimidation. Multiparty systems have resulted in opposition parties whose leaders have sometimes ended up in jails as enemy combatants. The International Monetary Fund (IMF), World Bank, G8 countries, and recently G20 countries are among the notable international bodies and institutions invested in the efforts that are being made to make changes in the lives of millions of people in Africa. Programs such as the African Development Commission and Millennium Development Goals have been outlined with a target of poverty reduction.

Challenges, Hopes, and Prospects

The end of apartheid in South Africa in 1994 marked the beginning of new hopes and prospects in Africa. It brought about not only the freedom of the black majority in South Africa but also an example of the rule of democracy, national reconciliation, and stability for the continent. Some African countries also began the long journey to democracy and human right commitments for their people.

Governments in Ghana, Mali, and Botswana are among the promising political developments of rule by the people, free and fair elections, and the accountability of leaders on African soil.

One of the new developments on the African continent is the newly emerging Asian influence. Richard Dowden (2009) wrote that China's influence on Africa is one of the significant changes in the geopolitics of our recent time. The engagement is based on construction, trade, and raw material extraction. This was marked by the Forum on China-Africa Cooperation held in November 2006, at which China announced a government fund for Africa of about \$5 billion. One of China's policies of engagement with Africa is the policy of noninterference with the internal affairs of countries. Thus, their funding comes with less stringent preconditions. This policy has been welcomed by African governments. This development, Dowden notes, has created an outside ally for Africa that is an alternative to the traditional Western countries.

Development in communication services is an encouraging sign of progress; it has created contacts within and outside Africa and has many implications for business and the exchange of experiences. Mobile phones are now reaching every corner of the continent. Mobile phones, the Internet, and satellite TV have brought about significant access to information and direct contact with the outside world. It is an encouraging development that access to information is being made available that could make a difference in the lives of millions of Africans.

One of the chronic problems that has remained as a challenge in Africa is the negative consequence of aid. Foreign aid, despite the good intentions behind it, did more harm than good for African societies. In many cases, the aid is directed to programs that encourage dependence instead of self-reliance. The programs also favor short-term activities, in which corrupt leaders can embezzle money and make fortunes, rather than contributing to long-term development efforts. April and Donald Gordon (2007) likened foreign aid to a two-edged sword in Africa. Although there are some benefits from aid, it is also used to advance donors' interests. One of the problems of foreign aid is that it comes with conditions that do not reflect the reality of Africa.

The emerging challenges of global warming and climate change are also having impacts on the African continent. Africa is paying the greatest price for climate change and global warming, while contributing the least in terms of carbon emission pollution. Many are making the argument that Africa should get a fair share in overcoming the challenges of global warming in terms of more aid directed to environmental protection and green technology development. In this regard, the shortage of energy is an area that needs to be addressed; electricity supplies are short even in the capital cities of African countries. This is being attributed to the boom in construction, development of diverse companies, growth in urbanization, and greater access to electrical

service for the masses, including those in the remote parts of Africa. Although this may be a sign of good development, on the other hand, it is also indicative of the lack of long-term planning to balance investment and its growing demand for energy with an expansion in energy supplies.

While addressing issues of global warming, climate change, green technology, and environmental issues, the challenges of population explosions need to be addressed as well. Regions such as sub-Saharan Africa are leading in high birthrate. In lieu of environmental deterioration and scarcity of resources, high birthrate could pose a challenge to development and stability, as it may lead to crises in the form of hunger, conflict, and massive migration.

On the political front, recent development and democratization processes in some African countries are an encouraging prospect because of their multiparty systems, free and fair elections, limited terms of office, and the transfer of power through peaceful means. Governments in Ghana, Mali, Botswana, and Zambia are some of the examples of promising signs that the African continent is on the way forward to democratic ideals in the political culture. In a related development, as a means of addressing the need for improved governance, the African Peer Review Mechanism has been put in place—a program that came recently as a system of appraising how well African governments are doing in terms of good governance, economic progress, and human rights. With this program, governments will periodically go through a review processes whereby they will be able to get some feedback about their leadership qualities.

The OAU, which was formed in 1963 as a voice to represent independent Africa, has now been replaced by the African Union (AU). Richard Dowden (2009) underscored that this is a step forward for the African countries in addressing common challenges for the common good. The AU has a practice of intervening in cases of genocide or crimes, as opposed to its predecessor, the OAU, which used to remain silent while many were losing their lives. The AU also rejects a coup as a means of power transfer in member countries. It also desires to extend the consolidation of the union further by creating a continental parliament following the example of Europe.

The loss of skilled young intellectuals and productive individuals, who are leaving the continent in greater numbers every year, poses another challenge to Africa. The exodus of its productive and skilled human resources is draining Africa's crucial asset. This export is not limited to human resources. Dowden (2009) observed that Africans take their money out of the continent and keep it in the outside world. Some of this money is illegally obtained through corrupt practices. Thus, Africa is not only suffering from a brain drain of its skilled human resources but also from a loss of its financial capital. This is a hindrance to development efforts that could bring about changes in the living conditions of Africans.

Central to the efforts and discourses about the place of Africa in the new century are issues of poverty reduction,

debt relief, trade and investment, and information technology. The goal of reducing poverty is one of the Millennium Development Goals (MDG). The achievement of this goal requires decreasing the number of poor people who live below the poverty line and increasing the gross national product. This is the hardest target to meet, as it requires so many changes and inputs, including but not limited to good governance that involves the participation of many and the accountability of leaders, viable strategies for trade and investment relevant to the conditions of Africa, and utilization of advances in technology. According to Gordon and Gordon (2007), so far most of the African countries are far behind in meeting the MDG target for 2015. An integral part of the goal is reducing the number of people living in an extreme condition of poverty. With the recent global economic and financial crises coupled with the already existing problems, the trend appears to be one that, instead of reducing, is increasing the number of poor people in regions such as sub-Saharan Africa.

Indebtedness is one of the burning problems of Africa. While the debt is mounting every year, so does the interest that comes with the debt, and debt is an important part of African countries' budgets. In some cases, the foreign aid that comes from the World Bank and IMF is used to pay already existing debts. This is a vicious cycle that is keeping Africa in the bondage of poverty. Gordon and Gordon (2007) noted that officials of the World Bank and IMF blame African leaders for not using the funding appropriately and wisely. Part of the new initiative to address the problem includes the goals of debt cancellation and increased aid to African countries. The G8 and recently the G20 nations are promising to meet these goals in order to help Africa get out of cyclical poverty.

Increasing trade and investment in Africa are development issues. Africa is being asked to boost its export capacity in order to increase its revenue. Trade with the world outside Africa has been limited to agricultural products, minerals, and fuels. Exports of other industrial products are scarce. The United States is among the major partners in trade with Africa, through its trade liberalization programs. China is becoming visible in trade and investment in African countries as well. Oil is becoming an important export commodity for many African countries, with a growing interest in it from China as well as from the United States. However, Gordon and Gordon (2007) presented the argument, shared by many, that trade liberalization alone is not adequate to relieve Africa of its poverty. Instead, there should be more aid directed toward sustainable development through diversified economies, including local and regional investments in meeting basic needs for health, education, clean water, energy, and transportation. Such development efforts also include investments in information technology. The growing trends of access to mobile phones, the Internet, and satellite TV are promising indicators of the expansion of information technology in

Africa. This development will bring favorable benefits in terms of information sharing with the outside world.

Conclusion

Africa is a center of interest for many. It has been a subject of media coverage more often for the ugly side of human suffering than for its hope for prosperity and opportunity. As the location of the origin of humankind, Africa represents the root of humanity all over the planet. It has also represented the black face of the human race. Africa is known for its ancient civilizations of Egypt and Ethiopia and the famous kingdoms of Ghana. It has attracted major religions of the world—Christianity and Islam right from their very beginning.

Europeans became interested in exploring the continent of Africa as far back as the 15th century. After an ordeal of successful and unsuccessful attempts, Europeans were able to establish contact with Africa—a contact that started at the coastal areas and gradually deepened into the heartland of the continent. They pursued this quest to establish trade relationships, to find new resources for raw materials such as gold, and to satisfy their intellectual curiosity about the unknown world. The contact between Europeans and Africans turned into the worst form of human relationship with the beginning of the transatlantic slave trade, in which millions of Africans were exchanged as commodities. The contact underwent changes when Europeans shifted their interest from slavery to the direct rule of Africans on African soil in what is known as colonialism. By the middle of the second half of the 19th century, most of the African continent had fallen into the hands of European colonial rule.

African countries became independent in the 1950s and 1960s after a long struggle for liberation, and, in the aftermath, they came to be administered by their own children. The postcolonial decades were not full of joy and satisfaction for the African societies. The African people faced serious challenges, such as political instability, civil war, poverty, disease, corruption, dictatorship, and underdevelopment in terms of basic services, such as education, clean water, health, and infrastructure. Development efforts of the last six decades have not been in the best interests of the African societies. Foreign aid has not helped the growth of Africa. Debt has become a challenge to many African countries. Trade has been based mainly on the export of agricultural products and oil but not of industrial goods.

Recent encouraging developments for the prospect of Africa lie in the areas of aid for sustainable development, debt relief and cancellation, investment in infrastructure and basic services, good governance, human rights, and accountability. Africa also seems to be benefiting from the current development of Asian interest in investment, and progress in communication technology such as mobile phones, the Internet, and satellite TV. New initiatives, such

as the MDG and poverty reduction strategies, could make a difference in the progress of the African continent in the 21st century.

Further inquiry and research are necessary to study the impacts of information technology, Asian interest, liberal democracy, one-party rule, green technology, and global financial and market developments on African societies.

CARIBBEAN

Past and Present

FERNANDO VALERIO-HOLGUÍN

Colorado State University

For many Europeans and North Americans, the Caribbean is known as a tourist destination and a dreamed-of earthly paradise: white beaches, palm trees, turquoise blue waters, and friendly natives. However, the Caribbean is more than this. It is the world's most racially and culturally diverse region; it is also one of the most important Latin American regions in modern history. The first genocide of an indigenous people on the American continent occurred in the Caribbean. The first discussion about human rights in Spain and the Americas began with the Dominican friars Fray Bartolomé de las Casas and Fray Antón de Montesinos. African slavery, which gave shape to modern capitalism, had its origin in the Caribbean. The Haitian Revolution, an unprecedented event, resulted in the world's first black republic and the second independent country on the American continent, after the United States. The Cuban Revolution, the first socialist revolution on the continent, occurred in the Caribbean as well. The Cuban Missile Crisis of 1962 brought the world to the brink of nuclear war for the first time.

The Caribbean is also a source of great cultural riches, of which are known only a few icons such as Wilfredo Lam in painting, Derek Walcott and V. S. Naipaul in literature, and in music Benny Moré, Celia Cruz, Dámaso Pérez Prado, Juan Luis Guerra, las Estrellas de la Fania, Bob Marley, and Harry Belafonte, a product of rapid media expansion. In baseball, the players Juan Marichal, Alex Rodríguez, Roberto Clemente, Sammy Sosa, George Bell, and Tony Bell, among others, are globally known. For an

archipelago inhabited by only 40 million people, the Caribbean has brought a cultural heritage to the world that deserves greater study and deeper appreciation.

The name *Caribbean*, which designates this geographic area, comes from the Carib ethnic group, which inhabited the Lesser Antilles before the arrival of the Spanish conquistadors. The word *Carib* became corrupted in the Italian language and was pronounced "caniba," a pronunciation that gave rise to the words *cannibal* and *cannibalism*, a phenomenon noted by Christopher Columbus on his first voyage (Veloz Maggiolo & Zanin, 1999). The Caribbean basin is composed of more than 1,000 islands, islets, and keys and has a population of 40 million inhabitants.

As a region, the Caribbean can be spoken of in a wider sense and in a stricter sense. In the wider sense, the Caribbean includes the coasts of Venezuela, Colombia, Central America, and the Mexican state of Yucatán. In the stricter sense, the Caribbean includes a chain of islands that extend from the Mexican state of Yucatán to the Venezuelan coast. This chain is divided between the Greater Antilles, which are composed of the islands of Cuba, Jamaica, Puerto Rico, and Hispaniola (shared by the countries of Haiti and the Dominican Republic), and the Lesser Antilles. The Lesser Antilles, for their part, are divided between the Leeward Islands (north of Martinique) and the Windward Islands (south of and including Martinique). The Leeward Islands are made up of the Virgin Islands, St. Kitts and Nevis, Montserrat, Anguilla, Saint-Martin/Sint Maarten, Saint-Barthélemy, Barbuda, Guadeloupe, La Désirade,

Marie-Galante, and Dominica. The Windward Islands are composed of Martinique, Saint Lucia, Barbados, St. Vincent and the Grenadines, Grenada, Trinidad and Tobago, Aruba, Curaçao, and Bonaire.

The formation of the Caribbean islands dates back to the Mesozoic Era. The islands, formed by volcanic activity as well as by fossil and coral sedimentation, are mountainous, reaching a height of 3,087 meters atop Pico Duarte in the Dominican Republic. The Caribbean belongs to the tropical region, with an annual average temperature of 27 degrees Celsius. There are two seasons: the rainy season from May to September, which coincides with hurricane season, and a partially dry season from November to April (Lot Helguera & Salmoral, 1995).

Pre-Columbian History: Taino Arawaks, Ciboneys, and Caribs

At the time of the arrival of the Europeans in 1492, various indigenous groups existed in the Caribbean: Taino Arawaks, Ciboneys, Ciguayos, and Caribs. Their population is estimated to have been no more than three-quarters of a million. The Tainos, which constituted the largest group, were of Arawak origin and inhabited the islands of Cuba, Hispaniola, Jamaica, Puerto Rico, and the Virgin Islands. An agricultural rather than a warrior society, they cultivated manioc, sweet potatoes, corn, sago, and cotton. They also engaged in hunting, gathering, and fishing (Veloz Maggiolo & Zanin, 1999).

On Hispaniola, the most densely populated island, the Tainos were organized into five *cacicazgos* (chiefdoms): Marién, Maguá, Maguana, Jaragua, and Higüey. Every chiefdom was governed by its respective *cacique* (chief). In the social hierarchy, the cacique occupied the most important place, followed by the nobles or *nitainos* and the shamans or *behiques*, the common folk or *tainos*, and the *aborias*, servants of the nobility. They gathered in villas grouped around a central plaza called a *batey*. The houses were called *bohios* and the larger ones *caney*s. Their religion was polytheistic and animistic. Their principal god was Yocajú-Bagua-Maorocoti, protector of the manioc harvest. Huracán was another important god. The Tainos celebrated rites of passage, in which they held celebrations accompanied by music and dances called *areitos*. Of special importance was the *cohoba* festival, in which the behique and the cacique inhaled a hallucinogenic powder called cohoba, with which they entered a trance state and were able to converse with the dead and transmit messages from the *cemis*, or gods.

Other ethnic groups in the region were the Ciboneys, the Ciguayos, and the Caribs. The Ciboneys were an ethnic group that inhabited eastern Cuba and southwestern Hispaniola. They were hunter-gatherer nomads and did not have a political organization like that of the Tainos. The Ciguayos inhabited the northeastern coast of Hispaniola, and their culture was similar to that of the Tainos, except that they had adopted the custom of war. They spoke a language

of Arawak origin and were possibly a Taino-Carib hybrid, due to Carib incursions into the eastern side of the island. The Caribs inhabited the islands of the Lesser Antilles. According to the Dominican anthropologist Marcio Veloz Maggiolo, their origin could date back to Amazonian ethnic groups, evidenced by the presence of *turens* (plates for cooking manioc), which indicates the cultivation of bitter manioc (Veloz Maggiolo & Zanin, 1999). The Caribs were a warlike ethnic group that made incursions into the islands of the Greater Antilles, abducting women and carrying them off to their home islands. Before the arrival of the Europeans, a hybridization process between the Caribs and the Tainos had begun as the children of Taino women abducted by Caribs were brought up speaking the Arawak language.

The Textualized Caribbean: Columbus, Las Casas, and Fernández de Oviedo

The colonization of the Caribbean meant, on one hand, the enslavement and subsequent extermination of the indigenous population and, on the other, the forced immigration of four to five million African slaves (Manuel, Bilby, & Largey, 1995). At the time of Columbus's arrival in the Caribbean, the indigenous population was estimated to be three quarters of a million, with Hispaniola being the most densely populated island at around a quarter million inhabitants. By the time of the Enriquillo Insurrection in 1511, the population of Hispaniola had been reduced to a mere 11,000. The extermination of the indigenous workforce consequently led to the importation of an African workforce. As Eric Williams, prime minister of Trinidad and Tobago, put it, the Europeans "used negroes they stole from Africa to work the land they stole from the Indians" (as quoted in Manuel et al., 1995, p. 3).

The arrival of the Spanish in the Caribbean marked the beginning of the modern European ethnography, or a "utopic ethnology" in the words of José Rabasa (1992), with the production of *Summary Apologetic History* by Bartolomé de las Casas. The first four authors to give an account of the Caribbean were Christopher Columbus in his onboard diary, Fray Bartolomé de las Casas in his *History of the Indies*, Fray Ramón Pané in his *Report About the Antiquities of the Indians*, and Gonzalo Fernández de Oviedo in his *General and Natural History of the Indies*. In these first texts, the Caribbean was invented and inventoried. They describe not only the flora and the fauna but also the inhabitants, for example, their habits, customs, traditions, rituals, physical appearance, and so forth. The four authors of these texts use different rhetorical strategies, which, in the majority of cases, have more to do with their own personal political positions than with the reality they proposed to analyze. For example, in Columbus's diary, of which we have knowledge only through Fr. de las Casas's summary, the Caribbean is constructed as an earthly paradise and the Tainos as noble savages. A common aspect of

these textualizations is that both the black Africans and the horrors of their slavery are neatly passed over.

Immigration

As a place of immigration, the Caribbean possesses an extraordinary fluidity. The first immigration was that of the Spanish conquistadors in their colonial enterprise, and this was followed by the forced immigration of millions of African slaves. During the colonial period, incessant wars among European empires and invasions of their respective territories obliged families to emigrate from one island to another. In the second half of the 20th century, Caribbean immigration to the United States and Europe should be considered within the context of peripheral migration toward the hegemonic centers of the so-called first world. This migration, put in motion by modernization and the globalization of the economy, has reached an unprecedented magnitude and intensity (Chambers, 1994).

Edouard Glissant considers the Caribbean as a “transitory” space, as its inhabitants often find themselves in transit toward somewhere else. Of course, the relationships between former colonies and their mother countries are a hallmark of modern immigration. Spain, England, and France have received the return of their formerly colonized subjects in a kind of boomerang effect. The replacement of the former colonial powers by the United States in terms of political, economic, and cultural influence has also displaced migratory patterns, as the United States has become the principal destination of Caribbean emigrants. Cities such as New York, Boston, and Miami have received the greatest number of Cubans, Dominicans, Puerto Ricans, and Haitians, but this immigration is not definitive. Many Caribbean immigrants return home temporarily or permanently, and with their return they reactivate the process of transculturation as a consequence of their contact with Anglo culture as well as with cultures from Latin America and other parts of the world.

Even when we think of the Caribbean only in terms of the African presence, other migratory patterns that have enriched Caribbean culture must be considered. The end of the 19th century saw a large number of immigrants from the Middle East: Syrians, Palestinians, and Lebanese. After the abolition of slavery, there was also a wave of Chinese immigration into Jamaica, Trinidad, the Dominican Republic, Cuba, and other countries. Other waves of immigration included the East Indians who established themselves in Trinidad and Suriname. The immigration of small numbers of Sephardic Jews has been noted as well, both in the 17th century and before World War II (Thomas-Hope, 1980).

Conflicts Between Nations: The Case of Haiti and the Dominican Republic

A conflict that merits special attention is the one between Haiti and the Dominican Republic, which is the result of

colonial heritage. It has its origin in the 1697 Treaty of Ryswick, by which Spain ceded the western part of Hispaniola to France. This treaty is of utmost importance, because it divided the island into two colonies: Saint-Domingue in the west and Santo Domingo in the east. For more than a century, the two colonies coexisted peacefully, which permitted the free exchange of products between them. Economic and social developments were unequal. On the one hand, the French colony was characterized by the massive importation of slaves and the intensive exploitation of the plantation economy by a white minority. On the other hand, the Spanish colony, although poorer than the French colony, experienced a slow economic recuperation based on livestock ranching in which feudal patriarchal relationships predominated. The immigration of approximately 4,000 Canary Islanders; the small importation of African slaves; the coexistence of free blacks, slaves, and whites in the extensive work of the livestock ranch; and the lack of strict social regulations resulted in a greater racial mixture than in the neighboring colony of Saint-Domingue (Cassá, 1986).

The Treaty of Aranjuez, signed by France and Spain in 1774, fixed the precise borders between the two colonies. Once the two former colonies became independent, two distinct countries came into being on the same island—one of the few cases of this in the world—but border disputes continued for more than a century, during which various treaties and accords were signed between the Haitian and Dominican governments. At the beginning of its independence from Haiti in 1844, after 22 years of Haitian occupation, the Dominican Republic demanded that the border be set at the limits established in the Treaty of Aranjuez, while Haiti claimed the territory occupied by its citizens after the cease of the various hostilities between the two countries. The Treaty of 1936, signed by Stenio Vincent, the president of Haiti, and Rafael Leonidas Trujillo, the president of the Dominican Republic, seemed to put border disputes between the two countries to an end.

However, the border conflicts instead reached their most crucial point in the genocide of 1937. As Gómez-Peña described a comparable issue with respect to the Mexico–U.S. border, it could be said that the Dominican-Haitian frontier became the eternal hemorrhage of “a wound in the middle of a family” (1993, p. 47). During the massacre of 1937, entire families were separated, and spouses, siblings, and children of Haitian, Dominican, and Dominican-Haitian nationality were murdered. The border literally became a river of blood in the Massacre River, whose name alludes to a previous massacre, as if since then Trujillo’s genocide had been foretold.

The primitivist discourse with respect to the Haitians has profiled Dominican identity both racially and culturally. Dominicans do not consider themselves to be black, but rather “Indians” or mestizo descendants of Spaniards and Taíno Indians. This myth has its foundation in the high percentage—reaching more than 80%—of African Hispanic Dominicans, while the majority of Haiti’s population is of purely African descent. The myth of supposed indigenous

racial admixture gained greater traction during the First American Invasion (1916–1924), when, faced with a variety of racial mixtures, the Americans began to register Dominican citizens' color as "Indian" in official documents. In addition, if we recall that the essence of a nation, according to Renan, is found, among other things, in "that which is forgotten" (as cited in Anderson, 1996, p. 6), that which the Dominicans have forgotten is that the Taíno Indians were almost totally exterminated at the beginning of the 17th century and that Dominican culture is eminently African in origin.

Dominican cultural identity has been constructed as a negation of Haitian culture through the primitivization of the "natural" frontiers. Racial, linguistic, and cultural differences are heightened into "internal frontiers" as a way of confronting the terror and anxiety caused by the instability of "floating frontiers." Haiti, as the primitive-other, the neighbor-other, and the other-within, becomes the unconscious primitive that Dominicans want to repress and, because of this, they have constructed a racial and cultural imaginary that differs greatly from their social reality.

