CONTENTS

VOLUME ONE

Preface	xi
About the Editor	xiii
About the Contributors	xiv
PART I. BIOLOGICAL ANTHROPOLOGY	
1. Biological Anthropology <i>H. James Birx, Canisius College and State University of New York at Geneseo</i>	2
2. Hominid Descriptions <i>Ignacio Arenillas and José Antonio Arz, University of Zaragoza</i>	13
3. Human Brain <i>Cris Campbell, University of Colorado at Boulder</i>	26
4. Human Adaptations <i>Jill M. Church, D'Youville College</i>	38
5. Human Growth and Development <i>Brittney M. Howell, Northern Kentucky University and Gateway Community and Technical College</i>	47
6. Human Biocultural Diversity <i>Brittney M. Howell, Northern Kentucky University and Gateway Community and Technical College</i> <i>Andrew Shooner, University of Cincinnati</i>	56
7. Race and Racism <i>Paul F. Brown, Minnesota State University, Mankato</i>	65
8. DNA and Genetic Engineering <i>John K. Grandy, Lee Medical Associates, Dunkirk, New York</i>	76
PART II. ARCHAEOLOGY	
9. Archaeology <i>Robert Bollt (1971–2010), Honolulu, Hawai'i</i>	92
10. Excavation and Preservation <i>Chang-Ho C. Ji and Robert D. Bates, La Sierra University</i>	101
11. Artifacts, Burials, and Ruins <i>Gregory D. Mumford, University of Alabama at Birmingham</i>	111

12. Aztecs, Incas, and Mayans	121
<i>Frances F. Berdan, California State University, San Bernardino</i>	
13. Technology	132
<i>Andreas Spahn, Eindhoven University of Technology</i>	
PART III. SOCIOCULTURAL ANTHROPOLOGY	
14. Concept of Culture	144
<i>Les Beldo, University of Chicago</i>	
15. Ethnography and Ethnology	153
<i>Isabelle M. Flemming, Ela Area Public Library, Lake Zurich, Illinois</i>	
16. Marriage and the Family	162
<i>Lisa M. Vaughn, Cincinnati Children's Hospital Medical Center/ University of Cincinnati College of Medicine</i>	
17. Kinship Systems	174
<i>Richard R. Jones, Lee University</i>	
18. Political Organizations	182
<i>Elaine M. Reeves, University of Toledo</i>	
19. Magic and Science	191
<i>Isabelle M. Flemming, Ela Area Public Library, Lake Zurich, Illinois</i>	
20. Shamanism	200
<i>Gwendolyn J. Reece, American University Library</i>	
21. Witchcraft and Sorcery	209
<i>Jacky Vallée, Vanier College, Montreal</i>	
22. Religions and Beliefs	218
<i>Hans Otto Seitschek, Ludwig Maximilian University in Munich</i>	
23. Cosmology and Mythology	227
<i>Anna Maria Destro, Eastern Piedmont University</i>	
24. Peasant Societies	235
<i>Kathleen Nadeau, California State University, San Bernardino</i>	
25. Food: Plants and Animals	245
<i>Frances D. Burton, University of Toronto</i>	
PART IV. LINGUISTICS	
26. Linguistics	258
<i>Patricia N. Chrosniak, Bradley University</i>	
27. Communication and Symbolism	269
<i>John Douglas Rhoades, St. John Fisher College</i>	
28. Storytelling	277
<i>Katie Elson Anderson, Rutgers University</i>	
29. Mass Media and Anthropology	287
<i>Sarasij Majumder, Rutgers University</i>	
PART V. APPLIED ANTHROPOLOGY	
30. Applied Anthropology	296
<i>Michael J. Simonton, Northern Kentucky University</i>	
31. Law and Anthropology	305
<i>Oliver W. Lembcke, Friedrich Schiller University in Jena</i>	
32. Forensic Anthropology	314
<i>Sara Rofofsky Marcus, Queensboro Community College, City University of New York</i>	
33. Paleopathology and Anthropology	322
<i>Christopher David Czaplicki, Canisius College</i>	

34. Medical Anthropology	331
<i>Arvilla Chapin Payne-Jackson, Howard University</i>	
35. Infectious Diseases and Anthropology	340
<i>Richard Albert Stein, Princeton University</i>	
PART VI. METHODOLOGY	
36. Dating Techniques	352
<i>Tori M. Saneda, Cascadia Community College</i>	
37. Interpreting Evidence	361
<i>Donald R. Perry, Branchport, New York</i>	
38. Cross-Cultural Studies	370
<i>Constance B. Williams, Queensborough Community College, City University of New York</i>	
39. Twin Studies	379
<i>Greta G. Boers, Duke University</i>	
PART VII. TEMPORAL FRAMEWORKS	
40. Geology and Anthropology	388
<i>Rhonda L. Quinn, Rutgers University and New York University</i>	
41. Paleontology and Anthropology	398
<i>Kris "Fire" Kovarovic, University College London</i>	
42. Prehistoric Cultures	409
<i>Pamela Hayes-Bohanan, Bridgewater State College</i>	
43. Ancient Civilizations	419
<i>Terry W. Eddinger, Carolina Evangelical Divinity School</i>	
44. History and Anthropology	432
<i>Michael J. Francisconi, University of Montana Western</i>	
PART VIII. THEORIES IN ANTHROPOLOGY	
45. Theoretical Anthropology	442
<i>Michael J. Francisconi, University of Montana Western</i>	
46. Ideology and Anthropology	453
<i>Kathleen Nadeau, California State University, San Bernardino</i>	
47. Enlightenment and Secularism	463
<i>James Pleger Bonanno, State University of New York at Binghamton</i>	
48. Marxist Anthropology	473
<i>Kathleen Nadeau, California State University, San Bernardino</i>	
49. Agency and Practice Theory	480
<i>Angela Kristin VandenBroek, University of Southern Mississippi</i>	
50. Open and Closed Societies	488
<i>Joachim Klose, Commissioner of the Konrad Adenauer Foundation for the Free State of Saxony</i>	
51. Culture and Personality	499
<i>Gerald Sullivan, Collin College</i>	
52. German Anthropology	510
<i>Dirk Solies, Johannes Gutenberg University of Mainz</i>	
53. Values and Anthropology	517
<i>Richard R. Jones, Lee University</i>	
54. Human Excellence: Past and Present	526
<i>Irina Jovan Deretic, University of Belgrade</i>	

VOLUME TWO

PART IX. EVOLUTION

55. Fossil Primates 538
Ignacio Arenillas and José Antonio Arz, University of Zaragoza
56. Human Evolution 556
Jeffrey H. Schwartz, University of Pittsburgh
57. Culture Change 565
Robert Bates Graber, Truman State University
58. Social Evolution 576
Robert Bates Graber, Truman State University
59. Evolution: Science, Anthropology, and Philosophy 586
H. James Birx, Canisius College and State University of New York at Geneseo
60. Evolution/Creation Controversy 600
Laura M. Bolt, University of Toronto

PART X. PRIMATE RESEARCH

61. Primate Taxonomy 612
John R. Grehan, Buffalo Museum of Science
62. Primate Locomotion 624
David Alexander Lukaszek, University of Alaska Fairbanks
63. Primate Behavior Studies 633
Ryan J. Trubits, Lancaster, New York
64. Primate Extinction and Conservation 647
Andrea Patricia Birkby, Fort Lewis College

PART XI. CULTURE STUDIES

65. Amazonia 658
Carlos Antonio Martin Soria, Instituto del Bien Común Peru
66. Australian Aborigines 668
Susanna Servello, Cremona, Italy
67. Inuit 676
Pamela Rae Huteson, Edmonds, Washington
68. Iroquoian Peoples 687
Neil Patrick O'Donnell, Canisius College

PART XII. CULTURE AREAS

69. Africa: Past and Present 698
Belete K. Mebratu, Medaille College

70. Caribbean: Past and Present	707
<i>Fernando Valerio-Holguín, Colorado State University</i>	
71. Europe: Past and Present	716
<i>Michael J. Simonton, Northern Kentucky University</i>	
72. India: Past and Present	725
<i>Ramdas Lamb, University of Hawai'i at Manoa</i>	
73. Polynesia: Past and Present	735
<i>Robert Bollt (1971–2010), Honolulu, Hawai'i</i>	
 PART XIII. SOCIAL BEHAVIOR	
74. Social Relationships	746
<i>Brittney M. Howell, Northern Kentucky University and Gateway Community and Technical College Melony L. Stambaugh, Northern Kentucky University</i>	
75. Rank, Status, and Role	756
<i>Debra M. Lucas, D'Youville College</i>	
76. Ceremonies	764
<i>Debika Saha, University of North Bengal</i>	
77. Festivals and Rituals	773
<i>Cynthia J. W. Svoboda, Bridgewater State College</i>	
78. Music and Dance	782
<i>Shayna Silverstein, University of Chicago</i>	
79. Conflict and Aggression	791
<i>Cris Campbell, University of Colorado at Boulder</i>	
80. Social Problems	801
<i>Robert M. Worley, Penn State Altoona</i>	
81. Gangs	810
<i>Patricia E. Erickson, Canisius College</i>	
82. Deviant Behavior	819
<i>Robert M. Worley and Vidisha Barua Worley, Penn State Altoona</i>	
83. Delinquency	827
<i>Melissa A. Menasco, Canisius College</i>	
84. Violence and Warfare	839
<i>Vidisha Barua Worley, Penn State Altoona</i>	
 PART XIV. ANTHROPOLOGY TODAY	
85. Folk Concepts	848
<i>Jay H. Bernstein, Kingsborough Community College, City University of New York</i>	
86. Migration and Globalization	856
<i>Marcia B. Dinneen, Bridgewater State College</i>	
87. Globalization	865
<i>Christopher Morris, University of Colorado at Boulder</i>	
88. Education and Anthropology	874
<i>Suzanne E. D'Amato, Medaille College</i>	
89. History and Literature in Anthropology	883
<i>Frank A. Salamone, Iona College</i>	
90. Women and Anthropology	895
<i>Anne Bennett, California State University, San Bernardino</i>	

91. Visual Anthropology	906
<i>Lisa M. Vaughn, University of Cincinnati College of Medicine/ Cincinnati Children's Hospital Medical Center Katie E. Englert, Northern Kentucky University</i>	
92. Computers and Anthropology	915
<i>Stefan Artmann, Friedrich Schiller University in Jena</i>	
93. Health and Illness	925
<i>Stephen D. Glazier and Mary J. Hallin, University of Nebraska–Lincoln</i>	
PART XV. ONGOING ISSUES IN ANTHROPOLOGY	
94. Sociobiology: Nature and Nurture	938
<i>Christian Spahn, Friedrich Schiller University in Jena</i>	
95. Psychology and Anthropology	950
<i>Jacob R. Hickman, University of Chicago</i>	
96. IQ: Viewpoints and Controversies	960
<i>Cynthia Crosser, University of Maine</i>	
97. Human Longevity and World Population	970
<i>Sang-Hee Lee, University of California, Riverside</i>	
98. Environmental Issues	977
<i>Erin E. Robinson, Canisius College</i>	
99. Human Ecology	986
<i>Lucas Bowman, Appalachian State University</i>	
100. Feminist Anthropology	997
<i>Christina Taylor Beard-Moose, Suffolk County Community College</i>	
101. Terrorism	1007
<i>James F. Miskel, Long Island University, U.S. Naval War College, and Norwich University</i>	
102. Human Rights and Dignity	1015
<i>Stefan Lorenz Sorgner, University of Erfurt</i>	
Index	1025

PREFACE

Since its emergence as a discipline in the middle of the 19th century, anthropology has focused on the study of humankind in terms of science and reason, as well as logical speculation. Within a comprehensive and interdisciplinary framework, anthropology aims for a better understanding of and proper appreciation for the place of our species within earth history and organic development. As such, the scientific theory of biological evolution has been indispensable for giving meaning and purpose to the awesome range of empirical facts and conceptual insights that now constitute the rich content of present-day anthropology. Furthermore, cross-cultural studies emphasize the vast differences among human groups from the perspectives of material culture, social behavior, languages, and worldviews.

Because of its holistic orientation, the anthropological quest includes four major but interrelated divisions of concentration: biological anthropology, archaeology, sociocultural anthropology, and linguistics. These four divisions represent many specific areas of academic interest and scholarly research, each area with its own unique topics and methods of inquiry. Early anthropologists sought not only to document human evolution, but also to record the cultural differences of other societies. They also speculated on the origin and history of human societies, cultures, and languages. Furthermore, early anthropologists benefited from and contributed to other special sciences, from geology and paleontology to sociology and psychology. To their advantage, anthropologists have remained open to the scientific discoveries in modern biology, for example, the DNA molecule, and the critical ideas in recent philosophy (e.g., the Marxist approach to solving social problems).

Following the pivotal writings on evolution by Charles Darwin (1809–1882), the early anthropologists took time and change seriously. They speculated on the origin and history of our species and its relationship to the other primates, especially the great apes. Sir Edward Burnett Tylor wrote *Primitive Culture* (1871), extending the framework of organic evolution to include the historical development of human societies and their cultures. In the early 1890s, Eugene Dubois discovered a *Homo erectus* specimen at the

Trinil site on the island of Java. Among others, these two events contributed to the emergence of anthropology as an academic discipline in its own right.

Throughout the 20th century, scientific research remained a major concern for anthropologists. The discovery of Machu Picchu by Hiram Bingham in 1911 and the tomb of Tutankhamen by Howard Carter in 1922 brought worldwide attention to archaeology. Later, at Columbia University, the writings of Ruth Benedict, Franz Boas, and Margaret Mead offered a cross-cultural perspective on human biology, language, thought, and behavior.

In 1959, in central East Africa, the discovery of a *Zinjanthropus boisei* skull at Olduvai Gorge in Tanzania by paleoarchaeologist Mary D. Leakey and the study of wild mountain gorillas in their natural habitats on the slopes of the Virunga volcanoes by zoologist George B. Schaller helped to usher in modern biological anthropology. And then there was the crucial extension of genetic research to the study of our own species in order to understand and appreciate the human animal within the wider framework of primate evolution.

Today, after about 150 years, the discipline of anthropology is as active and relevant as ever. Incorporating the ongoing advances in science and technology, specialists in anthropology find no lack of engaging topics for scholarly research. There is the challenge and need to study and protect endangered nonhuman primates, to continuously search for fossil hominid specimens and hominid-made stone artifacts, and to comprehend the many complex relationships between our biocultural species and its dynamic environment. Moreover, anthropologists have been very instrumental in increasing human tolerance for the biological variations and cultural differences that exist within the hundreds of societies that comprise our global species. As a new research area, applied anthropology strives to be relevant in this civilized but converging world (e.g., the emergence of forensic anthropology and biomedical anthropology).

The 102 chapters in this two-volume *21st Century Anthropology: A Reference Handbook* attest to the many research topics being investigated by current anthropologists and related scholars in science and philosophy. Each

of the 15 general categories offers not only the most recent empirical facts and explanatory concepts in the topics treated, but also those new areas that require further scientific research and philosophical reflection. And there are always new models, methods, theories, discoveries, and perspectives that will emerge in the ongoing development of anthropology throughout the coming decades.

Within these pages, one will explore many varied but fascinating topics (e.g., from the concept of culture, ancient civilizations, and human ecology to paleopathology, twin studies, and terrorism). It is hoped that the 102 intriguing subjects, which make up this reference handbook, will both enlighten and inspire some readers to join the ongoing anthropological quest.

Acknowledgments

At Sage Reference, I especially appreciate that its vice president and publisher, Rolf A. Janke, had recommended that I edit the two-volume *21st Century Anthropology: A Reference Handbook*. Furthermore, I am deeply grateful to developmental editors Sara Tauber and Sanford Robinson for providing excellent guidance during the long and arduous evolution of this extensive and unique project.

I also benefitted from the meticulous attention given to all the details of this comprehensive work through the expertise of production editor Carla Freeman and the copy editors Gretchen Treadwell, Patricia Sutton, and Cate Huisman.

In particular, I am very appreciative of Ravi Balasuriya for his outstanding artistic contribution in designing the striking cover for this two-volume set.

Moreover, I am deeply indebted to managing editor Sylvia S. Bigler at Canisius College, whose attentive focus on helping me to review these 102 chapters was an invaluable aid in the preparation of this reference handbook for publication. Without her professional administrative assistance and persistent moral support, the conception and completion of this project would not have been possible.

Furthermore, these editorial board members have been most helpful during the preparation of this two-volume set: Robert Bollt, Paul F. Brown, Patricia N. Chrosniak,

Irina Jovan Deretic, Jeffrey H. Schwartz, and Stefan Lorenz Sorgner.

The range and depth of these challenging but exciting topics clearly attest to the ongoing significance of and interest in the research so necessary for the comprehensive discipline of modern anthropology. It is with heartfelt thanks that I acknowledge the contributing authors for their scholarly chapters. The following writers were especially helpful in providing several entries or an essential contribution for this academic work: Ignacio Arenillas, José Antonio Arz, Les Beldo, Robert Bollt, James Pleger Bonanno, Cris Campbell, Irina Jovan Deretic, Isabelle M. Flemming, Michael Joseph Francisconi, Robert Bates Graber, Britteny M. Howell, Joachim Klose, Ramdas Lamb, Kathleen Nadeau, Neil P. O'Donnell, Jeffrey H. Schwartz, Hans Otto Seitschek, Stefan Lorenz Sorgner, Ryan J. Trubits, Robert M. Worley, and Vidisha Barua Worley.

Over the years, these individuals have offered encouragement and provided inspiration: Stefan Artmann, Pat Bobrowski, Brandin Robert Clark, Joshua Gerald Clark, Benjamin J. Cooper, Brian C. Crotzer, Christopher C. Dahl, Marvin Farber, Maximilian Flierler, Deanna L. Garwol, Edward G. Garwol III, Edward G. Garwol IV, Shirley A. Garwol, Debra G. Hill, Pamela Rae Huteson, Susanne Des Jardins, Albertha F. Kelley, Leonid A. Khinkis, Margaret M. Kraatz, Oliver W. Lembcke, David Alexander Lukaszek, Lawrence J. Minet, Dianne Marie Murphy, Rajko R. Pavlicic, Rev. Edmund G. Ryan, Maximilian Luitpold Schreck, Richard Albert Stein, Mark James Thompson, and Beatrix Vogel.

During the past 7 years, opera and film have sustained me during the daunting task of editing and contributing to 10 volumes for Sage Publications. I remain thankful for the music of Richard Wagner and Giacomo Puccini, as well as the performances of Pernell Roberts and Mario Lanza.

H. James Birx

Professor of Anthropology, Canisius College

Distinguished Research Scholar,

State University of New York at Geneseo

Scientific Advisory Board, Ethics Center,

Friedrich Schiller University in Jena

Scientific Board, Nietzsche-Forum Munich

ABOUT THE EDITOR

H. James Birx, PhD, DSci, is Professor of Anthropology at Canisius College in Buffalo, New York, and Distinguished Research Scholar at the State University of New York at Geneseo. He received both his MA in anthropology and PhD with distinction in philosophy from the State University of New York–University at Buffalo. His professional interests range from evolution science, through biological anthropology, to process philosophy.

Dr. Birx has been a visiting scholar at the University of Cambridge and twice at Harvard University. He has written more than 400 academic publications, including authoring 6 books and editing 14 other volumes, receiving awards for both his *Theories of Evolution* and the five-volume *Encyclopedia of Anthropology* (2006), and critical acclaim for his three-volume *Encyclopedia of Time* (2009).

Dr. Birx has lectured extensively at renowned institutions and prestigious universities around the globe, from Australia

to Russia. In 2010, he will give invited presentations at Alfa University, Aristotle University of Thessaloniki, University of Athens, University of the Aegean, University of Belgrade, University of Chicago, University of Munich (LMU), University of Oxford, and for the Nietzsche-Forum Munich. He will also be a scholar in residence at the State University of New York at Geneseo and then a distinguished visiting professor at the University of Belgrade for its faculty of philosophy.

Dr. Birx has been fascinated with anthropology since childhood, when he first learned about wild mountain gorillas and different human cultures. Over the years, he has visited numerous zoos, museums, and anthropological sites from Egypt, England, and Germany to Hawai'i, Mexico, and Peru. Of particular importance was his research in craniometry at the Orchid site ossuary in Canada, and in paleoanthropology at the Koobi Fora site in Kenya, Africa. His professional listings include *Who's Who in the World*.

ABOUT THE CONTRIBUTORS

Katie Elson Anderson is Reference and Instruction Librarian at the Paul Robeson Library, Rutgers University, in Camden, New Jersey, where she also serves as department liaison for the Department of Sociology, Anthropology, and Criminal Justice. She holds a master of library and information science (2007) from Rutgers University and bachelor's degrees in anthropology and German from Washington University, St. Louis, Missouri. Publications include chapters in *Scholarly Resources for Children and Childhood Studies: A Research Guide and Annotated Bibliography* (2007) and *Teaching Gen M: A Handbook for Librarians and Educators* (2009). Contributions to the *World History Encyclopedia* (2010) are forthcoming. Her research interests include the importance of new technologies to librarianship, teaching, and storytelling. Research for *21st Century Anthropology* has led to a stronger appreciation of and understanding for her son's request to "read me a story."

Ignacio Arenillas is Professor of Paleontology in the Department of Earth Science at the University of Zaragoza, Spain. His scientific career spans over 17 years, having earned his Licentiate in geology in 1992 and his PhD in geology in 1996 from the University of Zaragoza. Authoring over 100 publications, he specializes in marine micropaleontology, including paleoecology and paleoclimatology. His teaching includes disciplines in paleontology and biology.

Stefan Artmann is Scientific Manager at the Frege Centre for Structural Sciences and Institute of Philosophy, Friedrich Schiller University in Jena, Germany. He holds an MA (1996) and PhD (1996) from Heinrich Heine University Düsseldorf, and a PhD (2008) from Friedrich Schiller University in Jena. His principle areas of research are philosophy of information and computing, as well as philosophy of biology, and particularly the intersection of both: philosophy of artificial life and artificial intelligence. This involves interdisciplinary research with computer scientists, electrical engineers, and biologists. Current projects include the phi-bot project that explores the control of a simple robot by a slime mould, and another on the evolution of

semantic systems that constructs a general framework for describing and explaining the origin and dynamics of complex adaptive systems.

José Antonio Arz is Professor of Paleontology in the Department of Earth Science at the University of Zaragoza, Spain. He earned his Licentiate in geology in 1990 and his PhD in geology in 1996 from the University of Zaragoza. With more than 90 publications, he specializes in Cretaceous planktic foraminiferal biochronology, taxonomy, and paleoecology. His research focuses on evaluating the age and paleoenvironmental consequences of the Chicxulub meteoritic impact that caused the K-T mass extinction event. His teaching includes disciplines in paleontology, biology, and geology.

Robert D. Bates, PhD, is Assistant Professor of Near East Archaeology and the History of Antiquity at La Sierra University and Curator of La Sierra University Archaeological Collection in Riverside, California. He teaches classes in ancient languages, archaeological methods and theory, field archaeology, and the ancient history of the Mediterranean. He received his PhD in biblical archaeology from Andrews University in Berrien Springs, Michigan, and did postdoctoral research at the University of Chicago's Oriental Institute in Egyptian archaeology. He is a field director for the Madaba Plains Project excavating at Tall al-Umayri and Tall Jalul, Jordan. His research interests include Iron Age Jordan, ancient Egyptian history and archaeology, the history and culture of ancient Palestine, and technology in archaeology.

Christina Taylor Beard-Moose is Associate Professor of Anthropology and Women's Studies at Suffolk County Community College in Selden, New York. She has expertise in the history of feminist anthropology, feminism, women's studies, the women's spirituality movement in the United States, and the history of feminism. Her studies also include American Indians (prehistoric to contemporary issues), cultural and ecotourism, history of American anthropology, identity, performative expressions of identity, visual anthropology, 20th-century anthropological theory,

and ethnographic field methods. She received her PhD in anthropology in 2004 from the University of Iowa with a dissertation titled *Public Indians, Private Cherokee: Gendered Identity at the Intersection of Tourism, Acculturation and Cultural Continuity*.

Les Beldo is a PhD student in the Department of Comparative Human Development at the University of Chicago. He received his MA from the University of Chicago in 2008 and his BS from Central Michigan University in 2003. His research interests include psychological anthropology and cultural psychology, atheism and secularism, and cultural discourses on meaning and morality.

Anne Bennett is Assistant Professor of Anthropology at California State University, San Bernardino. She received her PhD from the University of Arizona. She has conducted fieldwork in Syria focused on the Druze sect. Currently, her research interest is in heritage Arabic speakers and the Arab-American community in Southern California's Inland Empire.