Value of Sports

According to Antonio Benítez Rojo, the Caribbean is a performer par excellence. In keeping with this idea, music and sport have been the two areas in which Caribbeans have distinguished themselves most highly. The most popular sports in the Caribbean are baseball, cricket, and soccer. Baseball is played mostly in the Greater Antilles (Cuba, the Dominican Republic, and Puerto Rico) because of the cultural and political influence of the United States. Michael A. Malec, in his important book *The Social Roles of Sport in Caribbean Societies*, suggests that sport constitutes an important object of study in order to understand Caribbean culture in relation to race, gender, class, and postcolonial relations, as well as politics. In this way, Malec states that sports have a social function in fostering cohesiveness, conceding a sense of community and offering a national identity (Malec, 1995).

Although baseball, cricket, and soccer are the best known sports in the Caribbean, other important sports are boxing, basketball, and horse racing. Baseball was introduced in Cuba, the Dominican Republic, and Puerto Rico by the Americans during their first invasion in 1916. In the Dominican Republic, home to a number of baseball academies, baseball has become the national sport, and its players, mainly working-class blacks, serve as role models for many boys who identify with them and hope to rise out of poverty. By 1989, approximately 20% of major league players in the United States were Dominican, and around 300 Dominicans were playing in the minor leagues (Klein, 1995). Among the most famous Dominican players are Juan Marichal, the first Dominican player to be named to the Hall of Fame; Sammy Sosa and Alex Rodríguez, who became members of the 500 home run club; Tony Peña; and George Bell; among others. Outstanding players from Cuba include Luis Tiant, José Canseco, and brothers

Liván and Duque Hernández, while Puerto Rico adds Roberto Clemente, Orlando Cepeda, Bernie Williams, Carlos Delgado, and Carlos Beltrán to the list.

Cricket was introduced by England to its Caribbean colonies in the 19th century, most specifically to Trinidad, Guyana, Barbados, and Jamaica. At first, teams were made up exclusively of white players, and the participation of Caribbean players had to wait until the first half of the 20th century. The victories of the West Indies team in Bourda, British Guiana, in 1930, and in England in 1950 contributed to the creation of a sense of pride for the Caribbean players in beating their English rivals (Cummings, 1995). Cricket, as well as baseball, has served symbolically to resolve conflicts between colonizers and the colonized. Other sports in which Caribbeans have excelled are basketball, boxing, horse racing, and track and field. In Puerto Rico, Félix "Tito" Trinidad won the welterweight world championship in boxing, and the Dominican Félix Sánchez won the gold medal in the 400 meter hurdles in the 2004 Athens Olympics.

Religions in the Caribbean

Although the Roman Catholic Church has a large number of followers, mostly in the French- and Spanish-speaking portions of the Caribbean, and Protestant denominations predominate in the English-speaking Caribbean, syncretic religions occupy an important place: Vodun in Haiti and the Dominican Republic; Santería in Cuba; Revival-Zion, Pukkumina, and Rastafarianism in Jamaica; the Shakers in St. Vincent; the Shouters in Trinidad; and the Jumpers in the Bahamas. In addition, there exists a series of celebrations and cults, such as the cult of Shangó and Rada in Trinidad and the cult of Norman Paul in Grenada (Turner, 1980).

Vodun and Santería are syncretic, polytheistic, and animistic religions that have their origins in the mixture of Roman Catholic practices and African religions. Music and dance play a fundamental role in the rites of both Vodun and Santería. Vodun had its beginnings in Dahomey, and adaptations were made to its new Caribbean environment. Its gods, called *loas*, have both human and divine characteristics. Each one of them is associated with a particular Catholic saint: Papá Legbá with Saint Peter, Zaca with Saint Isidore the Worker, Ogú Shangó with Saint George, and Erzulie Freda with the Virgin Mary. The priest who officiates at the ceremony is the *houngan*, while the priestess is called a *mambo*, and the place where the ceremony is celebrated is the *houmfor*. Each *loa* has its favorite food and drink, as well as favorite colors and objects. The sacrifice of animals, such as goats or chickens, is also part of the ritual practices. The *loa* takes control of the *houngan*, who serves as an intermediary between the *loa* and the worshipper. The *loa* takes possession of the *gros-bon-ange* or "great good angel," which represents the conscience, while the body, represented by the *petit-bon-ange* or the guardian angel, remains intact. The rites are accompanied by drum music, dance, and liturgical chants (Marks, 1980).

Santería is a syncretic religion of Yoruba origin practiced in Cuba and Trinidad. As its name indicates, Santería (a gathering of saints) possesses a pantheon of spirits called *orishas*, who also have their equivalents among Catholic saints: Shango with Saint Barbara, Ogún or Oggún with Saint Peter, Babalú Ayé with Saint Lazarus, Yemayá with the Virgin of Regla, and Ochún with the Virgin of Caridad del Cobre. Stones, leaves, and blood are symbolically important in this religion. Stones represent divinity, and as such must be cared for and fed. Leaves, for their part, are used to bathe the stones. Finally, blood, derived from animal sacrifice, serves to feed the stones (Turner, 1980). The *orishas*, which are gifted with a power known as *aché*, materialize in a human body only in the ceremony called “becoming the saint” when they “ride” the priest or priestess.

Rastafarianism rose in Jamaica with Marcus Garvey’s nationalist movement in 1920 and the movement to return to Africa. When Emperor Haile Selassie ascended the Ethiopian throne in 1930, Jamaicans recognized him as both a prophet and God, and they adopted the emperor’s precoronation name: Ras Tafari. In Rastafarianism, the black man is considered superior to both the black woman and the white man. The use of dreadlocks and *ganja* (or marijuana) as a sacred herb are important components of this religion. Its principal objective is the return to Africa in order to escape Babylon, or white oppression. Rastafarianism gained worldwide recognition through Bob Marley’s reggae, a musical genre created in the poor neighborhoods of Kingston (Turner, 1980).

Music in the Caribbean

Cuban writer and musicologist Alejo Carpentier affirmed, “Everything sounds in the Caribbean, everything is sound” (1981, p. 180). Cuba could be considered an extraordinary case for the quantity and types of music that have risen from this country. It would be enough just to mention bolero, guaracha, son, rumba, mambo, and cha-cha-cha. But to these Cuban rhythms, it would be necessary to add other Caribbean ones such as salsa, merengue, and calypso, which have been disseminated throughout Latin America. Carpentier emphasizes the centrality and impact that Caribbean music has had on culture and, in a special way, on literature. Many Caribbean writers have used the poetic language of music as a general principle that governs their work. Popular music has also had an impact on the identity process of the Caribbean subject by having recourse to some “collective sentiments” (Keil, 1985).

The most important elements in the process of creolization consist of the contributions of the Taíno, the Africans, and the Europeans. The indigenous contribution is slim due to the rapid annihilation of this ethnic group. The contribution cited by some musicologists consists of the *areíto*, ritual chants sung during the celebration of the hallucinogenic cohoba rite, which used the güiras and maracas still commonly used in contemporary Caribbean

music. The call-and-response style coincides with one of the aspects of African music and clearly was an important factor in the encounter between indigenous peoples and the African slaves (Manuel et al., 1995). The traces of African heritage in Caribbean music are found not only in call-and-response but also in syncopation and polyrhythms. Many musical instruments of African origin are in common use in the Caribbean, such as drums, güiras, and cordophones.

Some of the best-known Cuban musical genres are *guaracha*, *son*, and *guajira*. Guaracha had its origin at the beginning of the 20th century and reached its apogee in the 1930s. It possesses a humorous, mocking, and satirical character. It has a 2/4 beat and in the beginning was played with guitar, güira, and maracas. Later, it was played by orchestras like those of Sonora Matancera. Antonio Fernández, also known as Ñico Saquito, the founder of the quintet Los Guaracheros de Oriente, was one of the best known guaracha composers.

Son was born in eastern Cuba at the end of the 19th century. Originally, it was based on a four line quatrain that served as a refrain, and like the guajira, it could be used as a verse competition between two or more singers. Son, which is played with guitar, marimba, claves, bongos, and maracas, has a 2/3 beat in the claves with a syncopated bass. Among the most outstanding groups are Sexteto Habanero, Trío Matamoros, Sexteto Nacional, and, more recently, Los Van Van and Irakere.

Finally, guajira originated at the beginning of the 20th century and is considered to be an evolution of punto. It generally uses a 10-line verse known as a *décima*, but other strophic verse forms are used as well. Guajira, which uses guitar and a Spanish lute known as the *laú*, begins with a 3/4 beat but ends in 6/8. It can also be used in improvised verse competitions between two or more singers. Among its most outstanding performers are Joseíto Fernández, author of “Guantanamera”; Guillermo Portabales; and the duo Celina y Reutilio.

In the Dominican Republic, merengue and bachata are the most popular musical genres. Merengue is the national genre of the Dominican Republic. It was derived during the 19th century from the Spanish *contradanza* and influenced by African rhythms. Merengue from the countryside, also known as *perico ripiao* (literally “torn sparrow”), is played with a güira scraper, a double-headed tambora drum, marimba (a wooden box with metal keys also known as the thumb piano), and button accordion. During the 19th century, merengue was considered vulgar and low class by the Dominican elite. It was the dictator Rafael Leonidas Trujillo who introduced merengue into the dancing salon and used it in political propaganda. Modern merengue, played with electric instruments, became internationally known in the 1970s. Among its best known musicians are Johnny Ventura, Wilfredo Vargas, and Juan Luis Guerra.

Bachata, on the other hand, is both a rhythm and a dance derived from the *música de amargue* (music of bitterness) of the Dominican shantytowns in the early 1960s. At first, bachata was also considered to be vulgar and low class.

There are two types of bachata: popular bachata and middle-class bachata, also called techno-bachata or techno-amargue. In 1991, Juan Luis Guerra and his group 4:40 released the CD *Bachata Rosa* (Bachata in Rose). Bachata became a success in Latin America, the United States, and Europe. Other bachata composers and singers are Luis Días, Víctor Víctor, and Sonia Silvestre.

Puerto Rico is recognized for *salsa*, *plena*, and *bomba*. Salsa had its origin in New York toward the end of the 1960s among Puerto Rican and Dominican immigrants. Salsa combines musical elements of guaracha, son, and jazz. It is played by a combo with keyboard; wind and brass instruments such as saxophone, trumpet, and trombone; and percussion such as congas and timbales. The group La Fania All-Star was created by the Dominican Johnny Pacheco in New York in 1968 and included invited artists such as Tito Puente, Eddie Palmieri, Ricardo Ray, and Bobby Cruz. This group produced one of the most stellar sounds of this genre at its time. Plena is a result of the fusion of bomba and calypso in the beginning of the 20th century; it had its origin in marginalized neighborhoods. The instruments used in plena are guitar, accordion, and tambourine. Among the first plena musicians were Manuel Jiménez, Mon Rivera, and the group Pleneros del Quinto Olivo.

In Trinidad and Tobago, *calypso*, which is associated with that country's carnival celebration, had its origins at the end of the 18th century among the working class. Some say the word *calypso* seems to come from *cariso*, which was a kind of satirical song, while others prefer to refer its origins back to the African word *kaiso* (Manuel, Bilby, & Largey, 1995). Soca, as contemporary calypso is known, shows East Indian influence as well. Steel bands are well known not only for their inventiveness, but also for the sweet, sharp sound they produce. Cultural resistance constitutes an important political component, as they were created as a consequence of the prohibition of drums by the English.

Reggae is a genre that has spread from Jamaica throughout the world. Associated with the Rastafarian religion, reggae had its origins in the poor neighborhoods of Kingston among ska musicians. Reggae, a mix of Cuban son—called rumba in English—jazz, and ska, which in its turn is derived from American rhythm and blues, expresses the suffering and oppression of Jamaican blacks. With his charisma and charm, the Jamaican musician Bob Marley leapt to international fame.

Literature

Caribbean literature is a complex phenomenon, due not only to the multiplicity of languages but also to the mixture of races and social classes in Caribbean countries and their political status. The three Spanish-speaking countries are Cuba, Puerto Rico, and the Dominican Republic. The Spanish of these three countries generally shares characteristics for which it is known linguistically as Caribbean Spanish. The French-speaking countries are Haiti,

Martinique, Guadeloupe, Saint-Martin, and French Guiana. Creoles are spoken by the great majority of the population of these countries. Michael Dash distinguishes between Haiti, where 90% of the population speaks only a creole, and Martinique, an overseas department of France, where the reigning education system is that of mainland France. The English-speaking countries are Jamaica, the Virgin Islands, Trinidad and Tobago, Barbados, and St. Lucia, among others. Dutch is spoken in Aruba, Curaçao, Bonaire, Suriname, and Sint Maarten, along with Papiamentu, a creole of Dutch, Spanish, English, French, Portuguese, different African languages, and Arawak.

Caribbean literature is of an elitist character, since it is written in European languages in countries where creoles are spoken and rich oral traditions are extant. In addition, this is a literature written for markets in Spain and Latin America in the case of Spanish, or for markets in France, England, and the United States in the case of literatures in French and English. Edouard Glissant refers to this phenomenon by saying, "There may be individual Martinican writers but there is no Martinican literature" (as quoted in Dash, 1994, p. 310).

Caribbean culture is eminently popular in many of its manifestations, and literature does not escape this phenomenon. In Haiti, where there exists a complex mixture of race and social class between blacks and biracial Haitians, literature has often served to promote the prestige and interests of a certain class (Dash, 1994).

Nevertheless, the fact that it produces literatures in three distinct languages makes Caribbean literature one of the most important and distinctive of Latin American letters, and has produced writers of great quality: two Nobel laureates (Derek Walcott and V. S. Naipaul) and several perennial Nobel candidates: Alejo Carpentier, José Lezama Lima, Juan Bosch, and Edouard Glissant, among others. The literature of the Hispanic Caribbean in the second half of the 20th century was fully integrated into the publishing phenomenon known as the Boom of Latin American literature. Besides the aforementioned writers, other famous authors and their well-known works are Luis Rafael Sánchez with *La guaracha del Macho Camacho*, Guillermo Cabrera Infante with *Tres tristes tigres*, Marcio Veloz Maggiolo with *De abril en adelante*, and Pedro Vergés with *Sólo cenizas hallarás*.

In the English-speaking Caribbean, noteworthy novelists and their works are C. R. L. James (Trinidad) with the novel *Black Jacobins* about the Haitian Revolution, George Lamming (Barbados) with *In the Castle of My Skin*, and the poet Kamau Brathwaite (Barbados) with *Born to Slow Horses*. In the French-speaking Caribbean, besides Edouard Glissant and Aimé Césaire, both from Martinique, other distinguished writers and their works are the Haitian novelists Jacques Roumain with *Les gouverneurs de la rosée*, René Depestre with *Hadriana dans tous mes rêves*, and Jacques-Stephen Alexis with *Compère Général Soleil*, about the 1937 massacre of Haitians on the Dominican border.

In the Caribbean, there have been important literary movements such as the Beacon Group in Trinidad, Négritude in Martinique, Noirism in Haiti, and Poesía Sorprendida in the Dominican Republic. The most important of these has been Négritude, which began in Martinique with work of the poet Aimé Césaire. Other poets of the Hispanic Caribbean are among the writers of this movement, including Luis Palés Matos of Puerto Rico, Manuel del Cabral of the Dominican Republic, and Nicolás Guillén of Cuba. Négritude came to signify, aesthetically, a rescue of black values, and politically, an anti-colonial resistance to the hegemonic countries.

Besides poets and novelists, the Caribbean has given birth to important intellectuals who have had an impact on Latin American thought, such as José Martí (Cuba), Jean Price-Mars (Haiti), Franklin W. Knight, Juan Bosch (Dominican Republic), Franz Fanon (Martinique), and Marcus Garvey (Jamaica).

Fine Arts and Cinema

Another of the great riches of the Caribbean, besides music and literature, is its painting. If we were to characterize Caribbean painting, it would have the same racial and cultural diversity that exists in the region. There is no style or theme unique to Caribbean painting; its styles range from the costumbrism, landscape painting, and romantic exoticism of the 19th century to surrealism, figurativism, neofigurativism, and—in the last decades of the 20th century—abstractionism as a result of U.S. influence.

The 1920s and 1930s constitute two periods of splendor in Caribbean painting. Modernism in painting parallels the development of nationalism in Caribbean countries, and this combination gave rise to a modality of modernist costumbrism (Poupeye, 1998). Influenced by the ideas of José Martí, Aimé Césaire, Marcus Garvey, and Fernando Ortiz, painters undertook a search for national identity through the rural landscapes, modern architecture, and the revalorization of blacks and mulattos, among other themes. Some musical genres, such as rumba and merengue, were used as themes for many paintings, as in *El triunfo de la rumba* by Eduardo Abela (Cuba) and *El merengue* by Jaime Colson (Dominican Republic).

The movements of Négritude and Noirism also influenced Caribbean painting. In Cuba, the Minorista group and the Orígenes group, although literary in nature, were a notable influence on the formation of the Havana School, some of whose best painters are Amelia Peláez and René Portocarrero. During this same period, Marcus Garvey formed the United Negro Improvement Association, which had deep repercussions for Jamaican Rastafarianism and therefore on the painting of that country. In the Dominican Republic, painters such as Yoryi Morel, Darío Suro, and Jamie Colson became preoccupied by a search for national identity in rural themes. Likewise, in Puerto Rico, the *jibaro* (peasant) constituted a privileged theme in terms of cultural identity.

The trail blazed by Wilfredo Lam, who arrived in Cuba in the 1940s, was followed by many Caribbean painters. His masterpiece *La jungla* includes Cuban cultural icons like sugarcane and tobacco, which allude to Fernando Ortiz's seminal book *Contrapunteo del tabaco y el azúcar*. Among sensual forms in harmony with nature appear figures wearing African masks in a clear display of the influence of Pablo Picasso.

The 1970s gave rise to an important group of painters in the Dominican Republic who employed abstraction, symbolism, and tenebrism as a means of avoiding dictatorial censorship; Silvano Lora, Guillo Pérez, Eligio Pichardo, Ada Balcácer, and Domingo Liz belong to this group. The artists emerging in the 1960s had taken Dominican art in a different direction; Ramón Oviedo, Iván Tovar, Cándido Bidó, José Félix Moya, Alberto Ulloa, and Soucy de Pellerano turned to new forms, from figurative expressionism to chromatic drama, embracing surrealism and sometimes developing social and political themes.

Caribbean film, although somewhat of a late bloomer relative to that of other Latin American regions, has experienced a resurgence in the last few decades. A clear example of this development is found in Cuba, which after the Revolution created a high-quality cinema framed within the current of new Latin American cinema. State support was crucial in the development of Cuban cinematography. The Cuban Institute of Cinematic Arts and Industries (ICAIC), charged with film making and distribution, was created in 1959. A new generation of directors arose during the 1960s, including Humberto Solás, director of *Cecilia* (1982), *Lucía* (1968), and *Miel para Oshun* (2001) among others; and Tomás Gutiérrez Alea, doubtless one of the best Latin American directors, director of *Memorias del subdesarrollo* (1968), *La última cena* (1976), and the acclaimed *Fresa y chocolate* (1994). From then on, a group of directors educated at the ICAIC stepped into the spotlight, among which Juan Carlos Tabío, Jesús Díaz, and Fernando Pérez are preeminent. Pérez is the director of excellent films such as *Madagascar* (1994), *La vida es silbar* (1998), and *Suite Habana* (2003). Within a realist style, all of these directors have created a high-quality and introspective cinema detailing different aspects of Cuban culture.

In the Dominican Republic, from Agliberto Meléndez's first full-length feature *Un pasaje de ida* (1988), which expresses preoccupation with emigration to the United States, other filmmakers like Ángel Muñiz with *Nueba Yol* (1995), *Nueba Yol III* (1997), and *Perico ripiao* (2003) have joined the industry. René Fortunato, for his part, has dedicated himself to the documentary, producing excellent examples like *Abril, la trinchera del honor* (1988) and various videos about the dictatorship of Rafael Trujillo Molina titled *El poder del Jefe* (1991–1996). Since the year 2000, there has been a kind of miniboom in Dominican cinema, with films like *Cuatro hombres y un ataúd* (1996) by Pericles Mejía, *La maldición del Padre Cardona* (2005) by Félix Germán, and *Un macho de mujer* (2006) by Alfonso Rodríguez, among others. Puerto Rico has produced several

features such as *Linda Sara* (1994) by Jacobo Morales and *La guagua aérea* (1995) by Luis Molina.

Martinique has given rise to the group Images Caraïbes, charged with the diffusion and development of Caribbean cinema, which presents a biannual film festival in Fort de France. The director Euzhan Palcy directed *Sugar Cane Alley* (1983), based on the novel *La Rue Cases-Nègres* by Joseph Zobel, and Horace Ové directed the miniseries *The Orchid House* (1984) for the BBC. Jamaica's contribution to world cinema was the film *The Harder They Come* (1972) by Perry Henzel (Meehan & Miller, 2003).

Caribbean Food

Food and music are the two most evident and portable aspects of culture, and all immigrants carry these aspects with them. Caribbean food is no exception and is the best representative of its culture: a flavorful mix of ingredients. With the exception of manioc, sweet potatoes, and corn, many agricultural products are not native to the Caribbean but were brought from Africa, Asia, and Latin America, like certain tubers of African origin such as the yam and the yautia, and others of South American origin like the potato. One of the few remaining foods of the Taíno is cassava, made from bitter manioc. Manioc flour is also used to make a kind of empanada called cativia or manioc empanada. The Caribbean is also known for the variety and flavor of its tropical fruits: coconut, mango, pineapple, guava, nispera, mamey, mamon, cashew fruit, papaya, and bananas, among others.

Among the different varieties of meat, goat and pork are the most appreciated. Jamaica is famous for its goat curry and the Dominican Republic for its goat stew. Pork or spit-roasted suckling pig excites the passions of Puerto Ricans, Dominicans, and Cubans at Christmas. Jerk and “vegetable egg” or *ackee* are well-known Jamaican dishes. Among fish, red snapper, snook, yellowtail, herring, and salt cod are a common denominator in the cuisine of many Caribbean countries. Fish, shrimp, and crabs often appear prepared in coconut milk. Almost every Caribbean country has its own national soup as well: *ajiaco* in Cuba, *sancocho* in the Dominican Republic, and callaloo in Jamaica, Guyana, Barbados, and St. Vincent. *Mondongo* (tripe stew) is also common in several Caribbean countries. Wheat flour empanadas and manioc flour empanadas or cativias delight the Caribbean palate. Dishes based on plantains, such as the Dominican Republic's mashed plantain *mangú* and Puerto Rico's *mofongo* and *pionono*, as well as ripe plantain slices fried or sautéed in butter and sugar, are also very well known. Fried, boiled, or roasted chestnuts are very common in the Caribbean as well. Rice and red, black, or pinto beans are an indispensable part of the basic diet, especially in the Greater Antilles.

The tourism industry, one of the principal sources and in some countries the principal source of income, has created a gourmet Caribbean cuisine in tourist hotels. These

dishes are created from mixtures of tropical fruits, such as mango and pineapple, with different kinds of meat.

Caribbean Cultural Identity: Acculturation and Transculturation

Many authors have used the typical dishes of the Caribbean, such as sancocho, ajiaco, or callaloo, as the most appropriate image to define Caribbean culture as a combination of the different African, Spanish, indigenous, Asian, and Arab cultures. The process of transculturation of these different cultures began at the end of the 15th and beginning of the 16th centuries. It is necessary not only to consider the first instance between Spaniards and Taínos, but also to refer to later instances between Spaniards and Africans, Africans and Taínos, and among the different African ethnic groups—especially in the escaped slave communities, where groups were isolated during long periods. To create a taxonomy in order to enumerate the elements belonging specifically to African, Spanish, Taíno, or Arab culture would constitute a reductionism. Caribbean culture must be considered in its totality, as in what Darcy Ribeiro (1975) termed “a new people” arisen from the peoples who came before. According to Ribeiro, an anthropologist, new peoples are the result of the “conjunction, deculturation and fusion of African, European and indigenous ethnic matrices” (1975, p. 33). New peoples are characterized by the implementation of chattel slavery and the model of the plantation economy. As a new people, Caribbeans are neither indigenous, nor African, nor European. Rather, one must consider as a whole a series of values, attitudes, and self-images shared by Caribbeans.

The Caribbean Now and in the Future

The Caribbean is one of the most culturally diverse regions of the world. As diverse as it is from a cultural standpoint, it is equally diverse in political terms. Different forms of government currently exist in the Caribbean: Cuba was the first socialist country in Latin America; the formally independent democratic countries of Haiti and the Dominican Republic share the island of Hispaniola; several countries have a colonial status, including Puerto Rico (U.S.), the Virgin Islands (U.S. and U.K.), Martinique, Guadeloupe (France), Sint Maarten (Netherlands)/Saint-Martin (France), Aruba, Curaçao, Bonaire, Saba, and Sint Eustatius (Netherlands); and there are commonwealth countries such as Jamaica, and Trinidad and Tobago.

Currently, the common denominator in all Caribbean countries, from a political standpoint, is the influence of the United States in its intervention in the internal affairs and destinies of these countries. The Spanish-American War, supported by the Monroe Doctrine, marks a point of

departure for the United States' interventionist policies in the region: the status of Puerto Rico and the U.S. Virgin Islands as self-governing unincorporated territories; the Platt Amendment in Cuba up to 1905; the invasions of Haiti (1916–1932), the Dominican Republic (1916–1924, 1965–1966), and Grenada (1973, 1983); and support for Caribbean dictators Trujillo in the Dominican Republic and Papa Doc and Baby Doc Duvalier in Haiti.

With 40 million inhabitants, the Caribbean region's most pressing political agenda should be the formation of a self-sufficient Caribbean Economic Community, with which, by means of an open market, residents of each island could supply the others with products they do not produce themselves (Knight, personal communication, July 2007). If Eugenio María de Hostos's dreamed-of Antillean Confederation or the Caribbean Commonwealth has been a failure, then it is possibly the result of their cultural and political emphases to the detriment of economic affairs. Obviously, obstacles such as the dependence of colonies on the mother country and neocolonial relations with the United States persist.

Caribbean culture finds itself in a process of change much more rapid than previously experienced as a consequence of the emigration of Caribbeans to and return from hegemonic centers, which impacts their respective cultures when they bring back other habits, customs, values, and so forth. Although immigration and so-called globalization are not new phenomena in the Caribbean, the current process of transculturation is much more accelerated than that of 50 or 100 years ago. A musical example is that of salsa, which came into being in New York among Dominican, Puerto Rican, and Cuban immigrants and returned to the Caribbean to become the national genre of Puerto Rico.

EUROPE

Past and Present

MICHAEL J. SIMONTON

Northern Kentucky University

Often European studies are considered to be within the province of history, sociology, art, or political science—certainly not anthropology. But as early as the 1920s, Robert Redfield's student, Charlotte Gower Chapman, conducted a community study in Sicily. Some of the classic ethnographies in anthropology were conducted in Europe. Indeed, one of the seminal community studies was conducted by Conrad M. Arensberg and Solon T. Kimball in Ireland in the 1930s, published in 1941 as *Family and Community in Ireland* (1941/1974) and as Arensberg's *The Irish Countryman* (1937/1968), still is in print and is used as a teaching ethnography today. We would argue that the European culture area is as worthy of study as any other culture area, and this is especially so as the foci of anthropological studies have changed since World War II from isolated, technologically and politically simple societies to more urban and interethnic cultures. With as many anthropologists who study behaviors in the modern United States of America as there are today, it is illogical to hold on to the belief that anthropologists should not study Europe as well.

Of course some sources will be left out of a chapter such as this, and some may question the sources chosen to be included. To the students of Europe, we apologize; not everything could be included in a reference source such as this, and we have chosen to include those topics that we knew better than others. We hope that no one will feel slighted by this entry and that the choices made for

inclusion or exclusion will not be taken personally by any authors or other scholars.

What Is European Ethnography?

This chapter explores the ethnography of Europe. Ethnography comes from two Greek words, *ethnos* (εθνος), a group of people; and *graphos* (γραφησ), to write. Thus, ethnography is writing about a group of people—in this instance people in Europe. There is a prejudice in anthropology against European studies: Susan Parman (2005) wrote that some scholars consider the anthropology of Europe to be a self-contradictory phrase, that anthropologists are supposed to study “the other,” that is, Tibetan nomads or people in leopard skins; to study Europe, she wrote, is considered problematic. Parman wryly has quoted John C. Messenger Jr.'s assertion that Europeanists sometimes are considered people who study those with particularly interesting local vintages. Nonetheless, Europe is as worthy a province of anthropological research as any other culture area, and just because one has studied what Robert Redfield called “the great tradition” of Europe in school does not mean that he or she has the least familiarity with the various little traditions extant in Europe—such as those in Inis Beag, Kippel, Vasilika, Locorotondo, Hal-Farrug, or Cairn, any more than having taken a Spanish language class and visited Mexico city automatically

makes one familiar with rural Tarascan or Zapotec folk culture on the western side of the Atlantic.

Origins of European Anthropology

Were we to situate the origins of Western civilization with the ancient Greeks (more accurately referred to as Hellenes, as many of them actually lived in Asia Minor) and Romans, then we might describe “the other” of their day as “non-Western”—even though quite a few descendants of those “others” claim to be the heirs of their ancestors’ early Western enemies. That is to say, if we consider the origins of Western civilization to be the Greeks and Romans, then their contemporary transalpine peoples may be considered non-Western (and suitable for anthropological study even to “purists”). Descriptions of these early European “others” can be found at least as early as the fourth century BCE in the writings of Pytheas of Marseille, who may have traveled as far north as Iceland and east to Jutland and perhaps into the Baltic.

Other early authors who provided ethnographic descriptions of the northern peoples would include Xenophon, Pliny, Diodorus Siculus, Caesar, Strabo, Posidonius, and Tacitus, to name but a few of the better-known writers of the classical era. Although these descriptions sometimes are muddled or colored by war propaganda, they constitute some of the earliest ethnographic descriptions of non-Mediterranean Europeans. Later, medieval Arab travelers and geographers, such as Ibn Battuta, al Idrisi, and Ibn Khaldun, best known for their descriptions of life in Africa and south and west Asia, also explored southern and eastern Europe, and it is from them that we get an etic (outsider’s) perspective on European ethnography prior to the Renaissance. Some northern authors, such as Geraldus Cambrensis (Gerald of Wales) also made cultural observations during that period.

Late in the 18th century (1786), an Englishman, Sir William James, was attempting to translate ancient Indian Hindu religious texts from the ancient, holy language Sanskrit into English when he noticed Sanskrit’s similarity to ancient Greek and Latin—for example, in Sanskrit the divine father is *Dis Patir*, while in Latin it is *Deus Pater*. These similar words with similar meanings, but in different languages, became known as *cognates*, and they imply a common derivation for the languages. Thus, the Indo-European language family was discovered. Some of the larger and better known members of the Indo-European language family as it is found in Europe today include the Celtic branch (Irish Gaelic, Scots Gaelic, and Manx in the Goidelic subfamily, and Welsh, Breton, and restored Cornish in the Brythonic subfamily); the Italic, or Romance, branch (Italian, Spanish, Portuguese, French, and Romanian); the Germanic branch (High German, Low German, Yiddish, Swabian, Dutch, English, Danish, Swedish, Norwegian, and Icelandic; although geographically Iceland is not part of Europe,

Anderson [1971] included it culturally); Greek; and the Balto-Slavic branch (Russian, Polish, Czech, Serbo-Croatian, Lithuanian, and Latvian). Some smaller groups would include Romani and Basque; the latter is a linguistic isolate found in the Pyrenees border region between Spain and France that may have its origins in the late Pleistocene. In 1818, 32 years after James’s discovery, Rasmus Rask painstakingly compared the grammatical structures of the languages of Scandinavia. In 1822, folklorist Jakob Grimm (who, with his brother, Wilhelm, is best known for collecting and collating *Grimm’s Fairy Tales*) developed a set of laws to show how shifts in phonemes occur regularly between related languages. With these developments, historical linguistics was born, and research since has pinpointed the origins of the Indo-European language family to be in either the southeastern Ukraine or in eastern Turkey.

In the mid-19th century, writers such as Herbert Spencer and Sir Edward Burnett Tylor tried to explain society and social differences more scientifically and less philosophically. Indeed, Marvin Harris, in his *The Rise of Anthropological Theory* (1968), cited Spencer’s *Descriptive Sociology*, which laid out a design for the collection of ethnographic data, as the forerunner of the Royal Anthropological Institute’s classic field research guide, *Notes and Queries on Anthropology*. Despite their pioneering work, Harris argues that racial determinism was the form in which the culture sciences emerged from the industrial capitalism of the 19th century, an unfortunate offshoot of which persisted into the 20th century in the form of Nazism’s polemic arguments for the development of a “master race.”

One comes away from the late 19th- and early 20th-century authors with the impression that, although some wrote about life in Europe, they wrote about Europeans as a hypothetical control group to compare with non-Western cultures about which they had collected data. Nonetheless, in 1908, Belgian theorist Arnold van Gennep published *Les Rites des Passages*, in which he compared the rites and ceremonies of Europeans to those of non-Western cultures to determine what constitutes the patterns of liminal passages between the various stages of life. Van Gennep cited the authors of various ethnographic studies of extant societies around the world, including Europe.

However, in *Sex and Repression in Savage Society*, Bronislaw Malinowski, the father of participant observation, took Sigmund Freud to task for just such armchair theorizing in Freud’s 1914 *Totem and Taboo*, for which the 19th-century early evolutionists, such as Spencer and Tylor, were accused. Following Freud’s successes in the psychoanalytic field, he had become interested in the relatively new discipline of anthropology. Freud wrote several papers, which were well received, but his *magnum opus* as an anthropologist was to be *Totem and Taboo*, in which he explained the origins of the incest taboo, the Oedipus complex, and totemism. Freud’s hypothetical control group of mid Europeans and his presentation of a hypothetical

parricide within the primal horde (a term he borrowed from Charles Darwin) as facts led the anthropology community to become disenchanted with him. Yet Malinowski himself compared his ethnographic data on the Trobriand Islanders to just such a hypothetically described mid-European culture in his critique.

Also, prior to World War I, Swiss linguist Ferdinand de Saussure began to view the functional meaning of language as a synchronic system (*la langue*) separate from its changing, diachronic usages in speech (*la parole*), and he began his search for the underlying rules and grammar that form the unconscious “deep structure” of the language. Saussure broke up language into *phonemes* (sounds), which can be combined to generate *monemes* (words) that signify concepts. What allows this system to operate is the pairing of opposites, or *binary oppositions*. Saussure’s binary paradigm was used by Roman Jakobson of the Prague School of Linguistics in studies of the linguistic consequences of brain damage.

Development of European Anthropology

Physical Anthropology

Physical anthropology in the early 20th century was heavily concerned with osteometry, anthropometry, and the establishment of racial categories. Some notable figures conducted other types of research, such as Hungarian psychological anthropologist Geza Roheim, who made early laboratory ventures into primate studies, but by and large the determination of racial physical types was the order of the day. Franz Boas attempted to dispel the prevailing ideas about race at that time by demonstrating that, among Europeans, the supposedly long-headed (dolichocephalic) Mediterranean race and the supposedly round-headed (brachicephalic) Alpine race could occur within the same biological family, depending upon whether one were born in Europe or North America. Boas (1940) measured the cephalic index (the width of the head at its broadest point divided by the length of the head at its longest point, multiplied by 100) of Jewish immigrants from Europe, and then he compared them to the same measurements from their children who had been born in America. Boas found the European parents to be members of the Mediterranean race and their American children to be members of the Alpine race. Boas claimed that the differences were based on diet, not race, and he believed that he had disproven the claims about various races in Europe.

Nonetheless, the anthropometry of racial categorization continued. One of the more prominent proponents of this type of racial anthropology was Carlton Coon, who studied under Earnest Albert Hooton at Harvard. In 1929 and 1930, Coon conducted a study of Albanians that laid the groundwork for a number of his later works, such as his 1939 opus, *The Races of Europe*. Racial categorization was abused in

the 1940s and rapidly fell out favor following the Nazi atrocities of World War II. In 1951, this led Sherwood L. Washburn to call for an end to racial categorization in his proposition for a “new physical anthropology” that concentrated on genetics, primate studies, and fossil evidence.

Sociocultural Anthropology

Some of the earliest modern ethnographic research conducted in Europe was done by Alfred Haddon in Ireland in 1892, after the first Torres Straits expedition. Haddon also included anthropometric research in his study. Earnest Hooton and Wesley Dupertius also conducted anthropometric studies in Ireland in 1932 as part of Harvard University’s anthropological survey of Ireland. Two other young Harvard anthropologists were involved to conduct an ethnographic account of Ireland: Conrad M. Arensberg and Solon T. Kimball. Arensberg’s and Kimball’s pioneering work had its inception when they both served as research assistants under W. Lloyd Warner in his American community study of “Yankee City” (Newburyport, Massachusetts). Warner then accompanied Arensberg to Ireland in 1932, but left to be replaced by Kimball. Arensberg’s and Kimball’s *Family and Community in Ireland* is considered by many to be a foundation work not only in community studies but also in the ethnography of Europe. Indeed, Thomas M. Wilson, the current president of the Society for the Anthropology of Europe, refers to it in several of his works as a “sacred text,” to which other contemporary authors (especially those writing about Irish culture) feel compelled to measure their own work seven decades later.

Arensberg and Kimball conducted their study less as cultural anthropologists and more as social anthropologists in the tradition of Alfred Reginald Radcliffe-Brown, who had influenced Warner and whose structural-functionalism heavily influenced their work. Among their main contributions were their observations about the “stem family” and how rural inheritance patterns were integrated with marriage patterns, family structure, emigration, and careers. (Because of impartible inheritance and arranged marriages, some offspring never could marry and, thus, were stems off the family tree that never would bear fruit unless they left their rural homes.) The National University of Ireland-Galway recently (2001) published a third edition of *Family and Community in Ireland*, sponsored by the Social Science Research Council, with a major introduction by Anne Byrne, Ricca Edmondson, and Tony Varley. Anne Byrne also recorded the reactions of Arensberg’s and Kimball’s key respondents’ descendants to her reading to them of Arensberg’s actual field notes (Byrne, 2006).

World War I

During World War I, some American anthropologists were believed to have acted on the behalf of espionage

agencies to spy on German citizens in Central America (the reader may recall that this was the era of the Zimmerman telegram, which exhorted Mexico to invade the United States on behalf of Germany). This group of anthropologists is believed to have included Arthur Carpenter, Thomas Gann, John Held, Samuel Lothrop, Sylvanus Morley, and Herbert Spinden, according to David H. Price (2001).

In reaction to the alleged espionage against German citizens by American anthropologists, Franz Boas, the father of American Anthropology, who himself had immigrated to the United States from Germany, wrote a letter to *The Nation* in 1919 condemning four unnamed anthropologists for spying. In reaction to Boas's letter, the American Anthropological Association voted to censure Boas that same year. Price quotes a letter from Leslie Spier that indicates that although Boas was sympathetic to Germany, he believed both sides to be mutually culpable and mutually justified in the war. Spier argued that Boas's motivations were in the interests of disinterested (not necessarily uninterested) science, not "Germanophilism."

World War II

World War II halted much of the ethnographic work in the European theatre that had been begun in the previous decades, but certain studies continued under the leadership of Margaret Mead. During the war, much ethnographic work was virtually impossible because of political restrictions and actual danger, but under Mead a group of anthropologists and other social scientists served as part of the U.S. war effort in the Office of Strategic Services, the forerunner of the Central Intelligence Agency on the Culture at a Distance national character project. Mead (who, herself, was married to an Englishman—the anthropologist Gregory Bateson) had conducted a study to determine why there were so many shotgun weddings between American servicemen stationed in Britain and young Englishwomen who lived near the military bases. She determined that, despite a common language and the former British colonial status of the United States, the two nations were, in fact, two very different people, and that what the American boy took to be lighthearted playfulness, the English girl took to be a proposal of marriage. Lectures were given and town meetings were held that helped to avert what could have turned into a very unpleasant international incident with the United States' closest ally. The Office of Strategic Services was so impressed by Mead's handling of the situation that she was put in charge of the national character project that was to help the United States work more effectively with its allies and learn its enemies' weaknesses in order to defeat them. Mead led Conrad Arensberg, Sula Benet, Ruth Benedict, Rhoda Métraux, David Rodnick, Geoffrey Gorer, and John Rickman, among others in the assignment.

Because of the war, ethnographic data were gathered on the cultures to be described by reading novels, magazines,

and newspapers; watching popular films; and interviewing diplomats, merchants, military personnel, recent immigrants, and prisoners of war from the cultures in question. Among the studies relevant to the ethnography of Europe, Conrad Arensberg described the culture of east European Jews, and Sula Benet wrote about Poland; in 1951 she published her work as *Song, Dance, and Customs of Peasant Poland* (1951/1996). Ruth Benedict researched Rumanian culture. Rhoda Métraux described France and later collaborated with Mead on *Themes in French Culture* (1954). David Rodnick was assigned Czechoslovakia. Geoffrey Gorer studied France and Great Russia with John Rickman, and their study (1962) resulted in the controversial "swaddling hypothesis," in which, to put it colloquially, the Russians were "wrapped too tightly" (psychologically) as adults because they were wrapped too tightly (literally) as infants. Gorer and Rickman collaborated on *The People of Great Russia* in 1948. The description and some of the results of their projects were published by Mead and Métraux after the war as *The Study of Culture at a Distance* (1953). The national character approach to ethnography began to fall out of favor in anthropology by the 1960s, when it began to be seen as prejudicial.

Mid-20th Century

In the mid-20th century, French anthropologist Claude Lévi-Strauss, influenced by the linguists Saussure and Jakobson, produced anthropological structuralism, in which he provided a model of the human mind (*not* the biological organ, the brain) based on binary oppositions. He also was influenced by binary computer codes. Lévi-Strauss believed this to be a universal organizing system based on linguistic thought input. Thus, "primitive" thought is not primitive at all, but is based on the same set of logic as is "civilized" thought, leading Lévi-Strauss to reject Eurocentric interpretations of non-European cultures and mental statuses.

Post–World War II

The post–World War II era also brought a rise in the number of anthropologists, thanks in part to so many people in uniform having seen parts of the world that they never would have hoped to see before, and to the GI Bill, which afforded them the chance to earn a university education. It was in this period that more ethnographies of the folk cultures of Europe began to appear. One should note that for the most part these are the product of North American and British authors. One reason for this is that ethnographic research in European folk communities tends to be the domain of folklore specialists in Europe, rather than anthropologists. Hungarian ethnographer Tamás Hofer's 1968 article in *Current Anthropology* makes the case that, in Europe, scholars who study European folk societies are considered very different from those who study folk societies in non-Western cultures, and he quotes no less a figure than Claude Lévi-Strauss (1966),

who asserted that anthropology is a science that sees cultures from the outside. (As contradictions to this view, one might point out the work of Igbo anthropologist Victor C. Uchendu and Kikuyu anthropologist Jomo Kenyatta, or Chinese anthropologist Martin C. Yang.) The European looks at the historical process of folk ethnography on a national scale, not the deep ethnography of a single community in the American tradition, other than when it has been practiced by local, amateur scholars. Robert T. Anderson argued in his 1973 *Modern Europe: An Anthropological Perspective* that, in the 1950s, anthropological literature on contemporary European cultures was so sparse that “it could be covered in a month or so” (p. 3).

Susan Parman composed a list of some of the classic English language articles and chapters relevant to European anthropology as part of her groundwork for a session titled “American Perspectives in the History of the Anthropology of Europe” at the 1994 national meetings of the American Anthropological Association held in Atlanta and for the benefit of the Society for the Anthropology of Europe. She chose articles and chapters that she deemed “to illustrate the history, paradigmatic shifts, cultural context, and future of the anthropology of Europe.” (Parman’s list is available from the SAE’s Web site on H-net at <http://www.h-net.org/~sae/bibs/parmpick.html>.) Although Parman suggested a rather lengthy list, those items relevant to the 1950s were J. A. Barnes’ 1954 *Class and Committees in a Norwegian Island Parish*, E. Estyn Evans’s 1956 *The Ecology of Peasant Life in Western Europe* (although, we note, Evans was a geographer, not an anthropologist), Charles H. Lange’s 1957 *Acculturation in the Context of Selected New and Old World Peasant Cultures*, Julian Pitt-Rivers’s 1958 *Ritual Kinship in Spain*, and Robert Redfield and Milton B. Singer’s 1954 *The Cultural Role of Cities*. Ronald Frankenberg suggested that classic monographs also should be included in the list, such as his 1957 *Village on the Border* and his 1965 *Communities in Britain*, a suggestion seconded by Anthony Galt. We would add Lawrence Wylie’s 1957 monograph, *Village in the Vauchuse*.

In the 1960s, ethnographic monographs on the European culture area began to become more common. The author of this entry suggests that some of the classic ethnographies of Europe were produced during this decade, including Julian A. Pitt-Rivers’s *The People of the Sierra*, published in 1961. East European peasant conferences also were held during the 1960s and 1970s. It was during the 1960s that George and Louise Spindler became the editors of a monumental ethnography project that was published by Holt, Rinehart and Winston (many of their titles were republished by Waveland Press in the 1980s and 1990s and republished again by Thomson Wadsworth in the 2000s). The Spindlers’ project involved the publication of a series of ethnographies from dozens of authors, including such classroom classics as Joel Martin Halpern and Barbara K. Halpern’s 1967 *A Serbian Village in Historical Perspective*, Ernestine

Friedl’s 1967 monograph *Vasilika: A Village in Modern Greece*, Jeremy F. Boissevain’s 1969 *Hal-Farrug: A Village in Malta*, and John C. Messenger Jr.’s 1969 *Inis Beag: Isle of Ireland*.

The 1970s continued this trend with Hugh Brody’s 1973 *Inishkillane: Change and Decline in the West of Ireland*, John Friedl’s 1974 *Kippel: A Changing Village in the Alps*, Robin Fox’s 1978 *The Tory Islanders: A People of the Celtic Fringe*, and Nancy Scheper-Hughes’ 1979 *Saints, Scholars, and Schizophrenics: Mental Illness in Rural Ireland*. It was during this decade that Europeanist anthropologists began to concentrate less on the harmonious, traditional nature of European folk societies that guided Arensberg and Kimball’s functionalist portrait of Luogh, County Clare, and more on the changing nature of European folk culture and the dysfunctional fit of the old ways with the late 20th-century world. This was the decade of Margaret Mead’s 1970 *Culture and Commitment: A Study of the Generation Gap*, in which she argued that at no other time in human history could one know almost instantly what was taking place on the other side of the world. Mead wrote that this led to a gap in the way that people born before and after World War II experienced history and that younger people of the late 20th century—on a worldwide level—were more aware of what was going on the other side of the globe than their parents may have been aware of what was going on in the next country. Thus the old ways of life seemed dysfunctional in the changing world—including in the rural cultures of modern Europe.