Frances F. Berdan is Professor of Anthropology and Codirector of the Laboratory for Ancient Materials Analysis at California State University, San Bernardino. She earned her PhD in anthropology from the University of Texas at Austin in 1975. Her research and publications focus on Aztec culture and society and on indigenous adaptations to Spanish colonial rule.

Jay H. Bernstein is Assistant Professor and Reader Services Librarian at Kingsborough Community College—CUNY. He received his PhD in anthropology at the University of California, Berkeley, after conducting 2 years of ethnographic fieldwork among the Taman in the interior of West Kalimantan, Indonesia. He has also conducted fieldwork in Brunei Darussalam among the Dusun on the ecology and ethnobiology of human-rainforest interaction. He is the author of *Spirits Captured in Stone: Shamanism and Traditional Medicine Among the Taman of Borneo* (1997). His articles on a diverse range of topics have been published in many professional journals, including *American Anthropologist*. His study of nonknowledge appeared in 2009 as a two-part article in *Knowledge Organization*. His current work focuses on the measurement of author impact and multidisciplinary perspectives on information organization.

Andrea Patricia Birkby is Instructor of Anthropology at Fort Lewis College in Durango, Colorado, where she teaches primate-related courses in various departments. She holds an MA in applied anthropology from the University of Colorado, Denver, and a BA in psychology from Fort Lewis College. Her areas of interest and specialization include primate behavior and conservation, and research on orangutans and globalization.

Greta G. Boers is Librarian at Duke University. Her academic background includes a BA in anthropology from

Emory University and an MLIS from the University of South Carolina. She has lived in South Africa, France, Germany, and the United States. Her interest in the subject of twin studies is personal, as she is related to two sets of monozygotic twins, aunts and uncles; she is also 7 years older than her two dizygotic twin sisters. Her chapter was written as a way to make up for all the misery she put them through while growing up together.

Robert Bollt (1971–2010) was an archaeologist who specialized in ancient Polynesia. He obtained his PhD from the University of Hawai'i at Manoa in 2005. Recently he had concentrated on the Austral Islands in East Polynesia, where he found and excavated the archipelago's earliest known site to date. The results of this work are published in the monograph *Peva: The Archaeology of an Austral Island Settlement* (2008). He also excavated sites in Hawai'i and the Marquesas. His primary interests included Polynesian material culture and patterns of long-distance exchange among islands, determined by using geochemical sourcing analyses to trace stone tools to their geological source of origin. He also enjoyed experimental archaeology, especially stone tool-making. Additional interests included Polynesian subsistence strategies, faunal analysis, human-environment relations, sociopolitical transformation, and warfare.

Laura M. Bolt is a PhD candidate in biological anthropology at the University of Toronto, Canada. She received her master's degree from the University of Cambridge, UK, where her thesis addressed Darwinian sexual selection theory and the origins of music. Her published and forthcoming works explore topics such as Charles Darwin's social context, the development of Darwin's views on music and evolution, biomusicology, primate vocal communication, and ring-tailed lemur behavior.

James Pleger Bonanno is a PhD student at the State University of New York at Binghamton. He received his MA in European history from the University at Buffalo. His research interests include the Enlightenment, the French Revolutionary period, and European intellectual history. His current research involves the influence of French Revolutionary ideas in Italy during the Napoleonic period, and the emergence of Italian nationalism.

Lucas Bowman is currently pursuing a master's degree in geography at Appalachian State University in Boone, North Carolina. He holds a bachelor's degree in history with a minor in anthropology and geography. He also has interests in archaeology, performing cultural resource management with various companies across America. His current work revolves around early American banjo and the people who carry on this musical culture. Aside from academic interests, he is a caver and has participated in several cave-mapping surveys in West Virginia and Illinois. He also is an avid musician and plays with several bands.

Paul F. Brown is Professor and Chair of the Department of Anthropology at Minnesota State University, Mankato, where he has been on the faculty for 30 years. He received his BA in anthropology from California State University, Northridge, and his MA and PhD from the University of Colorado, Boulder. In 1980, he spent a year at Michigan State University as an NIMH postdoctoral fellow in medical anthropology. In 1985, he spent a sabbatical year doing postdoctoral work in skeletal biology and paleopathology at the University of Massachusetts, Amherst, under the direction of Dr. George Armelagos. He has conducted research on human biocultural adaptation in the Andes of Peru, osteological analysis of human remains from Minnesota and, most recently, research on race and racism in science and society.

Frances D. Burton is Professor Emerita in the Department of Anthropology, Scarborough Campus of the University of Toronto. She received her doctorate as the first graduate in anthropology from the City University of New York. A primatologist by training, her interest in food and food habits stems from her research primarily on macaques in Gibraltar and the hybrids of TaiPo (Hong Kong) and her interests in the stimuli of human evolution. She has recently published a book dealing with this issue, *Fire: The Spark That Ignited Human Evolution*, which speculates on the importance of insects in the diet of hominins, which led to an association with fire and its light, and the consequences deriving from the alteration of circadian rhythms. She has taught several courses concerning the anthropology of food as nutrient and culture, and has published on enhancing food production through simple means for the journal *Emergency Nutrition Network*.

Cris Campbell is a PhD candidate in the Anthropology Graduate Program at the University of Colorado, Boulder. He previously earned degrees from the University of Tulsa (BA, 1987), Duke University (MA, 1991), and Duke University (JD, 1991). His current work in biocultural anthropology builds on his earlier graduate studies in philosophy and focuses broadly on the interplay of these two disciplines. In particular, he studies hominid evolution, cognitive architecture, and human behavior as these topics relate to the problems of metaphysics, meaning, and motivation.

Patricia N. Chrosniak is Associate Professor in the College of Education and Health Sciences at Bradley University. She holds a BA in philosophy from Niagara University, an MS in speech and hearing science, and a PhD in educational psychology from the University of Illinois at Urbana-Champaign. She spent 5 years working on her doctorate at the National Center for the Study of Reading in Champaign, Illinois, where she participated in eye-movement research and research studies on text processing. Her main foci have been on anaphoric referencing, language transfer, and cross-linguistic influences in the interpretation of written texts by deaf individuals. Her

writings include a chapter on visual literacy in *Visual Data* (2009) and several chapters regarding language in the *Encyclopedia of Anthropology* (2006) and the *Encyclopedia of Time* (2009). Among the scholarly organizations where she has regularly presented her research on language processing and cross-linguistics are the National Reading Conference (NRC), the Association of College Educators of the Deaf, and the American Association of Applied Linguistics (AAAL).

Jill M. Church is Librarian and Head of Periodicals Department at D'Youville College in Buffalo, New York. She received a BA in anthropology and an MLS from the State University of New York at Buffalo. She has authored many articles for the *Encyclopedia of Anthropology* (2006) and the *Encyclopedia of Time* (2009). She is active in her regional chapter of the Association of College and Research Libraries and is working to find ways to improve the research skills of students. Her research interests include the broad areas of archaeology and biological anthropology, in addition to evaluating research skills and improving indexing and access to electronic resources.

Cynthia Crosser is Reference Librarian in Social Science and Humanities, and Subject Specialist in Psychology, Human Development, and Education, at the University of Maine. She received an MA in psycholinguistics from the University of Florida and an MS in library studies from Florida State University. She is currently pursuing an advanced degree in literacy from the University of Maine.

Christopher David Czaplicki received a BS degree from Canisius College in Buffalo, New York, majoring in biology, with a minor in both neuroscience and anthropology. He has previously written several other entries for Sage Publications, including "Degenerative Diseases" in the *Encyclopedia of Time* (2009).

Suzanne E. D'Amato is Associate Professor at Medaille College in Buffalo, New York. She holds a BS in elementary education (human relations cluster) from State University of New York College at Buffalo, an MS in elementary education and a MEd in administration and supervision from Canisius College. Her doctorate in curriculum and instruction was earned from University of Buffalo in 1994. To complement her interest in education, she studies anthropology, and she presented a paper titled *Anthropology and Education* at the University of Montana in 2003. Several of her entries appear in the *Encyclopedia of Anthropology* (2006) and the *Encyclopedia of Time* (2009). She has taught for a remarkable 49 years, 10 of which are in higher education.

Irina Jovan Deretic is Assistant Professor of Ancient Greek Philosophy at the University of Belgrade. She was a guest professor at the Friedrich Schiller University in Jena, Germany (summer semesters 2007, 2008), Pandion University, Athens, Greece (2001), and Yeditepe University,

Istanbul, Turkey (2004). She was awarded the Sasakawa Scholarship and the Onassis Scholarship. Her fields of interests are ancient Greek philosophy, German hermeneutics, Hegel's philosophy, philosophical anthropology, philosophy of language, and national and international Russian and Serbian literature. She authored both *How to Name the Being* (2001) and *Logos, Plato and Aristotle* (2009), which has been selected as one of the best theoretical books in Serbia, as well as 70 academic papers in Serbian, English, German, Slovenian, and Macedonian. She has participated in more than 20 conferences and seminars. With Stefan Lorenz Sorgner, she organized an international conference on Humanism and Posthumanism, in honor of Professor H. James Birx, at the University of Belgrade (April 2009). She is a member of the executive board of the Serbian Philosophical Society and has been a member of the editorial board of the Serbian journals *Theoria* and *Literary Word*.

Anna Maria Destro is Consultant Professor of Anthropology at the Eastern Piedmont Medical School. She graduated in psychology and philosophy at the Universities of Padua and Milan, maturing a broad interest in culture studies, with a particular dedication toward medical humanities. She was recipient of the Fulbright Scholarship in 1992, and accordingly studied at the State University of New York at Stony Brook in a program focused upon cultural identities and differences. During that time, she was also a fellow of the Martin Luther King Center and Bellevue Hospital, New York. She was appointed to the International Philosophy of Nursing Executive Committee (IPONS), and she is currently a member of the American Sociological Association. She is dedicated to Amish culture studies and, in particular, she works on a project endorsed by the Department of Anthropology at the Catholic University of Milan in 2004. She is presently part of the teaching staff of different Italian universities (Turin, Milan, Pavia, Novara).

Marcia B. Dinneen is Head of Reference Services at Bridgewater State College, in Bridgewater, Massachusetts. She is also a visiting lecturer, teaching English composition and literature courses at Bridgewater State. She received her MLS from Columbia University and PhD from the University of Rhode Island. She has written a number of articles for peer-reviewed journals and reference books. Her dissertation topic on travel as a metaphor has led to articles in the *Literature of Travel and Exploration: An Encyclopedia* (2003) and a continuing interest in the whys and wherefores of migration.

Terry W. Eddinger is Vice President for Academics and Professor of Old Testament at Carolina Evangelical Divinity School in High Point, North Carolina. He earned his PhD in Old Testament with an emphasis in ancient Near Eastern history and archaeology from The Southern Baptist Theological Seminary in Louisville, Kentucky, in 1995. In addition to teaching biblical Hebrew and Old Testament studies at Carolina Evangelical Divinity School,

he has been a member of the Karak Resources Project since 1996, which conducts archaeological fieldwork and research on the Karak Plateau in central Jordan. He excavated at al-Mudaybi, an 8th century BCE fortress, with the Karak Resources Project in the summers of 1997 and 2001. He also worked with the Mitrou Archaeological Project in central Greece in the summers of 2007 and 2008, where he led a team in conducting an archaeological survey of the East Lokris region. Also, he excavated at Tell Halif, Israel, with the Lahav Research Project in 1993 and spent 6 months in western Iraq with the United States Marine Corps in 2005. His travels have taken him to many places in Europe, the Mediterranean Basin, and the Middle East including Bahrain, Belgium, Crete, Germany, Greece, Iraq, Israel, Jordan, Kuwait, Malta, Portugal, Spain, and the United Arab Emirates.

Katie E. Englert is Adjunct Instructor of Anthropology for Northern Kentucky University. She holds a BA in photojournalism/anthropology from Western Kentucky University (2000) and an MA in anthropology from the Australian National University (2005), where she completed her MA thesis, *Pictures Worth Thousands of Words: Youth, Ethnicity, and Photography*. She is interested in visual anthropology, and her latest visual work was conducted in the Eastern and Southern Highlands of Papua New Guinea. Currently, she resides in Portland, Oregon.

Patricia E. Erickson, JD, PhD, is Professor of Sociology and Criminal Justice at Canisius College. She received her JD from the State University of New York at Buffalo and her PhD from the University of Denver. In recent publications, she has addressed such issues as a critical assessment of child-abuse and child-neglect policy in the United States, the substantive due-process concerns raised by recent sex-offender statutes, and justice consciousness in the context of the practice of law. She is the coauthor (with Steven K. Erickson) of *Crime, Punishment, and Mental Illness: Law and the Behavioral Sciences in Conflict* (2008).

Isabelle M. Flemming is Reference Librarian at the Ela Area Public Library in Lake Zurich, Illinois, where she teaches workshops, acts as computer specialist, and provides in-depth reference assistance for patrons. She is a member of the American Library Association and three of its specialized divisions. She received an MA in history, specializing in history of science, from the University of Florida, and an MLS from the University of Illinois at Urbana/Champaign. She has published a short story and also published and written articles for an upcoming encyclopedia publication. Formerly an antiques dealer, much of her research has covered the history and use of objects, decorative and practical, particularly from the 19th and early 20th centuries. In addition, she has created a reference Web page designed to make searches simpler. Her research interests lie in the related fields of the history of culture and ideas, with a special focus on the future of virtual worlds and their impact on society.

Michael J. Francisconi is Professor of Sociology and Anthropology at the University of Montana Western. As one of four children raised in a railroad worker's house in Pocatello, Idaho, he became a nontraditional student at Boise State University, where he received his BS in sociology while employed as a full-time staff member. He continued his full-time staff and student status during his years in the graduate programs with the Department of Sociology and Anthropology at the University of Oregon in Eugene. He used his theories of applied education while processing the papers of the International Wood Workers of America for the Special Collections Library at Oregon, and, while working on his dissertation, he both taught and pursued his research at Diné College on the Navajo Nation in Tsaile, Arizona. After receiving his PhD in anthropology from the University of Oregon, he and his family moved to Dillon, Montana, where he became the sole sociologist and anthropologist at the University of Montana Western. He has taught there since 1996, in addition to instructing graduate students in the sociology of education through the University of Montana. His book *Kinship, Capitalism, Change: The Informal Economy of the Navajo Nation* (based on his research and teaching on the Navajo Nation) was published in 1998. He continues to publish through Sage and other journals. His areas of focus include social theory, political sociology and anthropology, economic anthropology, social movements, and cultural ecology.

Stephen D. Glazier is Professor of Anthropology and Graduate Faculty Fellow at the University of Nebraska–Lincoln. He received his PhD in anthropology from the University of Connecticut in 1981. He served as editor of *Anthropology of Religion: A Handbook* (1999), *The Encyclopedia of African and African American Religions* (2001), and (with Andrew S. Buckser) *The Anthropology of Religious Conversion* (2003). Currently, he researches Sango and Spiritual Baptist healers on the Caribbean island of Trinidad.

Robert Bates Graber is Professor Emeritus of Anthropology at Truman State University. He received his AB from Indiana University and his MS and PhD from the University of Wisconsin–Milwaukee. He is author of many scholarly articles and several books, the latest of which is *Plutonic Sonnets* (2008)—a sonnet cycle centering on the discovery and naming of planets and elements. His current research interest is quantitative analysis of social and cultural evolution.

John K. Grandy is Physician Assistant (RPA-C) for Lee Medical Associates in Dunkirk, New York, and has been practicing medicine for 5 years. His area of specialty includes internal medicine and psychiatry. He earned his degree as a physician assistant at D'Youville College in Buffalo, New York. In addition, he earned a master's degree from the University of Buffalo Division of Roswell Park Cancer Institute with concentrations in molecular immunology and neurophysiology. Prior to these two degrees, he completed a

bachelor of science degree at Canisius College in Buffalo, New York, with a major in biology and minors in anthropology and the classics. His research interests include internal medicine, psychiatry, consciousness studies, genetic engineering, philosophy, and the DNA molecule. Working in medicine and psychiatry exposed him to the importance of genetic relationships to diseases and successful treatments. The time he spent working in psychiatry piqued his interest in neurophysiology and neuropharmacology, which in turn increased his desire to study consciousness not only from a clinical or scientific standpoint, but also from a philosophical standpoint. It was while he was publishing articles on both consciousness and the DNA molecule that he developed his theories of DNA consciousness. During his work on the chapter in *21st Century Anthropology*, he realized that genetic engineering may provide ways to further understand this process.

John R. Grehan is Director of Science at the Buffalo Museum of Science. He holds a PhD in zoology from Victoria University of Wellington (New Zealand) and is also an adjunct faculty member at Buffalo State College and a research associate in the Invertebrate Section at the Carnegie Museum of Natural History. His research interests include evolutionary biogeography, evaluation of morphology as phylogenetic evidence for human–great ape relationships, and the integration of phylogenetic and geographic evidence for reconstructing the biogeographic origins of hominid ancestry.

Mary J. Hallin is a doctoral candidate in geography, with a specialization in anthropology of indigenous peoples at the University of Nebraska–Lincoln. She has worked in Cameroon for 5 years. Her dissertation examines collaboration between traditional and biomedical practitioners in northwestern Cameroon.

Pamela Hayes-Bohanan is Reference Librarian and Coordinator for Library Instruction Services at the Clement C. Maxwell Library at Bridgewater State College in Massachusetts, where she is also a Spanish Instructor. She is active in the College's Writing Across the Curriculum network, the Diversity and Inclusion Research Institute, and developing strategies for the integration of information literacy into the college curriculum at all levels. She serves on Bridgewater's One Book One Community steering committee and the library's Events Planning Committee, and is an occasional contributor to the *Internet Review of Books*. Her primary research interests are in censorship and book banning, information literacy, and Latin American studies. She has previously written articles in such reference resources as *Ready Reference: Censorship* (1997), *The Latino Encyclopedia* (1996), and *The Seventies in America* (2006), among others. She received her master of library science degree from the University of Arizona in 1991 and her master of Spanish literature degree from Miami University of Ohio in 1990. Prior to coming to Bridgewater State College in 1997, she served as head of reference at the McAllen Memorial Library in McAllen, Texas, where she served a bilingual community of active library users.

Jacob R. Hickman is a doctoral candidate at the University of Chicago in the Department of Comparative Human Development, where he specializes in psychological anthropology and cultural psychology. Jacob investigates the psychological and cultural dynamics of migration, resettlement, and social change in general. His current work constitutes a comparative ethnography of personhood and morality in Hmong communities that have resettled to the United States and Thailand from Laos. He has also published research on the changing health concepts among Hmong in Alaska (“‘Is It the Spirit or the Body?’ Syncretism of Health Beliefs Among Hmong Immigrants to Alaska,” *NAPA Bulletin*, 2007; and “Treating Hmong Children in America: Two Case Studies,” in *The Child: An Encyclopedic Companion*, 2009) and the dynamics of ethnic identity in Western Highland Guatemala (“Inverse Typology and Ethnic Identity: An Analysis of Inverse Image Theory in Two Guatemalan Communities,” *The Journal of the Utah Academy*, 2003).

Brittney M. Howell is Adjunct Faculty of Anthropology at Northern Kentucky University and Anthropology Instructor at Gateway Community and Technical College. She received her bachelor of science degree in anthropology at Central Michigan University and her master of arts degree in anthropology at the University of Cincinnati, and she is a registered professional archaeologist. Her research interests include osteology, medical anthropology, human growth and development, and the anthropology of children. She has conducted skeletal analyses of human decapitation sacrifices in Peru, forensic analyses of human remains in Albania, and research into the factors contributing to childhood undernutrition and the associated skeletal pathologies. Her research in anthropology has taken her to Alaska, Scotland, Arizona, and the Midwest, and she has presented her research at numerous professional conferences. Her recent research examined the health perceptions of early adolescent Latina girls using community-based participatory research methodology and was published in *Family and Community Health* (2008). She has also used participatory-research methodology to evaluate the effectiveness of a hospital-based home-visitation program aimed at assisting at-risk and first-time mothers in creating a nurturing, healthy environment for their children (accepted by *Infants and Young Children*).

Pamela Rae Hutson attended Fairbanks University, University of Alaska Southeast. She authored Inuit-related entries for the *Encyclopedia of Anthropology* (2006), including “Aleut” and “Inuit Acculturation.” She also contributed to the *Encyclopedia of Race, Ethnicity, and Society* (2008) with “Aleuts” and “Canada, First Nations,” and to the *Encyclopedia of Time* (2009) with “Myths of Creation.”

Chang-Ho C. Ji is Professor of Education and Middle Eastern Studies at La Sierra University in California, where he also teaches statistical and quantitative research methods.

He holds a PhD from the University of California at Riverside, and from 1995 to 2002, he directed two large-scale archaeological survey projects in the regions of Iraq al-‘Amir and the Dhiban Plateau in Jordan. In addition, he conducted several salvage excavations at Khirbat Mahatta, Khirbat Bayada, the Wadi as-Sir, and the dolmen sites near Iraq al-‘Amir, Jordan. Currently, he serves as the director of the Khirbat ‘Ataruz excavation project and the Dhiban-Machaerus regional research project in Jordan. His additional research interests lie in the areas of prehistoric dolmens and stone monuments in the Middle East, Europe, and Asia, ancient Israelite and Iron Age religion, and the Hellenistic–early Roman history of the Levant. His research also extends to psychology of religion and Islam and their influence on social attitudes and behaviors, particularly in relation to authoritarian personality, principled moral reasoning, and social conservatism.

Richard R. Jones is Associate Professor of Anthropology at Lee University in Cleveland, Tennessee. He received his PhD in anthropology from Wayne State University and his MA in linguistics from Oakland University. He has contributed to the *Encyclopedia of Anthropology* (2006), *Jacking in to the Matrix Trilogy* (2004), and other edited works. His current research interests include popular culture, ethnographic research of Christian groups on the Karak plateau in Jordan, migrant Arab communities in Chile and elsewhere, and archaeological survey in eastern Tennessee.

Joachim Klose is Commissioner of the Konrad Adenauer Foundation for the Free State of Saxony. He studied theology, physics, philosophy, theory of science, logic, and statistics in Magdeburg, Berlin, Dresden, Munich, and Cambridge (Harvard University). In 1997, he earned his PhD at the Ludwig Maximilian University in Munich. He was the president of the Catholic Academy of the Dresden-Meissen Diocese, and since 2006 has held the commissioner position at the Konrad Adenauer Foundation. He has organized and held many lectures on the difficulties of the transformation process of the former East Germany from a closed to an open society after the fall of the Berlin Wall in 1989. For his work, he was awarded the Prize of Innovation for Adult Educational Work in the Free State of Saxony (2002).

Kris “Fire” Kovarovic, PhD, is Lecturer in Human Evolution at Durham University, UK. As an undergraduate, she attended McGill University in Montréal to pursue a degree in anthropology and archaeology. Possessing limited talent for flint-knapping, she discovered an archaeological passion for bones rather than stones. She then crossed the Atlantic for an MSc in archaeology at University College London’s (UCL) Institute of Archaeology in 1997 and has remained in the UK since that time. She obtained her PhD in the Department of Anthropology at UCL, spent time as a postdoctorate in the Human Origins Program at the Smithsonian Institution, and then returned to UCL to take up a

Leverhulme Early Career Fellowship prior to moving to Durham. Her research interests include palaeoenvironmental reconstruction and faunal analysis, particularly at Plio-Pleistocene hominin sites in East Africa. She has participated in fieldwork at Laetoli, Tanzania, and currently codirects a long-term study of modern mammalian bone accumulations in Kenya. Her present research project investigates ecological trends at a number of Rift Valley localities and explores the differences in habitat signals provided by analyses of bovid fossil dentition and skeletal remains.

Ramdas Lamb is Associate Professor of Religion at the University of Hawai'i. Prior to entering academia, he was a Hindu monk in the Ramananda order in northern India for nearly 10 years. Since the early 1970s, he has done field research on the monastic traditions and the religious cultures of northern and central India. Among his publications are *Rapt in the Name: The Ramnamis, Ramnam, and Untouchable Religion in Central India* (2002). He has written numerous articles in journals, encyclopedias, and edited volumes on various aspects of religious traditions and movements in South Asia. He also works with a non-profit foundation (Sahayog Foundation) educating rural youth in central India.

Sang-Hee Lee, PhD, BA, is Associate Professor of Anthropology at the University of California at Riverside. She received her PhD from the University of Michigan in 1999 and her BA from Seoul National University in Korea in 1989. Her research examines the evolution of human morphological variation, and how different mechanisms (such as taxonomy, sex, age, and time) explain what is observed in fossil data.