The 1970s also included two classic survey works by Robert T. Anderson, who, with his then wife, Barbara Gallatin Anderson, had conducted field research in both Denmark and France. (The Danish experiences were humorously described in her 1990 book, *First Fieldwork: The Misadventures of an Anthropologist*.) Robert Anderson’s surveys were *Traditional Europe: A Study in Anthropology and History* (1971) and *Modern Europe: An Anthropological Perspective* (1973). In *Modern Europe*, Anderson argues that European subsistence-farming peasants had become market-oriented commercial farmers over the previous century and that many elements of the transformation were the result of a “silent revolution” brought about by the new availability of mass-produced goods and the new ability to purchase them. Anthony Galt recurred to this theme in his 1990 case study, *Town and Country in Locorotondo*, the research for which was completed in the 1970s and early 1980s. Galt credits the availability of construction and manufacturing jobs during the rebuilding of Europe with having transformed occupational, social, residential, and domestic life in rural southern Italy.

The Late 20th Century and the Society for the Anthropology of Europe

According to current Society for the Anthropology of Europe president, Thomas M. Wilson, and the former editor

of *MAN*, Hastings Donnan, in their comprehensive survey text, *The Anthropology of Ireland*, anthropologists and other social scientists began to influence government policies in the late 1980s in the Republic of Ireland by way of economic and social partnerships with the government. As noted above with regard to Conrad Arensberg, Solon Kimball, John Messenger, and Nancy Scheper-Hughes, anthropology had been the province of nonnative researchers, frequently North Americans, who analyzed remote rural populations. The change from this pattern to that of the late 1980s makes the input of anthropologists into government policy a noteworthy contribution that helped to forge the “Celtic Tiger” economy prior to the recession of the late 2000s. Now anthropologists are assisting the Irish government to understand and deal with divergent cultures following the influx of new ethnic minorities—especially Poles, Latvians, and Nigerians—and American-trained anthropologists, such as Chris Curtin at the National University of Ireland, Galway, are heading up social science departments in the country.

In 1986, the Society for the Anthropology of Europe (SAE) was envisaged as a section of the American Anthropological Association. An organizing letter went out to colleagues stating the purposes of the organization, including (among other things, according to the SAE’s Web site on H-net) the enhancement of the visibility and legitimacy of Europeanist anthropology and reinforcement of a set of national and international connections among Europeanists. In the fall of 1987, SAE’s organizers held their first elections. Susan Carol Rogers was the founder and served as the first president of SAE. James Taggart served as the first SAE program chair, in 1986 and 1987. At the 1986 breakfast roundtable that Taggart led, Stanley Brandes spoke on “Religion, Folklore and Ideology”; John W. Cole addressed “Class, Culture and Political Economy”; Ernestine Friedl discussed “Sex and Gender”; Jane Schneider looked at “Historiography and Anthropology”; and Katherine M. Verdery talked about what was to become a major topic in the news in the following decades: “Ethnicity and Regionalism.” Taggart was followed by William Douglas in 1988 and by Linda Bennett in 1989. The 1989 inaugural Distinguished Lecture was presented by Ernest Gellner and was titled “The European Roots of British Anthropology.” The previous year had had no Distinguished Lecture but rather several major addresses, including one by Carlo Ginsberg titled “The Inquisitor as Anthropologist” and another by Laurence Stone titled “Money, Sex, and Murder in 18th Century England: A Story and Its Meaning.” Further breakfast roundtables followed in 1987, 1988, and 1989 with participants whose names form a “Who’s Who” of Europeanist anthropologists, including, among others, Ruth Behar, Linda Bennett, George Saunders, Nancy Scheper-Hughes, and Jeremy Boissevain.

The 1990 SAE program chair was Ellen Badone, known for her 1989 study of Breton death imagery, *The Appointed Hour: Death, Worldview, and Social Change in Brittany*.

The 1990s continued the SAE tradition of Distinguished Lectures and breakfast roundtables. The 1990 breakfast was led by Lawrence Taylor, known for his studies of Catholicism and salmon fishing culture in County Donegal, Ireland, but the topics shifted to the changing, post-Communist Europe with Katherine Verdery’s presentation titled “National and Ethnic Issues in the Eastern European ‘Transition to Democracy’” and to migration within the continent with Caroline Brettell, known for her study of illegal Portuguese immigration in France (*We Have Already Cried Many Tears*), speaking on *Migration in Europe*. Brettell also served as president of the SAE in the mid-1990s, and she was followed by Peter Allen in the later 1990s. In the 1990s, the focus also shifted to southern and eastern Europe, where rapid political changes made for rapid social and cultural changes, and in his 1998 presidential address, Peter Allen commented not only on the influence of Brown University scholars on the SAE but on how many of them were Greek or other Mediterranean specialists, including former SAE presidents Michael Herzfeld and Jill Dubisch. Allen then pointed out that, since the fall of the Iron Curtain, it was time to consider a merger of the SAE with the East European Anthropology Group in light of contemporary political realities.

Other topics in the 1990s were the new nationalism in Europe, political activism, the reemergence of a European Right, the rise of the supranational European Union (EU), the location of the boundaries of the European culture area, and east-west differences within the culture area—if it even existed. During this period several authors, including John Messenger, Ernestine Friedl, George and Sharon Gmelch, Joel Halpern and Barbara Kerewsky Halpern, Susan Carol Rogers, Nadia Seremetakis, Regina Bendix, Susan Parman, Caroline Brettell, and Stanley Brandes allowed their fieldwork slides to be reproduced for sale to members to be used for pedagogical purposes, a practice which, sadly, ended in 2005.

In what we consider to be one of the most important statements on the anthropology of Europe in the last decade—Susan Parman’s lengthy 2000 presidential address to the SAE at its meeting in San Francisco—Parman reaffirmed the organization’s commitment to a four-field approach to the anthropology of Europe. In her address, Parman pointed out that anthropologists are willing to discuss issues and ethnic groups that frequently are ignored by practitioners of other disciplines, such as historians, political scientists, and economists. She cited a 1973 text by geographer Terry Jordan, *The European Culture Area*, in which Jordan referred to the European culture area as though it were a homogenous, Christian, Caucasian conclave of healthy, well-educated urbanites (an image that some Europeanists have to battle with within the ranks of American anthropology itself) and ignored the Jews, Gypsies, Turks, and Muslims who also were responsible for creating what we see as the Europe of today.

Now these other groups are being studied in the four-field manner peculiar to American anthropology that includes archaeology, biological anthropology, cultural anthropology or ethnology, and linguistics, along with its (ironic for a four-field approach) “singular way” to study Europe. Archaeologically, we can gain a perspective on the relatively late emergence of Europe as an important player on the world scene. The author of this entry suspects that this is a perspective that may be lacking in the other disciplines noted at the beginning of this paragraph. Biologically, anthropology can dispel unsubstantiated beliefs in racial superiority. In Parman’s own words, the “American anthropology of Europe has tended to focus less on race and place and more on understanding centers of power that generate identities.” With regard to linguistics, she notes the irony that now English is becoming Europe’s new *lingua franca*. (One recalls John Messenger’s lectures in graduate school in the late 1970s, when he would comment on the near universality of English usage in Denmark at the expense of Danish.) Finally, Parman argues, the American cultural perspective’s tradition of pragmatism and empiricism, as revealed in ethnography, allows the ethnographer to describe cultural fact, while it allows the readers to come to their own conclusions. This four-field ethnographic pragmatism, Parman maintains, is distinctively American and contrasts with European theoreticism. It is for this reason that we have concentrated on the American perspective in European ethnography in this entry.

We would note, also, the role of American biological anthropology and archaeology in uncovering and demonstrating instances of ethnic cleansing in Europe. Following the Balkan tragedies of the 1990s, forensic anthropologists and archaeologists aided authorities in providing evidence of the reported genocidal atrocities in the former Yugoslavia. Jon Stereberg, a forensic archaeologist, has substantiated proof of gas attacks that occurred in 1992 from examinations of the victims’ clothing, while another forensic archaeologist, Clyde Collins Snow, has conducted research into Bosnian burials.

Anthropology of Europe in the 21st Century

In his 2002 SAE presidential address, David A. Kideckel, an Eastern Europeanist, described Europe as an “anthropological laboratory of globalization” because of the influx of Kurdish, Turkish, Vietnamese, Chinese, West Indians, and North Africans who were transforming the social and cultural landscape. Kideckel sees a European backlash (post-9/11) to strengthen its borders and cleanse its ethnicity concurrent with the expansion of the EU and waves of immigration, which we find to be analogous to the waves of European immigration to the Americas a century ago (see Ireland in the 1990s, above). Kideckel views this as a rich ground for study by anthropology, especially in the rapidly transforming states of Eastern Europe, and he believes that anthropology should be prepared to

prevent its misuse for purposes of nationalistic racism recurrent to the 1930s.

Likewise, Anastasia Karakasidou, SAE president from 2006 through 2008, concurs with Kideckel that an understanding of the globalizing events in Europe is key to understanding the changing theoretical orientations of anthropology. Thomas M. Wilson, known for his work in Ireland and with the meanings of borders, is the 2008–2010 president of the SAE.

European Ethnography Today

At the 2008 SAE roundtables at the American Anthropological Association meetings in San Francisco, the presentations included such diverse topics as Amy Ninetto’s “Intellectuals, Cosmopolitanism, and Internationalism in Europe,” in which she argued that intellectuals have been seen as the “culture producers” in the past but that now they are redefining what it means to be European from a cosmopolitan vantage point that may conflict with the perspectives of others. Jack Murphy’s “A Culture of Lawlessness? Juvenile Criminality in Europe Today” noted the rise in crimes committed by minors in Europe. Murphy examined two opposing perspectives on the problem: a “youth culture of criminality” and gang mentalities versus racial, ethnic, or class divisions in criminal behavior. Emanuela Guano discussed “Practicing Citizenship in Contemporary Europe” and how people steer their courses through the various entitlements and responsibilities that come with citizenship. Douglas Holmes explored the new identities that people are creating for themselves in Europe as the EU tries to be diverse in some ways, but homogenous in others at the same time. Levent Soysal surveyed European Difficulties, European Accolades with regard to the EU and its effect on the ethnography of Europe. Krisztina Fehervary looked at the explosion of communications technology in Eastern Europe and its creation of transnational communities in formerly isolated areas, as well as the transformation of our positions as ethnographers. This has been a constant theme in the teaching of the author of this encyclopedia entry—that through the use of the communications revolution (as well as with some “boots on the ground” familiarity with the culture in question) we are capable of conducting virtual ethnography in a 21st-century modification of Margaret Mead’s World War II Culture at a Distance project. We believe that this can have a transformative impact on the discipline of anthropology in this century.

Future Directions

Some of the areas for future research in European anthropology that might be considered would include the effects

of the current worldwide recession on the Celtic Tiger economy now that Ireland is seeing a return to the unemployment and economic implosion that characterized it in the past, and the effects of the recession on European unification—might there be a secessionary trend among some states that find themselves worse off now than before they joined the EU? How will the failure of the Lisbon treaty affect the balance of power when Brussels demands a new referendum in Ireland, the only country that could legally vote on it, despite Irish law? Other areas for investigation might include the economic transformation of the former Iron Curtain countries and the rise in racist ideologies with a return to the recessionary politics of ethnicity of the 1930s that the 1990s Balkan tragedies show us are not that far in the past.

Conclusion

This chapter has explored the subject of European ethnography as a subject of anthropology, rather than folklore, as it is done in Europe. The author chose to look at it from a historical angle so that the reader might develop a sense of the processes whereby the anthropology of Europe has come to the state in which we find it in the early 21st century. First we looked at a justification for an anthropology of Europe, which is every bit as worthy of investigation as other areas of the world.

A brief definition of ethnography was followed by a review of the origins of the ethnography of Europe in ancient and medieval times. The rise of Europeanism in anthropology in the 19th century was mainly from the viewpoint of biological anthropology and racial classification. This led to a consideration of the atrocities of World War II. In the 1930s, a major pioneering study was conducted in Ireland by Conrad M. Arensberg and Solon T. Kimball that became a standard for the measurement of other European ethnographies for the rest of the century. Margaret Mead's World War II Culture at a Distance project produced several ethnographies of the European culture area, and George and Louise Spindler's Case Studies in Anthropology series introduced several new generations of students to the ethnography of Europe. The segment on the later 20th century and the creation of the SAE led into the anthropology of Europe today and topics for future research.

INDIA

Past and Present

RAMDAS LAMB

University of Hawai'i at Manoa

“Sources” are always “texts,” it has been increasingly realized, and no text is “innocent.” It always embodies power relations and contains implicit principles or strategies of construction and deployment. (Sarkar, 1989, p. 4)

For over 2,000 years, Westerners have been traveling to India and returning with incredible tales of a mysterious and exotic land. Many of the early descriptions came from adventurers who were also splendid storytellers, fond of weaving fascinating and fantasy-filled accounts of their exploits and experiences. Since that time, a rich and varied fabric of narratives and interpretations has been stitched together to form the legacy of Indian studies. One of the most formidable tasks for one seeking to understand an academic survey of Indian history, culture, and religion is the investigation and comprehension of the various threads that constitute this creation, so that they may be more accurately used in any contemporary study of the land and her people. In this context, the path resembles that of the ancient Indian sages who filled their days seeking to discriminate the real from the unreal.

It must be remembered that the concept of objective recording and analysis by dispassionate observers, foundational in an academic study, is a relatively recent phenomenon, itself possessing a decidedly subjective quality. A serious reflection on both the process of humanities research and the psychological nature of humankind, however, makes it apparent that objectivity is an exceedingly

relative concept, existing more as an orientation than as an absolute. We all bring into our data collection, record keeping, and research not only our knowledge and understanding but also our preconceptions, preferences, and prejudices. These all play important roles in the processes of observation, information gathering, analysis, and interpretation. This is as true for the native informant as it is for the academic and the historian. Thus, the more we, as researchers, are able to understand the general predispositions that have led to what we accept as sources, the more clearly we can utilize them in our own work. In reflecting on his years of field research in India, Harold Gould notes that the observer is inevitably a “biased mechanism” whose perception is conditioned by personal and intellectual biases (Gould, 1974, p. 66).

Early Studies

India has an ancient and indigenous intellectual tradition, dating back to Vedic times. The earliest recorded accounts of the religious and social life in India come primarily from Brahmin and Buddhist scholars, each group having proffered a vast corpus of material covering a wide range of religious and secular topics. With the development of sectarian writings like the Puranas, the sectarian Upanishads, and the literature of the Tantric and the devotional schools, many additional viewpoints found their way into the

corpus of sacred literature. The composers of all these early works had distinct agendas that motivated their perspectives and guided their writings.

In addition to the indigenous material, a variety of accounts from foreign travelers and traders from the West and the East provide insight into and help create the groundwork on which anthropological research in India finds footing. Beginning in the centuries just prior to the first millennium CE, Greek and then Roman traders made their way to India and began to reflect in writing about the land and its people. The earliest of these may have been the Greek Megasthenes, who was an ambassador to Chandragupta Maurya in the early 3rd century BCE. Although only fragments of his book, *Indika*, survive, they reveal details about prevalent customs, beliefs, mythology, and even geography (Rowe, 1965). In the fifth century CE, Chinese Buddhist scholar Fa-Hien traveled to India and spent close to 15 years studying Buddhism and the other cultural and religious traditions. His writings provide insight into monastic lives during that time period. Two centuries later, the Buddhist monk Hiuen Tsiang also visited and spent nearly a decade and a half traveling in the subcontinent studying the people and their traditions. The writings of these travelers added to the corpus of early works of anthropological value.

In 1017, the Persian scholar and scientist Abu Rayhan Biruni (Al-Biruni) arrived in India with the conqueror Mahmud of Ghazni. Al-Biruni remained for more than a decade conducting ethnographic fieldwork. He was a prolific writer and has been called the first anthropologist because of the way he conducted his research. He learned several Indian languages, studied cultural and religious traditions, conducted participant observation of religious and ethnic groups, and recorded his findings and experiences in what he sought to be as unbiased a way as he could. His two books on India, especially *Ta'rikh al-Hind*, are considered important anthropological works that provide valuable insight into the social, religious, and political life of medieval India.

The year 1498 brought the arrival of Vasco da Gama in the southwestern coastal town of Calicut (Kozhikode). Within a few years, the Portuguese had established trade in India. Although Portuguese knowledge of the indigenous people's religion and culture was almost nonexistent, their feelings of animosity toward the Muslims in India were great, fueled by past interactions in Africa and the Mediterranean. This led to violent confrontations and the need for military support for Portuguese adventurism in India. Missionaries began to accompany the seafaring traders to convert Asian subjects, and the presence of the military helped make possible aggressive efforts at proselytizing as well. Thus, by the early part of the 16th century, Christianity, commerce, and colonial expansionism had become closely bound together in the European encounter with Asia (David, 1988). While European traders were successful in securing a great deal of Indian goods for the West, the early missionaries were not as prosperous. Francis Xavier, a Spanish Jesuit, arrived in the 1540s to

assist in the conversion efforts of the Portuguese. The church calls him the apostle of the Indies for his apparent leadership in establishing Christianity in India, yet he actually seems to have detested the land and her people. His stay there was relatively short because of the "un-Christian" ways of the Portuguese there and the Hindus' lack of interest in his religious wares. In a letter to Ignatius Loyola in 1548, he demeaned Indians as "very barbarous, vicious, and without inclination to virtue, no constancy of character, no frankness" (as quoted in Wolpert, 1979, p. 138). He left for Japan the following year, leaving the "heathens" to the efforts of others.

In 1583, a merchant named Ralph Fitch was one of the first Englishmen to make his way to India, and he wrote of his experiences in letters sent home. His descriptions were lively and interesting, and they helped stimulate British interest in the land. Unlike Xavier, Fitch found India possessing both goods and goodness, with a nonviolent but strange people who worshiped the cow and had hospitals for lame animals (Wolpert, 1979). Although he wrote as an outsider lacking insight into the existing culture, his views of the people and their ways nevertheless are far less clouded by the kinds of preconceptions and prejudices that distinguish other English writings of the colonial period.

During the next two centuries, additional European missionaries made their way to India. The Portuguese spread Catholicism, while Dutch missionaries brought Calvinism. Abraham Roger, one of the early Dutch missionaries, wrote reflections and observations of his time spent in India. His description of the caste system is presented from the traditional orthodox perspective; his informant was a *Brahmin*, a member of the priestly caste (Jackson, 1907). Many subsequent missionaries and ethnographers tell of encountering Brahmins anxious to give their perspective and interpretation of whatever the foreigners observed or sought to understand. When the narrow religious orientation and objectives of the missionaries were coupled with the narrow version of orthodox Hinduism to which the missionaries were exposed by these informants, an extremely limited view and understanding of prevalent beliefs and practices resulted. English-language writings by the British during the period depict Indian religious traditions as having no truth or viability. At best, they were seen as but forms of superstition and paganism. Many of these early writings focused on caste and its inequities, presenting Christianity and the missionaries as saviors of the impoverished and the low caste. At the same time, the racial prejudices of the authors are often blatant. These early works set the tenor for much of the subsequent literature that would be produced about India by westerners.

British East India Company

As religious, economic, and political interests in and designs for the subcontinent grew, so did the corpus of

literature. Simple reflections in the form of memoirs, written by travelers, British East India Company (“the Company”) workers, and missionaries gave way to more elaborate accounts, usually composed by scholars who served as administrators for the Company. These writings became additional sources for use in subsequent sociological and anthropological research that has occurred. The establishment of British suzerainty in India after 1757 generated an increasing administrative need for a better understanding of Indian social and religious structures. In the period from 1768 to 1771, Alexander Dow, an officer in the Company’s army, published a three-volume translation of *Tarikh-i-Firishta*, an early-17th-century Persian account of the history of Muslim India by Muhammad Kasim Hindu Shah, Firishta. In the introduction, Dow acknowledges the obvious prejudices against Hinduism in the original, yet his translation and commentary help perpetuate these very prejudices. He prefaces his work with two essays, in which he refers to the native as inclined “to insolence and ease; and he thinks the evils of despotism less severe than the labour of being free. . . . His happiness consists in a mere absence of misery” (Dow, 1772, p. vii).

There was already a developing interest in Sanskrit in England. In 1776, N. B. Halhed published a translation of the *Manusmriti*, an orthodox Hindu law book. His introduction expresses the belief that has come to handicap most subsequent writings on Hinduism, namely, that such Brahmanic texts provide an accurate picture of the religious customs, beliefs, and practices of the Indian people. Several years later, in 1784, a British linguist and lawyer, William Jones, started the Asiatic Society in Calcutta with the goal of promoting both greater research and greater understanding of Asian peoples, societies, and cultures. He was keenly interested in Sanskrit and comparative linguistics, and his efforts led to an increase in the number of Hindu texts being translated. At the same time, the British government, through the Company, was in control of the Bengal region of eastern India, and there was a conscious effort to collect both historical and ethnographic data on the newly conquered land. Henry Verelst, then governor of Bengal and Bihar, stressed the importance and need of gathering such information, especially with respect to leading families and their customs. British officials and missionaries were used for much of this work (Srinivas & Panini, 1973). In 1815, the Company began publishing a series of gazetteers that contained information on the various aspects of India and her people, including culture, agriculture, religious beliefs, castes, economics, and politics. The first one looked at the Bengal region and eastern India, while subsequent texts in the series focused on the various provinces and districts in the colony as well. The series was valuable to both the Company and the subsequent colonial government and was periodically expanded and updated over the next century or so. The last publication during British rule was a 25-volume work completed in 1933.

During the 18th and 19th centuries, the political and economic elite in the countries of Europe saw their right to rule their colonies as axiomatic. In this vein, Charles Grant, a director of the East India Company in the late 1700s and early 1800s, was a staunch supporter of the notion that India belonged to the British, who were justified in keeping it under their control at almost any cost. Like others after him, especially missionaries, he justified this attitude by promoting the idea that the British could surely “govern our Asiatic subjects more happily for them than they can be governed by themselves” (Embree, 1962, p. 143). The writings of Grant, an evangelical Christian, were instrumental in shaping the British attitude toward and involvement in India. In a report on Company affairs, for example, he inserted his evaluation of the people of India:

Upon the whole, then, we cannot avoid recognizing in the people of Hindostan, a race of men lamentably degenerate and base, retaining but a feeble sense of moral obligation, yet obstinate in their disregard of what they know to be right, governed by malevolent and licentious passions, strongly exemplifying the effects produced on society by great and general corruption of manners, and sunk in history by their vices. (Singer & Cohn, 1968, p. 8)¹

The more ignorant and decrepit the portrayal of Indians, the more Company and British authorities could justify the extension of their dominion over India’s land, people, and goods. Much of the ethnographic data collection of the time was done to further this goal. In the process, Indians were characterized as not only incompetent to meet their own needs, but even incapable of satisfactorily articulating them. Bernard Cohn divides the writings of the day into three general categories: the orientalist, the administrator, and the missionary.² As for their epistemological stance, he writes, “Each had a characteristic view, tied to the kinds of roles which foreign observers played in India and the assumptions which underlay their views of India” (Singer & Cohn, 1968, p. 6). Because of Grant and other Christians in the Company, it had been helpful to missionaries who had traveled to India, most of whom were armed with a strong social and religious revolutionary zeal but little formal education. Then, toward the end of the 18th century, British administrators came to be wary of missionary activities, since they seemed to be generating a resistance by Hindus toward Christianity and British government activities as well. Lord Minto, governor-general of India (1807–1813), had strong objections to the evangelists, noting that the written material they generated and used was filled with anti-Hindu rhetoric that condemned all Hindus to ignorance and damnation.

The 19th century was a pivotal time period in the development of anthropology as an academic discipline, which occurred in the environment and context of imperialism. Many of the early ethnographers in India functioned to further the hegemonic designs of both politicians and missionaries with their assumptions of superiority over the natives. The amassing of ethnographic material on

customs, beliefs, and habits of the tribes and castes required patience for detail but little in the way of scholarly insight, insider perspective, or respect for the people being studied. The phenomenological approach that came to be seen as integral in many subsequent anthropological studies was nonexistent here. Because so many of the scholars who visited and wrote about India were employed by the Company, this affected not only what data they collected but how it was interpreted. Most found the rituals and beliefs of the Hindu too alien to their own Judeo-Christian viewpoints and cultural conceptions to be seen as having any merit. The intended purposes of these observations and investigations were, after all, the forging of economic, political, and religious inroads, with the ultimate goal of establishing control. Empathetic understanding was hardly a consideration. European intellectuals of the time were being strongly influenced by the ideas of early 19th-century French social thinkers like Henri de Saint-Simon and Auguste Comte. Comte asserted that the evolution of human thinking and belief can be seen in theological conceptualizations, the lowest being animism, followed by polytheism and then monotheism, the highest. This provided the missionaries in India an intellectual rationalization to go along with their ideological rejection of indigenous beliefs. They found easy justification in setting about degrading such beliefs verbally and in writing without stopping to consider their context or the positive role they might play in the lives of the people.

Due to the efforts of Grant and other evangelicals, a clause in the passage of the Charter Act of 1813 gave missionaries even freer rein to proselytize in India. Information for the bulk of their early writings was gathered from converts, high-caste intellectuals, and urban Indians who had business or political connections with the foreigners. Data collectors seldom possessed any real knowledge of local languages, religion, or culture, and their information was almost entirely dependent upon the whim and agendas of their few English-speaking informants. By the latter part of the 1800s, the theories of Charles Darwin and Herbert Spencer on human and cultural evolution were becoming popular, and many of the ethnographers at the time saw themselves as observers of the behaviors of inferior primitive peoples. Although this general attitude was ameliorated to some extent by the end of the century, these earlier writings continued to be utilized as sources by many historians and anthropologists. Limited understanding of what was heard and observed contributed to conflicting interpretations and conclusions.

Interest in and travel to India by Europeans swelled throughout the 19th century. This was especially true of the British, who were drawn by their government's growing economic and political control of the subcontinent. The collection of writings and memoirs of India continued to grow as well, and in 1823, the Royal Asiatic Society of Great Britain and Ireland was founded by Henry Thomas Colebrooke as a British counterpart to the society started by Jones.

Colebrooke had worked for the Company for 32 years and had also served for 9 years as president of the Asiatic Society. The British counterpart soon began its annual *Journal of the Royal Asiatic Society (JRAS)*. It was initially devoted to publishing ethnographic and historical studies of all of Asia, although research on India tended to dominate in its pages. While several members of Asian royalty were made honorary members, only with rare exception did the work of any Asians appear in the journal's pages. This is because they were not generally seen as having the scholarly acumen or even the intellectual ability to add any meaningful insight to their own history or cultural traditions.

As the number of literate Indians who dealt with the English grew, many came to realize that, like the Muslims before them, the British wanted to acquire control not only of their economic and political life, but of their religious life as well. This caused an increasing number of Indians to look upon the British with the same disdain, resistance, and resentment they had long felt for their Muslim rulers. It led many to resist further attempts by the British to expand their data collection, and it also inspired a group of educated Indians in Bengal to begin to counter the British depiction of India with their own version. Ram Mohun Roy (1774–1833) was one of the early figures in this movement. He was an active writer, starting several newspapers and journals in Calcutta, and he inspired Bengali intellectuals to discuss and promote philosophy and theology to help counter British depictions of them and their traditions. In 1828, he founded the Brahma Sabha, which in time became the Brahma Samaj. The goals of the organization were the reformation of what Roy saw as degraded religious ritualism and the rekindling of pride in Hinduism among the young intelligentsia. Bengal had been the center of British intellectual activity in India, and it soon became the center of indigenous intellectualism, giving birth to the vast majority of Indian English language writers and scholars during the 19th and early part of the 20th centuries.

The Sepoy Mutiny of 1857 turned out to be a blessing in disguise for the missionaries and their efforts in India. During the preceding decades, the Company had generally sought impartiality with respect to religion, being more concerned with business. At the same time, however, the evangelical influence on the British government had been growing, and there was once again a move to send more missionaries to Christianize India. As a result of the 1857 conflict, the government stripped the Company of its control in India and took it over in the name of Queen Victoria. In her proclamation in 1858, she stated that, as good Christians, the British had “the right and desire to impose our convictions on any of our subjects” (David, 1988, p. 88).

Early Academic Studies

In 1871, the Royal Anthropological Institute of Great Britain and Ireland was formed, and it began publishing

Indian Antiquary (IA) the following year. The aim of this journal was slightly different from that of *JRAS*; it concentrated more on customs, rites, festivals, and other dimensions of religion and culture. Occasional text translations appeared as well, as did writings by some Indians. Nevertheless, both the *JRAS* and *IA* were European in sensibility and outlook, for even the infrequent indigenous author had usually been trained by western scholars and looked at India through westernized eyes. Throughout most of the 1800s, field research remained essentially in the form of ethnographic work on tribes, undertaken primarily by missionaries, travelers, and government officials, including military officers. Work not relevant to church or government had a more difficult time procuring sponsorship, and thus it was less likely to be undertaken.

Friedrich Max Muller, the famous German philologist and orientalist, began his Sacred Books of the East series in 1876, and this marked the first time there was a concerted effort to make Asian scriptures accessible to the English-speaking world. Muller drew on the groundwork laid by the earlier Western Sanskritists, bringing together some of their students and other translators to work on his series. Most of the translation efforts were focused on classical Brahmanic texts, and little or no attention was paid to the contemporary Hindu tradition. The translators were based primarily in Europe, and their understanding of the concepts of Hinduism came solely from what they found in the way of classical literature. The ethnographers in India, on the other hand, were largely unaware of India's literary heritage. While the translators found a storehouse of ancient literary and cultural achievements, the ethnographers continued to perceive a strange amalgamation of primitive peoples and superstitious idol worshippers.

Access to translated accounts of early Hindu life and society did, nevertheless, stimulate and influence the development of sociological studies of India. One of the first attempts to look at the accumulating knowledge about India and its social institutions from a comparative and theoretical perspective came in the late 19th century. Although Karl Marx made use of some of the available Indian material in his 1853 work, *On Colonialism*, it is Sir Henry Maine's *Village Communities in the East and West* (1871) that stands out as one of the original comparative works, approaching the subject using a sociological methodology. It was not until the 20th century that this approach became an integral part of Indian studies.

The establishment of textual studies resulted in the addition of an assortment of new perspectives with which to view the religions and cultures of India. This approach generally presented a more positive side of India to the Western world and had an influence in both India and the West. It gave those studying India, especially sociologists, access to material in which to search for the origins and history of Indian social institutions. Translated texts also found their way into the hands of European and American philosophers and writers, from

Madame Blavatsky (1831–1891), founder of the Theosophical Society, to Ralph Waldo Emerson (1802–1882) and Walt Whitman (1819–1892). They were drawn by what was perceived to be deep metaphysical truths hidden in ancient Hindu literature. Although much of the work that resulted may not generally be considered academic, nevertheless it has had a profound influence on Western perceptions of India, and it has long inspired many who have subsequently done extensive scholarly work on the land and its religious and cultural beliefs and practices.

Hinduism

Hinduism started to have a new face for the West, but it was, for the most part, the orthodox Hinduism of classical Sanskrit texts, not the popular religion of the rural and contemporary people. This changing view of Hinduism in the West encouraged many educated upper-caste Indians to become involved in Sanskrit studies as well and to help promote the view of India and Hinduism as presented by these texts. Writing on these developments, the well-known Indian sociologist M. N. Srinivas suggests that the “discovery of India's past, and the antiquity, richness and versatility of its heritage, gave self-confidence to the elite and the material necessary for national myth-making” (Srinivas & Panini, 1973, p. 184). He further notes that the missionaries' criticism of Hinduism and their conversion of the poor fed the nationalist sentiments of the upper-caste Hindu elite and encouraged efforts to counter British writings about their traditions.

Nearly all of the 19th-century writings by Hindus about their own society and culture were authored by Bengali Brahmin philosophers and Sanskritists, not by academic scholars. The purpose of their work was, for the most part, to present the Hindu tradition in a favorable light and to counter some of the earlier one-sided presentations by European missionaries and officials. During the late 1800s, Indians also began to add to the treasure chest of ethnographic and other academic writings on India. Their work started to appear in European journals and occasionally in book form. Ramachandra Ghosha's *History of Hindu Civilization: As Illustrated in the Vedas and Their Appendages* (1889) was one of the first of a long list of indigenously written academic texts on India. It combines scholarship with an orthodox Brahmanic perspective to depict an idealized version of the history of Indian society and religion. Several years later, Pramatha Nath Bose published the first volume of his four-volume *A History of Hindu Civilization During the British Rule*. In it, he includes data on contemporary aspects of caste, culture, religion, economics, and education. For the next three decades, the authors of nearly all such writings continued to be predominately Bengali Brahmins, although the works of some Brahmins from Western India and the South emerged as well.

During the latter part of the 19th century, the writings of British thinkers such as E. B. Tylor, James George Frazer, Charles Darwin, and Herbert Spencer were influencing the approach to ethnography and the development of anthropology in India. Their views were far more theoretical than empirical, and this approach was often used. Early ethnographers believed that if they spoke with representatives of the high caste and the orthodox, they would get an accurate picture of the culture. They also functioned under the assumption that scientific observation is sufficient to reveal the vital dimensions of another's culture. After all, the observers believed themselves to be of superior intellect and culture and thus capable of thoroughly understanding primitive peoples, as Indians were clearly believed to be. In the process, the ethnographers tended to ignore those whom Edwin Ardener calls the "muted" voices (Ardener, 1975).

In 1886, the first anthropological society in India was founded by Edward Tyrrel Leith in Bombay, boasting such members as D. Ibbetson, Sir Herbert Risley, William Crooke, and R. E. Enthoven. The approach of these field researchers extended beyond data collection and began to bring some aspects of phenomenology into their work. Although prejudices continued to color much of their view of the contemporary situation, these same writers were generally impressed with what they found in the Sanskrit texts. Compared with the missionaries, most of them were better educated, often in classical European languages, and from upper-class families in England. Coming from a hierarchical society in which they often resided near the top, they could relate to the social structure as depicted in the classical texts, seeing it as beneficial for maintaining stability. Their appreciation of these texts facilitated their acceptance of the Brahmanic version of the ideal society as valid. With the help of Brahmin pundits, they came to believe that the difference between the prevalent state of Hindu society and the idealized version in the texts was due to the degradation of the society, exacerbated by 1,000 years of foreign domination. In the process, these Indologists helped promote Brahmanic law as the law of the land, thinking that a return to this system would be more readily accepted by Indians and would also improve the society, making it more secure, smoothly functional, and easier to control.

20th-Century Studies

The 20th century brought an increase in the number of indigenous scholars making substantial contributions to Indian studies. They started their own professional associations with the aim of furthering indigenous scholarship and ethnographic work. In 1902, Satish Chandra Mukherjee founded the Dawn Society in Calcutta, which encouraged and published the work of young Bengali scholars. Four years later, the Bangiya Sahitya Parishad (Bengali Literary

Association) was started by the National Council of Education with the purpose of furthering ethnographic studies. Indian universities in Calcutta, Lucknow, and Bombay became centers of indigenous anthropological research and writings. The work of scholars such as G. S. Ghurye, R. K. Mukherjee, D. P. Mukherjee, and D. N. Majumdar stood out and became accepted as genuine and valid representations of insider perspectives. However, since they were all from urban high-caste backgrounds and were almost all Bengali, the picture of Hindu society they constructed continued to be dominated by Bengali and high-caste urban points of view. Indian academic journals adopted the basic format of their European counterparts, with the exception that contributors and perspective were urban high caste Hindu rather than European.

The University of Calcutta opened the first department of anthropology in the country in 1921. Three years later, B. S. Guha earned a doctorate in anthropology from Harvard University; he was the first Indian to obtain such a degree. Among the more significant archaeological discoveries in India is that of Harappa in the mid-1800s by Charles Masson and Alexander Burnes. However, the efforts of Rakhaldas Bandyopadhyay (aka Rakhaldas Banerjee), superintending archaeologist for the Archaeological Survey of India, led to the unearthing of Mohenjodaro in 1922, and this discovery not only allowed for a far greater understanding of ancient India and culture but also brought more attention to indigenous archaeology.

As mentioned earlier, the legacy of intellectualism and scholarship in India is quite old. Indian philosophers and scholars have traditionally come from the urban high caste, and their own orthodox religious and cultural values and viewpoints have nearly always set the parameters of such learning. With the introduction of Western-style academic scholarship to India, it too became another vehicle with which some perpetuated, in academic discourse, the orthodox view of India and Hinduism, especially with respect to history, religion, and the caste system. This is not to suggest that Brahmins have not been able to look at their own culture and tradition dispassionately, or that none has produced quality and insightful scholarship, for this is far from the case. Clearly, some of the foremost academic work on India has been done, and continues to be done, by Brahmin scholars. However, acknowledgment of their social and economic background and influences is important. The Subaltern Studies Series is a recent example of writings by Indian scholars with the intention of being "self-consciously and systematically critical of elitism in the field of South Asian studies" (Guha, 1984, p. vii). The various articles in the series raise some fundamental questions about the nature of much of the writing and history making in South Asia. Significantly, the majority of the series' contributors are Bengali Brahmins, although some work of non-Bengali Brahmins, other-caste Hindus, Muslims, and Western scholars can also be found in the series.

Because caste consciousness has been such an integral part of Indian society, it is deeply seated in the Hindu psyche. Its justification and defense have been fundamental parts of the cultural and religious indoctrination of most upper-caste Hindus, even many of those with a secular upbringing. As a consequence, their writings on the topic of caste have traditionally been closer to a form of orthodox apologetics than to objectively oriented research into and critique of the system. For an upper-caste scholar who maintains reverence for his religious and cultural traditions yet seeks to undertake scholarly research, a conflict inevitably arises that pits his socioreligious belief system against his academic training. This, no doubt, has the potential to circumscribe research perspectives and subsequent analyses. Thus, while much of the indigenous work done on caste prior to Indian independence was by Brahmins, it tended to be less fieldwork dependent and more textual in nature, relying heavily on the early Sanskrit writings to produce theories on the origin and historical development of caste that were consistent with the prevalent views of the social and religious elite. Little attention was given to direct empirical investigations, which would run the risk of putting high-caste scholars in close and direct contact with those considered low caste or untouchable (also known as *Harijan*, Scheduled Caste, or simply SC).

In the 1930s, the perspective of the low caste began to be revealed in written form. With the help of British laws and patronage, some *Shudra* (lowest of the “touchable” castes) and *Harijan* (the name used for bottom caste members by Mahatma Gandhi in place of “untouchable”) became educated and found employment privately or in government service. Dr. B. R. Ambedkar, the most renowned SC of the time, began writing his critique of Hindu society and religion, continuing to do so until his death in 1956. An intriguing and charismatic figure who fought caste inequities all his life, he converted to Buddhism just before his death. His writings are extremely critical of the Indian government, orthodox Hinduism, and especially of Mahatma Gandhi, whom he felt had a misguided approach to helping those of the lowest caste that did them more harm than good. Ambedkar’s writings present a dimension of Hindu society that most high-caste Hindus were, and continue to be, incapable of understanding or accepting (see *The Annihilation of Caste*, 1990, by Bhimrao Ambedkar).

By the 1940s, the interest of social anthropologists working in India grew to incorporate village studies in addition to their traditional work on tribes. The belief was that one could extrapolate from village studies theories that would shed light on ancient social and religious life. Sociological studies on caste were mostly historical and still undertaken, whether by foreigners or Brahmins, from a predominantly high-caste perspective. However, secularized Hindus from other castes were beginning to take part in academic studies and added to the compendium of

indigenous literature about India and Hindu life. The Anthropological Survey of India (ANSI) was founded in 1945. Its vision statement (ANSI, n.d.b) set as one of its primary goals “mapping the bio-cultural profile of Indian populations.” During its first several decades, ANSI supported and promoted research that tended to focus on tribal issues, especially beliefs, practices, and health-related issues (ANSI, n.d.a). By the 1960s, caste and clan studies, as well as genetics and archaeology, received increased attention from the organization. Since that time, research trends have changed somewhat, due in part to a variety of contemporary ethnic and political influences. Tribal and genetic studies have continued to be important to ANSI members, as is reflected in their publications.

Shortly after the founding of ANSI, the Department of Anthropology was established at the University of Delhi. Lucknow University followed suit within a few years. The latter department was begun by Majumdar with an emphasis on a scientific approach to research and intensive fieldwork-based ethnography and archaeology. Indigenous anthropology in India was gaining attention and status, and there were several notable scholars in the field. The department took its inspiration from them (Khare, 2008). Still, most anthropologists working on India were trained or influenced by the work of British and American anthropologists such as Bronislaw Malinowski, A. R. Radcliffe-Brown, E. E. Evans-Pritchard, Franz Boas, and Robert Redfield. All these figures had studied “others” and never used the tools to look at their own cultures and peoples, so the work of Indian anthropologists in India brought a new dynamic to the process. The post-Independence period saw the Indian government increase funding for indigenous research scholars, but at the same time it sought to influence the types of research done. This functioned to add another set of agendas to the construction of Indian studies and the reconstructing of Indian history. Whenever a government funds research by its own nationals, it can go a long way toward determining what topics are to be studied. In Independent India, this has often been the case (Barnes, 1982).

In 1951, Ghurye, who was head of the Department of Sociology at the University of Bombay, founded the Indian Sociological Society. It functioned to promote indigenous research within India. In much of the work in Indology done since Independence, authors have continued to depict the orthodox religion and its value system as the primary, if not sole, religious paradigm within Hinduism. One often wonders if some such researchers are even aware of the myriad sets of values, beliefs, and practices that are prevalent. India is a land of diverse value systems and religious traditions; each subcaste, ethnic group, religious sect, and region has its own unique formulation that mixes pan-Hindu, regional, ethnic, and caste elements.

In his discussion of the social dynamics of “center and periphery,” Edward Shils (1975) asserts that the majority of the population in most premodern societies has existed

outside the domain of direct influence of the orthodox value systems dominating their respective societies. Most people have maintained and functioned within their own sets of values, understood as the “periphery” by those in the “center.” Periodically and in certain situations, however, these popular sets of values may be expressed within the parameters of the central value system to give the values, or their espousers, a veneer of orthodox legitimacy. For the most part, however, a sharp distinction remains on the functional level.

This theory can be correctly applied to India, both historically and in modern times, and it makes clear the limitations of depending on the orthodox view of culture and society as an accurate interpretation of the lives of the masses. Because of the social and religious separation between themselves and the low castes, urban high-caste Hindus generally have a limited understanding of the complex and nuanced value systems that motivate most other Indians, namely the rural low caste and tribals. Instead, they tend to assume that most of the beliefs and behaviors of the rural majority are being generated from and are simply modifications of high-caste values. While it is apparent that some high-caste scholars have been successful in their efforts to bracket out their own “casteness” while performing field research, others have not, and some do not even attempt to do so. As in the case of the writings of 18th- and 19th-century Europeans, such biases do not negate the work done, but they do demand contextualization to put the studies into proper perspective. As has been observed, the social position of observers determines what they are likely to see (Vidich, 1970).

In a social hierarchy like that in India, the determinants are often very clear. Srinivas's own work reveals a great deal of caste-influenced myopia. He reluctantly acknowledges in *The Remembered Village* (1976) that his friends and informants were all upper-caste Hindus. Even then, he suggests that the views on the religious beliefs and practices about which he writes were likely shared by *Harijans* with whom he had admittedly never talked or even interacted (Srinivas, 1976). Unfortunately, this approach was more the rule than the exception. Louis Dumont, a well-known French social anthropologist who was also considered an authority on Indian society, wrote of the importance of learning from the people themselves which modes of thinking are appropriate for scholars to use in researching them (Dumont, 1970). The difficulty here is that the people from whom Dumont apparently gained his understanding seem to have all been members of the urban religious and secular elite. There is an ease with such an approach for those who seek validation of traditional preconceptions and those who find such views convenient when constructing orderly academic theories about Hinduism. Other scholars have rightly questioned this often-used methodology. The well-respected sociologist Triloki Nath Madan suggests that intellectuals must cultivate a “skeptical attitude” when attempting to utilize

“simple-minded” dichotomies and other theories to explain complex societies (Madan, 1982).

Conclusion

Since the mid-20th century, research on India has become a regular part of many anthropology programs in the West. Departments and programs focusing on Indian studies and South Asian studies have also been established, and anthropological research has played a fundamental role. Anthropology has become a prevalent academic topic in most larger Indian universities as well. Bachelors and masters of science courses and degrees are offered throughout the country. The various subfields in the discipline include prehistoric archaeology, physical anthropology, social anthropology, linguistics, and applied anthropology. Increasingly, Indian universities are holding conferences focusing on the various subfields, as well as on issues such as poverty, human rights, tribal studies, and caste studies.

Although teaching is one of the career paths for graduates, it is not a highly emphasized career in the country, and graduates instead tend to seek out employment in other fields. These include the government sector, both locally and nationally, in the areas of urban planning, tourism, cultural resource management, community development, public service programs, and rural and tribal development. Other less prevalent but occasionally available career options include museum work, documentary film making, or jobs with nongovernmental organizations working in underdeveloped areas of the country. Indian anthropologists have also found employment with international organizations like UNESCO, UNICEF, and WHO. Because both government and private sector organizations view assistance and development of target groups as their goals, training in applied anthropology reflects this approach. Government sponsorship is done with the expectation that ideas and approaches will be instituted to further government efforts in those directions.

Using the concept of applied anthropology, an increasing number of academics in the field now see themselves as social advocates and activists rather than simply observers. Although this has had positive results in many situations, it has also become the justification for some to take a less than objective approach to information gathering and presentation. Good scholarship is hampered when researchers use a “the ends justify the means” argument to overlook truth and accuracy in using academic writing to promote a favored cause, even when that cause is a positive and worthwhile one. Nevertheless, the research and writings that have been produced have contributed immensely to the ongoing examination of Indian society and culture. While the promotion of the Brahmanic perspective has generally died away, it has often been replaced at larger Indian universities by a Marxist orientation that tends to be

highly critical of not only the orthodox religious perspective but also the increasingly capitalist direction of India. This reflects the kind of orientation that has become prevalent in various Western university departments.