Oliver W. Lembcke is Senior Researcher at Friedrich Schiller University in Jena, Germany, and director of the Hellmuth Loening Center. He received his MA in 1995 from Christian Albrechts University in Kiel and his PhD in 2004 from Friedrich Schiller University (FSU) in Jena. His expertise is in political theory, constitutional theory, and public law. He has published 16 books (8 of them as an editor) and over 60 articles on the relationship between law and politics from both an empirical approach and a normative perspective. In 2005, his studies on the German Constitutional Court received an award from both the Institution of Political Science and the Faculty of Social Sciences at FSU Jena. In addition, he has been a visiting scholar at Jagiellonian University in Krakow, both Fudan University and Tongji University in Shanghai, Tilburg University (the Netherlands), and the Free University of Amsterdam. He has given presentations at Tampere University (Finland), Harvard University, the German Historical Institute in Paris, University of Copenhagen, Leiden University, and Hebrew University, Jerusalem. As a political scientist at Friedrich Schiller University, his research interests now focus on ideas about the French Revolution and the political philosophy of Thomas Hobbes.

Debra M. Lucas is Head of Reference and Interlibrary Loan at D'Youville College in Buffalo, New York. In this position, she has the unique opportunity to be an active scholar who also actively assists those faculty and students involved in research and scholarly pursuits at D'Youville College. She has published articles in the *Encyclopedia of Time* (2009), *Encyclopedia of Anthropology* (2006), *St. James Encyclopedia of Pop Culture* (2000), and the *Journal of Information and Library Science*. Her articles have also appeared in several Buffalo magazines and newspapers. She was included in *Who's Who of American Women* (2009) and was selected as D'Youville Faculty of the Year at the Library in 2007–2008 and 2005–2006.

David Alexander Lukaszek, MA, BA, AAS, AOS, is currently a PhD student at the University of Alaska, Fairbanks. He has participated in conferences at the University of Moscow and the University of Montana and has contributed to the *Encyclopedia of Time* (2009) and *Encyclopedia of Anthropology* (2006). His research interests include osteology, functional morphology, methodology, and evolution history. He also has an interest in the philosophy of science.

Sarasij Majumder has a PhD in Anthropology from Rutgers University and is currently an Assistant Professor of International Relations at St. Mary's University in San Antonio, Texas. In Fall 2010, he will start as an Assistant Professor in Anthropology and Asian Studies at Kennesaw State University, Kennesaw, Georgia. His primary focus is politics around land and industrialization in contemporary India. He studies identities and conflicts arising out of ownership of agricultural land and economic development in India. He also looks at how villages and villagers are represented by activists, media, and the state as “peasants” or “farmers.” Theoretically, his research looks at the complex relations between the local and the global, connected with each other both materially and discursively. He has an MA and an MPhil in sociology from Delhi University, India.

Sara Rofofsky Marcus is Electronic Resources/Web Librarian at Queensborough Community College in New York. She earned her MLS from Queens College and her EdS degree in educational technology from the University of Missouri. Her PhD is in e-learning administration. Her prior employment includes teaching at the postsecondary level, both face-to-face and online, and working at a variety of libraries.

Belete K. Mebratu is Assistant Professor of Education at Medaille College in Buffalo, New York. He received his PhD from the State University of New York–University at Buffalo and has been a lecturer at Addis Ababa University in Ethiopia. He has published on, and given presentations about, topics concerning modern Africa.

Melissa A. Menasco is Assistant Professor of Sociology at Canisius College in Buffalo, New York. She received a BA

in mathematics from UCLA and a PhD in sociology from the State University of New York–University at Buffalo. Her postdoctoral research was in nonverbal communication, with an emphasis on deceptive behaviors. Specializing in the area of criminology, her primary interests include social control theory, as well as juvenile delinquency and its long-term consequences on adulthood. She is an editorial board member of the international academic journal *Sociological Inquiry*.

James F. Miskel is Consultant and Adjunct Professor at the U.S. Naval War College, Long Island University, and Norwich University. He received his PhD from the State University of New York. His research interests include national security and terrorism, with recent publications including *Disaster Relief and Consequence Management: What Works, What Doesn't* (2006) and *The Leviathan Effect* (2009).

Christopher Morris is a doctoral student in the Department of Anthropology at the University of Colorado at Boulder. He currently studies the politics of German-led development, pharmaceutical governance, and health sector reform in sub-Saharan Africa.

Gregory D. Mumford is Assistant Professor of Archaeology in the Department of History and Anthropology at the University of Alabama at Birmingham. He received a PhD in Egyptian archaeology from the University of Toronto and directs excavations at a late Old Kingdom fort (ca. 2200 BCE) at Tell Ras Budran in Southwest Sinai and a Late Period port town (ca. 664–332 BCE) at Tell Tebilla in the Northeast Delta (Egypt). Research interests include the late Old Kingdom to First Intermediate Period in Egypt and cross-cultural relations between Egypt and its neighbors, particularly in the Late Bronze through Iron Ages (ca. 1550–525 BCE).

Kathleen Nadeau is Professor of Anthropology at California State University, San Bernardino, with a PhD in anthropology from Arizona State University. Her research interests are in globalization and development issues: human rights, sustainable development and cultural and ecological diversity in agriculture, and cultural liberation theologies with a special focus on Asia and Asian America. She has written two books, *The History of the Philippines* (2008) and *Liberation Theology in the Philippines* (2001). She presently is coediting the *Encyclopedia of Asian American Folklore* (2010).

Neil Patrick O'Donnell is Adjunct Professor of Anthropology at Canisius College in Buffalo, New York, and currently teaches archaeology and sociocultural anthropology. He holds a BA in anthropology from Buffalo State College and an MA in anthropology from the State University of New York at Binghamton. His research focus remains on Iroquoian populations and the ramifications of first contact between multiple cultural groups. He is also a novelist (fantasy genre). His most recent publication is *People of the Sword* (2009), a melding of his anthropological research and Celtic heritage.

Arvilla Chapin Payne-Jackson is Professor at Howard University. She received her doctorate from the University of Pennsylvania, and her primary areas of research are medical anthropology, sociolinguistics, ethnographic evaluation, and service learning. She has conducted fieldwork in the United States, the Caribbean, Latin America, and Africa. She has published several books and monographs on ethnomedicine and numerous articles in all four fields. She has been an ethnographic evaluator and consultant for several federal agencies and community and nonprofit organizations.

Donald R. Perry received his PhD in 1983 from the Department of Ecology and Evolutionary Biology at the University of California at Los Angeles. With his pioneering access methods used worldwide for investigation of the canopy, his work has appeared in international publications and documentaries. He won the 1984 Rolex Awards for Enterprise to develop a radio-controlled cableway for canopy investigation. His book, *Life Above the Jungle Floor*, was used for the feature film *Medicine Man*. He also invented the Rain Forest Aerial Tram and most recently Ecotram™. The latter invention allows the physically challenged to see otherwise inaccessible sights of nature.

Rhonda L. Quinn is Visiting Professor in the Department of Earth and Planetary Sciences at Rutgers University and Affiliate Faculty Member in the Department of Anthropology at New York University. She earned her BA in 1996, MA in 1999 in anthropology, and BS in 1997 in geological sciences from the University of Florida. She completed her PhD in anthropology from Rutgers University in 2006. She studies the interaction of modern and extinct humans with the environment. She integrates stable isotopic systems with sedimentology and stratigraphy to elucidate environmental contexts of early genus *Homo* in the Turkana Basin and with bioarchaeology and zooarchaeology to reconstruct human diet and mobility of modern humans in coastal and island settings of Florida, the Cook Islands, and Fiji.

Gwendolyn J. Reece is Director of Research, Teaching, and Learning at American University Library. She completed a PhD in education at American University, an MA in religious studies from the University of California at Santa Barbara, and an MS in library and information science from Simmons College. Her research interests include shamanism, mysticism, the relationship between spiritual and religious traditions and the environment, Waldorf education, and philosophy of education.

Elaine M. Reeves is Reference Librarian and Information Literacy Lecturer at the University of Toledo, Ohio. As a graduate student of history at the University of Toledo, she studied the intellectual history of the French Revolution from a Marxist perspective, focusing on history and the potential for revolution to create positive change in society and culture. She has also presented her research on the voting patterns of women in 19th-century Wyoming. Her previous contributions to reference publications include several entries for the *Encyclopedia of Time: Science,*

Philosophy, Theology, and Culture (2009). She also reviews article submissions for the online journal *Communications in Information Literacy*.

John Douglas Rhoades, PhD, is Professor and Chair of the Anthropology Department at St. John Fisher College in Rochester, New York. He received his PhD in anthropology from Syracuse University in 1976 and has conducted fieldwork on the sociolinguistic position of Swahili in Kenya by investigating perceptions of its supposed neutrality as manifested through language questionnaires and content of humor on language use. His publications include *Linguistic Diversity and Language Belief in Kenya: The Special Position of Swahili* (1977), and his topical interests in anthropology include communication, bilingualism, language planning, ethnolinguistics, theory and method in cultural anthropology, and intercultural communication, with area interests in Africa and China. Current research interests include language adaptation, ethnographic methods and field languages, and the relationship between kinds of linguistic structures and language functions.

Erin E. Robinson is Associate Professor of Sociology at Canisius College in Buffalo, New York. She received her PhD in sociology at the University at Buffalo, where she researched mobilization patterns of social movement in communities facing environmental hazards. Her research has involved ethnographic field methods and the use of frame analysis as both a research tool and mode of analysis for researching social movement. Her primary research interests are environmental sociology, community mobilization, grassroots networking and collaboration, and social construction of risk. Currently, she is studying semantics and the transformation of meaning in urban space surrounding the development of community gardens.

Debika Saha is Reader in the Department of Philosophy at the University of North Bengal. In the fall of 2008, she was a visiting research professor at the Center for Research in Values and Philosophy at The Catholic University of America in Washington, D.C., where she taught a seminar on sacred and secular concepts.

Frank A. Salamone is Professor of Anthropology and Sociology at Iona College in New Rochelle, New York. He has conducted fieldwork in a number of settings, including Nigeria, the United States, Venezuela, and East Africa. He has authored over 100 articles and authored, edited, or coedited more than 15 books. His most recent books are *The Lucy Memorial Freed Slaves' Home* (with Virginia Salamone, 2007), *The Italians of Rochester 1940–60* (2007), and *The Culture of Jazz: Jazz as Critical Culture* (2009). His present research projects include the history of anthropology, particularly a book on Elsie Clews Parsons in the works, and popular images of the anthropologist.

Tori M. Saneda is a tenured faculty member at Cascadia Community College in Bothell, Washington. She holds an MA and is a PhD candidate at The Ohio State University. Her interests include Mayan archaeology, origins of state-level

societies, globalization, development, modernization, indigenous peoples, teaching modalities, and the learning college.

Jeffrey H. Schwartz is Professor of Physical Anthropology at the University of Pittsburgh, where he is a Resident Fellow in its Center for the Philosophy of Science. He is also a Research Associate at the American Museum of Natural History. He has published more than 150 articles and reviews and authored 10 books, including *Sudden Origins: Fossils, Genes, and the Emergence of Species* (1999), *The Red Ape: Orangutans and Human Origins* (2005), and *Skeleton Keys: An Introduction to Human Skeletal Morphology, Development, and Analysis* (2007).

Hans Otto Seitschek is Assistant Professor of Philosophy at Ludwig Maximilian University (LMU) in Munich. In 2000, he received his MA in philosophy (Catholic theology, psychology) at LMU. He also received his PhD (*summa cum laude*) from LMU in 2005 with a thesis titled *Political Messianism*. He is a founding member of the International Eric Voegelin Society (April 2004), a member of the scientific board of the Nietzsche-Forum Munich, the Goerres Society, and the German Society of Philosophy, and he is on the editorial board for the *Encyclopedia of Time* (2009). His current research interests are ancient philosophy, philosophical anthropology, practical philosophy (philosophy of politics), philosophy of history, philosophy of religion, religion and politics, and Christian metaphysics.

Susanna Servello received her *Laurea magistrale* (the main postsecondary academic degree in Italy) in humanities from the University of Parma, and she authored the book *Vandana Shiva: A Woman for the Third Millennium Geography* (2008). Among the interdisciplinary courses she attended are Emerging Questions About Globalization and Capitalism (2007); Person and Personality (2005); Future Problems in Sciences, Politics and Economy (2003); Decentred Cooperation as a Way to Peace (2003); and Thinking the Difference (2003). In 2007, she won the Special Award for Ecological and Nonviolent Culture of the Italian Laura Conti Prize, and in 2008, she authored *Vandana Shiva*. She has also collaborated with the international cultural magazine *Grand Tour Cult*, and she works for Diabasis Publishing House and Delta Publishing House as an editor and an author of the art/literary review *Ottocento*.

Andrew Shooner received his bachelor of arts degree from The Ohio State University. He is currently completing his master's thesis at the University of Cincinnati in anthropology. His thesis research reviews methods for the digital recording and computer analysis of Southwestern rock-art pictographs. His past research has included human adaptation, satiety and overnutrition, and race and the eugenics movement. Other research interests include visual semantic systems in Southwestern rock art, emerging archaeometric technologies, cybernetics, and systems theory. He has received numerous awards and accolades including the University of Cincinnati Graduate Enrichment Grant and the University Graduate Scholarship. He has also presented his thesis

research at the Society for American Archaeology annual conference in Austin, Texas.

Shayna Silverstein is a Lecturer in ethnomusicology at the University of Chicago. Her dissertation explores popular dance music in Syria in relation to gender, sectarianism, nationalism, and cultural heritage. She lectures at the University of Chicago and Dartmouth College and has consulted and staffed a variety of arts programs and cultural initiatives including the Silk Road Project, Smithsonian Center for Folklife and Cultural Heritage, Make Music Not War, and the Lower Manhattan Cultural Council. She is trained in violin performance and dance and received her BA in history from Yale University.

Michael J. Simonton is Lecturer of Anthropology at Northern Kentucky University. His current research is a longitudinal study of aging in northwest Ireland that follows the same group of people through 25 years of their life courses. His other research interests have been focused on the origins and migrations of ancient Celtic peoples just prior to and during the Iron Age. He has tried to use a combination of ancient history, linguistics, oral literature, and archaeology to trace the movements of two culturally and geographically related peoples across Europe who have followed different routes to end up as neighbors on the other side of the continent.

Dirk Solies is Assistant Professor of Philosophy at the Johannes Gutenberg University in Mainz, Germany. He studied philosophy, German literature, and politics, earning an MA in 1992 from the University of Munich for a work on Nietzsche's theory of causality, and a PhD in 1998 from the Johannes Gutenberg University of Mainz for a dissertation titled *Nature in the Distance: The Meaning of Georg Simmel's Philosophy of Culture for the Aesthetics of Landscape*. He was awarded the science prize for philosophy for his advancement of intellectual dialogue (Lions Club Oppenheim). In 2008, he became a Doctor in Philosophy for his habilitation thesis *How Life Came Into Philosophy: The Concept of Life in 19th Century Philosophy*. His main areas of interest include Darwinism, Hegel, Nietzsche, and Schopenhauer, as well as theories of culture and applied ethics.

Stefan Lorenz Sorgner is Instructor of Philosophy at the University of Erfurt in Germany. He holds a BA in philosophy from King's College, University of London; an MA from the University of Durham; and a PhD from the Friedrich Schiller University in Jena. His main fields of research include Nietzsche, philosophy of music, bioethics, and posthumanism. He has edited several volumes and contributed numerous articles to encyclopedias and academic journals.

Carlos Antonio Martin Soria, a lawyer and social scientist, received a PhD in Latin American Studies from Flinders University of South Australia in Adelaide. He also completed graduate studies in law and the social sciences, focusing on Amazon studies. His research areas

include environmental law, indigenous peoples law, and ecological issues concerning Chile, Ecuador, and particularly Peru.

Andreas Spahn is Assistant Professor of Philosophy at Eindhoven University of Technology. He studied philosophy, German literature, and science of communication at the University of Essen, Germany, and the University of Notre Dame. He received his PhD from the Ruhr University Bochum in Germany with a work on hermeneutics published in 2008. His current research includes philosophy and ethics of technology, environmental ethics, and ethical issues of hermeneutics and communication.

Christian Spahn, Assistant Professor, received his PhD in philosophy in 2006 from RWTH Aachen University, Germany, and a master of arts and letters degree from the University of Notre Dame. His areas of specialization are philosophy of biology, German idealism, and Hegel's conception of the philosophy of biology and its systematic implication for modern biophilosophy. He conducted his postdoctoral research as a fellow in the Department of Philosophy at Friedrich Schiller University in Jena, and works in the Interdisciplinary Research Association (BMBF), where philosophers and natural scientists from different fields such as neuroscience, evolutionary biology, and cognitive psychology try to integrate the new results of evolutionary research and philosophical debates into a modern, critical, and adequate interpretation of the place of humankind in nature. He has also taught many classes about the influence of evolutionary biology on the interpretation of culture, and humankind and philosophy, with a special focus on evolutionary epistemology.

Melony L. Stambaugh is an Adjunct Faculty member of Anthropology at Northern Kentucky University and a job coach for the Northern Kentucky Area Development District. She received her bachelor of science degree from Northern Kentucky University in applied cultural studies and her master of arts degree from the University of Cincinnati in anthropology with a focus on cultural anthropology. Her research interests include social network analysis, social organization, kinship, peasant studies, and Celtic, Native American, and Mesoamerican studies. She has conducted analyses of nonprofit organizations in Ohio, research of gender roles in modern Native American powwows, and research into the effects of fluoride in public water systems. Her research in anthropology has taken her throughout the Midwest, Ireland, and Mexico. Her work has been presented at professional conferences including the Central States Anthropological Society, Anthropologists and Sociologists of Kentucky, Kentucky Academy of Science, University of Cincinnati Graduate Poster Forum, University of Cincinnati Anthropology Department Student Conference, and Northern Kentucky University Celebration of Student Research and Creativity.

Richard Albert Stein is Research Associate in the Department of Molecular Biology at Princeton University,

and currently conducting postdoctoral research on yeast biology. He received his MD in 1996 from the “Iuliu Hatieganu” University of Medicine and Pharmacy in Cluj-Napoca, Romania, and practiced clinical medicine for 2 years. Subsequently, in 2005, he earned his PhD in biochemistry from the Department of Biochemistry and Molecular Genetics at the University of Alabama at Birmingham and continued to work on the molecular biology of microorganisms, publishing several articles in journals including *Molecular Microbiology*, *Proceedings of the National Academy of the USA*, *Journal of Structural Biology*, and *Journal of Biological Chemistry*. In addition to his work in basic research, he has a strong interest in exploring the interface between biomedical and social sciences, and particularly in understanding how certain human behaviors are linked to emerging and reemerging infectious diseases worldwide. He has published several articles on antibiotic resistance, zoonotic infections, and public health issues in the *Annals of Internal Medicine*, *International Journal of Clinical Practice*, and *International Journal of Infectious Diseases*, and his invited book reviews have appeared in publications such as *The American Journal of Physical Anthropology*, *The Journal of the American Medical Association*, *The Journal of Infection*, *The New England Journal of Medicine*, and *Annals of Biomedical Engineering*.

Gerald Sullivan is Professor of Anthropology and Archaeology at Collin College in Plano, Texas. He was trained at the University of Virginia and received his PhD in 1998. His publications include *Margaret Mead, Gregory Bateson and Highland Bali: Fieldwork Photographs of Bayung Gedé, 1936–1939* (1999). He began researching extensively in the Margaret Mead Papers in 1994 and continues this research to the present day. His work has also appeared in edited volumes, journals, and standard reference works. He is currently working on a second book on Mead and Bateson’s scientific project tentatively titled *The Making of Balinese Character*. Most of his published work has focused on the history of anthropology with special attention to Margaret Mead and Gregory Bateson’s scientific projects in their ethnographic contexts. He is broadly interested in the history of the human sciences as an expression of the culture of liberalism in a globalizing age. He is also interested in the cultures of Southeast Asia, especially Bali, and New Zealand.

Cynthia J. W. Svoboda is Associate Librarian at Bridgewater State College. She received her BS from Bridgewater State College and her MLIS from the University of Rhode Island. Her research interests include American history, Canadian history, archaeology, aviation, popular culture, and Asperger’s Syndrome.

Ryan J. Trubits received a BA degree from Canisius College in Buffalo, New York, majoring in both anthropology and history, with a minor in philosophy. The recipient of the national Eugene Buechel Award for excellence in anthropological achievements, his research focuses on

primate behavior, hominid-pongid evolution, and the emergence of language. His interdisciplinary education included a semester of study at the University of Galway in Ireland, as well as academic experiences in Poland and Germany. He aspires to enlighten the public on the interconnectedness between the apes and our own species in terms of comparative biology.

Fernando Valerio-Holguín holds a PhD in Hispanic Literature from Tulane University. Currently, he is a Professor of Caribbean Literature and Culture at Colorado State University. Poet, novelist, and critic, Valerio-Holguín has published more than 40 articles on literature, cinema, music, and culture in journals and has presented papers in more than 30 international conferences. In 1999, he was invited by the Julian Samora Research Institute at Michigan State University to give a presentation celebrating Dominican Republic Independence Day. In 2002, he was invited to present the paper “The Novela-Bolero in the Era of Mechanical Reproduction” in the colloquium *Bolero: The Romantic Son of the Americas*. In 2005, he obtained a grant from the British Academy to edit the book *The Latin American Literary Bolero* and present the paper “The Order of Popular Music in Dominican Narrative” at the University of Newcastle-Upon-Tyne, United Kingdom. In 2007, he was invited by Oxford University to present the paper “Dominican-American Writers: Hybridity and Ambivalence” at the Oxford Round Table.

He has published the following books: *Viajantes insomnes* (Sleepless Travelers, 1982), *Poética de la frialdad* (Poetics of Coldness, 1996), *Autorretratos* (Self-portraits, 2002), *Memorias del último cielo* (Memories of the Last Heaven, 2002), *Café Insomnia* (Insomnia Café, 2002), *Banalidad posmoderna: Ensayos sobre identidad cultural latinoamericana* (Post-Modern Banality: Essays on Latin American Cultural Identity, 2006), and *Rituales de la Bella Pagana* (Rituals of the Pagan Beauty, 2009). He has edited *Arqueología de las sombras: La narrativa de Marcio Veloz Maggiolo* (Archaeology of the Shadows: Marcio Veloz Maggiolo’s Narrative, 2000) and *La novela-bolero en Latinoamérica* (The Latin American Literary Bolero, 2008), and coedited *The Caribbean(s) Redefined* (1997), *(De)Constructing the Mexican-American Border* (1998), and *La República Dominicana en el umbral del Siglo XXI: Cultura, política y cambio social* (Dominican Republic at the Threshold of 21st Century, 2000).

Jacky Vallée is a doctoral candidate in cultural anthropology at the University of Montreal. His research deals with the subcommunity of young users of alcohol among the Eastern James Bay Eeyou. He also teaches anthropology at Vanier College in Montreal. Areas of interest in anthropology include indigenous peoples, with a special focus on native peoples of Canada, gender and sexuality, spirituality, cultural contact, and experiential anthropology.

Angela Kristin VandenBroek is Library Associate at Louisiana State University and a master’s student at the

University of Southern Mississippi. She is currently writing her thesis on the interplay of agency and identity among Muslim-American women in Baton Rouge, Louisiana. She obtained her BS at Grand Valley State University in Michigan and plans to pursue a doctoral degree in cultural anthropology, with an emphasis on agency and identity theory.

Lisa M. Vaughn, PhD, is Associate Professor of Pediatrics at University of Cincinnati College of Medicine/Cincinnati Children's Hospital Medical Center in Cincinnati, Ohio. She is formally trained as a social psychologist and medical educator and has concentrated on issues relevant to marginalized populations throughout her career. Her primary research interests concern sociocultural issues affecting the health and well-being of families, especially for immigrant and minority populations in the United States. Given a life-long interest in other cultures, she has worked with universities and communities all over the world including Guatemala, South Africa, Denmark, and the Dominican Republic. A strong advocate of community-based participatory action research and the use of creative methodologies to give people "voice," she has authored numerous publications and research articles including *Culture Smart! Guatemala* (2007); *Feminist Conversations: Women, Trauma and Empowerment in Post-transitional Societies* (2009); "Families and Cultural Competency: Where Are We?" and "'Picturing' Health: A Photovoice Pilot of Latina Girls' Perceptions of Health" in *Family & Community Health*; and "Intercultural Adjustment for Cultural Competency in Shared Context" in *The International Journal of Interdisciplinary Social Sciences*. Currently, she is working on a cultural psychology text, a photography and social action manuscript, and a research study about cultural health attributions in culturally diverse populations.