Coupled with the writings of orientalist, missionaries, and Indologists over the last several centuries, the aggregate of literary works that have been produced provides an abundance of perspectives and viewpoints from which to examine India and Indian studies. A fundamental portion of these writings is a direct product of ethnographic and anthropological research. The work of both Indian and Western scholars has increasingly shown an awareness of the need to use multiple techniques and perspectives in everything from the development of theoretical considerations to the collection, interpretation, analysis, and presentation of data. While such an approach is understood, it is still missing in much of what ultimately gets produced. Studies based on limited research and narrow perspectives and agendas, be they academic, religious, or political, have proven to be too myopic to grasp and express the diversity and subtleties that are inevitably existent in any people's social and religious belief systems, especially in a land as culturally and religiously varied as India. Nevertheless, if adequately contextualized, much of this work can have scholarly value and yield revealing insights. As Western scholars are able to set aside many of the traditional Western and academic preconceptions of India and Hinduism, and as Indians are able to set aside indigenous biases, these scholarly works will inevitably lead to a more genuine understanding of the land, her complexities and diversities, and her wonders.

Notes

1. This was originally an extract from *Report on East India Company Affairs* #14, General Appendix I (1833).

2. The category *orientalist* becomes subsumed in the 20th century under the term *Indologist*.

POLYNESIA

Past and Present

ROBERT BOLLT (1971–2010)

Honolulu, Hawai'i

In 1832, Captain Dumont d'Urville basically defined the term *Polynesia*, which is derived from the Greek words for “many” and “island.” It comprises the islands found within the “Polynesian Triangle,” with Hawai'i in the north Pacific, New Zealand in the southwest, and Easter Island (Rapa Nui) in the far southeast. This definition stood in opposition to Micronesia (little islands) and Melanesia (black islands, due to the dark skin color of its inhabitants). Polynesia is further subdivided into two regions, West Polynesia (Tonga, Samoa, Futuna, 'Uvea, and a few smaller islands) and East Polynesia, which includes the central archipelagoes of the Cooks, Australs, Societies, and Marquesas and the more isolated islands and archipelagos of Hawai'i, Easter Island, and New Zealand (far to the southwest but culturally “East Polynesian.”)

The colonization of the widespread islands of Polynesia stands among the most amazing feats of human exploration ever. They are very diverse, including atolls, high volcanic islands, and temperate continental ones. Polynesians not only reached every one of these but managed to establish a foothold on even the most inhospitable. Polynesia was the last region of the world to be settled by humans, and the Polynesians themselves were arguably the greatest seafarers ever. Expert navigators guided great double-hulled voyaging canoes, well stocked with necessary plants and domesticated animals, over vast distances utilizing the sun, stars, currents, birds, and winds as their guides. The variables of

each island demanded different strategies of colonization and settlement. As the centuries passed following initial landfall, these conditions changed, resulting in a dynamic interplay between the islands and their inhabitants.

By the time of European contact in the late 18th century CE, some islands, generally the biggest and most plentiful such as Tahiti, had developed into highly stratified chiefdoms. In contrast, other regions such as the atolls of the Tuamotus had retained a much simpler social system. Still other islands, Pitcairn for example, had been altogether abandoned. How and why these processes took place reveal a great deal about the nature of human societies and how humans interact with their environments. Humans transformed these islands from inhospitable forests to productive agricultural landscapes, with significant consequences for local biota; the sociopolitical entity known as the chiefdom developed in response to a complicated web of natural and cultural influences.

Ancient Polynesian Origins: The Austronesians

Polynesian origins begin with the homeland of the Austronesian settlers of the Pacific Islands. *Austronesian* is a linguistic term for the most widespread language family in the world, stretching from Easter Island in the east all the way to Madagascar in the west. It was colonized by

Austronesian speakers about 600–700. Linguistic and archaeological evidence indicates that the original ancestral Austronesian homeland was located in the lower Yangzi region of China, among the Neolithic cultures of the Hemudu (5000–4500 BCE) and the Majiabang (4200–3000 BCE). These cultures apparently adopted the settled mode of life that came with rice agriculture in the area. They spread southward via the rivers, arguing for some kind of transportation technology, which, judging by the house structures, was easily conceivable. Eventually, the spread reached Fujian in southern China and crossed the channel into Taiwan, where it developed into the Dapenkeng, the earliest ceramic-making archaeological culture on the island, dating to around 3500–3000 BCE. Contact with nearby Fujian through maritime transportation may have led the way to the succeeding cultural phases beginning around 2500 BCE. Taiwan's and Fujian's pottery and lithics show enough similarities to be considered parts of a single tradition around that time. Influx of the Longshanoid culture into Fujian and Taiwan is also evident in the period around 2500–1500 BCE.

The Austronesian colonization into the Pacific may have begun in part because of a trade network between Taiwan and the small P'eng-hu islands. Essential resources, such as basalt for adze making as well as other, more perishable materials, might have spurred on the advancement of seafaring technology. The P'eng-hu islands, near Taiwan, appear to be the only possible source for the basalt adzes found in Taiwan. The fact that the Austronesians sailed across 45 kilometers of open sea to these islands makes it likely that their seafaring abilities grew enough in Taiwan to make longer voyages possible.

From around 3500–3000 BCE, the Austronesians began their move south into Near Oceania, a process that would take around 1500 years. Linguistic evidence and lexical reconstructions, which try to determine at approximately what time certain words (and hence, their significance) appeared, supports the hypothesis of a Taiwanese origin for the Austronesians. The axiom that the homeland will be where the greatest variety of languages is found is lent weight by the fact that there are around 21 or 22 different indigenous languages of Taiwan. This is backed up by the cultural history of Taiwan as determined linguistically. It appears from archaeological evidence that the Taiwanese mode of life (rice agriculture, pottery, etc.) is similar to that of mainland Chinese culture of around the same time. The hypothesis that major advances in seafaring occurred by this time is supported by the large amount of (reconstructed) seafaring terminology in the vocabulary. Words for different parts of the canoe appear, of particular significance being the word *outrigger*, as well as do numerous other maritime terms. In addition, there are manifold increases in the number of recognized fish, plants, and avifauna, suggesting the discovery of new terrain and the accompanying new species. The Austronesians were fishermen who brought with them the domesticated pig, dog,

and chicken. They were also horticulturalists who, from lexical reconstruction, had essential crops such as taro, breadfruit, coconut, and banana.

As the Austronesians spread to the south and west into Melanesia, a meeting of cultures occurred. The indigenous inhabitants, who had been there for at least 35,000 years, spoke languages completely unrelated to those of the Austronesian family. The mixing of these cultures in Near Oceania, which genetic studies have also confirmed, are thought to have been concentrated in the Bismarck Archipelago and resulted, in the mid-second millennium BCE, in a new entity entirely that historians call the Lapita people.

The Lapita People

The term *Lapita* refers to a specific site (Site 13) on the Foué Peninsula on the west coast of New Caledonia, where the first examples of a unique and intricate dentate-stamped pottery were found. As their pottery is the virtual hallmark of the Lapita people, a short discussion of it is an appropriate way to begin a discussion of them. The first specimens were found in 1910, but it wasn't until 1952 that Edward Gifford and Richard Shutler Jr. named the pottery style, and hence the people who made it, "Lapita" after a village close to Site 13. Examples of this specific style of pottery are found from Melanesia to West Polynesia, indicating a migration of vast proportions and impressive speed (around 500 years in total). The earliest examples of the Lapita people's pottery appeared around 1500–1400 BCE in the Bismarcks and the Santa Cruz islands; thus, it appears that at this time, the Lapita people remained in Near Oceania. They eventually expanded beyond the Solomon Islands and reached Vanuatu, the Loyalty Islands, and New Caledonia around the mid to late second millennium BCE and thereafter West Polynesia (Fiji, Tonga, Samoa) in the late second millennium and early first millennium BCE.

Lapita pottery comes in a wide variety of forms, such as jars, bows, stands, and globular pots with outturned rims. Incised designs often occur. The pottery was made without wheels, using a paddle and anvil technique. Because there is no evidence of pottery kilns, it is thought that the vessels were probably fired in open air blazes, often leading to incomplete oxidization. The designs could be in imitation of tattoo motifs (or vice versa), often including representations of human faces. (Tattooing needles have been found in Lapita sites.) These decorated vessels were likely non-utilitarian ritual and prestige objects; practical everyday use was probably restricted to plainware vessels. The faces could well be associated with ancestor cults. Few Lapita skeletons have been found, but in 2004, in Vanuatu, archaeologists found 13 headless examples, one of which was buried with three skulls. The absence of the heads is likely associated with a form of ancestor worship involving the

reverence of the departed's skull. To extend this tradition to the decorative arts is but a small stretch.

The most highly decorated vessels appear in the earliest sites, such as those in the Bismarcks. There was an increasing trend toward simplification as the centuries passed, and the decorations gradually vanished from pottery in West Polynesia not long after colonization. This suggests a change in the sociopolitical structure in West Polynesia, while in Melanesia the tradition lived on for centuries after. Archaeology has increasingly revealed that these islands and archipelagoes were exchanging pottery, obsidian, chert, stone tools, oven stones, ornaments, and other necessary materials, over hundreds of kilometers, for centuries. Chemical analysis of the pottery and obsidian furnish empirical evidence for long-distance exchange. This exchange in materials gradually dwindled over time, as island populations became increasingly self-sufficient, something that would occur in West and East Polynesia as well.

The Lapita people were above all seafarers whose sailing and navigational skills were unprecedented for the region, and the two to three centuries it took them to move the 4500-kilometer distance from the Bismarcks to West Polynesia is a blink of the eye in archaeological terms. The reason for these rapid colonization events is a matter of speculation, for given the necessarily small populations of Lapita people at that time and the sufficient size of the islands they were colonizing, factors such as population pressure are simply not enough to explain these adventurous voyages of intentional settlement. Among several factors, the sociopolitical system probably was a very large factor, yet this was a phenomenon that we will see again in the colonization of East Polynesia.

The Lapita people's colonization voyages were well-stocked with all the necessities that such ventures required. The Polynesians colonized their islands with a very specific cultigen inventory, which was for the most part derived from Southeast Asia. This inventory consisted of five main groups of starch staples: aroids, yams, bananas, and breadfruit, in addition to other foods such as the Tahitian chestnut and others that originated in Melanesia and were picked up during the Austronesian expansion. They also brought with them the domesticated pig, dog, and chicken, and perhaps the stowaway rat.

The Pacific islands in their natural state contained no edible plants, consisting of forested and, for human purposes, useless, land. The only sources of terrestrial protein were birds and, in some cases, reptiles. Consequentially, the Lapita people, and their Polynesian descendants after them, practiced what archaeologists call the "transported landscape." Essentially they recreated the environments they came from, which they had also transformed. We may postulate that one of their first actions upon settling an island was to burn the existing vegetation to make room for swidden agriculture, horticulture, and arboriculture.

The consequences upon the natural environments were sudden and irreversible. Indigenous and endemic species

of plants were forced to compete, mostly unsuccessfully, with introduced ones. The establishment of agricultural systems also required deforestation. The universal practice of shifting, or slash-and-burn, cultivation had an especially profound impact. As tracts of land were set fire for planting dry land crops such as yams and sweet potato, the relatively thin soils on the hill slopes became denuded of their natural forest cover, thus exposing them to accelerated erosion. After prolonged periods of repeated burning, which could grow out of control, little other than pyrophytic *Dicranopteris* ferns and *Miscanthus* grass were able to grow on the hillsides. This had the overall effect of reducing the total amount of an island's arable land. At the same time, however, as soils washed off the hill slopes, they eventually accumulated on the valley floors and enriched them, making them ideal for wetland taro cultivation. As a population expanded and more land was cleared, the processes of deforestation, erosion, and sedimentation fed upon themselves. Small islands with low elevations were especially vulnerable to advanced deforestation.

Landscape modification also combined with human and animal predation to severely affect native species. The archaeological record has revealed that numerous land and sea bird species went extinct or were extirpated from a variety of islands. Human predation and habitat destruction were probably the two principal factors that led to these events. Recent studies have demonstrated that these extinction events were extremely rapid, occurring within around 200 years. This is significant in terms of correlating initial colonization to the earliest archaeologically visible sites. This trend, like others of island colonization, continued throughout the settlement of West and East Polynesia.

The Lapita people constructed sizable coastal settlements, often consisting of up to 30 to 40 family groups, forming small villages. These settlements were sometimes on stilted platforms over shallow waters. They thus had access to the sea and to their inland gardens, crop fields, and orchards. Although there is no evidence for irrigation, wetland crops such as taro could have easily flourished in naturally occurring swampland. Fish was the main source of protein, as it would be for their Polynesian descendants, with the domesticated animals being increasingly relegated to high-status individuals. Being near reefs was essential, as inshore fishing practices are confirmed by the faunal record of fishbone. They subsisted primarily on inshore, reef-dwelling species such as parrotfish, and less upon benthic or deep-dwelling fish such as groupers, and even less upon pelagic or open-sea species such as tuna. Shellfish were also an important part of the diet. Fishing gear included shell fishhooks and trolling lures, but it is likely that net fishing (with nets made of plant fiber) was of great importance, although such perishable materials are only very rarely recovered in archaeological sites in humid, tropical environments (unless the sites are waterlogged and therefore anaerobic).

The sociopolitical organization of these Lapita societies was likely fairly simple, with households basically competing among one another for prestige through the accumulation of such things as valuable exchange goods. Linguistic evidence provides the reconstruction of basic terms such as *chief*, *mana* (power, good grace with the gods and ancestral spirits), and *tapu* (taboo, forbidden), concepts that became widespread in later Polynesian society. Social relations are nearly impossible to deduce from the archaeological evidence alone, so linguistics is relied upon to gain whatever insight is possible. These were not, however, what we refer to as the chiefdoms that would later arise in West and East Polynesia. With the settlement of West Polynesia, numerous changes began to occur, both sociopolitical and technological, and the Polynesians effectively became what we call Polynesians there.

The Settlement of West Polynesia

West Polynesia comprises the archipelagos of Fiji, Samoa, and Tonga as well as the smaller islands of Futuna, 'Uvea, Niuaotupapu, and Tokelau. When the last of the Lapita people colonized West Polynesia in the late second millennium and early first millennium BCE, significant changes began to take place, and the unique Polynesian culture emerged as an entity unto itself. This conception of the time of the emergence of a unique Polynesian culture is fairly recent; it took hold after archaeological excavations in West Polynesia in the 1950s and 1960s, prior to which many scholars believed that the Polynesian culture emerged more or less “whole” from Asia. However, it is important to keep in mind that this viewpoint preceded the discovery of the Lapita people.

Geographically, Fiji, being the westernmost archipelago in West Polynesia, was probably the first to be settled, followed by the Lau Islands, then Tonga and Samoa, including the smaller, more isolated islands in the region. Again, we see a very rapid colonization event of significantly sizeable islands within a couple of centuries, a phenomenon that was a direct continuation of the earlier Lapita migrations. Once again, there is evidence for interaction networks between these archipelagos in the early phases of occupation, as they were exchanging pottery, chert, basalt adzes, and perishable materials as well as marriage partners and other things that cannot be recovered archaeologically. While artifacts such as fishhooks and ornaments remained consistent with the earlier Lapita examples, new distinct adze forms developed. Once again these interaction spheres gradually diminished over the centuries following colonization, as the islands became increasingly self-sufficient, although contact between them was never entirely broken off.

Again, it must be noted that the finely decorated dentate-stamped and incised Lapita ware was gradually replaced by plainware utilitarian vessels. It was during these centuries

that what we call “ancestral Polynesian” culture emerged. We can thus say that West Polynesia was in fact the Polynesian homeland that earlier scholars assumed was to be found in Asia or even South America. The name “Hawaiki,” later used by East Polynesians to describe where they ultimately came from, most likely refers to West Polynesia, in which the unique ancestral Polynesian society developed. The lexically reconstructed language that was spoken is referred to as proto-Polynesian.

Like their Lapita predecessors, the West Polynesians relied on horticulture, arboriculture, and swidden agriculture, and there is no evidence for irrigation canals for wetland taro. The transported landscape concept is equally applicable in West Polynesia as well, as they remade their islands to suit their needs. The accompanying devastation of endemic species of flora and fauna also occurred, and birds were hunted and their environment destroyed. The West Polynesians maintained essentially the same groups of crops as their Lapita ancestors, and their domesticated animals (pig, dog, chicken) as well. Again, fish and shellfish were the primary sources of protein. Social organization became more complex, as family groups formed that traced their descent from a common ancestor with a single male leader in charge of both secular and sacred matters, the predecessor to the later chief. Again, this evidence, which cannot be recovered archaeologically, is reconstructed linguistically through cognate terms found throughout West and East Polynesia.

The pottery sequence, so important to our knowledge of the Lapita people, went through three different phases, eventually, *perhaps*, disappearing altogether in the early first millennium CE throughout West Polynesia except for Fiji. We could explain the lack of pottery in East Polynesia as resulting from its dying out in the west, but this still does not explain why it apparently died out in West Polynesia. Technologically, its absence could be due to the use of earth ovens to cook food and the use of such things as coconuts and wood to make more durable vessels that could survive harsh conditions such as would have been the case in long-distance voyaging.

West Polynesian culture was (and is) distinct from East Polynesia's in numerous ways. We must keep in mind that, according to the most recent archaeological information, East Polynesia was not settled until around the late first millennium CE. The first and perhaps most mysterious difference is the total lack of pottery making in East Polynesia; only a handful of imported sherds have been found in the earliest strata of the earliest sites there. Morphologically, there is little continuation in the styles of ornaments and fishhooks. However, the fishhooks of East Polynesia were at first primarily made of pearl shell, which is far more abundant there than in West Polynesia and lends itself to the manufacture of a wide variety of forms. Adze types are also dissimilar to a certain degree, although certain aspects allow direct correlations. Simple manufacturing tools, such as shell fruit scrapers, stone flake tools

such as scrapers, and coral and sea urchin files for things such as fishhook manufacture, remain virtually identical in both West and East Polynesia.

Other differences between the two regions include reverence for only one major deity in West Polynesia as opposed to multiple deities in East Polynesia. Clearly these are not deduced from archaeology, but rather from linguistic and ethnographic studies. Another difference is in ceremonial architecture. Whereas the *marae* in East Polynesia was a constructed stone platform with varying degrees of elaboration and reserved for ceremonies, the *malae* of West Polynesia was simply an open-air area for public gatherings. We may deduce from this that, as the chiefdoms became increasingly more complex, so did the religious systems.

Aside from the obvious differentiation of languages that occurred, these are but a few examples of the differences, but they serve to suffice as a basic introduction. It is important to note that, to date, no site has been found in West Polynesia, which would presumably date from the late first millennium CE, that would serve as a direct link to the earliest sites in East Polynesia, leaving us with an important gap in the overall colonization sequence. We may now turn to the subsequent colonization of East Polynesia; followed by a discussion of the later development in both West and East Polynesia.

The Settlement of East Polynesia

East Polynesia was colonized, according to our best archaeological information to date, in the late first millennium and early second millennium CE. This leaves us with a mysterious gap of around 2,000 years between the Lapita colonization of West Polynesia and the West Polynesian colonization of East Polynesia. In the 1980s and 1990s, a “pause” debate was a serious concern in Polynesian archaeology. It revolved around the question of whether or not Lapita settlers, once having reached West Polynesia, abruptly stopped their eastern migration for approximately 2,000 years before they colonized East Polynesia. (That they had the sailing technology to do so is beyond doubt.) The “long pause” advocates maintained that the archaeological and linguistic evidence was overwhelmingly in favor of this pause. The “short pause” advocates acknowledged that while solid evidence might be missing, reason and theory suggested that no such significant pause could have logically occurred. They believed that it was only a matter of time before tangible proof surfaced that there was only a short pause, that is, that East Polynesian sites dating from the late first millennium BCE would eventually be discovered.

Pivotal to this controversy were the subsistence and exploitation strategies of the colonizers, which are differentially viewed by the two viewpoints. Long pause or late settlement advocates appealed to economic efficiency in

arguing that horticultural prominence, substantial landscape degradation, and perhaps a slower rate of population growth ought to follow, not precede, a colonization phase that emphasized pristine indigenous resources. Consequentially, early-phase sites (although likely not the very first) were expected to contain large deposits of animal remains, especially those of wild foods such as birds. Short pause or early settlement advocates believed that, in part, population growth caused the expansion of economic activities and that the greater abundance and variety of remains eventually moved archaeological evidence into visibility. The short pause chronologists emphasized the horticultural aspect of colonization, while the long pause advocates highlighted the hunting-gathering facet. The short pause school assumed that once a new island is colonized, the settlers will almost immediately begin to clear forest for horticulture. The long pause school, conversely, believed that new islands were settled primarily because they were rich, untapped sources of animal protein that would permit a leisurely existence for generations.

Archaeology, as of now, has still not yielded any evidence of East Polynesian settlement earlier than about 900 CE, so the question of why the eastern Lapita people stopped their migration in West Polynesia remains a mystery, although hypotheses abound. The differences in material culture between early East Polynesian sites and first-millennium CE West Polynesian sites are clearly recognizable, suggesting a period of change between the two regions that we have no archaeological links to at present. Now, most of the short pause advocates have yielded in the face of the increasing number of Archaic period (ca. 1000–1450 CE) East Polynesian sites, whose dates remain consistent, mainly grouping within the early second millennium CE. However, let us turn to what the facts themselves tell us.

Just as ethnographers in the early 20th century argued for an Asian homeland for the West Polynesian culture, they also suggested that a different East Polynesian homeland existed, from which the people emerged to settle every archipelago from New Zealand to Hawai'i to Easter Island. The first and most obvious candidate for this homeland was Tahiti, being the biggest island in central East Polynesia (meaning that this excludes New Zealand and Hawai'i). This model held sway for decades before serious archaeological work began to be done, first in the Marquesas in the late 1950s and 1960s. Prior to these excavations, the time depth of East Polynesia was thought to be only around a few centuries, and many believed that nothing of value could be unearthed by archaeology. When serious archaeological work began, radiocarbon dating of artifacts revealed many dates of origin that were as early as 100 BCE. However, radiocarbon dating was then in its infancy; now these sites have been redated and are known to be far younger, from the early first millennium CE.

However, the inaccurate early dating prompted archaeologists to turn their attention away from Tahiti and the

Societies to the Marquesas as a homeland, especially since some (imported) sherds of plainware pottery had been found in the earliest deposits. Now, however, with the excavation of many more Archaic period sites throughout East Polynesia, we see a very different pattern emerge: The dates from one end of East Polynesia to the other all fall within the early first millennium CE, indicating that, like the colonization of West Polynesia, the colonization of this vast region was accomplished with almost unbelievable speed. In addition, the Archaic artifact assemblages are virtually identical throughout East Polynesia at that time. Consequentially, archaeologists have now turned away from the concept of a single archipelago as an East Polynesian homeland to a model of a regional homeland, composed of interaction networks much like those that existed during the early phases of Lapita colonization of West Polynesia.

Central to the idea of a regional homeland is the fact that important resources are unevenly distributed from island to island throughout East Polynesia. Two of the most important raw materials are fine-grained basalt for adze making and pearl shell for fishhook manufacture. Islands that did not have one or the other may have had to import it from an island that did. Following the colonization of an island, multiple trips back to the home island or to neighboring ones might have been necessary to supply the new population. Geochemical fluorescence analysis of volcanic basalt has traced adzes to geological sources hundreds of kilometers from where they were found. Most of these tools are found in Archaic period deposits, indicating that communication did take place until about 1450 CE, after which evidence of imported artifacts gradually diminishes.

Afterward, by the time of European contact in the late 18th century, long-distance voyaging had virtually vanished from most of East Polynesia; only the resource-poor (especially because they are without basalt) atolls of the Tuamotus maintained trade out of necessity. Again, we have seen this decline in interaction in the Lapita sequence and the West Polynesian one as well. Postulated reasons for the decline in interaction include increasing self-sufficiency and therefore the economic impracticality of building and outfitting canoes for long-distance voyages; climatic change; resource depletion, especially of timber; and sociopolitical change. Some islands had lost all touch with others, even their nearest neighbors, and may have given up the construction of voyaging canoes altogether.

This regional homeland model has important implications for how researchers now view the initial colonization process and has also changed how archaeologists now view artifacts associated with Archaic deposits (pre-1450 CE). The number of shared characteristics can be attributed to the exchange and diffusion of ideas and technology in the centuries following colonization, when long-distance interaction was taking place, rather than simple diffusion from a single homeland. As archaeological work progressed in the decades after the 1950s and

more early sites were studied, the regional homeland model developed. This view suggests that the archipelagos of East Polynesia were colonized very rapidly, almost simultaneously (confirmed by radiocarbon dates), and then maintained a degree of contact among themselves for some centuries after, for trade and other reasons. During this period of interaction, the sharing of ideas allowed for the development of a uniquely East Polynesian culture throughout the archipelagos.

The way researchers have regarded long-distance voyaging has contributed a great deal to these changing models of colonization. For much of the 20th century, it was thought that voyaging was a very difficult and dangerous endeavor. Indeed, some researchers believed that the islands must have been settled accidentally. Beginning in the 1970s, however, experimental voyaging demonstrated that two-way journeys were completely possible even between the farthest islands of East Polynesia. Voyages were certainly long and required a well-equipped canoe, a skilled crew, and expert navigators, but they were manageable and perhaps not quite as hazardous as previously thought. In addition, studies using computer simulations that took numerous factors into account, such as distance, sailing difficulty, and wind direction, have launched hundreds of “voyages” between islands in order to calculate success rates. The statistics of safe arrivals are high enough to suggest that intentional voyaging might have been a very active element in the colonization of East Polynesia. Two-way voyages would have allowed colonizers to make return journeys home for supplies, marriage partners, and to meet other needs, and only rarely could an island have been so cut off as to remain in abject isolation.

One of the great feats of East Polynesian voyaging was the reaching of South America, proven by the fact that the sweet potato, which originated there, was taken back by the Polynesians and spread throughout Polynesia to the farthest corners, including Hawai'i and New Zealand, the latter of which emphasized its cultivation over all other staples. Despite two-way voyaging, however, some islands and archipelagos remained in relative isolation, namely Hawai'i, Easter Island, and New Zealand, the three corners of the Polynesian Triangle. Not all the introduced animal species, namely the pig, dog, and chicken, made it to these marginal areas, perhaps because of the impracticality of return voyaging. The pig and chicken were absent in New Zealand, and the pig and the dog were absent in Easter Island.

Early East Polynesia: The Archaic Period (ca. 1000–1450 CE)

The Archaic East Polynesian artifact assemblage is quite unique and lacks immediate parallels in the West Polynesian material culture of the mid-first millennium CE. We are therefore probably missing the hypothetical “first landfall” sites that would ideally contain typical West

Polynesian artifacts and perhaps pottery. As Archaic East Polynesian material culture is already distinct from its West Polynesian ancestor, it can be inferred that this culture had some time to develop on its own. Therefore the Archaic represents an early period in East Polynesian prehistory, but not the earliest, suggesting a period of time, perhaps of around one to two centuries, in which the culture was developing its own distinctive style. Diagnostic artifacts include perforated tooth pendants (whale, human, dog, seal, porpoise) that were strung together to form necklaces and bracelets, bone reel units that could be combined with tooth pendants to form a necklace, pearl shell pendants, tattooing needles, coconut graters, a variety of one-piece pearl shell fishhooks, pearl shell harpoon tips, and a wide array of adze types.

However, West Polynesia lacks abundant pearl shell; one-piece fishhooks of this material are exceedingly rare, and those that have been found may have been imported. Most West Polynesian fishhooks were made of turban shell, which is far more brittle than pearl shell and lends itself to the manufacture of only a very few forms. Ornaments of the Archaic East Polynesian type are also unknown in West Polynesia. Other items common, but not restricted, to Archaic assemblages are shell chisels, files and abraders of sea urchin spine and coral, and octopus lures made from cowrie shells, which are not unique to East Polynesia. The few sherds of pottery that have been found in East Polynesia come from Archaic strata and probably represent imports. The Archaic kit occurs with little variation throughout East Polynesia. Habitation sites appear often to have had round-ended huts, and there was no distinctive religious architecture. This is not surprising, since, as noted above, in West Polynesia the open-air *malae* have little or no resemblance to the ceremonial structures of the later, post-Archaic period, East Polynesian *marae*.

The colonists of East Polynesia also brought with them the social framework that had developed subsequent to the Lapita colonization of West Polynesia. The social classes in ancestral Polynesian society (the chief, the warrior, the expert/craftsman/specialist, and the sea expert/navigator) continued to exist in East Polynesia. The following short discussion applies to sociopolitical developments in both West and East Polynesia.

With the settlement of the East Polynesian islands, what was probably once a largely egalitarian society began to change in response to varying environmental and social conditions. By the time that European contact occurred in the late 18th century, significant linguistic and sociopolitical variation had taken place from region to region. The number of classes or ranks differed greatly between chiefdoms, from two at the lowest extreme (basically chiefs and nonchiefs) to many gradations of chiefly and nonchiefly status with very specific rights and privileges relegated to each. The processes that led to such cultural differentiation were fundamentally bound up in the ongoing dialectic between human society and the island environments. Both

social and environmental factors, among others we can only hypothesize about, caused such changes to occur. For example, chieftainship was an ascribed, inherited office that carried both sacred and secular power. The dialectic between achieved and ascribed status was a crucial element of the Polynesian sociopolitical system. Although the chief was so by birthright, other social classes, namely warriors and priests, were a source of competition for power. People born outside the chiefly class were thus able to escape the confines of the class system and actually compete with the chief himself. Ecological factors also played an important part in the differential development of island chiefdom. In the late 18th century, highly stratified societies were found on large, productive islands (Tahiti, Hawai'i, Tonga), whereas far more egalitarian ones were found in impoverished environments such as the Tuamotu atolls. Middle-range societies existed where conditions that can be described as marginal existed, where land was circumscribed and natural disasters such as drought were a threat to the society.

The Later Periods of West and East Polynesia

We can now turn to the developments that occurred in West and East Polynesia up until European contact in the late 19th century, when their traditional societies came to an abrupt end. In addition to archaeological evidence, we also possess invaluable ethnographic accounts, which mariners and missionaries wrote during their sojourns in the islands. If the long pause debate is a mystery in and of itself, so are the facts surrounding the first millennium CE in West Polynesia. The paucity of sites that date from that period contributes to the gap in our knowledge, both of that era of West Polynesia and of how it impacted the subsequent colonization of East Polynesia. One of the few facts (unless proven otherwise in the future) is the disappearance of pottery (except for in Fiji), as mentioned above. Changes in the adze kit might also have developed, but on the whole, in archaeological terms, not much else seems to have changed, although certainly the sociopolitical systems evolved, the chiefdoms became more complex, and the languages continued to differentiate. In terms of complexity, Tonga surpassed both Samoa and Fiji. As populations grew, agricultural intensification did also, although which caused which is academic. Systems of irrigated pond-field agriculture contributed to the efflorescence of wetland taro. Far more is known about the period after the first millennium CE and before European contact. The most visible change is the development of monumental architecture in East Polynesia.

Forming a relatively tightly knit group of archipelagoes and islands, contact was maintained throughout West Polynesia throughout the second millennium CE, which is well documented archaeologically and ethnohistorically.

As we shall see again in East Polynesia, West Polynesian population centers drifted away from the coast and moved inland where their crops were. Stone house platforms compose much of the visible archaeological landscape. The *malae*, or ceremonial and public gathering places, were marked by stone walls.

In the latter part of the second millennium CE, Tonga, the most complex of the West Polynesian chiefdoms, went on to conquer and annex several small surrounding islands. Reflecting its great power, Tonga featured large burial mounds for the upper classes; these mounds were covered with cut and dressed limestone slabs. James Cook and his crew were eyewitnesses to a ceremony of offerings presented to the mounds of former great chiefs, called Tu'i Tonga. In Samoa, unique star-shaped mounds were used for chiefly and religious functions, as were mounds of less elaborate shapes. The development of fortifications in Fiji, Tonga, and Samoa strongly suggests increased warfare as settlements and valleys became increasingly competitive.

Fiji (also considered part of Melanesia), like its Lapita ancestors, continued its pottery tradition, which also became increasingly simplified, becoming mostly plainware. This reflects that some degree of contact was maintained with Melanesian islands such as Vanuatu, whose obsidian is found in Fijian archaeological sites from that period, is certain, as is its contact with its West Polynesian neighbors, Tonga and Samoa, where artifacts of Fijian origin have been found. Fiji possessed both lowland raised fortified settlements surrounded by ditches and more extensive hilltop terraced ones, both designed to protect valuable cropland, such as irrigated terraced taro plantations. Fiji is, more than any other island group in Polynesia, known for its cannibalistic practices, documented both archaeologically and ethnohistorically.

The Later period (post-1450 CE) of East Polynesia, often referred to as the Classic period (ca. 17th to early 19th centuries CE), emerged as the endpoint of centuries of adaptation to divergent environments and the sociopolitical development that ensued. Many changes accompanied this transition from the Archaic period. As interisland and interarchipelago voyaging lessened after around 1450 CE, languages differentiated at a greater pace, and islands developed along more individual lines. Overall East Polynesian trends do occur, however. These include a demographic shift away from the coast and into the valleys, the efflorescence of monumental architecture, and a reduction in the variety of forms of utilitarian items, most notably fishhooks and adzes. As in West Polynesia, while agriculture intensified and populations grew, habitation shifted away from the coast, becoming more and more concentrated in the backs of valleys near the crops. It is also likely that during this time, intervalley competition over resources intensified, making the coastal habitation more dangerous due to the possibility of raids from the sea.

Competition was evident not only in increased warfare but also in the monumental architecture of the era. This

correlated directly to the ability of chiefs to command the surplus necessary to mobilize a labor force. All reliable radiocarbon samples from *marae* in the Societies date to within the last centuries prior to European contact. Ceremonial architecture such as the *marae* of the Societies, Cooks, Australs, and Marquesas and the *heiau* of Hawai'i were built during this period. This monumental architecture developed in a context of competitive, possibly hostile interaction. Some of these structures were directly related to conflict, dedicated to gods of war. Furthermore, the fortified settlements of New Zealand and Rapa Nui were also constructed during the Classic period.

Another trend is apparent in the material culture of the Classic period, which changed distinctly from its Archaic predecessor. Variety among utilitarian objects such as fishhooks and adzes decreased dramatically, some changing entirely while some forms remained the same. Archipelagoes increasingly favored fewer adze and fishhook forms. These changes in adze form may also be linked to different lifestyles; perhaps prominent Archaic forms were designed largely for canoe-making, while later forms were made for tree chopping to clear land. These changes in the tool kit agree well with the overall environmental and social trends here explored and merit further attention.

In addition, pearl shell was used less and less as a material for making utilitarian items (fishhooks, coconut scrapers, tattoo needles), presumably because it was harder to obtain. Instead, where it was not abundant, it tended to be restricted to ornamental use. Local substitute materials became preferable for manufacturing fishhooks, such as turban shell or bone. In terms of morphology, small jabbing hooks, most suitable for inshore fishing, become predominant in Classic assemblages; such hooks are comparatively less prominent in Archaic ones. This decision regarding fishhook styles appears to have been linked to an emphasis on inshore fishing, which can be correlated with the diminished use of canoes and, consequentially, diminished long-distance voyaging that characterized the Archaic period.

The Endpoint Culture, European Contact, and Evangelization

The first Europeans to happen upon Polynesia were the Spanish in 1595 under the command of Alvaro de Mendaña de Nehra. Further European discoveries, such as that of Easter Island, were made in the 17th century, but the majority were made in the 18th. These renowned voyages of Pacific exploration will forever be associated with the names of such famous navigators as Louis de Bougainville, James Cook, George Vancouver, and Jean-Francois de Galaup, Comte de La Pérouse. The great age of European exploration involved tremendous feats of navigational skill (albeit with the use of sophisticated instruments that the Polynesians never had), with the voyages taking years to

complete as the islands were charted and mapped. It is due to the meticulous journals of men such as Cook that we possess much of ethnohistoric information that we do.

Trade between the Europeans and the Polynesians began simply, with metal objects such as nails (which could be fashioned into fishhooks) being prized, as well as trade beads, pipes, glass, and other exotic things. In return, ships would acquire fresh meat, fruit, and water. Unfortunately, European contact brought European diseases, such as influenza and venereal diseases, which had decimated the local populations by the end of the 19th century. As a result of these diseases, an island that might previously have had a population estimated at around 3,000 would have only 200 or 300 inhabitants afterward. Fortunately, the populations have grown back substantially in the past 100 years, although probably not to the extent of the prehistoric ones.

While American and European economic interests such as whaling depended upon many of the Polynesian islands for resupplying, the missionaries of all Christian religions accompanied them for other purposes. Catholics, Protestants, and Mormons were the first to arrive, and further sects and branches followed closely behind. Conversion was a different process from one area to another. Hawai'i's paramount chief, later known as King Kamehameha, embraced Christianity in the late 18th century so that he could acquire Western arms and ships in order to conquer the entire archipelago. On the other hand, residents of the Marquesas, which had a far less stratified chiefdom, clung tenaciously to their traditional religion and independence from France until well into the 19th century. Evangelization of course marked an end to the traditional religions and imposed many restrictions on dress, marriage, sexual relationships, and so forth. However, it is thanks to some of these missionaries, such as William Ellis, that we have detailed ethnohistoric accounts of traditional life and dictionaries and word lists of languages that are no longer spoken as they were in their pristine condition. These help greatly to fill in the gaps in the archaeological record and flesh out what we know about prehistoric life.

What the Europeans witnessed from one point of the Polynesian Triangle to the others were societies with very similar social structures and languages. For over a century, hypotheses abounded as to how these islands, separated by vast stretches of empty ocean, could exist with such homogeneity; the most extravagant of these proposed that the islands were mountains, once part of a giant continent that subsided beneath the ocean, leaving the peaks in isolation. The social structure, as stated above, ranged between two extremes. At one end were the highly stratified chiefdoms such as those on Hawai'i, Tahiti, and Tonga, with high chiefs and numerous levels of subordinate chiefs, and commoners forming the greater part of the population. These high chiefs were considered semidivine, and they fought amongst themselves for absolute power. At the

other end were the simplest societies, such as those on the Tuamotu atolls, where the chief acted more as a headman than an absolute ruler.

Two of the most important concepts to the Polynesian social system were *mana* and *tapu*, *mana* being a form of positive force that people and objects could possess depending on their success, and *tapu* (from which we derive the word *taboo*) being an absolute restriction on certain things. For example, a chief could place a *tapu* on eating pigs for a given period of time, or certain sacred areas could be *tapu* to certain of the lower social classes. *Tapu* foods, such as turtle, pig, and varieties of fish, were forbidden to all but members of the highest social orders, and these foods were forbidden to all women and children as well.

Religion was generally polytheistic, with priests and shamans often responsible for communication between the real and divine worlds. In the most stratified societies, the high chief would also take on the function of intermediary between people and gods and revered ancestors. Most of the population subsisted on farming individual family-managed (sometimes technically belonging to the chief) plots of land and fishing. The first fruits would typically be given to the chief as his hereditary due. Other classes, in existence since the time of ancestral Polynesian society, were specialists such as navigators, artists, performers, and toolmakers, whose labors would be paid for with food and other goods. Warfare was endemic practically everywhere in Polynesia. Sometimes it consisted of sportlike battles in which there would be few casualties, but at other times killing played a far more crucial role. Human sacrifice and cannibalism were probably universal, the latter being so secretive and restricted that few European accounts can be relied upon. Contrary to many popular depictions of the inhabitants as living in a state of half or complete nakedness, *tapa* (barkcloth) robes were often worn by both sexes. Children were given almost complete liberty and adoption was common (as it still is).

In sum, Polynesian islands were both very diverse and very homogenous, with a descent from a common ancestry. Societies that took centuries to develop were completely overturned by the clashing of worlds, and truly traditional Polynesian life had vanished forever by the late 19th century. Its remnants provided subjects for Western artists such as Paul Gauguin (who died in the Marquesas, his adopted home), and Herman Melville, whose novel *Typee* (a fictionalized account of his stay in *Taiipi* valley on Nuku Hiva in the Marquesas) launched his writing career and introduced the romance of Polynesia to the rest of the world.

Conclusion

Today, the islands and archipelagoes of West and East Polynesia are independent nations, self-governing states, or overseas territories. For example, in West Polynesia, Fiji

and Tonga are independent nations, as is half of Samoa, but the other half, American Samoa, is a U.S. territory. In East Polynesia, the Cook Islands are an independent nation in free association with New Zealand (also an independent nation). The rest of central East Polynesia (Tahiti, the Australs, the Tuamotus, and the Gambiers) is French Polynesia, an overseas territory of France; Easter Island is part of Chile; and Hawai'i is the 50th state in the United States of America.

These varying government systems have important implications for the economies of the different regions. French Polynesia, for example, no longer exports enough copra to support itself and depends mainly on tourism for income; the rest of the economy is supported by France. Also, the archipelagoes of French Polynesia have French as the primary language; whereas English is the primary language in the closely related but politically separate Cooks, as it is in West Polynesia, New Zealand, and Hawai'i, of course; while Spanish is the primary language on Easter Island. Most of the islands throughout Polynesia are no longer subsistence economies and depend largely on imported (and therefore expensive) goods and foods.

Fortunately, the implications of archaeological discoveries and long-distance voyaging are becoming increasingly relevant to Polynesians in the modern world. Experimental voyages have helped to restore a tremendous sense of cultural pride among Polynesians from all over West and East Polynesia. These voyages have shown that such undertakings were feats of tremendous skill and bravery. Importantly, they have managed to traverse the modern political boundaries that separate East Polynesians from one another. For example, while the closely related Cooks and Australs compose the same archipelago (the Cook-Austral chain) they currently represent the interests of two different nations, and yet it is becoming increasingly clear to the Polynesians who live there that such boundaries are entirely artificial. In the past, they faced and surmounted considerable difficulties by working together to colonize untouched islands, remake them, and then help each other in the precarious centuries following landfall. These accomplishments are equally applicable to future issues, when today's overseas territories may well become tomorrow's independent nations that will no longer be able to rely on welfare. Fortunately, this sense of cultural pride through the revival of tradition has already taken root in many areas.

This chapter describes the importance of support systems such as family, friends, communities, and religious groups. Such support systems form the core of an individual's social network. Anthropologists are interested in these relationships and how information flows through networks. Along with this, we will describe the history and major current uses of social network analysis (SNA) in anthropological research, as well as introduce common barriers to the effective use of SNA. These obstacles include ethical and power issues that come into play with some forms of SNA research. We conclude with a discussion of diverse anthropological case studies that used SNA methodology, pulling from the diverse contexts of nonprofit organizations, business, early childhood development, medical anthropology, and even primatology.

Social relationships form between two or more people through interactions. It is these complex, and often symbolic, interactions with other people that make us distinctly human. The entire discipline of anthropology is concerned with social relationships of some sort. To give a description of how linguists, cultural anthropologists, biological anthropologists, and archaeologists study social relationships is a daunting and formidable task. However, SNA is proving to be a powerful methodology for many anthropologists, as well as diverse groups of other social scientists.

SNA is one of many methodologies used to study and analyze groups of people, be they individuals, organizations,

communities, or even countries. This methodology analyzes whether a relationship exists between these units, called *nodes*, and places a value on that relationship. SNA is not a new technique and has been in use since the early 1930s. However, its usage has increased over the past 20 years as a valuable tool for anthropologists, economists, sociologists, planners, program evaluators, and those in the corporate world, among other researchers. Social network analysis is particularly well suited for understanding complex systems and relationships, as it depicts systemic elements and their interactions to form a complex whole. By identifying the individuals interconnected, a researcher can also identify leaders or those developing as leaders. It is for this reason that SNA has become so valuable in the business world.

Social networks are formed in society through contacts in many aspects of daily life. While most people think of a social network as a collection of people that they know socially, it is more than just personal friendships and connections. Social networks include the people we know professionally—through work, school, and volunteerism. This extends to the people that our friends and relatives know as well. Such networks can be studied from the perspective of identification of the network, effectiveness, and meaning.

Social network analysis research focuses on two types of social networks: *sociocentric* and *egocentric* networks. Sociocentric networks aim to depict the relationships among members of an entire group. Anthropologists may

use this form of analysis to study clubs, classrooms, or entire villages. The purpose of sociocentric network analysis is to understand the structure of the group and how it relates to individual or group behavior or perceptions. Egocentric networks consist of the relationships of an individual. The respondent, called *ego*, names the people he knows and the social network is mapped out. Egocentric data enable the researcher to study social support networks, the relationship between disease and certain help-seeking behaviors, and many other interpersonal interactions (Gravlee & Kennedy, 2002).

A factor aiding the popularity of the SNA methodology is the availability of computer software that helps create *sociograms* to facilitate analysis. A sociogram is a visual display of the individuals (nodes) and their connections. These connections encompass a wide range of relationships, such as communication ties, formal ties, kinship ties, and proximity ties. These ties are visually distinguished from each other, and the length of the ties indicates the social distance between individuals. The most popular SNA software is UCINET because it is continually updated and provides many forms of data manipulation and network methods and tools. Additionally, this software is robust and capable of handling large amounts of data for numerous individuals, such as for sociocentric analyses. Other network data analysis software programs include Egonet, NetMiner, STRUCTURE, NetDraw, FATCAT, JUNG, and StOCENET.

The anthropological use of SNA can be viewed in direct contrast to traditional anthropological research. Instead of the key informant, individual-centered ethnography, SNA assumes that all actors are linked in an intricate latticework of social relationships, affecting their worldview and influencing their behaviors. Understanding these relationships at a deeper level delves into the realm of sociology and social psychology in terms of viewing people as groups of social beings. Anthropologists are becoming more concerned with understanding structural relations because they are often more valuable in describing behaviors than demographic characteristics like age, sex, and religious beliefs. People's social relationships vary widely depending on the circumstances of the different environments in which they interact; people have an ability to "status shift." That someone can be a quiet individual at work and an outspoken member of his or her community gives testimony to the fact that these relationships cannot be explained by demographics, since that individual retains those demographic characteristics regardless of the social context. Anthropologists are still conducting traditional ethnographies and engaging in SNA, which adds to the breadth of the discipline.

History of Social-Network Analysis

Long before the term *social network analysis* was coined, there were examples of its use. This begins with Lewis Henry Morgan's analysis of kinship of the Iroquois. In the

mid-19th century, Morgan's *League of the Iroquois* (1851) detailed and diagramed kinship of the six nations that composed the Iroquois Federation. In fact, many early anthropologists recognized the importance of kinship in the societies that they were studying. Anthropologists then began to study kinship extensively and use diagrams to represent relationships. However, SNA is not an exclusive tool of anthropologists and can be found in use in many disciplines including sociology, psychology, mathematics, information technology, business, political science, and the medical field.