Constance B. Williams is Assistant Professor, Coordinator of Circulation, and College Archivist in the Kurt R. Schmeller Library of Queensborough Community College, the City University of New York. She has been employed at Queensborough Community College for over 14 years, including a position as coordinator of Library Services to the Homebound, and she has also worked in medical and corporate libraries. She holds a master's degree (AMLS) from the University of Michigan, in Ann Arbor, Michigan, and a master of science in secondary education/English from Queens College, the City University of New York.

Robert M. Worley, PhD, is Assistant Professor of Criminal Justice at Penn State Altoona. He received his PhD in criminal justice from Sam Houston State University. His research interests include inmate-guard inappropriate relationships, violent crime, and legal issues in criminal justice. His publications have appeared in journals including *Criminal Justice Review*, *Deviant Behavior*, *American Journal of Criminal Justice*, and the *Criminal Law Bulletin*, among others.

Vidisha Barua Worley, Esq., PhD, is Assistant Professor of Criminal Justice at Penn State Altoona. She received her PhD in criminal justice from Sam Houston State University. She also holds a master's degree in criminal law from the Law School at the State University of New York at Buffalo. Her publications include the *Press and Media Law Manual* (2002) and *Terrorism in India* (2006). She also served as executive editor of the *Buffalo Criminal Law Review*. Her research areas include police and prison officers' civil liabilities for the use of tasers and stun guns, ethical issues in criminal justice, forced medication of death row inmates to induce synthetic sanity, the federal judiciary, and terrorism. She is a licensed attorney in New York.

PART I

BIOLOGICAL ANTHROPOLOGY

BIOLOGICAL ANTHROPOLOGY

H. JAMES BIRX

Canisius College and State University of New York at Geneseo

Anthropology is the scientific study of humankind (Birx, 2006a). It strives for a comprehensive understanding of and proper appreciation for our species within the earth's history. As such, anthropology is grounded in the empirical facts of the special sciences and the logical argumentation of critical thought. Furthermore, scientific evidence is supplemented with rational speculation, especially when facts are lacking. Ongoing advances in science and technology continuously add new information to the growing discipline of anthropology, thereby strengthening some concepts and hypotheses, while modifying or dismissing others.

Besides incorporating the scientific method, anthropologists view the natural history of humankind within an evolutionary framework (Fortey, 1998; Hublin, 2006; Mayr, 2001). Our species is seen as a product of organic evolution in general, and primate history in particular. The human species is related to apes, monkeys, and prosimians. Both fossils and genes substantiate the biological and historical unity of primates in terms of the factual theory of organic evolution (Coyne, 2009; Ridley, 2004).

Biological anthropologists (Kennedy, 2009) use the comparative method in order to understand and appreciate the evolutionary relationships among primate fossils, as well as living species. They compare and contrast fossil skeletons (especially jaws and teeth), DNA molecules, and morphologies (both anatomy and physiology), as well as

psychological and behavioral patterns. A convergence of facts and concepts clearly shows that the human animal is closely related to the four great apes, or *pongids* (orangutan, gorilla, chimpanzee, and bonobo).

This anthropological quest is both intradisciplinary and interdisciplinary. Specialists in the discipline work together to achieve a comprehensive and coherent view of our human species; for example, biological anthropologists work closely with prehistoric archaeologists at a fossil hominid site, while sociocultural anthropologists work closely with anthropological linguists in studying other societies with different cultures (particularly nonliterate peoples with a "primitive" technology). One goal is to derive meaningful concepts and generalizations from the vast range of empirical evidence (Fuentes, 2007).

More and more, as naturalists and humanists, anthropologists are multidisciplinary in their approach. They strive to be relevant in the modern world. Consequently, one speaks of applied anthropology (e.g., forensic anthropology and biomedical anthropology). Anthropological knowledge adds to human enlightenment, particularly in terms of increasing tolerance for human biological and sociocultural differences. In the discipline of anthropology, teaching and research go hand in hand; that is, biological anthropologists aim for a clearer view of humankind that concerns its evolutionary past, present convergence on the earth, and future possibilities (perhaps its migration beyond our planet and even outside this solar system).

Biological anthropologists focus on the organic evidence of primates (e.g., their fossils, skeletons, teeth, genetic makeup, and physical characteristics, as well as psychological and social behavior patterns). They present this evidence in a comprehensive and intelligible manner, while searching for meaningful concepts and generalizations about primate evolution in general, and our species in particular.

The German naturalist Johann Friedrich Blumenbach (1752–1840) is considered to be the father of biological anthropology (previously known as physical anthropology) because he focused on studying the human variations in those biological characteristics that manifest themselves within a population and among populations. Although the academic discipline of anthropology did not yet exist, his pioneering research paved the way for the later, intensive studies of our species and the other primates—from comparative paleoanthropology to comparative genetics.

Charles Darwin (1809–1882) was a major influence on the emergence of biological anthropology. As presented in his two major works, *On the Origin of Species* (1859) and *The Descent of Man* (1871), his theory of evolution suggested that much light would be shed on the history of life-forms and the nature of our own species (Darwin, 1859, 1871). The origin and development of humankind, as well as its evolutionary relationships to the other primates, now became the subject matter for scientific inquiry. No longer was our species viewed as being isolated from other life-forms or organic history. As such, the discipline of anthropology dedicated itself to rigorously studying humankind in terms of science and reason (Bollt, 2009).

As biological anthropologists, early naturalists worked alone in their search for fossil hominid specimens. Usually, outside funding was not available and significant findings were often dismissed by the scientific community. However, as more evidence was discovered, the theory of human evolution was taken seriously. Since the middle of the 20th century, paleoanthropologists have stressed a multidisciplinary approach (both intradisciplinary and interdisciplinary) in their research (Wolpoff, 1999). As a result, at a fossil hominid site, a scientific team of international specialists may include chemists, geologists, paleobotanists, paleozoologists, prehistoric archaeologists, photographers, and artists. Specialists also work with paleoanthropologists in museums and laboratories. Some biological anthropologists specialize in primate-behavior studies or primate-genetics research (including twin studies, as well as growth and development research). Today, thanks in part to anthropologists, there is a growing awareness of the critical relationship between our species and the natural environment, both inorganic and organic. Academic books (Angeloni, Parker, & Arenson, 2009; Haviland, Walrath, Prins, & McBride, 2008; Park, 2010; Relethford, 2010; Stanford, Allen, & Antón, 2009), professional journals, museum exhibits, college and university courses, and educational programs in the mass media are making the scientific evidence in biological anthropology available to a widening

audience of teachers and students, as well as the interested public. The presentation of facts, concepts, hypotheses, and perspectives is very helpful in discrediting racism and promoting evolution.

Evolutionary Framework

The idea of evolution neither originated with the thoughts of Charles Darwin nor had its final formulation in his scientific writings; as such, one may speak of the evolution of evolution from an early concept in antiquity to its present status as a brute fact of the modern worldview (Birn, 1984, 1991b).

Pre-Socratic Speculations

During the pre-Socratic Age, several early philosophers as natural cosmologists anticipated the evolutionary framework in their rational speculations on the nature of things. Rejecting legends and myths, as well as personal opinions and religious beliefs, these critical thinkers emphasized deriving explanatory concepts by rigorously reflecting on their own experiences within nature and the use of reason. Although they were neither scientists nor evolutionists, their answers to general questions about this universe did establish a dynamic worldview that paved the way for further discoveries in the future development of the special sciences, from geology and paleontology to biology and anthropology.

Among the pre-Socratic thinkers, Thales claimed that life first appeared in water; for him, water is the fundamental substance of this cosmos. He argued that, over time, aquatic organisms changed and eventually there were life-forms that could adapt to and survive on dry land. It is reassuring that Thales, as the first Western philosopher, had glimpsed the biological significance of change throughout planetary time. In his rational speculations, he had grasped both the fluidity of life and the unity of this universe.

Extending this vision, Thales's student Anaximander held that, in the development of life-forms from water to land, lineage leading to the human animal had once passed through a fishlike stage of development. It is tempting to refer to this pre-Socratic thinker as the father of comparative morphology; one may imagine Anaximander comparing the innards of a dead fish with those of a human corpse, and consequently being very impressed with the similarities (rather than with the differences).

Reflecting on the flux of reality, the naturalist metaphysician Heraclitus argued that change is the quintessential characteristic of this universe. Looking for order in this dynamic world, he further claimed that all changes in nature are cyclical. As a result, for Heraclitus, there is the endless repetition of day and night, life and death, the four seasons of the year, and even the cosmos itself. For later naturalists to accept the evolutionary framework, it was necessary for them to take both time and change seriously.

4 • BIOLOGICAL ANTHROPOLOGY

Of particular importance was Xenophanes, who recognized both the organic and historical significance of fossils as the remains of once-living but often different organisms related to the living life-forms of today. The fossil record is crucial, in that it provides empirical evidence to substantiate the fact of organic evolution. Despite our present knowledge of genetic variations, it would be difficult to convince many people of the truth of organic evolution if no fossil evidence had ever been discovered. However, the more paleontologists search, the more fossils they find (including paleoanthropologists discovering fossil hominid specimens).

Lastly, Empedocles even offered an explanation (although a bizarre one) for the origin of organisms. He speculated that in the past, the surface of the earth had been covered by free-floating organs of different sizes and shapes; they haphazardly came together, forming organisms (some, of course, were monstrosities). Those organisms that could adapt to the environment survived and reproduced, while the monstrosities perished. What is implicit in this explanation are the basic ideas that constituted the evolutionary framework of both Charles Darwin and Alfred Russel Wallace: multiplicity, variation, adaptation, survival, and reproduction or extinction. Unfortunately, with irony, the proto-evolutionary ideas of these five pre-Socratic thinkers were squelched by the greatest thinker of ancient Greece—Aristotle.

Aristotle

Aristotle was the “father of biology,” including comparative studies in embryology, morphology, and taxonomy. His encyclopedic interests ranged from cosmology and meteorology to botany and zoology. Aristotle assumed that the human mind is capable of discerning a natural design within the mixed species on this planet. He referred to this terrestrial order as the great chain of being, or ladder of nature. For him, each species is eternally fixed in nature, each type of organism occupying a special place in the great chain of nature depending upon its degree of complexity and sensitivity or intelligence. This hierarchical ladder ranged from the simplest mineral at its bottom to the rational human at its apex. Since Aristotle dismissed both the creation and extinction of species, as well as the appearance of new ones, he was not an evolutionist (although he was interested in the development of individual organisms). Because many thinkers gave priority to the fixed Aristotelian worldview, a serious evolutionary framework did not emerge until the scientific writings of Charles Darwin and Alfred Russel Wallace over 2,000 years later.

Before Darwin

Challenging the fixed Aristotelian worldview, the Roman philosopher and poet Lucretius presented a dynamic interpretation of both the earth’s history and the material universe. In his groundbreaking work *On the*

Nature of Things, he argued that our planet itself has created plants and animals, and even outlined the sociocultural development of our own species from cave-inhabiting early creatures to the citizens of the Roman empire. Furthermore, Lucretius boldly held that life-forms (including intelligent beings) inhabit planets elsewhere in the cosmos. His ideas paved the way for a naturalistic study of humans within nature.

During the Italian Renaissance, the artist and visionary Leonardo da Vinci recognized the biological and historical significance of fossils as the remains of once-living but usually different species—in fact, he had found these fossils in the top rock strata of the Alps. Moreover, his dynamic view of the earth’s history in terms of geology argued that the age of our planet must be at least 200,000 years (an astonishing claim in the eyes of his contemporaries). Furthermore, Leonardo’s study of the human body foreshadowed serious comparative-anatomy research.

In 1735, Carolus Linnaeus fathered modern taxonomy. He recognized the close similarities among the human animal and the apes, monkeys, and lemurs. Consequently, he placed all of these forms in the primate order. Although he was not an evolutionist, Linnaeus discovered that species are capable of producing varieties of themselves (an example of microevolution).

Decades later, as a result of taking the implications of geology and paleontology seriously, Jean-Baptiste de Lamarck wrote the first serious book on organic evolution. In his *Philosophy of Zoology* (1809), he argued that species are mutable and have changed throughout organic history. Without a testable explanatory mechanism or sufficient empirical evidence, Lamarck was unable to convince other naturalists that life-forms had evolved throughout geological time. Ironically, however, Lamarck’s book appeared exactly 50 years before the publication of Charles Darwin’s *On the Origin of Species* (1859).

With its emphasis on science, reason, and a historical perspective that took both time and change seriously, the Age of Enlightenment established an intellectual atmosphere that allowed for the emergence of three important earth sciences: historical geology, comparative paleontology, and prehistoric archaeology. Ongoing advances in biology (especially embryology, morphology, and taxonomy) and extensive travels by curious naturalists (e.g., Haeckel, Humboldt, Huxley, and Lyell) provided overwhelming scientific evidence and convincing rational argumentation for the vast age of this planet, the evolution of life-forms, and the great antiquity of our own species. Clearly, rocks and fossils and artifacts did not support a strict and literal interpretation of the biblical story of creation as presented in the book of Genesis in the Holy Bible. It was now necessary for some ingenious naturalist to bring all of these facts and concepts together in a comprehensive and intelligible view of life on earth in terms of biological evolution. Unintentionally, this task fell to the young geobiologist Charles Darwin (Birn, 2009).

Charles Darwin

Three major events contributed to Darwin's developing his scientific theory of organic evolution: his unique experiences as a naturalist aboard the HMS *Beagle* during its 5-year circumnavigation of the world in the Southern Hemisphere (1831–1836), his reading Charles Lyell's three-volume work *Principles of Geology* (1830–1833), and his later fortuitous reading in 1837 of Thomas Robert Malthus's *An Essay on the Principle of Population* (1798).

For Darwin, the convergence of evidence from geology, paleontology, and biology (as well as the implications of both biogeography and variations in organisms) argued for the pervasive mutability of species throughout immense periods of the earth's history within a naturalist framework. Of particular significance, he offered natural selection as the primary mechanism to explain biological evolution. Darwin's scientific facts and rational arguments for his evolution theory were first presented in *On the Origin of Species* (1859). However, at that time, the sensitive naturalist did not yet extend his theory of evolution to include the human animal.

In his *The Descent of Man* (1871), Darwin now seriously considered the evolutionary implications for understanding and appreciating the place of our own species within natural history. He argued that, biologically, the human animal is closest to the three great apes known to science at that time (orangutan, gorilla, and chimpanzee), with which it shares a common ancestral group whose fossils would be found in Africa. Furthermore, as had Huxley in England and Haeckel in Germany, Darwin even claimed that our species differs merely in degree, rather than in kind, from these three great apes. As such, his ideas were a major contribution to the emergence of biological anthropology. Even so, the resultant creation-evolution controversy still continued as an ongoing debate between biblical fundamentalists and scientific evolutionists. Today, the religious position is grounded in the alleged argument for intelligent design.

Although convinced of the veracity of his evolution theory, Darwin was still perplexed by four questions (among others): What is the true age of planet earth? Why is the fossil record so incomplete? How are organic variations inherited from generation to generation? Can slow biological evolution account for the emergence of the complex human eye? Throughout the following decades, ongoing advances in science and technology (especially in dating techniques and computers) would help to answer these four questions in favor of the evolution theory and a naturalist viewpoint.

After Darwin

The discipline of anthropology emerged during the middle of the 19th century. Greatly inspired by the writings of Charles Darwin, several naturalists were very interested in

extending the evolutionary framework to include our own species. In general, early biological anthropologists were eager both to find fossil evidence to substantiate human evolution and to compare the morphology of living primates in order to demonstrate the remarkable similarities among lemurs, monkeys, apes, and the human animal. In particular, some biological anthropologists extended taxonomy to include a racial classification of human groups in terms of different physical characteristics. (Rigorous primate-behavior studies and primate-genetics research would not appear until the middle of the 20th century.) Although conflicting interpretations of evolution were offered by naturalists, and even though anthropologists could not agree on the number of human races, there was no doubt that our species was both the product of organic evolution and closely related to the great apes, especially the chimpanzee.

During the succeeding decades, biological anthropologists would specialize in areas ranging from paleoanthropology and primatology to forensic anthropology and biomedical anthropology. The theory of evolution offers a comprehensive and intelligible framework in which both the physical characteristics of the human animal and its place within natural history made sense in terms of science and reason. Today, one may speak of the biological unity of *Homo sapiens sapiens* in terms of the DNA molecule.

Science of Genetics

As the father of biology, Aristotle was interested in the embryological and morphological development of organisms. He held that a female contributes the matter and a male contributes the form to an embryo, which then develops according to an innate, preestablished goal within the embryo itself (a movement from potentiality to actuality). However, Aristotle was not an evolutionist, since he held to the eternal fixity of all species within his assumed static hierarchy of planetary existence that ranged from simple minerals to complex animals. This worldview dominated Western thought until the persuasive scientific theory of evolutionist Charles Darwin.

The monk Johann Gregor Mendel discovered the basic principles of inheritance as a result of his rigorous, long-term experiments with the common garden pea plant *Pisum*. A particulate theory of inheritance was presented in his monograph *Experiments in Plant Hybridization* (1866), in which he not only distinguished between dominant and recessive characteristics for the same trait, but also presented the principles of segregation and independent assortment. Unknown to himself and the scientific community, which did not understand or appreciate the far-reaching significance of his pioneering discoveries, Mendel had established an empirical foundation for the science of genetics.

In 1900, building upon Mendel's findings, Hugo DeVries both discovered the phenomenon of incomplete dominance

and presented his mutation theory. Within several decades, evolutionists realized that, taken together, genetic variation and natural selection form the explanatory foundation of organic evolution. Thus emerged neo-Darwinism, or the so-called synthetic theory of biological evolution, with its focus on dynamic populations or gene pools.

If naturalist Charles Darwin had given to biological anthropology the factual theory of organic evolution, then James Watson and Francis Crick (along with Maurice Wilkins and Rosalind Franklin) gave to it a genetic foundation by discovering a working model for the DNA molecule, the so-called code of life or language of heredity (Watson, 2003). Since 1953, this groundbreaking discovery has had awesome consequences for understanding and appreciating life-forms, from a bacterium to the human animal. The DNA molecule gives undeniable evidence for the historical continuity and chemical unity of all life-forms on planet earth. In particular, it now clearly links our species with the four great apes or pongids: orangutan, gorilla, chimpanzee, and bonobo.

The DNA molecule has the structure of a double helix with six parts: a phosphate group, the sugar deoxyribose, and four bases (adenine, thymine, guanine, and cytosine). Changes to the sequence of bases, or nucleotides, in the genome may result in changes in the phenotype or biological expressions of an organism. Mutations may be major or minor, and of positive, neutral, or negative value for the organism in terms of its adaptation to and survival in a dynamic environment. Successful reproduction will pass on the altered hereditary information to the gene pool of the next generation. Therefore, one may hold that the members of a population represent differential reproduction. Over time, a species may produce a variety of itself, and this variety may eventually become a new species; further evolution may result in the emergence of higher taxonomic groups, such as new families, orders, or classes of organisms. Nevertheless, within the sweep of organic evolution, a very sobering fact is that the extinction of species is the rule rather than the exception.

The next step for naturalists and biological anthropologists was to extend the science of genetics to comprehend the evolution of populations (gene pools) in terms of both changes in gene frequencies and the appearances of mutations within dynamic environments, as well as natural and social selection (Hartl & Clark, 2006; Wells, 2002). Such studies shed significant light on biological variations in human populations, consequently challenging earlier anthropological views on race and racism (Mielke, Konigsberg, & Relethford, 2006).

In the early decades of the 20th century, anthropologists could not agree on either the number of alleged distinct races that comprise our human species or the criterion or criteria to be used in determining the assumed number of human races; the number of races ranged from 3 to over 200 (obviously, the methodology was faulty). Unfortunately, however, the concept of human race was extended by some

anthropologists to justify racism, resulting in a racial hierarchy from inferior groups to superior groups (Birx, 2003; Wolpoff & Caspari, 1997). Nevertheless, as a result of understanding and appreciating human variations in terms of the DNA molecule and dynamic populations, modern biological anthropologists now speak of the genetic unity of *Homo sapiens sapiens*, with organic differences being scientifically meaningful only below the subspecies level of classification. Human differences in blood groups, skin pigmentations, and morphological types are significant only in terms of adaptive genetic variations from gene pool to gene pool. The biological anthropologist Ashley Montagu (1905–1999) was instrumental in discrediting race and racism, while advocating the evolutionary framework (Montagu, 1997). Today, it is stressed that humans manifest cultural differences that are far greater than their biological differences. Of particular interest are ongoing twin studies, which are hoped to shed more light on the influences that both biology and culture have on determining the physical and social differences among human beings.

The mapping of the human genome, in order to discover which gene or genes determine specific characteristics or traits, has made possible the genetic engineering of the DNA molecule (Ridley, 2000; Scherer, 2008). Of course, such research holds both awesome promises and foreboding perils for the future existence and evolution of our species. In particular, ongoing stem cell research may eliminate hereditary diseases and even improve the human organism. As with any new science, there is (at first) widespread apprehension and the possible abuse of such powers. Even so, one may argue that the long-range benefits of genetic engineering and stem cell research far outweigh any short-range problems, given common ethical guidelines and rational value judgments to prevent the misuse of scientific research and its application.

Today, one may even speak of emerging teleology. As the use of and advances in both nanotechnology and genetic engineering increase, our species will more and more be able to guide the once-random process of organic evolution, including directing human evolution for chosen goals on planet earth and elsewhere. If the human gene pool departs significantly from its present makeup, then one may anticipate (in the remote future) the emergence of a new species, *Homo futurensis*.

Hominid Evolution

Biological anthropologists as paleoanthropologists compare and contrast fossil bones and teeth in order to discern whether a specimen is pongid-like or hominid-like, and where it most likely should be placed within the long and complex evolutionary history of hominoids (Anderson, 2005; Arsuga & Martínez, 2006; Birx, 1988; Cela-Conde & Ayala, 2007; Tattersall, 1993). Dental features, as well as the cranium and innominate bone, greatly help to determine

how close an apelike specimen is to the emergence of our own species. Modern computers and improved dating techniques significantly aid paleoanthropologists in constructing viable models depicting human evolution in light of the growing fossil record, as well as genetic research information when it is available. Furthermore, fossil and genetic evidence sets limits to probable models for human evolution in particular, and primate evolution in general.

For early biological anthropologists, the theory of evolution implied that our own species has an evolutionary past that links it to the fossil apes of about 7 to 5 million years ago. Thus, it is not surprising that some early naturalists wanted to discover the so-called “missing link” among those fossil hominoid specimens that are ancestral to both the living apes and the human animal of today. However, a debate emerged as to whether this evolutionary link would be found in Africa or in Asia. Inspired by the writings of Charles Darwin in England and Ernst Haeckel in Germany, the Dutch naturalist Eugene Dubois decided to leave Europe for Indonesia, where he was convinced that his research would unearth a fossil form midway between apes and humans. In the early 1890s, with incredible luck, Dubois actually did find a hominid specimen that he classified as *Pithecanthropus erectus* or erect ape-man (now relegated to the long *Homo erectus* stage of hominid evolution); it was found at the Trinil site on the island of Java. Skeletal features revealed that this fossil specimen was an early hominid dated from at least 500,000 years ago. Darwin would have been delighted with this discovery, but he himself had favored Africa as the cradle of human evolution, since the gorillas and chimpanzees (two of our closest evolutionary cousins) still inhabit this continent.

Eugene Dubois’s success inspired other naturalists to search for more fossil hominid evidence in Java. Subsequently, several decades later, G. H. R. von Koenigswald found an even earlier fossil hominid at the Djetis site, which he referred to as *Pithecanthropus robustus* (now also relegated to *Homo erectus*).

In 1924, anatomist Raymond A. Dart analyzed a fossil skull that had been fortuitously found at the Taung site in the Transvaal area of South Africa. He correctly determined that it was a hominid child over 1 million years old. It represented the australopithecine group of fossil hominids that existed for several million years. This discovery of *Australopithecus africanus* from Taung suggested that Darwin had been correct in maintaining that fossil apelike forms in Africa (not in Asia) had given rise to those hominids that are ancestral to our species. This incredible discovery inspired other naturalists to continue the search for fossil apes and fossil hominids in Africa. Even so, more evidence for human evolution was next found at the Zhoukoudian site near Beijing, China, due to the ongoing research of Davidson Black and Franz Weidenrich (including Pierre Teilhard de Chardin, among others). The specimens represented

Sinanthropus pekinensis, a form of *Homo erectus* that lived about 350,000 years ago.

Later, with steadfast determination, the anthropologist Louis S. B. Leakey was convinced that the earliest fossil hominids would, in fact, be found in central East Africa. In 1959, after searching for 30 years, his second wife Mary found the cranium of *Zinjanthropus boisei* at Olduvai Gorge in Tanzania—a 1.75-million-year-old specimen. Although the cranium was that of the first fossil hominid ever found in central East Africa, it nevertheless represents a side branch that became extinct (as several other forms did) during the early evolution of hominid species.

In 1961, Louis S. B. Leakey himself found the skull of *Homo habilis* at Olduvai Gorge. This specimen was 1.9 million years old, and associated with the Oldowan pebble-tool culture. *Homo habilis* not only stood erect and walked upright with a bipedal gait, but also made simple stone implements. Unlike other hominid forms that became extinct, this bigger-brained and culture-making species gave rise to *Homo erectus*, the next phase of hominization. The astonishing success of the Leakey family, including both Richard E. F. Leakey (who also found a *Homo habilis* skull, but at Koobi Fora) and later Meave Leakey in Kenya, encouraged other biological anthropologists to search for hominid fossil specimens elsewhere in central East Africa (Morell, 1995).

During the 1970s and 1980s, three other major discoveries were made: the Lucy skeleton found by Donald C. Johanson and his team at the Hadar site in the Afar Triangle of Ethiopia (Johanson & Edey, 1981; Johanson & Shreeve, 1989; Johanson & Wong, 2009), the human Laetoli footprints found at a site in Tanzania by Mary Leakey and her team, and the *Homo erectus* skeleton found by Richard Leakey and his team on the western shore of Lake Turkana in Kenya. By the 1990s, there was no doubt that Africa had played the major role in the origin and early evolution of hominid species (Leakey & Lewin, 1992). More recent fossil specimens make it clear that many different hominid forms once occupied Africa during the past 4.5 million years. To date, the fossil australopithecine complex is represented by at least eight hominid species: *aethiopicus*, *afarensis*, *africanus*, *anamensis*, *boisei*, *garhi*, *robustus*, and *sediba*. No doubt, in the coming years, more incredible fossil hominid specimens will be discovered in both Africa and Asia.

One remaining puzzle in human evolution is the “sudden” extinction of the Neanderthal people and the remarkable success of their contemporaries, the Cro-Magnon people (Sauer & Deak, 2007; Tattersall & Schwartz, 2000). A probable explanation for the Neanderthal extinction is that they could not compete with the far more intelligent Cro-Magnon people, who most likely had a more complex language and certainly an advanced material culture (including stone and bone carvings, as well as exquisite cave murals). New findings and ongoing research may answer questions concerning the biosocial relationship between these two groups of early *Homo sapiens*. For now,

one fact is certain: The Cro-Magnon people gave rise to the modern human being as *Homo sapiens sapiens*.

Actually, there is no common consensus among paleoanthropologists concerning the classification of fossil hominid specimens. Some paleoanthropologists argue that skeletal differences represent numerous species, and perhaps even distinct genera. Other paleoanthropologists place different skeletons into the same species, or maintain that they merely represent sexual dimorphism. Nevertheless, three generalizations seem true: (1) Hominid evolution has taken place over 4 million years; (2) fossil hominid specimens represent many species that became extinct; and (3) evidence shows that sustained bipedality preceded Paleolithic culture, which preceded the modern cranial capacity. No doubt, present models for and interpretations of hominid evolution will be modified in light of future discoveries.

Primate Taxonomy

In the footsteps of Aristotle and Linnaeus, modern taxonomists are interested in classifying living primates into groups that reflect both their similarities and evolutionary relationships. However, besides relying upon comparative studies in embryology and morphology, modern taxonomists also use computer technology and research information from comparative genetics. In general, primates are characterized by a large brain, great intelligence and memory, an emphasis on vision (rather than smell), grasping hands and remarkable motor-sensory coordination, and complex psychosocial behavior. These special features were slowly acquired over millions of years as adaptive characteristics to enhance survival—and therefore reproduction—in the trees. Only the human species spends its entire lifetime on the ground.

There is no common consensus among modern taxonomists concerning the classification of the primates. However, most biological anthropologists agree that six major groups comprise the living primates of today: prosimians, New World monkeys, Old World monkeys, lesser apes, great apes, and our own species (Campbell, Fuentes, Mackinnon, Panger, & Bearder, 2007; Rowe, 1996).

The earliest group of primates to emerge was the diversified, arboreal prosimians. Living representatives include the tree shrews, lorises, tarsiers, and lemurs. Although they once inhabited the trees in both hemispheres, all prosimians are now found only in Africa and Asia. The classification of tree shrews as primates is debatable, but this is to be expected since they represent an evolutionary link between the earlier ground-dwelling insectivores and the later tree-dwelling prosimians. Nevertheless, the tree shrews show an emphasis on vision and motor-sensory coordination, as well as grasping digits and a comparatively large brain.

Monkeys evolved out of the prosimians in both hemispheres. Thus, a distinction is made between the New

World monkeys of the Western Hemisphere and the Old World monkeys of the Eastern Hemisphere.

New World monkeys are arboreal and divided into two groups: one group consists of the small marmosets and tamarins, while the other group includes the larger monkeys, such as the spider monkey and the howler monkey. Old World monkeys are very diversified, with some representatives spending considerable time on the ground, such as the baboons. Biological anthropologists are particularly interested in studying the behavior patterns of the terrestrial baboons, since these largest of the monkeys inhabit open woodlands and grassy savannahs when on the ground. Consequently, baboon behavior may shed light on the social behavior of our earliest ancestors, the proto-hominids, who became successful in adapting to life on the ground in terms of biological characteristics and behavior patterns. Other Old World monkeys include the mandrill, drill, gelada, colobus, and vervet of Africa; the langurs of India; and the macaques of Asia (e.g., the rhesus monkey). Larger, more intelligent, and far better adapted to arboreal habitats, the monkeys dominated the trees in both hemispheres and nearly brought the prosimians to extinction.

The apes are placed into two groups: the lesser apes or hylobates, and the great apes or pongids. They are larger and more intelligent than the monkeys. The hylobates include the gibbon and siamang. The pongids include the orangutan, gorilla, chimpanzee, and bonobo. Fossil and living apes are found only in the Eastern Hemisphere, where they evolved from some earlier Old World monkeys. Evolutionary relationships among the fossil and living primates are determined by genotypic and phenotypic similarities. However, interpretations of the evidence vary among paleoanthropologists and primatologists. One intriguing question remains: Which of the four pongids is closest to our own species? Many biological anthropologists maintain that the human animal is closest to the chimpanzee (Diamond, 1992) and bonobo. Yet, there are a few naturalists who argue that *Homo sapiens* is actually closest to the orangutan (Schwartz, 2005). Although fossil ape specimens are rare, future discoveries may shed more light on the evolution of early hominids from even earlier fossil pongids.

Primate Behavior

Since the writings of Huxley, Haeckel, and Darwin himself, evolutionary naturalists recognize the biological similarities among the primates: They all have large eyes, flexible digits, a complex brain, and great motor-sensory coordination. Over millions of years, primates adapted successfully to life in the trees. They not only adapted to their arboreal habitats in terms of physical characteristics, but also in terms of social behaviors (Fleagle, 1998; Jolly, 1985; Strier, 2007). Our own species is particularly similar to the four great apes: orangutan, gorilla, chimpanzee, and bonobo (McGrew, Marchant, & Toshisada, 1996). With the

acceptance of evolution, it is not surprising that in the middle of the 20th century, some biological anthropologists began to study wild primates in their natural habitats. In general, the more complex the physical features of a primate species, the more complex is its behavior patterns. The prosimians exhibit simpler social structures than the monkeys, while the six apes (especially the four pongids) manifest the most complex behavior patterns outside our own species.

Prosimians

In the Eastern Hemisphere, prosimian behavior is reflected in the solitary tree shrews, pair-bonded adult lorises and tarsiers, and the lemurs of Madagascar that are monogamous or live in small social groups with female dominance. The ring-tailed lemur (*Lemur catta*) communicate through sounds, smells, and body movements (e.g., social grooming). Their behavior patterns are social adaptations to life on the ground, enhancing survival and therefore reproduction.

Monkeys

New World monkeys are arboreal and live in small social groups. The red howler monkey (*Alouatta seniculus*) eats fruits and leaves, defends a home range, and communicates through loud howls. Also important is cebid-behavior research on the spider monkey and woolly monkey of South America.

Among the Old World monkeys, of particular importance is the common baboon (*Papio anubis*) in Africa (Smuts, 1985; Strum, 1987). On the ground, a baboon troupe is headed by the dominant adult alpha male. Since these baboons are often terrestrial during the day, in the open woodlands and on the grassy savannahs, their social behavior may give biological anthropologists a glimpse into the group behavior of the early hominids, who adapted to and evolved in similar environments. However, there are some primatologists who speculate that early hominid behavior may have been closer to the social behavior of living chimpanzees and bonobos. Significant behavior research continues on the terrestrial langurs and macaques of Asia.

Apes

The two lesser apes, or hylobates, are the gibbon (e.g., *Hylobates lar*) and the larger siamang (*Symphalangus syndactylus*). They are found only in the tropical rainforests of Southeast Asia, where they have adapted very successfully to life in the trees. Gibbon behavior varies from adult male/female pair bonding to small social groups. Gibbons actively defend a territory through loud sounds and aggressive displays, which warn off intruding groups.

It was to be expected that some primatologists would focus their research on studying the behavior of the great

apes. Most important are past and ongoing close-range, long-term observations of the pongids in their natural environments.

Inspired by paleoanthropologist Louis S. B. Leakey, three female primatologists established the rigorous study of wild apes in their natural habitats: Biruté Galdikas, Dian Fossey, and Jane Goodall. Their steadfast and pioneering observations resulted in remarkable discoveries concerning the behavior patterns of the three pongids. These social findings supplemented the biological evidence that already supported the close evolutionary link between the great apes and our species.

In their natural habitats, wild orangutans (*Pongo pygmaeus*) live only on the islands of Borneo and Sumatra in Indonesia. Galdikas devoted her research to observing the orangutans on the island of Borneo (Galdikas, 1996, 2005). Her close-range, long-term observations of this pongid have added greatly to understanding and appreciating this great ape of Asia. She not only focused on their behavior patterns, but also prepared orphaned infants for their return to the tropical rainforests. In doing so, her devotion to studying and caring for orangutans has helped to ensure their survival, while also informing the world that this great ape needs to be protected from both human harm and the threat of extinction. Unfortunately, orangutans are now facing extinction due to the encroachment of human civilization, especially because it causes the deforestation of their environment and disrupts their behavior. Furthermore, adult orangutans are killed in order to capture their infants; subsequently, these young orangutans often die in captivity.

Adult orangutans are primarily loners, living in trees and surviving primarily on fruits and leaves. There is no complex social behavior. Nevertheless, orangutans are intelligent. Unfortunately, in captivity, where they are removed from an active life in the trees, orangutans are prone to boredom and obesity; placing them in natural settings therefore improves their health and extends their longevity. Fortunately, for biological anthropology, Galdikas continues her efforts to understand and appreciate this “red ape” of the primate world. Following in her footsteps, other primatologists will devote their efforts to studying this pongid in order to save this endangered great ape from vanishing completely.

The largest ape ever discovered is *Gigantopithecus* from fossil sites in China, India, and Vietnam. It existed from the Miocene epoch to about 500,000 years ago, but is now known only from its massive jaws and huge teeth (especially its premolars and molars). In part, the extinction of *Gigantopithecus* may have been due to the evolutionary success of a competitor, *Homo erectus*. Evidence suggests that, astonishingly, this fossil pongid might have stood over 9 feet tall and could have weighed at least 500 pounds. Future research may discover a skeleton of this astonishingly huge ape, which is related to the living orangutan through primate evolution.

The gorilla is the largest of the four great apes, and the two isolated subspecies are found living only in the forested areas of equatorial Africa. In the footsteps of zoologist George B. Schaller, Dian Fossey dedicated her research to studying the wild mountain gorilla (*Gorilla gorilla beringei*) on the slopes of the Virunga volcanoes in central East Africa (Fossey, 1983). Not content with merely observing them from the safety of trees, she was the first primatologist to actually make contact with this large pongid. Her efforts were rewarded with surprising findings that demolished the traditional view of the gorilla as a dangerous and ferocious ape. In fact, Fossey discovered that the gorilla is actually a shy, gentle, intelligent but introverted pongid.

Gorillas are very intelligent and live in small social groups, each dominated by an adult silverback male who determines when the group members will move, eat, or rest. There are also loner adult males. Gorillas eat fruits and leaves, and fear few predators (except human poachers with weapons). Unfortunately, the natural range and population of wild gorillas are diminishing due to the ongoing encroachment of human settlements.

For about 50 years, Jane Goodall has devoted her efforts to studying the wild chimpanzee or common chimpanzee (*Pan troglodytes*) at the Gombe Stream National Park near Lake Tanganyika in central Africa (Goodall, 1986, 2000). She has made significant discoveries about the social behavior of this very humanlike great ape. Chimpanzees are very intelligent, are both arboreal and terrestrial, systematically make and use simple tools, and are capable of learning and communicating through symbols. They exhibit both intriguing and disturbing behavior patterns. Chimpanzees are aggressive, promiscuous, live in loosely structured and constantly changing social groups, and are capable of killing both their own infants and adults.

Chimpanzees communicate through distinct sounds, body movements, facial expressions, and social grooming. One remarkable discovery is that they modify twigs in order to “fish” ants and termites from their mounds, adding these insects to their diet. Chimpanzees crack open nuts using rocks or branches, and also use a bone pick to extract bone marrow. They also hunt and kill monkeys, adding meat to their otherwise usual diet of fruits, nuts, seeds, and leaves. One particular activity is especially interesting: adult males will participate in a so-called “rain dance” during a thunderstorm.

Since 1929, scientists have known about the chimpanzee-like bonobo (*Pan paniscus*) or the so-called pygmy chimpanzee. Nevertheless, only during the past two decades have a few biological anthropologists studied the wild bonobos in the forests of Zaire in central Africa (de Waal & Lanting, 1997). Although they frequently walk on their knuckles, bonobos are capable of walking upright for short distances; they are taller and thinner than the common chimpanzee. Bonobos eat fruits, plants, and monkeys. There is strong bonding among adult females, and social

groups may even be dominated by them. The social behavior of this peaceful pongid is grounded in “make love, not war” (in sharp contrast to the sometimes vicious behavior of the common chimpanzee). Sexual activity is pervasive among bonobos, strengthening group interactions and diminishing social tensions. Like chimpanzees, bonobos share about 98% of their DNA with the human animal.

Several primatologists have focused their research on ape communication studies; for example, Francine Patterson has taught two lowland gorillas American Sign Language. However, her success and similar work by other biological anthropologists have come under sharp criticism by scientists who claim that the great apes are merely mimicking the behavior of their teachers. Even so, anthropological research has revealed that pongids have greater mental ability than is suggested by merely observing their social behavior in natural habitats.

Forensic Anthropology

Since the middle of the 20th century, the discipline of anthropology has striven to be relevant in terms of solving problems in the modern world. One area of applied anthropology is forensic anthropology (Birn, 2002; Komar & Buikstra, 2008), which has increased greatly in its popularity during the last 10 years. An outgrowth of biological anthropology, forensic anthropology focuses on the skeleton of our own species. As such, forensic anthropologists analyze and describe a human skeleton in order to determine the biological characteristics of a human corpse and, ideally, to make a positive identification of the deceased individual.

All human beings belong to the same genus, the same species, and the same subspecies: *Homo sapiens sapiens*. Consequently, each human individual is a biological variation on a common theme, that common theme being the genetic unity of humankind. Biological anthropologists specialize in understanding and appreciating our species in terms of primate evolution and human variation. The detailed study of a skeleton is crucial to forensic inquiry (Schwartz, 2007). The human skeleton has 206 bones, ranging from the large femur to the three small ear bones or ossicles (Birn, 1991a); the glaring similarity among the hominid and pongid skeletons, of both living and fossil species, is convincing evidence for human evolution and our common ancestry with the great apes. Osteological and dental remains help the forensic anthropologist determine the age, gender, height, weight, health, and ethnic background of an individual. Such studies may also reveal anomalies, mutations, and the results of past diseases and injuries. However, when present, other biological evidence may also determine the cause or manner of death, as well as help to identify suspects. Yet, in some cases, a positive identification is never achieved.

Furthermore, forensic anthropologists help to reconstruct a death scene. Forensic inquiry may determine that

the death of an individual is due to murder, accident, suicide, or a natural cause; in some cases, the cause of death may remain unknown.

Forensic anthropologists use methods that have emerged in the history of biological anthropology and prehistoric archaeology (e.g., in the methods they use for the careful investigation of a death scene). Today, data banks of human bones and genetic fingerprints are now available for comparative studies, as well as the use of modern computers. Additional information comes from the DNA molecule, serology, entomology, toxicology, and ballistics (among other areas of specialty).

Forensic anthropologists may study such diverse subjects as Neanderthal fossil remains, the 5,200-year-old Iceman (named Ötzi) from the Alps, mummies from ancient Egypt (e.g., the remains of King Tut) and the Incas of Peru, and individuals from bogs, war grave sites, and recent catastrophes. Likewise, forensic scientists help to reconstruct both a death scene and the face of a human corpse. However, only human remains from the past 50 years have legal significance; in these cases, the forensic anthropologist may be an expert witness at a trial.

Conclusion and Future Directions

The discipline of biological anthropology continues to shed light on the origin, evolution, and diversity of our own species, as well as its relationship to other primates (both fossil and living forms). Each year, new discoveries in paleoanthropology add more empirical evidence that enhances our understanding of and appreciation for hominid evolution. No doubt, over the coming decades, other exciting findings will be made in both Africa and Asia. Ongoing discoveries of fossil specimens will likely help to explain the emergence of both bipedality and our modern cranial capacity. As such, the present model of hominid evolution will be modified in order to accommodate all the new facts and concepts. Likewise, more nonhominid fossil specimens will be found, shedding new light on the evolution of primates throughout the Cenozoic era.

Ongoing advances in genetics and psychology will clarify the biological, social, and evolutionary relationships among the primates. Findings from continued primate behavior studies, both in captivity and in the wild, will help to narrow the gap between the human animal and the great apes, especially in terms of language acquisition (Bickerton, 2010) and the making of stone implements. One urgent need is to protect the nonhuman primates from the threat of extinction. It is deeply regrettable that the four pongids (orangutan, gorilla, chimpanzee, and bonobo) are now vanishing animals primarily because of the encroachment of human civilization. It would be a tragedy if these wonderful species became extinct. Of course, there is a need to protect all the primates. It is also important that future biological anthropologists continue to research the

relationship between humans and apes in terms of the origin and transmission of infectious diseases within ever-changing environments.

Human growth and development research, especially twin studies, will help clarify the dynamic relationship between biology and culture, discrediting unfounded racial classification systems and overcoming their resultant entrenched racism. And there is also a need to examine the influence of culture and the environment on the human gene pool and the biological variations that emerge from external changes in the natural world.

Of course, the ongoing teaching of both biological anthropology and the evolutionary framework is quintessential for the spread of rational thought and scientific evidence necessary for a proper interpretation of our human species within natural history. Consequently, research in biological anthropology needs to remain open to new facts, concepts, hypotheses, and perspectives.

HOMINID DESCRIPTIONS

IGNACIO ARENILLAS AND JOSÉ ANTONIO ARZ

University of Zaragoza

The hominids are included in the superfamily Hominoidea, which groups together humans, great apes (chimpanzees, bonobos, gorillas, and orangutans), lesser apes (gibbons and siamangs), and all the fossil relatives (e.g., *Oreopithecus*, *Sivapithecus*, *Dryopithecus*, and *Australopithecus*). Formerly, the hominoids were divided into hominids (humans) and pongids (great and lesser apes), the last ones of which were later subdivided in pongidae (chimpanzees, bonobos, gorillas, and orangutans) and hylobatidae (gibbons and siamangs). For this reason, the term “hominid” has been traditionally restricted to humans and their extinct relatives (i.e., those fossil taxa belonging to the human phylogenetic lineage). This definition is commonly used even by many anthropologists. However, taxa strictly grouping in hominids are not only humans, but also chimpanzees and gorillas, which form the family Hominidae. The original meaning of the *hominid* term referred only to the modern meaning of tribe Hominini (i.e., *Homo sapiens* and other extinct species closely related to humans). In spite of the fact that the terms *hominin*, *hominid*, and *hominoid* are different, Hominini has been considered preferable to describe in this chapter the species of our own evolutionary lineage (tribe Hominina). Fossil (and modern) monkeys and apes (including chimpanzees, bonobos, gorillas, and orangutans) are described in the section “Fossil Primates.”

Description of Modern Humans: *Homo sapiens sapiens*

The only living species of the family Hominini is *Homo sapiens sapiens*. Some taxonomists also include in this group the chimpanzees (*Pan*), subdividing them into two subgroups (Panina and Hominina). Nevertheless, others consider that chimpanzees and humans must be separated into two groups (Panini and Hominini, respectively), and this is the classification used here. Our species, which was defined as *Homo sapiens* by Carolus Linnaeus in 1758, is characterized by a highly developed brain and capable of complex language, abstract reasoning, and full consciousness of its thoughts, sensations, perceptions, emotions, and self-awareness. Its intelligence allows it to explain and manipulate natural phenomena through philosophy, science, art, and religion. Members of this species are capable of building fires, cooking their food, clothing themselves, and developing numerous complex technologies, including space exploration.

Homo sapiens belongs to the genus *Homo*, tribe Hominini, subfamily Homininae, family Hominidae, superfamily Hominoidea, infraorder Catarrhini, group anthropoidea or simiiformes, suborder Haplorhini, and order primates. Physically humans tend to be weaker than other similarly sized apes, as gorillas or chimpanzees. Just like apes,

H. sapiens has clear sexual dimorphism. The average height in adult humans is 1.40 to 1.80 m in males and 1.30 to 1.70 m in females, and the average weight is 60 to 80 kg in males and 45 to 65 kg in females, although it varies significantly from place to place. *H. sapiens* has a rounded and large neurocranium, a small and vertical face, a prominent vertical forehead, and an orthognatic face (straight jaw, vertical and flat face), although with slightly protruding jaws. The foramen magnum is placed directly underneath the skull, and brain capacity is 1,250 to 1,850 cm³ with 1,350 cm³ the average. Humans have proportionately shorter palates and much smaller teeth than other hominids and are the only extant primates to have short canine teeth. The dorsal spine is curved (S-shaped), and the foot bones have lost their mobility. Although humans are relatively hairless compared with other hominids, they have notable hair on the top of the head, underarms, and pubic area. The color of their skin and hair is determined by the presence of pigments called melanin, with skin varying from very dark brown to very pale pink, and hair varying from preponderantly black to blond or red.

Genetically, humans are characterized by 23 pairs of chromosomes. Their gestation period is 9 months, and their life span is approximately 84 years for females and 78 years for males in the developed world. The individuals mature sexually at 12 to 15 years, developing physically until 18 years in females and 21 years in males. They are infants from 0 to 3 years, children from 3 to 7 years, juveniles from 7 to 12 years, and adolescents from 12 to 18 years. Humans are omnivorous, capable of consuming both animal meat and vegetation. Their technology has allowed them to colonize all the ecosystems and adapt to all climates, including hostile environments such as Antarctica and outer space. Unlike other apes, humans are capable of fully bipedal locomotion, moving by means of their two posterior limbs and leaving their arms for manipulating objects through their hands. They have opposable thumbs, a character shared with all hominids.

From Linnaeus on, *H. sapiens* has been traditionally subdivided in terms of races or ethnic groups based on visible traits (especially height, skin color, cranial or facial features, and hair texture). Formerly, some dared to subdivide *H. sapiens* into subspecies, such as *H. sapiens afer* (for negroids as paleocongid, sudanid, nilotid [nilotes], and bantid [bantus] races), *H. sapiens europaicus* (for caucasoids as nordic, mediterranean, alpine, baltic, ladogan, dinaric, armenid, arabid, turanid, dravidic, and iranoafgan races), *H. sapiens asiaticus* (for mongoloids as nordsiberian, uralian [mongols], oriental, Indonesian, tungid [inuits], ainuid, and Amerindian races), and *H. sapiens australasicus* (for australoids as australian-tasmanian, melanesian, veddoid, and negrito races), and also *H. sapiens khoisanii* (for capoids as khoid and sanid races [khoikhoi and khoisans]), *H. sapiens pygmaeus* (for the bambutoid race [pygmies]), *H. sapiens aethiopicus*

(for the aethiopic race), and *H. sapiens americanus* (for Amerindians). Nevertheless, for scientific as well as social and political reasons, the conception of human race is often controversial. Recent genetic evidence has definitively questioned this taxonomic categorization. The total human genetic variations are approximately 0.5%, of which 85% can be found within any given population, 7% among populations within a race, and only 8% among various races. Human genetic sequences are therefore remarkably homogeneous compared with other species. Much of the genetic variation is found in the regions of the genome affected by the environment, mainly in genes affecting physical appearance, such as skin color. Today, most scientists who study human genotypic and phenotypic variations use concepts such as populations or clinal gradation. The race definitions are imprecise and arbitrary, and generally derived from customs, resulting in many exceptions and much gradation. Therefore, the gradual changes of phenotype in humans over a geographical area only allow us to subdivide *H. sapiens* into gene clines and populations, not into subspecies or races, as is possible in other species.