Formal social-network studies were developed in two social science fields independently of one another. Psychotherapist Jacob L. Moreno is credited with developing sociometry around 1932, a quantitative method for measuring social relationships, and the sociogram, the tool for representing these relationships. At this time, sociometry was used by psychologists and consisted of investigating who was friends with whom in order to explore how these relationships served as limitations and/or opportunities for action and for their psychological behavior (Scott, 2000). Although social scientists had spoken of *webs* or *networks* of people, it was Moreno's invention to use spatial geometry to graphically represent these relationships in a sociogram. People were "points" and relationships were "lines" and people were placed closer together or farther apart based on the strength of their relationship. This makes it immediately apparent upon viewing a sociogram who the individuals were and how they were related. Moreno's gestalt orientation toward psychotherapy led him to investigate how mental health is related to the social networks to which people belong.

Moreno recognized its utility in identifying well-connected people and how information flowed through a group. He coined the term *sociometric star* to refer to the important leaders that were able to influence many others in the network. In Figure 74.1, the sociometric star is the friend choice of everyone in the network, yet individual A only chooses two individuals as friends.

Figure 74.1 A Sociogram Depicting the Sociometric Star
SOURCE: Scott (2000).

Moreno also studied these microlevel personal interactions and SNA to infer the basis of large-scale *social aggregates*, which included interaction with the economy and the state (Moreno, 1934). Shortly thereafter, psychologist Kurt Lewin, pioneer of social psychology and action research, picked up on this study of group behavior as a series of interactions with the environment that could be studied mathematically using vector theory and typology in the mid-1930s. Lewin (1951) aimed to mathematically explore the interdependence between the group and the environment as a system of relations. Lewin's early work in SNA brought him close to what would later develop into systems theory. In 1953, Cartwright and Harary (1956) pioneered graph theory applications to group behavior that drew on Lewin's use of mathematical models for group behavior. Their use of SNA was also characterized by an important shift in thinking about group behavior. These models facilitated a shift in thinking of cognitive relationships existing in people's minds to the understanding of interpersonal balance in social groups. This allowed researchers to build models of the interdependence among the different individuals' views and attitudes in a group (Scott, 2000, p. 12).

Around the same time, anthropologists Alfred Radcliffe-Brown, Claude Lévi-Strauss, and also Émile Durkheim posited their views that the main purpose of social, or cultural, anthropology was to identify social structures and the formal relationships that connect them, and that this could be accomplished with discrete mathematics. They began investigating subgroups within social networks and ways to identify these subgroups from relational data. Another important development at this time was the way in which relational data was obtained. Social scientists began using anthropological observation methods to record and diagram the formal and informal relationships of people within networks.

In the 1950s, Manchester University's department of social anthropology began focusing not on group cohesion, but on group conflict and how social relationships affect not just the individuals involved, but the society as a whole (Scott, 2000, p. 26). This placed emphasis on not only the relationships, but also the nature of those relationships, a fundamental tenet of SNA. The Manchester anthropologists were unable to record their findings in the simplistic kinship diagrams of their field, and so turned to Radcliffe-Brown and others for the use of SNA. Anthropologist Harrison White, of Harvard University, is credited with further developing the mathematical and schematic nature of SNA in the 1960s and 1970s, which allowed notions like *social role* to be mapped and measured.

The development of SNA tells us much about how the different social science fields can use this methodology to achieve their goals. Although different researchers have different backgrounds and theoretical orientations, Scott (2000) states that SNA is especially valuable because it does not mandate a specific theoretical framework (p. 37).

SNA can be thought of as a series of methods instead of a theoretical orientation; however, all researchers engaging in SNA are attempting to reveal the structure of societies or social groups. SNA is well suited to uncover social structures, predict the emergence of leaders and relationships, and represent these relationships graphically.

Support Systems

The dynamic of the family creates a social network that uses the power of shared DNA and marriage as the basis of forming a support system through kinship. This system is further expanded through friendship, adoption, and godparenthood. In looking at the social network of kinship as a support system, clues are given by the terms used between members to describe their relationships, and by the frequency of contact between them. For example, an individual may consider the relationship with a cousin stronger than that with a cousin twice removed, regardless of any difference in the biological relationship. A survey of the members of a kinship group to determine the terms used and the frequency of contact between members can identify the support system within the larger context of the complete kinship group.

Support networks can also be found in neighborhoods, care facilities, education systems, and workplaces. Jacobson's (1987) work on the support systems found in elder care facilities looks at the meaning of social support as a framework for analyzing the network. A spontaneously organized breast cancer self-help group is the subject of study into how consensus is used to negotiate belief systems and knowledge (Mathews, 2000). The support network found in the agricultural society of Madagascar looks at how the network contributes to the economic system (Gezon, 2002).

Each of these studies examines very different types of support systems from various angles, showing good examples of the depth and breadth of the possibilities for finding support systems. The viewpoint of each of these studies shows the manner in which a network can be viewed, whether from the viewpoint of the families, as in the elder care facilities, or the members who formed the network, as in the self-help group. The final example of the economic system in Madagascar views the network from the viewpoint of those who are on the fringe of the network rather than the central members. This is much like a discussion involving kinship where determining who is ego is important to determine the relationships to that individual.

Current Trends in SNA

Popular uses of SNA extend to the creation of online communities such as MySpace, Facebook, LinkedIn, and Spoke as SNA gains popularity and momentum. Greatly

increased access to personal computers has expanded the available tools to more easily analyze and create networks. The current popularity of SNA among the public can be traced to the game “Six Degrees of Kevin Bacon.” This actor has appeared in such a wide variety of films throughout his career that it is possible to connect him to any other actor through the films that they have in common. For example, actress Sophie Marceau was in *The World Is Not Enough* with Pierce Brosnan, who was in *The Thomas Crown Affair* with Rene Russo, who was in *Major League* with Tom Berenger, who was in *Gettysburg* with Sam Elliott, who was in *Tombstone* with Bill Paxton, who was in *Apollo 13* with Kevin Bacon, for six degrees.

Other current trends in SNA are in researching organizational structure, nonprofits, and nongovernmental organizations (NGOs). Provan and Milward (2001) define a network as “a collection of programs and services that span a broad range of cooperating by legally autonomous organizations” (p. 417). They go further to point out that there are “network administrative organization(s)” that facilitate networking by the distribution of funds (p. 418). Examples of network administrative organizations include the United Way and Community Shares. Both of these organizations raise funds and subsequently distribute funds to nonprofit organizations. This often places them at the center of a network of nonprofit organizations.

Provan and Milward’s (2001) work examines the effectiveness of networks between organizations providing public services. They argue that “networks must be evaluated at three levels of analysis: community, network, and organization/participant levels” (p. 414). One point made by Provan and Milward is that the boundaries of a community in a discussion of community-based networks do not necessarily follow geographic boundaries (p. 416).

The discussion of nonprofit organizations in Europe is the basis of Fowler’s 1996 work. This discussion takes into consideration the larger network of “economic, political, social, ecological, and other systems” that NGOs are situated within (p. 60). It is important to understand that nonprofit organizations and NGOs do not create exclusionary networks. They operate within the context of governments, businesses, the general public, and the people they service. Fowler’s analysis shows these as a linear equation. However, the network of nonprofit organizations as shown by Lind (2002) shows that this network is not linear in that the participants and volunteers in many cases overlap to create less of a straight line and more of a circular configuration. It is this overlap that creates the basis for a power structure.

The “dramatic change in the division of responsibility between the state and the private sector for the delivery of public goods and services” (p. 1343) is the focus of Besley and Ghatak’s work (2001). They look at the arrangements between these entities and the need for analysis to discern who should be responsible for the delivery of public goods and services. Besley and Ghatak

go into a detailed mathematical model to determine the value of the investments made in the delivery of public goods and services. They explain as follows:

Any discussion of NGOs is further complicated by the fact that they have not only increased in number and taken on new functions, but they have also forged innovative and increasingly complex and wide-ranging formal and informal linkages with one another, with government agencies, with social movements, with international development agencies, with individual INGOs (international NGOs), and with transnational issue networks. (Besley & Ghatak, 2001, p. 441)

This is another acknowledgment of the network that exists between nonprofit organizations. Fisher (1997) makes a call in this paper for “detailed studies of what is happening in particular places or within specific organization[s]” (as cited in Besley & Ghatak, 2001, p. 441). One caution made by Fisher is that “NGOs are idealized as organizations through which people help others for reasons other than profit and politics” (as cited in Besley & Ghatak, 2001, p. 442). Something that benefits one person or group may have an adverse effect on another person or group.

Power Issues and Ethics

Riner’s (1981) look at the networks created by corporations describes the concept of membership on multiple boards, or connections through directors, as *interlocking*. Riner states, “Interlocking occurs when an individual serves simultaneously as a member of two or more of these boards. Directorate interlocking connects individual decision-making components in a global network which may be considered the core institution of fifth-level organization” (p. 167). The literature suggests that this interlocking is one of the levels, the fifth level, of networking that links organizations to each other by showing the links of key people—volunteers, staff, and board members—in both current and historical positions. Riner also discusses interlocking in relation to what was termed by Pratt in 1905 as a business senate that controls the United States (p. 168). This echoes C. Wright Mills’s (1999) assertion in *The Power Elite* that it is the power elite who are actually in control, rather than the elected government. Mills’s theory states, “They [the power elite] are in positions to make decisions having major consequences” (p. 4). Riner’s work defines and describes interlocking in reference to corporate boards. One of the case studies in the following section applies this concept to the boards of nonprofit organizations to establish the existence of a social network in Cincinnati.

Yeung’s (2005) work looks not at the network itself, but at the meaning of the relationship that forms the network; by looking at only the network without analyzing the meaning of the relationship, the cultural meaning of the relationship is lost (p. 391). Fisher (1997) quotes Milton Friedman as saying that “the power to do good is also the

power to do harm” (p. 442). Something that benefits one person or group may have an adverse effect on another person or group. It is clear that these aforementioned authors have done groundbreaking work on power and power networks. However, power can also be misrepresented in data collected for SNA. A number of research studies have investigated the respondent bias in egocentric analyses (see Romney & Weller, 1984) and have concluded that people often overestimate their centrality when they are asked to self-report their social networks (Johnson & Orbach, 2002, p. 298). Whether by intentional deceit or accidental oversight, researchers have found, people’s responses and their actual behaviors often have little overlap. Researchers also learned that an individual’s response accuracy depends on the frequency of the respondent’s interactions and the long-term behavior patterns the respondent had directly observed in the group. Johnson and Orbach have found that as individuals are more familiar with, and knowledgeable of, their networks, the smaller their “ego bias.” Studies have also concluded that self-reported power relationships may be biased based on the respondent’s centrality, social rank, and reputation in the group (Krackhardt, 1990).

Another danger that appears in SNA is the loss of subject anonymity. Despite the anthropologists’ attempts to conceal the names of their informants, the nature of a social network lends itself to the ability of anyone familiar with the network in question to identify the informants based on their reported connections. This becomes an issue especially in cases of applied anthropologists working in a corporate setting. Many times, corporations use SNA to study the structure and efficiency of their business. Employees may be required to participate in the study by their employer with the understanding that their responses will be kept confidential. However, many times the nature of the answers can be easily attributed to an individual or department. Further, the results of SNA can be used to determine policies that may affect jobs, hiring, and promotions.

Case Studies

Social-network studies are used by many professionals and appear in a wide variety of research journals and publications. This cross-cultural discipline continues to evolve as researchers share and borrow across their respective fields. The following case studies provide a brief glimpse into the ways anthropologists have used SNA methodology to study nonprofit organizations, business, health, kinship, and even primatology.

Nonprofit Social Networks

Anthropologists do not always study the individual, or egocentric networks. The diversity of the field of anthropology results in the ability of anthropologists to study

larger entities, such as organizations, institutions, and even networks of entire countries. In *The Seven Degrees of Cincinnati: Social Networks of Social Services*, Stambaugh (2008) diagrammed the structure of nonprofit organizations to show the connections created through key people: board members, employees, and volunteers. In this study, three groups were charted showing three distinct social-network structures. The first group, civic organizations located in the uptown area of Cincinnati, showed a distinct center of power based on the proportion of connections to other nonprofit organizations. The assumption of power was further confirmed from a financial angle by comparing the annual income of the civic organizations through publicly available tax returns. Additional evidence of the amount of power held by this organization was seen in the organizations it represented. The organization, the Uptown Consortium, was formed by an alliance of the five major employers in uptown, each of which is also a nonprofit organization.

Additional analysis of these organizations shows that they have connections to another 198 organizations through funding or shared real estate. The projects undertaken by the Uptown Consortium benefit the five organizations that formed it, rather than the communities in which they are located. This causes some tension between the community councils that represent each of the seven communities in uptown, and the Uptown Consortium. Essentially, this has created two separate and competing communities in uptown; the daytime community of commuting workers and the nighttime community of residents.

The second case study looks at the relationship between the Cincinnati City Council and the 51 community councils recognized throughout the city. There are 52 communities that make up Cincinnati, each with a distinct personality. What distinguishes this case study from the uptown example is the lack of connections of key people creating centralized power. This example has 23 community councils with connections to other nonprofit organizations, leaving 28 community councils with no apparent interlocks. Also, the nature of a community council requires that the members must live in the community, which precludes membership on more than one community council. With the exception of the community councils located in uptown, there appears to be little linking the community councils to each other apart from some secondary connections. This lack of connections diffuses the potential power of the community councils, leaving it with the city council.

The third case study looks at nonprofit youth organizations located in Cincinnati beginning with the Great Rivers Girl Scout Council and the Boy Scouts of America, where we would expect to find connections to other youth-based organizations. What is striking about this case as opposed to the uptown case is that the youth organizations do not appear to be connected to similar organizations. This creates a network that moves money into these two youth

organizations, but not to other youth-based organizations that could become the basis for a power network.

Social Networks in Business Anthropology

Using SNA in business anthropology tends to be more straightforward than other anthropological uses. In business and organizations, managers and senior leaders are concerned with networks and relationships that affect their employees' workflow. Usually, managers believe they understand such relationships, but they are often not aware of certain informal work relationships. Krackhardt and Hanson (1993) argue that it is these informal networks that have the greatest effect on workflow in organizations. The authors state that in an atmosphere of trust, managers can conduct SNA surveys and glean information on informal networks in their organizations. Generally, SNA questionnaires should address three different types of social networks in the workplace: (1) the advice network, (2) the trust network, and (3) the communication network (p. 105). People also have to feel safe that their responses to the surveys will not be disseminated widely to their colleagues and that they will not be penalized for their responses. If trust is there, then managers can collect SNA data, cross-check the responses for accuracy, and analyze the information statistically or with SNA software (p. 106).

Krackhardt and Hanson (1993) provide a case study that illustrates just how important it is to ask employees questions about all three networks: advice, trust, and communication. The authors conducted SNA for a computer company with a task force that was experiencing difficulty getting work done. The SNA diagram of advice indicated that the project leader was, in fact, the leader in giving work-related, technical advice. However, the trust SNA showed the project leader to be completely outside the network with only a single link indicating trust from one individual. It was clear from looking at these two SNA diagrams that no one on the team trusted the project leader, and this distrust was the main barrier for getting work done (pp. 106–107). Once this information is captured from SNA, it is imperative that managers know what to do with it. All too often, it is concluded that if an individual lies outside an SNA diagram, he or she is expendable. Since there are three types of social networks in business, and since all workers provide a valuable contribution to the organization with their experience, it is not always the case they these outliers need to be fired. The authors state that managers need to use this information to foster relationships between employees within the information networks that will enable them to make contributions to the company (p. 111). In fact, in the case study provided here, the CEO of the computer company chose an individual who was central to the trust SNA diagram to share responsibility with the current project leader. The two coleads were then able to complete the project and no one had to be removed from the project or fired altogether.

SNA has also been used extensively in various studies on the effect of leadership on team performance. Mehra, Smith, Dixon, and Robertson (2006) state that too much literature is devoted to the study of leadership styles and not enough is dedicated to studying group dynamics when teams consist of more than one leader. They reiterate the fact that many groups consist of informal leaders and these networks are best studied through SNA methodology because it is a relational approach allowing for multiple leaders within a group. SNA also models both vertical (i.e., between formal leader and subordinates) and lateral (among subordinates) leadership within a team.

Mehra et al. (2006) collected sociometric data from a sample of 28 field-based sales teams to investigate how the network structure of leadership perceptions by team members related to team satisfaction and performance (pp. 232–233). They collected extensive data from all members of the field teams, between 6 and 22 individuals, who were each headed by a single formal leader. Team members were given a roster of names from the whole team and asked to rate whom they perceived to be leaders on the team. The teams were then classified as either distributed, teams with more than one leader, or leader-centered teams, those consisting of a single leader. The authors report that distributed leadership does not necessarily lead to greater team performance unless the leaders see themselves and each other as leaders and team members work together. Their study divided the distributed leader networks into distributed-coordinated and distributed-fragmented and found that teams with a distributed-coordinated leadership network had significantly higher performance records than single-leader or distributed-fragmented leadership (p. 241).

Studies in marketing, business, and management are greatly benefiting from the increase in SNA studies in recent years. SNA has been able to shed light on formal and informal social networks, different leadership styles, and their effects on satisfaction and performance in the workplace. Many new research possibilities have been opened up by the important work of the small group of social scientists who use SNA for business studies.

SNA Studies of Childhood

Jeffrey Johnson and Marsha Ironsmith (1994) and colleagues (Johnson et al., 1997) have used SNA to study children and childhood. In 1994, Johnson and Ironsmith provided a literature review on the utility of sociometric studies with children. The literature focuses on the development of peer groups, as well as the child's place within one, to understand behaviors associated with the peer group and to identify children at risk for social rejection (1994, p. 36). Social rejection in childhood is often later associated with delinquency, mental illness, and poor academic achievement (Roff, Sells, & Golden, 1972; Wentzel & Asher, 1995).

Johnson and Ironsmith's (1994) work describes issues of reliability, validity, and analyzing group structure and

networks over time when utilizing SNA with children. The authors argue that previous sociometric studies with children were largely inadequate because they ignored group structure. Johnson and Ironsmith state that SNA provides a unique opportunity to study the complex social structures and development of young children. SNA has also allowed researchers to identify the influence of cliques and subgroups on the acceptance or rejection of children in their social networks (p. 45). Additionally, Johnson and Ironsmith argue that SNA is useful for measuring changes in the social structure over time.

Johnson et al. (1997) conducted a study with 65 children in a child care center over the course of 3 years. Their methods included sociometric interviews and behavioral observations of the 3- and 4-year-old children. The authors trained the preschool children to use a 3-point "happy face Likert scale" where they were asked how much they like to play with each of the other children. The researchers then read the children a story or gave a short analogies test in order to minimize the chance that the children would discuss the interview with the others. The authors further controlled the validity and reliability of their study by utilizing undergraduate research assistants who were unaware of the hypotheses being tested to conduct the observations. This study found that as children get older, their play preferences are more likely to match their social interactions (p. 402). Johnson et al. also concluded that three of the four cohorts studied had a close correspondence between the results of the interviews and the behavioral observations. Last, the researchers argued that by age 4, the children had stable, organized social networks. Because of this, age 3 is stated to be the ideal time for interventions to minimize the negative effects of social rejection.

Social Networks in Medical Anthropology

Medical anthropologists can use SNA in a variety of ways, such as to evaluate how change happens, to understand why knowledge or meaning is created and its flow (Introcaso, 2005, p. 95), and the key individuals in the complex webs of communities. It is known in psychological, medical, and some SNA research that people are healthier when they experience social relationships with others. It is not just mental health that is better when individuals are connected to others; social support networks improve people's general health. People encourage each other to engage in preventative health behaviors and provide support for each other when they are ill. In fact, studies have shown that individuals without many social relationships had a death rate 2 to 5 times higher than the individuals who had many social connections (Berkman & Syme, 1979). In addition, social networks contain many important features for medical anthropologists to capture because much initial diagnosis and healing is done in the

home or among close friends and community networks. People tend to act as sources of health advice in a number of instances, as described in the following roles:

1. People who have long experiences with a particular illness or treatment
2. Individuals who have extensive experience of certain life events
3. Medical and paramedical professionals and occasionally their spouses
4. Organizers of self-help groups
5. Clergy members (Helman, 1994, p. 66)

Social networks are important for medical anthropologists to understand because it is often the untrained individuals closest to the patient who are consulted for initial health advice. Pescosolido, Wright, Alegria, and Vera (1998) used SNA to identify patterns of use of mental health services in Puerto Rico. The authors state that a greater emphasis has been placed on the community for developing and supporting mental health initiatives as healthcare reform aims to reduce the levels and duration of care in managed-care settings. Despite this major shift from admittance in a long-term care facility to long-term, community-based care centers, there has been little research conducted to evaluate the effectiveness of this shift (p. 1058). SNA can help understand how the community influences usage of mental health care centers and clinics in Puerto Rico and elsewhere.

Stating that ethnic groups of low socioeconomic status have low rates of mental health care utilization, Pescosolido and colleagues chose to study the relationships of this community in Puerto Rico. The researchers found six main patterns of use in mental health care. This information can be used to identify key players in the community. Armed with this knowledge, agencies can increase education and resources for these key community individuals to help increase mental health care usage, because "knowledge always inextricably combines with action, interactions, and relationships of practice" (Introcaso, 2005, p. 97).

Identifying key players in social networks can also be used for epidemiological studies. Most notable examples of the impact of social relationships and the spread of disease include the black plague in Europe and the spread of smallpox and other European diseases to the Americas (McNeill, 1976). Morris (1994) states that there are three main social systems to investigate with the spread of disease. First, mobile vectors such as rats can spread disease. This allows for widespread infection in a short period of time. Second, there are diseases that require casual or indirect contact, like the measles, that have a relatively short infectious period. Last, there are diseases that are only spread through intimate contact, such as sexually transmitted diseases, that "travel along the most selective forms of social networks" (p. 27). Anthropologists and epidemiologists are beginning to use SNA to identify vectors and new potential victims of sexually transmitted

diseases because traditional epidemiological-projection models have proven insufficient.

Network Analyses in Primatology

Social network analysis has not been utilized to its fullest potential with nonhuman primates until relatively recently. Nonhuman primates provide excellent conditions for SNA because they do not have the same symbolic interactions as humans. This makes them a simpler example of social groups that can be studied with SNA (Sade & Dow, 1994, p. 152). Although they may not have the same complexity of symbolic interactions, primates do acquire roles. Primatologists are concerned with understanding these roles, how they are acquired, and their interactions. Roles arise from continual relations of individuals based on age, sex, and dominance—all integral to developing the group's social structure.

Much pioneering work on understanding nonhuman primate social networks was done by Jane Goodall and Dian Fossey. With this as a foundation, sociograms have been employed in primate studies since the 1960s as anthropologists and primatologists used them as simplified kinship diagrams. Sade (1965) began to utilize sociograms for showing how nonrelated rhesus monkeys form social networks based on grooming behavior. These relational sociograms showed that grooming behavior was much more pronounced among related members of the group than nonrelatives. This research also enabled Sade to recognize how social relationships formed in rhesus groups. Sociograms were also useful for Clark (1985), who published research on the galago contradicting the previous literature, which characterized them as solitary primates. Clark used sociograms to show that while galagos may forage alone, they in fact had social networks that linked individuals of all age and sex classes. Chepko-Sade, Reitz, and Sade later (1989) went beyond the use of sociograms and made predictive models with hierarchical cluster analysis to determine the outcome of a fissioning group of rhesus monkeys. Relationships the researchers defined as weak had broken completely a year later, resulting in the fissioning of the entire group.