Description of Fossil Hominins

Through DNA comparison, geneticists consider that humans (*Homo*, tribe Hominini) and chimpanzees (*Pan*, tribe Panini) diverged in evolution 5.5 to 6.5 million years ago. It is noticeable that while very few fossil species related to chimpanzees have been identified, a significant number of fossil species of the human evolutionary lineage have been recognized. This is likely because organic materials fossilize better in savannah-type environments (where our ancestors preferably lived) than in forest environments (where the ancestors of the great apes preferably lived). According to known evidence to date, the tribe Hominini includes seven genera, six of which are fossil (*Sahelanthropus*, *Orrorin*, *Ardipithecus*, *Australopithecus*, *Paranthropus*, and *Kenyanthropus*) and the seventh of which (*Homo*) has only one living species, ours. For a better and more ordinate description, they have been grouped into primitive hominin fossil species (*Sahelanthropus*, *Orrorin*, and *Ardipithecus*), australopithecines (*Australopithecus* and relatives), ancestral habilis humans (*Homo habilis* and relatives), erectine humans (*Homo erectus* and relatives), archaic sapiens humans (*Homo heidelbergensis* and relatives), and modern fossil *Homo sapiens*.

Primitive Fossil Species

Three fossil genera have been included in this group and represent our most primitive relatives: *Sahelanthropus*, *Orrorin*, and *Ardipithecus*. Although the first two (*Sahelanthropus* and *Orrorin*) have been provisionally assigned to our Hominini evolutionary lineage, they may be

ancestors of chimpanzees as well as humans. They therefore belong to the basal group of both tribes Panini and Hominini, and perhaps should be taxonomically separated in other different tribes. Very few fossil remains of these taxa have been found, but they have allowed paleoanthropologists to partially cover the information gap in the hominid fossil record between 5 and 10 million years ago.

The genus *Sahelanthropus* includes only one known species discovered in Chad (central Africa): *Sahelanthropus tchadensis*, so the genus characteristics have been analyzed based on the fossil remains of the species: a nearly complete cranium and a number of fragmentary lower jaws and teeth. It is the oldest discovered hominin, dated at between 7.4 and 6 million years old (late Miocene). Its brain capacity is only 340 to 370 cm³ in volume and similar to that of modern chimpanzees. It has an elongated skull, far-set eyes, a supraorbital ridge, and a vertical face. Although it is yet unknown whether *S. tchadensis* was bipedal, some paleoanthropologists suggest this due to the fossils of its foramen magnum (a hole at the base of the skull over the spinal column). *Sahelanthropus* could represent a common ancestor of humans and chimpanzees, since most molecular-clock analyses indicate both species (*Homo* and *Pan*) diverged 5.5 to 6.5 million years ago (1 to 2 million years after *S. tchadensis*). Other possibilities are that *S. tchadensis* was the ancestor of chimpanzees or gorillas—or simply related to humans, chimpanzees, and gorillas, but the ancestor of neither. In any case, this taxon is very related to the common ancestor of all hominids, and it is therefore a very interesting fossil. Even if *S. tchadensis* was a proto-gorilla or a protochimpanzee, this taxon would not lose its significance, since few chimpanzee or gorilla ancestors have been found in Africa.

The genus *Orrorin* also includes an only-known species discovered in Kenya (central East Africa): *Orrorin tugenensis*. The genus characteristics have been analyzed with the fragmentary fossils (arm and thigh bones, lower jaws and teeth) of that species. *O. tugenensis* is considered the second-oldest known hominid ancestor, and it could be related to the ancestral-human lineage or even be a direct human ancestor. It has been dated between 5.6 and 6.2 million years old (late Miocene), and its discovery is important because it could be an early bipedal hominin. The characteristics of its femur and humerus suggest that *O. tugenensis* was skilled at tree climbing but not at brachiation, and could have been able to walk upright bipedally. Its size was similar to the modern chimpanzee, at about 1.40 m tall. Its teeth indicate that its diet was mostly fruits and vegetables, with occasional meat. *Orrorin* lived in the dry evergreen forest environment of Africa, not on the savannah, as many hypotheses on human evolution had assumed. This fact could indicate that the origin of bipedalism occurred in an arboreal precursor living in a forest and not a quadrupedal ancestor living in an open savannah. Our oldest ancestors, such as *O. tugenensis*, could have been able to move bipedally over branches with

the vertebral column oriented vertically, such as orangutans do today, using their arms for balance and keeping their legs straight. This adaptation moved them away from our closer extant relatives (chimpanzees and gorillas), which are more adapted to tree climbing and to quadrupedal locomotion while on the ground.

The genus *Ardipithecus* is a hominine genus that lived during the Miocene-Pliocene transition in central East Africa (Ethiopia), between approximately 3.8 and 6 million years ago. Most paleoanthropologists consider it an ancestor of *Australopithecus* because of a likeness in teeth. Its species was the size of modern chimpanzees, and the structure of its toes and the position of the foramen magnum suggest that it walked upright bipedally. Since it lived in shady forests and not on savannahs, the hypothesis on the origin of bipedalism in an arboreal precursor acquires new evidential support. Two species of *Ardipithecus* are known: *Ardipithecus ramidus* and *Ardipithecus kadabba*, although both were initially described as a subspecies of *A. ramidus*.

Ardipithecus kadabba is the older of the two *Ardipithecus* species and lived between 5.2 and 5.8 million years ago, during the Miocene-Pliocene transition. Its canine teeth show primitive features shared with *Sahelanthropus* and *Orrorin*, distinguishing them from more recent human lineages. Some paleoanthropologists argue that the presence of a canine cutting complex in this species, which is present in modern chimpanzees but not in *A. ramidus* and recent humans, indicates a need for relocation in hominid-evolutionary history, and it is reasonable to infer that this species was a primitive hominine lineage which was lost but very close to the most recent common ancestor of *Homo* and *Pan*.

On the contrary, the other species, *Ardipithecus ramidus*, is clearly related to the human lineage. It was initially dated between 3 and 4.4 million years old, but it could have lived as far back as 5.8 million years. Its teeth are intermediate between *Ardipithecus kadabba* and *Australopithecus afarensis*. Members of this species were bipedal and forest dwellers, and about 1.15 to 1.20 m tall and 25 to 30 kg in weight.

Australopithecines

The Australopithecines together form those extinct hominines that have been sometimes included in the genus *Australopithecus*. Today, the australopithecines are subdivided to three genera: *Australopithecus*, *Paranthropus*, and *Kenyanthropus*. Some taxonomists consider that *Australopithecus* and *Paranthropus* belong to a single genus, *Australopithecus*, although most prefer to distinguish between both australopithecine groups. Some paleoanthropologists have defined a new taxon to group them: tribe Australopithecini, separating them from the tribe Hominini that would include only *Homo*, and perhaps *Kenyanthropus*.

The genus *Australopithecus*, first described by Raymond A. Dart in 1925, is made up of the gracile australopithecines,

which shared several traits with the modern great apes and humans, although it is closely related to the genus *Homo*. They lived in eastern and northern Africa between 4.2 and 2 million years ago. They are considered the ancestors of the genus *Homo*, and include, for the first time, a clear bipedal hominine. The species of *Australopithecus* displays a remarkable sexual dimorphism, being that males are larger than females. The sexual dimorphism in the lumbar spine, seen for the first time in *Australopithecus*, has been considered an evolutionary adaptation of females to better bear a lumbar load during pregnancy, something that was not necessary in nonbipedal primates. *Australopithecus* has five known fossil species: *Australopithecus anamensis*, *Australopithecus afarensis*, *Australopithecus africanus*, *Australopithecus bahrelghazali*, and *Australopithecus garhi*.

Australopithecus anamensis lived during the early Pliocene between approximately 3.9 and 4.2 million years ago in eastern Africa (around Kenya and Ethiopia). Its fossils (including cranial fragments, upper and lower jaws, teeth, and parts of arm and leg bones) still resemble those of common chimpanzees (mainly the jaws), but their teeth are much more similar to those of humans. It is believed that *A. anamensis* was primarily a tree-climbing species and arboreal dweller—a behavior retained from the early hominine. Nevertheless, it is known that members of this species walked upright bipedally, and probable that lived in a more open environment. Its dentition indicates that its diet was exclusively herbivorous and frugivorous. This species shares many traits (teeth and jaws) with *Ardipithecus ramidus*, which may be its direct ancestor, but the arm and leg bones are already more similar to those of humans.

Australopithecus afarensis is a gracile australopithecine that lived between 2.9 and 4.2 million years ago (late Pliocene) in eastern Africa (around Kenya and Ethiopia). It had a considerable sexual dimorphism in size, being that adult males were 1.45 to 1.55 m in height and 45 to 70 kg in weight, but adult females were 1.05 to 1.15 m in height and 25 to 40 kg in weight. *A. afarensis* had a brain capacity of 380 to 540 cm³ (470 cm³ on average), and its face was prognathic (the mandible protruded farther than the maxilla). Its canines and molars were still relatively larger than those of modern humans, but they were very reduced when compared with the common chimpanzees and other apes. Its postcranial skeleton (mainly its pelvis) strongly indicates that it was bipedal, although it was probably partly arboreal and tree climbing. Some consider that *A. afarensis* was almost exclusively bipedal, since its feet features made it difficult if not impossible to grasp branches with the hind limbs. Footprints associated with *A. afarensis* showing bipedal locomotion have been found at Laetoli in Tanzania. However, its diet was frugivorous, so its arboreal activity was likely great. Its capacity to transmit sounds would not be greater than that of the current chimpanzees. It is considered to be an ancestor of *Australopithecus africanus* and the genus *Paranthropus*, and its own more direct ancestor is *A. anamensis*.

A species closely related to *A. afarensis* is *Australopithecus bahrelghazali*, an enigmatic fossil since it is the only gracile australopithecine found in central Africa (concretely in Chad). The only found fossil (mandible fragment and teeth) belongs to an individual dated at 3.6 million years old, but it is probable that the species lived between 3 and 4 million years ago in the late Pliocene.

Australopithecus africanus is the most famous gracile australopithecine. It lived between 2.5 and 3.3 million years ago in southern and eastern Africa. *A. africanus* shares many traits with the older *A. afarensis*, but its fossils indicate that it was significantly more like modern humans. It was sexually dimorphic, being that adult males were 1.35 to 1.45 m in height and 40 to 60 kg in weight, and adult females were 1.1 to 1.2 m in height and 25 to 30 kg in weight. Its skull was higher and more rounded and the face was less prognathic (flat and vertical) and shorter than its ancestors. Its teeth were also smaller, with smaller canines than those in other hominoids such as chimpanzees. The brain capacity of *A. africanus* was 410 to 520 cm³ (455 cm³ on average). Its cranium resembled that of the chimpanzee, but it shared human similarities in its teeth, eye orbits, and most importantly, foramen magnum, which indicates a humanlike posture. The discovery of *A. africanus* allowed paleoanthropologists to show that a large cranial capacity had succeeded bipedal locomotion in the human evolutionary timeline. It was considered to be a direct ancestor of *Homo*, although others believe *A. africanus* did not have descendants or evolved into *Paranthropus* instead of into *Homo*. Stone tools have not been found associated with *A. africanus*, which indicates that its intelligence was still very limited.

Australopithecus garhi is a gracile australopithecine whose fossils were found in Ethiopia in rocks of 2.5 million years ago. It probably lived between 2 and 3 million years ago. Its cranium and face were very similar to *A. afarensis* and *A. africanus*, although its molar and premolar teeth had some similarities with those of *Paranthropus*, since they are larger than those of the other gracile australopithecines. The brain capacity of *A. garhi* was about 450 cm³ on average, similar to other australopithecines. It was considered to be the missing link between the genus *Australopithecus* and the genus *Homo*, although it is believed that it was only a competitor species to the true ancestral species of *Homo* and therefore not a direct human ancestor. However, 2.5- or 2.6-million-year-old stone artifacts (closely resembling Oldowan technology) were discovered together with *A. garhi* fossils, indicating the first tools are older than the appearance of the genus *Homo*, which was not previously believed. If this is confirmed, then *A. garhi* (and *Australopithecus*) was the first toolmaker, relegating *H. habilis* (and *Homo*) to second place.

The genus *Paranthropus* (Broom, 1938) groups the robust australopithecines that lived between 1.1 and 2.7 million years ago, and it includes three known species: *Paranthropus aethiopicus*, *Paranthropus boisei*, and

Paranthropus robustus. They were bipedal hominine that descended from gracile *Australopithecus*. They were very well-muscled australopithecines, with a more massively craniodental build, and tended to have a gorilla-like sagittal crest on the cranium which anchored massive temporalis muscles of mastication. *Paranthropus* coexisted and shared a habitat with some *Homo* species, such as *H. habilis*, *H. ergaster*, and even *H. erectus*. Its brain capacity was larger than that of the gracile australopithecines, and stone tools have been found associated with *Paranthropus* fossils. However, there is considerable debate whether or not those tools were made by them or by contemporaneous *Homo*, so the true *Paranthropus* intelligence is still under debate. They represent a hominine evolutionary branch distinctly diverging from the human lineage.

Paranthropus aethiopicus was a robust australopithecine that lived in eastern Africa (Kenya) between 2.2 and 2.7 million years ago (transition between Pliocene and Pleistocene). It is therefore the earliest example of *Paranthropus* and shares many primitive traits with *A. afarensis*. For this reason, *P. aethiopicus* is considered to be a direct descendant of *A. afarensis* and the ancestor of the other robust australopithecines. It had a prognathic face (but flatter than other hominins) and a large sagittal crest. The cranial capacity of *P. aethiopicus* was approximately 410 cm³ on average. This species lived in a mixed savannah and woodland environment, probably in a more arid habitat than gracile australopithecines, and had a strictly herbivorous diet.

Paranthropus boisei (originally called *Zinjanthropus boisei*) is the most famous and largest robust australopithecine. They lived in eastern Africa (Tanzania, Kenya, Ethiopia, and eastern Congo) between 1.2 and 2.6 million years ago (early Pleistocene). Like the other australopithecines, they exhibited great sexual dimorphism, with adult males being 1.35 to 1.45 m in height and 55 to 80 kg in weight, and adult females being 1.05 to 1.15 m in height and 35 to 45 kg in weight. The skull was prognathic, with a vertical, long, and broad face; a robust mandible; and a pronounced sagittal crest. Curiously, the shape of their foramen magnum is more similar to *Homo* than that of the other australopithecines. The brain capacity of *P. boisei* was 500 to 550 cm³ (520 cm³ on average). Their cranial characteristics are indicative of a herbivorous diet consisting of hard or tough foods (tubers, nuts, and seeds).

Paranthropus robustus is the other well-known robust australopithecine that lived in southern Africa (South Africa) between 1.2 and 2 million years ago (early Pleistocene). Adult males were 1.2 to 1.3 m in height and 45 to 70 kg in weight, and adult females were 1 to 1.10 m in height and 35 to 45 kg in weight, indicating major sexual dimorphism. Its cranium was characterized by a heavy chewing apparatus (pronounced sagittal crest, and large jaws and jaw muscles), and teeth (molars extremely robust, and molarized premolars) that were well adapted to serve in the dry savannah environment. The cranial capacity of *P. robustus* was approximately 450 to 530 cm³ (500 cm³ on average).

Finally, the australopithecines also include a genus called *Kenyanthropus*, of which only one species is known: *Kenyanthropus platyops*. It lived in eastern Africa (Kenya) between 3.2 and 3.5 million years ago, although some paleoanthropologists consider that it might have lived up to 2 million years ago. *K. platyops* had a small brain capacity, but it also had high cheekbones and a flat face that relates it closely with the human lineage. This species has been considered to be the missing link between *Australopithecus* and *Homo*, since it has intermediate characteristics between the typical gracile australopithecines and typical humans. Concretely, its traits are intermediate between *Australopithecus afarensis* and *Homo rudolfensis*, relegating *Australopithecus africanus* to a second place in human-evolution history. However, this fossil is very problematic, since it is so distorted by matrix-filled cracks that meaningful morphologic traits are next to impossible to assess with confidence.

Ancestral Humans: *Homo habilis*

Paleoanthropologists have always considered that the appearance of *Homo* coincides with the first evidence of stone tools (Oldowan industry) at the beginning of the Lower Palaeolithic, 2.5 million years ago. However, it is not clear that ancestral humans invented these first tools since this lithic industry has been associated with more primitive australopithecines (*Australopithecus garhi*). Three ancestral human species have been found: *Homo habilis*, *Homo rudolfensis*, and *Homo georgicus*.

Homo habilis is a primitive human that lived in eastern and southern Africa (Tanzania, Kenya, Ethiopia, eastern Congo, and South Africa) between 1.6 and 2.2 million years ago (early Pleistocene). *H. habilis* was short, with adult males being 1.15 to 1.25 m in height and 35 to 50 kg in weight, and adult females being 0.95 to 1.05 m in height and 30 to 35 kg in weight. It had long arms compared with modern humans, but it also had a clear reduction in the prognathism of its face (which was broad and vertical), suggesting its close relationship to modern humans. Its foot bones show less mobility than its predecessors. Its cranium was more rounded with wide-set eyes, and its foramen magnum was placed in a more central position than in the other australopithecines. The cranial capacity of *H. habilis* was 590 to 680 cm³ (650 cm³ on average). *H. habilis* fossils are often accompanied by primitive Oldowan stone tools. The intelligence and social organization of *H. habilis* was probably more sophisticated than in the other australopithecines or chimpanzees. For a long time, it was considered the first species of *Homo* to appear, descending from a species of australopithecine (perhaps from *A. africanus* or from another unknown species related to *A. afarensis*). However, this honor could be snatched away by *H. rudolfensis*, not so much by age as by taxonomic interpretation. It is also believed to be the ancestor of the more sophisticated

Homo ergaster, but there is strong debate over whether or not *H. habilis* is a direct human ancestor. Its small size, likeness to australopithecines in body morphology, and primitive attributes (e.g., narrow birth canal and legs longer than arms) have led some paleoanthropologists to propose excluding *habilis* from the genus *Homo* and, instead, including it in the genus *Australopithecus*, naming *Australopithecus habilis*.

Homo rudolfensis is an ancestral human, originally considered to be a member of *H. habilis*, which lived in eastern Africa (Kenya and Malawi) between 1.9 and 2.4 million years ago (late Pleistocene). It has remarkable differences with respect to *H. habilis*, with a flatter face (vertical, long, and broad), wider molar and premolar teeth, and more complex roots and crowns. Adult males were probably 1.30 to 1.40 m in height and 40 to 50 kg in weight, and adult females were 1.10 to 1.20 m in height and 30 to 40 kg in weight. The cranial capacity of *H. rudolfensis* was probably 550 to 750 cm³ (650 cm³ on average), and, like *H. habilis*, its fossils are associated with primitive Lower Palaeolithic stone tools. According to its fossil record, it may be the oldest species of the genus *Homo*. Nevertheless, as in the case of *H. habilis*, there is debate over whether or not *H. rudolfensis* belongs to the genus *Homo* (some paleoanthropologists include this species in the genus *Kenyanthropus*), and over which one of these is the more probable ancestor of the later human species, or if it was some third species yet to be discovered. It has been suggested that *H. rudolfensis* evolved from *Kenyanthropus platyops*, while *H. habilis* seems to have evolved from *Australopithecus garhi*, raising debate on the real taxonomic position of both species and which is the evolutionary lineage that ended in the modern human.

Homo georgicus is an ancestral human species that lived in the Caucasus region (Georgia) 1.8 million years ago, according to the fossils known to date. Initially it was considered to belong to *Homo ergaster*, but size and morphological differences led paleoanthropologists to consider defining a new species, apparently more primitive than this one. It is the most primitive hominine species discovered outside of Africa. This species presents a strong sexual dimorphism. It is thought that adult males were 1.40 to 1.50 m in height and 45 to 55 kg in weight, and adult females 1.10 to 1.20 m in height and 30 to 40 kg in weight. Its skull was similar to *Homo ergaster*, but with a smaller face and more prognathic. The cranial capacity of *H. georgicus* was 600 to 680 cm³ (650 cm³ on average). They probably were capable of making tools, and some specialists have proposed that the Acheulean industry existing 1.4 to 1.6 million years ago in Israel is theirs. They ate animal meat, which was important for their survival during the winter season. *H. georgicus* has been considered a human group descended from *H. habilis*, which probably evolved in Africa and was capable of emigrating to Eurasia. This species may be the ancestor of two later species: African

Homo ergaster and Asian *Homo erectus*. Nevertheless, its taxonomic position is still debatable.

Ancestral Humans: *Homo erectus*

Many paleoanthropologists include the diverse species considered ancestral humans (i.e., the human type intermediate between ancestral *habilis* humans and modern *sapiens* humans) as belonging to a single species: *Homo erectus*. However, most prefer to distinguish at least two species: the African *Homo ergaster* and the Asian *Homo erectus*. This discussion concerning the taxonomy of this human group is still open, depending on whether *H. erectus* is considered a geographically widespread species found in Africa, Asia, and even Europe, or considered an exclusively Asian lineage that evolved from the less cranially derived African *H. ergaster*. In addition, two other very derived species have been proposed: *Homo soloensis* and *Homo floresiensis*, and they deserve special mention.

Homo erectus and its relatives were the first early human species able to constitute hunter-gatherer societies, procuring plants and hunting animals from the wild, without significant recourse to the domestication of either. They used more diverse and sophisticated stone tools than their predecessors, first using the Oldowan industry and later the Acheulean industry from 1.65 million years ago. More important, they were the first humans to make creative use of fire. Moreover, they may have communicated with a protolanguage much more developed than the basic communications used by chimpanzees, but without the developed structure of the modern human language. Their brain capacity generally coincides with the more sophisticated tools found together with its fossils and with the type of societies that they formed.

Homo ergaster is considered the African *Homo erectus*, but its morphological characteristics suggest that it be considered a new species. It lived in eastern and southern Africa (Ethiopia, Kenya, Tanzania, and South Africa) between 1.4 and 1.9 million years ago (early Pleistocene). It had a more reduced sexual dimorphism than the previous hominine. Adult males were approximately 1.8 to 1.9 m in height and 75 to 90 kg in weight, and adult females were 1.7 to 1.8 m in height and 60 to 70 kg in weight. The body proportions (longer legs and shorter arms) of *H. ergaster* were, for the first time, similar to those of modern humans. It had a smaller and more orthognathic face, a more rounded cranium, and a smaller dental arch. The cranial capacity of *H. ergaster* was 700 to 850 cm³ (800 cm³ on average). They made various tool types, such as hand axes and cleavers, belonging to the Acheulean industry 1.6 million years ago. Moreover, evidence (such as charred animal bones, fossils, and traces of camps) suggests that they made use of fire. It is believed that *H. ergaster* is a descendant of ancestral humans, such as *H. habilis* or *H. rudolfensis*.

Lately, *Homo erectus* has been considered an exclusively Asian species that lived between 0.2 and 1.8 million years ago (late and middle Pleistocene). Since it is the most successful and long-lived species of the *Homo* genus, it is generally thought to have a considerable number of subspecies. Although physical characteristics must therefore be described for each subspecies, *H. erectus* was characterized (on average) by a sexual dimorphism slightly greater than that in modern humans, adult males being approximately 1.60 to 1.70 m in height and 60 to 70 kg in weight, and adult females being 1.50 to 1.60 m in height and 45 to 55 kg in weight. Its face was almost orthognatic, with minimal jaw projection. It also had a long and low skull with a pronounced supraorbital ridge. The cranial capacity of *H. erectus* was between 750 and 1,250 cm³ (950 cm³ on average), or even more, although this depended on the particular subspecies.

The first fossils of this species were found in the central part of the island of Java (Indonesia) and called *Pithecanthropus erectus*. Later, other similar fossils were found in China near Beijing and called *Sinanthropus pekinensis*. Today, some paleoanthropologists subdivide *H. erectus* into two great informal groups: Indonesian pithecanthropines and Chinese sinanthropines. Only one pithecanthropine subspecies has been considered [*Homo erectus erectus*], while five subspecies are suggested for the sinanthropine group: [*Homo erectus wushanensis*, *Homo erectus yuanmouensis*, *Homo erectus lantianensis*, *Homo erectus hexianensis*, and *Homo erectus pekinensis*].

The oldest *H. erectus* specimens are found among the sinanthropines, the oldest of them being the Wushan Man (*H. e. wushanensis*) discovered in Longgupo (Chongqing, China), which lived at least 1.8 million years ago. The second-oldest member of the sinanthropines is the Yuanmou Man (*H. e. yuanmouensis*) identified in Yuanmou (Yunan, China), whose fossils are associated with stone tools, pieces of charred animal bones, and ash from campfires; they probably lived 1 to 1.7 million years ago. These oldest sinanthropines had a brain capacity of approximately 750 to 990 cm³ (870 cm³ on average) and an estimated stature of about 1.60 to 1.70 m in males. Members of *H. e. lantianensis*, popularly known as the Lantian Man, were found in Lantian (Shaanxi, China), and probably in Gongwangling (near Lantian), though these were promoted to a subspecies (*Homo erectus gongwanglingensis*); they lived between 0.4 and 1 million years ago. This last group probably also includes sinanthropine fossils found in Yunxian (Hubei, China)—sometimes considered to be another different subspecies (*Homo erectus yunxianensis*) and dated as living between 0.4 and 0.7 million years ago. The brain capacity of this intermediate erectine group varied between 800 and 1,200 cm³ (1,000 cm³ on average). Another sinanthropine subspecies is *Homo erectus hexianensis*, which was discovered in Hexian (Anhui, China); it was dated at 250,000 to 300,000 years old, and its brain capacity was 1,025 cm³. Finally, fossils of *H. e. pekinensis*, originally called

Sinanthropus pekinensis, were found at Zhoukoudian (near Beijing, China), associated with stone tools and evidence of the use of fire, and dated between 460,000 and 230,000 years old; their brain capacity was already 900 to 1,250 cm³ (1,100 cm³ on average), and males had an estimated stature of about 1.55 to 1.65 m.

Homo erectus erectus included pithecanthropines that lived on the island of Java (Indonesia) between 0.7 and 1.6 million years ago. Their brain capacity was 800 to 950 cm³ (900 cm³ on average). The most famous of them is Java Man of Trinil (eastern Java), initially called *Pithecanthropus erectus*, who lived between 0.7 and 0.9 million years ago. The oldest members of this group were found in Sangiran (central Java), and initially called *Meganthropus palaeojavanicus* due to their supposed—but unfounded—giant size; they lived between 0.9 and 1.6 million years ago. Many paleoanthropologists considered this specimen an old subspecies of *erectus* (i.e., *Homo erectus palaeojavanicus*), and others even considered it to be a new species.

The last pithecanthropines awakened strong controversy over their real taxonomic position and their relationship with the evolutionary history of modern humans. Generally, they are regarded as a subspecies of *H. erectus* and named as *Homo erectus soloensis*, informally javanthropines. They are an anomalous pithecanthropine due to their age and characteristics. While most subspecies of *Homo erectus* disappeared according to the fossil record roughly 250,000 years ago, they persisted up until 30,000 years ago. Some of them reached a cranial capacity of more than 1,400 cm³, and their culture was unusually advanced. They are the largest of the pithecanthropines, adult males being approximately 1.75 to 1.85 m in height and 70 to 80 kg in weight, and adult females being 1.6 to 1.7 m in height and 55 to 65 kg in weight. These individuals were first considered as a subspecies of *Homo sapiens* and thought to be the ancestors of the modern aboriginal Australians. Today, some paleoanthropologists separate this anomalous group into a new species, *Homo soloensis*, considered as the culmination of the Asian erectine lineage. The first fossil remains come from the Ngandong-Solo River (Java, Indonesia) and were originally nicknamed Solo Man, classified as *Javanthropus soloensis*, and dated at only 50,000 to 25,000 years old. In the same region, other similar and more complete human fossils were found, including individuals with a brain capacity of 1,050 to 1,250 cm³ and dated at 300,000 to 100,000 years (they were classified as the subspecies *Homo erectus ngandongensis*). Populations of similar humans have been found throughout southeastern Asia (China, Vietnam), and even in India, Jordan, and Australia. In China, the most famous fossils of this probable species were found in Dali (Shaanxi, China), known initially as Dali Man and *Homo daliensis*, and in Jinniushan (Liaoning, China). These human fossils were dated between 300,000 and 200,000 years old. Their supraorbital ridge was less robust and this cranium

more rounded than the oldest pithecanthropines, with a brain capacity of 1,100 to 1,250 cm³. They could belong to the oldest group of this species, and could be included as a subspecies: *Homo soloensis daliensis*. Most controversial are the remains of similar “javanthropines” found in Narmada (Hathnora, India), dated from 150,000 to 200,000 years old and with a brain capacity of 1,150 to 1,420 cm³; they have been considered another subspecies of *erectus* (*Homo erectus narmadensis*) but seem to belong to this human group. Most problematic are the relationships of javanthropines with the 50,000- to 60,000-year-old human fossils found in Malakunanja and Nauwalabila (northern Australia). Interesting is the question related to the origin of *Homo soloensis*. Its last specimens seem to have coexisted with *Homo sapiens* in southeastern Asia. Many paleoanthropologists find strong relationships between this group and European *H. heidelbergensis*, and consider that they are in fact *H. heidelbergensis* or another archaic human relative that migrated to Asia, replacing the older *H. erectus*.

A lot more problematic is the last group of humans related to erectine humans: *Homo floresiensis*. It is possibly a new species remarkable for its small body and brain capacity with respect to other humans, and its survival until very recent times. A complete subfossil skeleton of *Homo floresiensis*, nicknamed “Hobbit” for its minute size, was found on the island of Flores (Indonesia) and dated to be only 18,000 years old. Other diminutive individuals, who have been identified and associated with small stone tools, lived between 13,000 and 94,000 years ago. There are suspicions that this small human species may have survived longer in other parts of Flores to become the source of the Ebu Gogo stories, told among the local people, in which small, hairy, language-poor humanoid creatures dwelled in caves on the island (similarly, on the nearby island of Sumatra, there is notice of another small mythological humanoid known as Orang Pendek). They were 1.05 to 1.10 m in height, and probably 25 to 30 kg in weight, considerably shorter than the physically smallest populations of modern humans such as pygmies and negritos (1.35–1.55 m). They also had small brains, with a cranial capacity of 380 cm³, lower than in chimpanzees and in primitive australopithecines. Despite this, their remains are associated with sophisticated stone tools of the Upper Palaeolithic, indicating an advanced behavior. The origin and nature of this human group is a controversial issue today within the scientific community. Some anthropologists have suggested that these individuals were microcephalic modern humans or affected by endemic cretinism. Others have related *H. floresiensis* to primitive gracile australopithecines (as *A. afarensis*), not previously thought to have expanded beyond Africa, that survived up to modern times. However, their cranium and body features resemble those of *H. erectus*, with which they seem to have a phylogenetic relationship. The erectine origin of *H. floresiensis* is the more accepted hypothesis,

despite the size difference. To explain the small size of this species, it has been suggested that populations of *H. erectus* underwent strong insular dwarfism (caused by the limited food environment on their islands), a form of speciation also seen on Flores in several species, including a dwarf *Stegodon* (a group of elephant-type proboscideans). Since Flores remained isolated even in the recent glacial periods characterized by low sea levels, the discoverers of *H. floresiensis* suggest that this species, or its erectine ancestors, could have reached the isolated island of Flores only by water transportation, perhaps arriving on bamboo rafts about 100,000 years ago.

Archaic *Homo* Species

Numerous vaguely defined taxa, most of which are not widely accepted, are included in the group informally known as archaic sapiens humans. Among them are *Homo antecessor* (defined by Bermúdez de Castro, Arsuaga, Carbonell, Rosas, Martínez, and Mosquera in 1997), *Homo heidelbergensis*, *Homo neanderthalensis* (nicknamed Neanderthals), *Homo rhodesiensis*, and *Homo helmei*.

Homo antecessor is an archaic sapiens species that lived in Europe between 0.8 and 1.2 million years ago. It is considered the earliest known human form of Europe, although individuals of *Homo georgicus* from Georgia are older. Its physical traits are intermediate between the oldest *Homo ergaster* and the most modern *Homo heidelbergensis*. The sexual dimorphism of *H. antecessor* was the same as in its European successors *H. heidelbergensis* and *H. neanderthalensis*, but less than in its probable ancestor *H. ergaster* or *H. georgicus*. Adult males were approximately 1.70 to 1.80 m in height and 70 to 90 kg in weight, and adult females were 1.60 to 1.70 m in height and 60 to 70 kg in weight. Hands and feet of *H. antecessor* were similar to those of modern humans, therefore indicating modern locomotor and manipulatory behaviors. Its individuals had a rounded cranium with a protruding occipital bun, a single supraorbital ridge, and a long, vertical face with hollow cheeks (in contrast to the flat face of *H. ergaster* and *H. erectus*). It had less robust mandibles, smaller molars, and premolars that were more molarized than its predecessors. Its teeth had primitive characteristics that resembled *H. ergaster*, but its dental eruption pattern had the same developmental stages as *H. sapiens*. The cranial capacity of *H. antecessor* was 1,000 to 1,150 cm³ (1,050 cm³ on average). Its fossils are associated with a great variety of tools, including hammer-stones and retouched flakes. Certain evidence, such as cuts where flesh had been flensed from the bones, indicates that *H. antecessor* practiced cannibalism.

H. antecessor is very probably the ancestor of *Homo heidelbergensis* in the *Homo neanderthalensis* lineage. Since *H. antecessor* also has intermediate characteristics between *H. ergaster* and *H. sapiens*, it is also considered a

link between both species. Although the only known fossils of *H. antecessor* come from Atapuerca (Spain), some other specimens in Europe and northeastern Africa may also belong to this species. One of these is the fossil human identified in Ceprano (Italy), called *Homo cepranensis*, and nicknamed Ceprano Man. It lived between 0.8 and 0.9 million years ago, and its features seem to be also intermediate between *H. ergaster* and *H. heidelbergensis*. More problematic are the African specimens *Homo mauritanicus* and *Homo uxoris*. Both specimens have been considered to be modern African *Homo erectus* or *Homo ergaster*, the first one dated at 0.7 million years old and the second one at 0.7 to 0.9 million years old. By priority, some claim that the *H. antecessor* name should be changed to *H. mauritanicus*, but the morphological differences, at least in their mandibles (the only part found of *mauritanicus* to date), are too great to consider them to be of the same species.

All of these specimens, in addition to *H. georgicus* and older *Homo erectus*, open the debate on the origin of *H. antecessor*. There are two hypotheses: a northern-African origin and an Asian origin. According to the Asian hypothesis, the Caucasian *H. georgicus* is considered the probable ancestor of both the European *H. antecessor* and the south Asian *H. erectus* (and perhaps even of the African *H. ergaster*). In this case, *H. georgicus* would be the first human to leave Africa, being the link between *H. habilis* and all the later erectine humans (including *antecessor*), requiring that specimens similar to *H. georgicus* be found in Africa. Nevertheless, according to the fossil data known to date, there are great morphological and age differences that prevent establishing a clear phylogenetic relationship between *H. georgicus* and *H. antecessor*. The other hypothesis suggests that *H. antecessor* evolved from the African *H. ergaster*, although it is not known whether this event occurred in Africa (and therefore it is an immigrant to Europe) or in Europe.

Homo heidelbergensis is considered a descendant of *H. antecessor* and the direct ancestor of *Homo neanderthalensis*. It lived in Europe between 0.7 and 0.15 million years ago. They were very tall and corpulent, and had a sexual dimorphism similar to modern humans, with adult males being approximately 1.75 to 1.85 m in height and 70 to 90 kg in weight, and adult females 1.65 to 1.75 m in height and 55 to 70 kg in weight. The physical characteristics of its body (pelvis and limbs) were similar to *Homo neanderthalensis*. Their skulls were elongated, with a depressed, wide nasal bridge and a prominent supraorbital ridge. They showed significant sexual dimorphism in their teeth and jaws, but in general they had wider molars and thicker incisors than did *H. neanderthalensis*.

The cranial capacity of *H. heidelbergensis* was 1,100 to 1,450 cm³ (1,275 cm³ on average), overlapping the average of modern humans. They used core techniques to make tools, which were very varied. Their stone-tool technology is very close to the Acheulean industry used by *H. erectus*, although more advanced (including the possible use of red

ochre as paint). Some accumulation of individuals at specific postmortem sites could indicate ritual burial, but there is not enough evidence. It is possible that *H. heidelbergensis*, like its descendant *H. neanderthalensis*, acquired a primitive form of language. Since there were similar archaic sapiens humans living in Africa, such as *Homo rhodesiensis*, there is a controversy over whether or not the *H. sapiens* lineage evolved from an African *H. heidelbergensis*, or this species is exclusively European descending from *H. antecessor* and being the ancestor of only *H. neanderthalensis*.

Homo neanderthalensis, nicknamed Neanderthals, lived between 25,000 and 150,000 years ago almost exclusively in Europe, but also in parts of western and central Asia, including the Near East and the Siberian Altay mountains. They have been considered for a long time to be a subspecies of *H. sapiens*, but genetic evidence has shown that these are two different species, although they share 99.5% of their DNA. It has been calculated that both species shared a common ancestor about 500,000 years ago, and this ancestor could have been *H. heidelbergensis*. Nevertheless, other more recent studies indicate that the common ancestor lived about 800,000 years ago, suggesting that *H. antecessor* (and not *H. heidelbergensis*) was the true ancestor of both human lineages. This conclusion is more harmonious with the paleontological evidence and morphological divergence found in the fossil record. The postcranial skeleton of the Neanderthals was heavier and stronger than that of modern humans, with a more robust bone structure, although it was generally shorter. Adult males were approximately 1.6 to 1.7 m in height and 70 to 80 kg in weight, and adult females 1.5 to 1.6 m in height and 50 to 60 kg in weight. Their skulls were low, flat, and elongated, with an occipital bun, a projecting midface, and a thick supraorbital ridge.

The cranial capacity of *H. neanderthalensis* was 1,200 to 1,750 cm³ (1,420 cm³ on average). The assertion that Neanderthals had a brain capacity much larger than modern humans has persisted a long time among paleoanthropologists, but it is probably an effect of the statistical deviation in the analysis of the fossil record of Neanderthals. Similar studies in fossil *Homo sapiens* specimens (e.g., *Homo sapiens idaltu*) concluded that they had a 1,490 cm³ cranial capacity. Nevertheless, their intelligence might have been very advanced. They used more advanced tools than *H. heidelbergensis* and *H. erectus*, having created a predominantly flint industry known as the Mousterian of the Middle and part of the Old Palaeolithic. They made sophisticated stone flakes, hand axes, and spears. According to the reconstructions of their vocal tract (with the presence of a hyoid bone), and neurological (with hypoglossal canal size similar to modern humans) and genetic evidence (with the presence of the same version of the FOXP2 gene as in modern humans, which plays a role in human language), it is considered that the Neanderthals had an elaborate protolanguage that was more musical than the language of

modern humans. Moreover, they were almost exclusively carnivorous, being considered the apex predator (hunting large animals, such as the mammoths) for making good use of their stone flakes. They intentionally buried their dead in graves with goods, used pigment ochre, and practiced ritual cannibalism or defleshing. All these ritual treatments of the dead probably denote the development of a religious ideology.

It is widely accepted that *H. neanderthalensis* evolved from *H. heidelbergensis* in Europe and then became extinct, to be replaced or absorbed by modern humans traveling from Africa. Their last populations lived in southern Iberia, around the coast of Gibraltar, 24,000 years ago. Neanderthals and modern humans coexisted in Europe for millennia, surely intermixing their cultures, but very probably the species never genetically interbred, which has been proposed, since they were not interfertile, as they were separate species. Their last populations adopted the more advanced Châtelperronian culture (Upper Palaeolithic), a culture considered to have belonged first to our species *Homo sapiens*, which later passed this culture on to the Neanderthals.

Homo rhodesiensis, nicknamed Rhodesian Man and sometimes classified as *Homo sapiens arcaicus*, is a possible direct ancestor of *Homo sapiens* that lived in Africa between 125,000 and 450,000 years ago (and probably even longer ago). Their fossil remains show some primitive traits shared with *H. ergaster* and *H. antecessor*, and other traits that allow us to link them to *H. heidelbergensis*, but they also had other traits that relate them to *H. sapiens*. Adult males were approximately 1.60 to 1.70 m in height and 60 to 70 kg in weight, and adult females 1.50 to 1.60 m in height and 50 to 60 kg in weight. They had an elongated skull with a large supraorbital ridge, and high and narrow cheekbones. Their cranial capacity was 1,250 to 1,350 cm³ (1,310 cm³ on average).

H. rhodesiensis belonged to the Acheulean industry of stone tools (Lower Palaeolithic), but perhaps its first appearance is related to the beginning of the second phase of the Acheulean 600,000 years ago, in which the tools became thinner, more symmetric, and more trimmed than in older groups (ascribed to *H. ergaster* or to African *H. antecessor*). Most current paleoanthropologists believe this archaic human group to be within the variability of *H. heidelbergensis*. Nevertheless, others consider that there are three archaic human lineages: the African *H. ergaster*–*H. antecessor*–*H. rhodesiensis*–*H. sapiens* lineage, the European *H. antecessor*–*H. heidelbergensis*–*H. neanderthalensis* lineage, and the Asian *H. ergaster*–*H. erectus*–*H. soloensis* lineage. No direct linkage of these species can so far be determined.

Some paleoanthropologists have suggested that, within the African record, there is room for another intermediate species within the *H. sapiens* lineage: *Homo helmei*, also known as *Africanthropus helmei* or Florisbad Man.

Another name given to this group has been *Homo njarasensis*. It is anatomically intermediate between *H. rhodesiensis* (or *H. heidelbergensis*) and *H. sapiens*, and is considered as the direct ancestor of the first subspecies of human moderns, *Homo sapiens idaltu*, and therefore the origin of our species. This group is considered sometimes like the African version of *H. neanderthalensis*. It lived between 130,000 and 300,000 years ago. The cranial capacity of *H. helmei* was already 1,250 to 1,550 cm³ (1,390 cm³ on average), and its supraorbital ridge was very reduced. Its stone tools belonged to the Levalloisian, Mousterian, and Aterian cultures of the Middle Palaeolithic of Africa (which include microliths, as well as bone tools and carvings). Most paleoanthropologists do not consider this species as valid, but its possible validity is based primarily on the emergence of the Mode 3 technology (Mousterian and Aterian), which could be associated with a speciation event within the human lineage.

Fossil Evidence: Origin and Evolution of *Homo sapiens*

It is broadly accepted that modern *Homo sapiens* has only one extant subspecies (*Homo sapiens sapiens*) and only one fossil subspecies (*Homo sapiens idaltu*). The earliest *H. sapiens* fossils were found in the Omo River and at Herto (Ethiopia), respectively dated at 160,000 and 195,000 years old, and they are assigned to the subspecies *H. s. idaltu*. They lived in central East Africa (Ethiopia, Eritrea) between 125,000 and 195,000 years ago. They had a brain capacity of 1,450 cm³, and their supraorbital ridge is still slightly prominent. They are considered anatomically and chronologically intermediate between archaic humans (*Homo helmei*) and more recent, fully modern humans (*Homo sapiens sapiens*).

Modern *H. s. sapiens* is first present in the fossil record at the Kibish Formation and Mumba (Tanzania), dated from 130,000 years ago, and at Border Cave and Klasies River Mouth (South Africa), dated from 110,000 to 120,000 years ago. These are only slightly earlier than early *H. sapiens* at Skhul and Qafzeh (Israel). The Skhul human fossils were dated from 80,000 to 120,000 years ago, and those of Qafzeh from 92,000 to 115,000 years ago. These early humans may have been descendants of the first migrants to leave Africa. They have become classified as a new subspecies, *Homo sapiens palestinus*, although this taxon is not widely accepted. Nevertheless, these humans seem to have become extinct or retreated back to Africa 80,000 years ago, possibly to be replaced by Neanderthals escaping the colder regions of Ice Age Europe.

All other modern human fossils found outside of Africa are of more recent times. The oldest fossils of modern humans outside of Africa are those of Mungo (Australia), nicknamed as Mungo Man. They have been dated at 42,000 years old. In Asia, 40,000-year-old fossils of

H. s. sapiens have been found in Ordos (Mongolia), and others 32,000 years old in Naha-Okinawa (Japan) and 27,000 years old in the Zhoukoudian upper cave (China). Finally, the oldest modern humans found in Europe come from Pesteră cu Oase (Romania), Compe Capelle (France), Mladeč and Predmostí (Czech Republic), and Cro-Magnon (France)—all between 23,000 and 36,000 years old (they and the rest of early-European modern humans are nicknamed Cro-Magnons or cromagnons).

DNA analysis indicates that modern humans originated in Africa about 180,000 or 200,000 years ago. According to the recent African origin (RAO) and out-of-Africa theory, *H. s. sapiens* developed 180,000 years ago, possibly in East Africa, being the capoids or the khoisan form (formerly classified as *H. s. khoisanii*), the oldest representative of our subspecies. This first lineage is the mtDNA haplogroup L0, and it has been nicknamed the “mitochondrial Eve.” Khoisan mitochondrial divergence has been dated no later than 110,000 years ago.

Three main lineages of modern humans diverged between 80,000 and 120,000 years ago. The first lineage (mtDNA haplogroup L1 and Y-DNA haplogroup A) colonized southern Africa (ancestors of bambutoids as pygmies, formerly classified as *H. s. pygmaeus*). The first lineage to branch from haplogroup A has been nicknamed the “Y-chromosome Adam.” Those early human fossils found at Border Cave and Klasies River Mouth (South Africa) perhaps belong to this old lineage. The second lineage (mtDNA haplogroup L2 and Y-DNA haplogroup B) appeared 80,000 years ago and settled in central and western Africa (ancestors of negroids as paleocongrids, nilotids and bantids, formerly classified as *H. s. afer*). Finally, a third lineage (mtDNA haplogroup L3) remained in eastern Africa (perhaps ancestors of aethiopids, formerly classified as *H. s. aethiopicus*).

This last lineage (L3) was significant because it was the first *H. s. sapiens* to have left Africa, crossing the Red Sea 70,000 years ago. Previously, other early modern humans had ventured out of Africa briefly, as indicated by 90,000-year-old human fossils found in Israel (*H. s. palestinus*), but they became extinct. These people probably were more related to the first lineage (L1) than to the second (L2) and third (L3) African lineages.

It is known that humans are genetically highly homogeneous, which may have resulted from the Toba catastrophe 70,000 to 80,000 years ago. A supervolcanic event at Lake Toba (Sumatra) could have reduced the world human population to 10,000 individuals or even less, extinguished *H. s. idaltu* in Israel, and created a bottleneck in the human evolution of *H. s. sapiens*. According to this hypothesis, humans left Africa for the first time after the Toba supervolcanic event, migrating to Arabia and the Middle East. From that time, human survivors began to have a fully modern behavior, including the ritual of burying the dead.

The mitochondrial L3 lineage crossed the Red Sea in two waves: the first wave occurring 70,000 to 80,000 years

ago across the narrow span of water between the Horn of Africa and the Arabian Peninsula, and the second wave occurring 60,000 to 70,000 years ago, crossing the Red Sea more toward the north and settling in the Near and the Middle East. The first ones formed an old Arabian group (mtDNA haplogroup M and Y-DNA haplogroup M130) 60,000 years ago, which headed along the southeast coast of Asia (India, Sri Lanka, Indonesia, Filipinas, Malasia, and Polynesia) reaching Australia 50,000 to 55,000 years ago. The haplogroup M is nicknamed the Coastal Clan and is considered an ancestral east Eurasian lineage that derived from the australoid people, such as the australians-tasmanians, melanesians, veddooids, and negritos (those formerly classified as *H. s. australasicus*). The 42,000-year-old Mungo Man (Australia) is the oldest fossil probably belonging to this migrant lineage. They surely supplanted and replaced the last erectine humans (*Homo soloensis*) from southeastern Asia and Australia.

The second group derived from those first African emigrants (L3) went north and radiated in the Near and the Middle East, appearing as the mtDNA haplogroups N and R, and Y-DNA haplogroup M89. Descendants of these two groups moved out and explored the surrounding areas (Turkey, Caucasus, and central Asia), initiating a second great migration out of Africa and eventually colonizing the whole world. Because almost all of the mitochondrial lineages found in Europe and Asia descend from N and R groups, these people are considered the Eurasian Clan.

Europe was colonized 45,000 years ago by migrants from central Asia, the Near East, and the Middle East, slowly displacing the Neanderthals. They were people who emerged from the Near and the Middle East (mtDNA haplogroups N and R), and that bore mtDNA haplogroups J, T, and meaningfully pre-VH. Most people moved north across the Caucasus, bringing their lineages into Europe during the middle Upper Palaeolithic. These lineages were represented in Europe for the first time by the Cro-Magnons, heralding the end of the era of the Neanderthals in Europe. Descendants of early Europeans began to split off and form their own groups, represented by the mtDNA haplogroup HV (derived from pre-VH). Around 15,000 to 20,000 years ago, colder temperatures made living conditions nearly impossible for much of the Northern Hemisphere. Early Europeans retreated to the warmer climates of Iberia, Italy, and the Balkans. Their population sizes were drastically reduced, and much of the genetic diversity that had previously existed in Europe was lost. After the ice sheets began their retreat 15,000 years ago, this people moved north again and recolonized Europe. Some of these lineages (mtDNA haplogroups V and H, derived from HV 15,000 to 30,000 years ago) expanded toward Western Europe, others (mtDNA haplogroups K and U, derived from R 50,000 years ago) towards northern Europe, and finally others (mtDNA haplogroups I and W, derived from N 30,000 years ago) toward Eastern Europe.

Other groups derived from R, the mtDNA haplogroup U6, moved to northern Africa. After the last glacial maximum, expansions led people across the Strait of Gibraltar, allowing for some gene flow between North Africa and southwestern Europe.

Radiating out from central Asia and the Middle East, the mtDNA haplogroups B and F and Y-DNA haplogroups M89 and M9 (appearing 40,000 to 60,000 years ago) conquered the Far East (south and east Asia) 40,000 years ago. They formed the different southwestern Asian mongoloid groups that, together with Siberian groups, were formerly classified *H. s. asiaticus*. Fossils found in Ordos (Mongolia) that are 40,000 years old, and in the Zhoukoudian upper cave (China) that are 27,000 years old, are evidence of this new wave of human migrants toward southwestern Asia, replacing and/or mixing with the australoid M haplogroup in the south Asian coastlands. Descendants of early southern and eastern Asians began to split off and form their own groups, reaching the Philippines and Indonesia, and finally Melanesia, Polynesia, and Micronesia in more recent times.

Radiating out from the central Asian homeland and derived from N, R, and/or M 50,000 to 60,000 years ago, the mtDNA haplogroups Z, A, B, X, C, and D colonized Siberia approximately 30,000 years ago. They formed the group known as the Siberian Clan. Some of these lineages (A and B) also reached Korea, Japan, and southeastern Asia during this epoch. Human fossils 32,000 years old found in Naha-Okinawa (Japan), and nicknamed Yamashita-Cho Man, belong to this lineage. The haplogroup Z migration heading west, out of Siberia, came to an abrupt end around the Ural mountains and Volga River (Russia). Finally, several other Siberian lineages colonized America for the first time.

America was occupied by Asian people bearing mtDNA haplogroups A, B, D, and X, and the Y-DNA haplogroups M130 and M217; they crossed the Bering Strait from Siberia into Alaska during the last glacial maximum, when a land bridge, called Beringia, united the continents of Asia and America. Most parts of these haplogroups arrived from Siberia, except for the M217 group, which arose from east Asia. These groups were the ancestors of all Amerindians (sometimes classified as *H. s. americanus*). The reduced genetic diversity found in America indicates that these lineages arrived only 15,000 to 20,000 years ago. In fact, only the Y-DNA haplogroup M3 (derived from Siberian M242) is entirely American. Since a branch of haplogroup X found in Amerindians (such as Sioux and Navajo) is almost entirely absent from Siberia, an alternative hypothesis of the migration route toward America has been suggested: the Solutrean hypothesis, asserting that stone-tool technology of the Solutrean culture in prehistoric Europe (France, Spain) may have influenced the development of the toolmaking culture of the Clovis Paleo-Indians in America. This hypothesis suggests that peoples from

Europe may have been among the earliest settlers in the Americas about 13,500 years ago.

Future Directions

Homo sapiens sapiens began its existence between 180,000 and 200,000 years ago, but its lineage began to evolve more than 4 million years ago. After hundreds of thousands of generations, the hominids have trended toward being less physically skulled but showing a disproportionate encephalization. According to this trend, future humans could have larger heads and shorter legs and arms, retaining each time more and more traits previously seen only in juveniles (neoteny). Surely our future adults will resemble the morphology of our present babies. Nevertheless, future human evolution may not be governed by the same principles that govern the evolution of other animals, since humans differ from other species by their advanced social organization and language, as well as the use of advanced technology, controlled energy, and clothes. Many paleoanthropologists claim that the human brain has not changed for 150,000 years. On the contrary, genetic research shows that certain genes, related to brain size, did change between 6,000 and 35,000 years ago, suggesting that humans are still evolving.

A species gradually evolves through natural selection into a new species, but this usually occurs in small, geographically isolated populations. This type of evolution is very slow for a large and widespread species such as humans. Therefore, this type of evolution is not very probable for humans, since the tendency for genetic intermingling among humans is very large, and the mixing will increase in the future.

Today, there is no existing species that might compete or threaten the human species, as the Neanderthals were out-competed by *H. sapiens*. However, a species could arise that would be a rival of our own species: an explicit, new species, artificially created through genetic manipulation of ourselves or another species, or based on computers and cybernetics (artificial intelligence).

We have a high adaptability to changing environments and, excepting for a cosmic catastrophe, we will probably survive through the future climatic turnovers. Nevertheless, humans are capable of modifying their environment, so there is a risk that humans themselves will modify their environment in such a way that they cannot survive in it any longer. If earth would suffer a global disaster in the future, whether due to our fault or by other causes, humans could try to find a way out: the colonization of space. Today, it is a theme mainly of science fiction, but there are already several space programs that have, as their objectives, autonomous self-sufficient human habitation and the establishment of space colonies on the moon or on Mars. Space-colonization technology could, in theory, allow human expansion at a high, but subrelativistic, speed

toward interstellar colonization, permitting self-contained habitats with life spans from decades to centuries. If the isolation of this type of interstellar colony were prolonged long enough in time, then the birth of a new human species could become possible through the basic principles of evolution (natural selection, adaptation, genetic drift, etc.)—but in an extraterrestrial environment.

HUMAN BRAIN

CRIS CAMPBELL

University of Colorado at Boulder

Whereas claims of human uniqueness used to revolve around the soul, they now revolve around the brain. Ever since Thomas Willis and his Oxford circle colleagues discovered in the late 1600s that the brain governs behavior, scientists have devoted considerable attention to this complex and inscrutable organ. Until recently, most approaches to the brain have been introspective and deductive. Philosophers and scientists traditionally have attempted to explain the brain's workings by examining its current functioning. They study, in other words, modern minds. While this top-down approach has yielded many insights, the limitations are obvious. To understand the human brain, a historical or evolutionary approach is necessary. It is only by locating the brain in deep time and tracing its evolutionary development that we may hope to arrive at a more complete understanding of that which makes us uniquely human.

Background

Humans have large brains, in both absolute and relative terms. Presumably, it is this fact that prompted the normally restrained Charles Darwin to declare, in *The Descent of Man* (1871), that no one could possibly doubt the connection between large brains and higher mental powers. Whether Darwin was expressing a scientific truth or a cultural prejudice remains an open question. For reasons

poorly understood and rarely questioned, humans are enamored of size—if something is big, it is usually deemed remarkable and important. In many instances, this habit of mind serves us well. Size often signals something important about function. In other instances, the privileging of size is misleading. This has been especially true of the human brain.

In the century after Darwin, it became commonly accepted that fish gave rise to amphibians, amphibians to reptiles, reptiles to mammals, and mammals to man. Implicit within this overly neat phylogenetic ordering was the idea that brain size increased with each phase change, and that each progression involved the addition of brain tissue. Indeed, it was this idea that inspired Paul MacLean's "triune brain" model, which divides the brain into three parts (archipallium, limbic system, and neocortex) according to the sequence of their evolutionary appearance. Within the primate order, the story was much the same. As told by W. E. Le Gros Clark, primate evolution was largely a matter of progressive trends, one of which was expansion and elaboration of the brain. According to this traditional view, the most primitive primates (*prosimians*) had the smallest and simplest brains, more advanced primates (*simians*) had larger and more complex brains, and the most advanced primates (*great apes*) had even larger and more complex brains. Humans occupied the top rung of this primate *scala naturae*, and their brains were the biggest and most complex.

Against this backdrop, it should come as no surprise that those studying human evolution simply assumed, as Darwin himself seems to have done, that the transition from monkey to ape to human was largely a matter of growing bigger brains. Like most Victorians of his age, Darwin believed in progress, and his theory of natural selection reflected this belief. Firmly embedded within this progressivist paradigm, early anthropologists devoted themselves almost exclusively to the study of the brain, and more particularly crania. Paul Broca, who founded the Anthropological Society of Paris in 1859, contended that the new science of *craniology* was of such importance that anthropologists should focus exclusively on skulls. Speaking for many scientists of the day, Broca asserted that larger brains translated into greater intelligence. Given the prejudices of the time, this naturally meant that men had larger brains than women and Europeans had larger brains than Africans. In *The Mismeasure of Man* (1981), Stephen Jay Gould examined the evidence supporting these ideas and demonstrated that the data, if not simply made up or erroneous, supported none of these conclusions.

Obsessions over brain size have long vexed evolutionary thinking in general and anthropological studies in particular. In 1912, the discovery of fossils that came to be known as Piltdown Man seemed to confirm the idea that human evolution was largely a matter of growing bigger brains. Although there were good reasons to doubt the validity of the find, Piltdown's large braincase fulfilled the a priori expectation that encephalization was the key to human evolution. Piltdown's large brain cemented its status as a human ancestor. It took another 40 years before Piltdown was exposed as a hoax. During the interim, scientific acceptance of an actual fossil in the hominid lineage—*Australopithecus africanus*, discovered by Raymond Dart in 1924—was long delayed because it did not possess a large enough brain.

Given this history, one might think, incorrectly, that anthropology has freed itself from its early focus on big brains. One of the ongoing debates in paleoanthropology revolves around the parameters of the genus *Homo*. Sir Arthur Keith, whose distinguished career ultimately was tarnished because he championed the big-brained Piltdown as a human ancestor, maintained that *Homo* should be defined by cranial capacity. For Keith and others this *cerebral rubicon* was 750 cubic centimeters. Any bipedal hominid below this threshold was not *Homo* and anything above it was *Homo*. Not everyone agreed with this definition, which became apparent in the 1960s when the Leakeys discovered a fossil cranium below the 750 cc threshold and named it *Homo habilis*. Nearly 50 years later, anthropologists are still debating the boundaries of our genus, with cranial capacities playing a prominent, albeit slightly reduced, role in those debates.

These controversies have not, in the end, done much to advance our understanding of the human brain. Part of the problem has been the narrow focus of these studies, which

tend to orient themselves around fossil hominid skulls on the one hand and fully modern brains on the other. While this approach has merit, it is important to recognize that hominid brains have a much deeper evolutionary history. Any thorough understanding of the human brain requires some basic knowledge of primate brain evolution.

Primate Brain Evolution

The earliest fossil primates (adapids and omomyids) are approximately 55 million years old. Among a host of other diagnostic features for fossil primates, several significant ones involve cranial modifications that implicate the brain. In general terms, these derived characteristics include (1) brain enlargement, (2) enhanced vision, and (3) reduced olfaction. Because the insectivorous mammal that gave rise to primates remains unknown, it is difficult to determine whether brain enlargement is a valid descriptor of stem primates. The weight of evidence suggests that early primate brains were not enlarged and were comparable in size to primate sister taxa (*Scandentia*, *Dermoptera*, *Chiroptera*, *Insectivora*) at the base of the Archontan radiation. Although the earliest primate brains were not particularly encephalized, they were different. In basal primates, the extreme forward rotation of the eye sockets indicates an increased reliance on vision and decreased reliance on olfaction. Extreme orbital convergence suggests selection pressure for stereoscopic and binocular vision. A side effect of this convergence is that it constricts the space available for olfactory organs and their connections to the brain. Because early primates occupied arboreal habitats, the factors favoring enhanced vision may have included the need to locate branches for leaping-grasping locomotion, and the ability to prey on insects moving through the canopy.

Whatever the ultimate cause, there is no doubt that primate brains are visually specialized. Compared with those of other orders, a disproportionately large area of the primate brain is dedicated to visual processing. During the more recent course of primate evolution, the neocortex has expanded disproportionately. Because visual areas comprise approximately 50% of the primate neocortex, a great deal of this expansion is due to increased visual acuity. Primates have two distinct visual pathways in the brain: One (the magnocellular system) analyzes movement and form, while the other (the parvocellular system) processes detail and color. Visual area enhancement in early primates selectively altered the magnocellular system for detecting form and movement, whereas in later primates—including early anthropoids—the parvocellular system for discerning detail and color appears to have been selectively targeted. Because stem and early primates presumably were nocturnal and insectivorous, the enhanced development of the parvocellular system in later primates is often associated with an adaptive shift toward diurnality and frugivory. This shift, in turn, appears to have directly impacted the social behaviors for which primates are especially noted.

It is one thing for a small primate to hunt surreptitiously for insects at night and quite another to forage openly for fruit during the day. The former can be done in relative isolation and small groups, whereas the latter is best accomplished in the company of others and large groups. Social groups have several advantages, not the least of which is predator detection and defense. Complex social behavior requires considerable visual acuity—group members must be able to recognize one another, assess nonvocal behaviors, and respond accordingly. Group members must be able to process emotional and other states communicated through facial and gestural displays. It is not surprising, therefore, that there is a significant correlation between primate social-group size and neocortex size. There is a similar correlation between neocortex size and feeding ecology—frugivorous primates usually have larger neocortices than folivorous primates. This ecological correlation is typically explained in terms of mental mapping. Frugivory requires larger range size, with resources being patchy and temporal. The mental maps necessary to track these resources seem to require larger brains, larger groups, or both.

As is apparent, vision, sociality, and ecology interact in complex ways to alter the brains and behaviors of primates. This has been true throughout the course of primate evolution. Because none of these factors is uniform in space or time, primates have responded to these pressures differentially and variably. The resulting encephalization and reorganization has not, therefore, been uniform during the course of primate evolution. Encephalization and reorganization have occurred sporadically and independently within different lineages. Primate evolution has not simply been one long course of selection for bigger brains and increased intelligence.

Under the old classification scheme, the idea was that prosimians led to simians and simians to apes. With each supposed transition, there was a grade shift involving brains and behavior. Cladistic analyses have shown that this progressive phylogeny is no longer tenable. While it may be true that Strepsirrhines (lemurs, lorises, galagos) have smaller and less specialized brains than most Anthropoidea (a clade of primates including Platyrrhini and Catarrhini), this observation says nothing about supposed trends in primate brain evolution. Anthropoids did not evolve from Strepsirrhines; they are separate lineages, each with its own unique evolutionary history. Among anthropoids, Platyrrhines (New World monkeys) and Catarrhines (Old World monkeys and apes, including humans) display highly divergent patterns of encephalization and reorganization. Anthropoid brain evolution is, therefore, mosaic. There are no consistent directional trends, a fact made apparent by measures of encephalization for living anthropoids.

Brain Sizes and Encephalization Quotients

It has long been understood that absolute brain size, standing alone, says little about behavioral complexity. As body

size increases, so does brain size. This is due in large part to the principle of proper mass, which holds that a certain amount of neural tissue is required to perform a particular function. Because larger animals have more intrinsic functions than smaller animals, they require larger brains to coordinate their autonomic, sensory, and motor activities. Whales, for example, have brains weighing thousands of grams. Their absolutely massive brains, however, do not make them more intelligent than primates, whose brains typically weigh hundreds of grams. Expressing brain weight as a percentage of body weight simply reverses the size problem. Using this ratio, small animals such as mice appear to be relatively more encephalized than whales and primates.

In an effort to correct these problems and identify some measure of brain-body size that correlates with behavioral complexity, Harry Jerison (1973) proposed the use of encephalization quotients, or EQ. The idea is straightforward—EQ is the ratio of an animal's actual brain size to the brain size expected for an animal of its body size. On its face, EQ provides some measure of quantifiable objectivity. Despite this fact, EQs are neither straightforward measures of behavioral complexity nor definitive markers of intelligence. Embedded within EQ measurements are several assumptions, the most important of which is that there is a universally applicable, nonlinear scaling relationship between brains and body size. Researchers cannot, however, agree on the exponent that should be used to calculate EQ. Estimates vary widely from .20 to .75. Given this disagreement, the notion that an EQ value of 1.0 expresses a biological norm, or brain-size expectation given a certain body weight, is open to question. Consequently, EQ measurements and comparisons should be interpreted with caution. They simply serve as a useful first step in considering primate brain evolution and development. With these caveats in mind, Table 3.1 contains EQs for several species of extant anthropoid primates.

As is apparent, extant anthropoids are more encephalized than expected for mammals of similar body size. Despite this fact, EQ variation among anthropoids is great. *Alouatta* (howler monkeys) occupies the low end at 1.24 and *Homo* the high end at 7.18. Of particular interest is the fact that hominoid apes are not generally more encephalized than New or Old World monkeys. After humans, the primate with the highest EQ is not our closest relative the chimpanzee (*Pan*), but is instead the capuchin monkey (*Cebus*). Gorillas, for their part, are at the low end of EQs for anthropoids. Considered together, the EQ data should dispel the progressivist notion that apes are more evolutionarily advanced than monkeys. Judged by measures of EQ alone, this clearly is not the case.

When considering EQs, it is important to understand there is no such thing as a typical "primate brain." Although all living primates share a common ancestor dating back to the Eocene, today there are nearly 300 extant primate species, each one of which has a unique evolutionary history. For each species, this history involves structural reorganization of the brain, along with changes

Table 3.1 Mean EQ for Selected Anthropoid Primates (Platryhines or New World Monkeys, Cercopithecidae or Old World Monkeys, and Hominoidea or Apes)

Taxon	Mean Eq
<i>Alouatta</i>	1.24
<i>Aotus</i>	1.60
<i>Ateles</i>	2.39
<i>Brachyteles</i>	2.05
<i>Calicebus</i>	1.66
<i>Cebus</i>	3.25

in cell types, metabolic chemistry, vascular patterning, and neural connectivity. While some of these changes are the straightforward consequence of allometric enlargement, the majority cannot be so explained. The lack of any consistent pattern and the differences among species suggest that primate brains have undergone mosaic evolution, and there has been differential selection for particular kinds of behaviors. While primate brains may be similar in terms of gross morphology, this does not mean that chimpanzee brains are more sophisticated versions of macaque brains, or that human brains are simply scaled-up versions of

chimpanzee brains. Each species has something unique about its brain. Given the many differences in primate ecologies and behaviors, this is not surprising.

Despite species-specific differences, there are some features of primate brains that appear to be unique to the order. Primates may be the only mammals that possess mirror neurons. These visuomotor neurons were first observed in macaques and are unique because they fire not only when an individual performs an intentional task (such as reaching for and grasping an object), but also when an individual observes another performing precisely the same task. Mirror neurons, in other words, appear to fire empathetically during the observance of purposeful acts performed by others. For this reason, mirror neurons have been linked to a range of primate specializations, including imitation, intentionality, agency, empathy, learning, and language. Taken together, these skills play a major role in social cognition. Significantly, mirror neurons also appear to play a major role in tool use. Although primates are not the only animals that have complex social systems and that use tools, the quality and complexity of primate behavior in these arenas differs from that of most other taxa. Another specialized neuron is found only among hominoid (i.e., great apes) species. Alone among primates, hominoids possess projection neurons known as spindle cells, found in the anterior cingulate cortex, an area associated with precision gripping and the regulation of cognitive-emotional processes. The remarkable fact that these cells exist only in our closest relatives (chimpanzees, gorillas, orangutans), in quantities that decrease as the phylogenetic distance from humans increases, suggests strong selection pressure for these specialized cells in our lineage.

Hominid Brain Evolution

Although progressive encephalization does not characterize primate brain evolution generally, it does characterize hominid brain evolution specifically. From *Australopithecus* to *Homo*, absolute brain size nearly tripled from an average of 450 cc to 1,250 cc. Some, but not all, of this expansion can be attributed to selection for increased body size. Correcting for body size and calculating EQ for hominids is not always easy, given that accurate estimates of body mass depend on postcranial remains. Because relatively few fossil crania are found with articulated or reliably associated postcranial remains, direct measures of body size are not often available. In their absence, researchers rely on various cranial proxies to estimate body mass. With these caveats in mind, Table 3.2 provides EQ values for selected hominids.

Because australopithecines had slightly larger brains and EQ values than living chimpanzees, modest encephalization is an appropriate marker (along with bipedalism) for the earliest hominids. As is evident from Table 3.2, absolute and relative brain sizes increased over time. Paleoanthropologists cannot, however, agree on the tempo and mode of hominid brain evolution. Some see steadily

Table 3.2 Mean Endocranial Volumes and EQs

Taxa	Mean (ma)	Mean Volume (cc)	EQ
<i>A. afarensis</i>	3.11	446	4.87
<i>A. africanus</i>	2.66	462	5.21
<i>H. habilis</i>	1.76	610	7.06
<i>H. rudolfensis</i>	1.87	789	7.35
<i>H. ergaster</i>	1.74	801	6.25
<i>H. erectus</i>	0.81	941	7.32
<i>H. heidelbergensis</i>	0.27	1,266	8.64
<i>H. sapiens</i>	0.01	1,330	9.63

increasing cranial capacities and support a gradualist model. Others support a punctuated model and see an increase in cranial capacity with the appearance of early *Homo*, a long period of relative stasis, and another increase with the appearance of *Homo sapiens*. Regardless of which model is correct, two things should be kept in mind. First, our knowledge of within-species variation is lacking. Among modern humans, normal (i.e., nonpathological) brain sizes vary by as much as 1,000 cc (from 750 cc to 1,750 cc), without any apparent relationship to functioning or intelligence. Second, our sample sizes are small. For

hominids, there are approximately 200 crania from which brain sizes can be reliably estimated. Of these, only 74 represent the human ancestral lineage if one assumes a phylogeny of *A. afarensis*, *A. africanus*, *H. habilis*, *H. rudolfensis*, *H. ergaster*, and *H. erectus* (Africa only) leading to *Homo sapiens*. Table 3.3 plots these 74 cranial capacity measurements without any adjustments for body weight.

Regardless of how one chooses to characterize this scatter, the pattern of encephalization is clear, even after adjusting for body-size increases. Brain enlargement has several consequences, not the least of which is that it dramatically alters patterns of neural connectivity and developmental trajectory. Size, however, is not the only factor that can cause organizational change. The study of endocasts (molds of cranial interiors which reveal brain size and external morphology) shows that the hominid brain underwent significant reorganization over the last 3.5 million years. Although hominid brains are similar to most primate brains in terms of basic design (i.e., they are structurally homologous), the relative sizes of various structures have differentially enlarged or reduced over time. Among hominids, lateralization is an example of such change. Hemispheric lateralization is often associated with specialization of cerebral and motor function. Australopithecine brains show a hemispheric asymmetry that becomes more pronounced as one gets closer to *Homo*. A similar pattern characterizes the enlargement of Broca's and Wernicke's areas in hominid brains, both of which are associated with language. Another distinctive feature of hominid brains, vis-à-vis ape brains, is the relative reduction of the primary visual striate cortex and corresponding enlargement of the parietal lobe association cortex.

Table 3.3 Absolute Brain Size: *Homo* Ancestral Lineage

SOURCE: Data from Holloway, R., Broadfield, D., & Yuan, M. (2004). *The Human Fossil Record: Vol 3. Brain Endocasts: The Paleoneurological Evidence* (pp. 297–300). (J. Schwartz & I. Tattersall, Eds.). New York: Wiley-Liss.

Considered together, these and other distinctive changes to hominid brains indicate two things. First, hominid brains in general and human brains in particular are not simply scaled-up versions of ape or chimpanzee brains. Second, differential enlargement and reduction of brain structures indicate a mosaic pattern to hominid brain evolution. This is an important point, given that natural selection does not see brain structures. Selection can only see behaviors that are mediated by brain structures. If those behaviors enhance fitness, then selection will favor those individuals whose brains are organized in a way that facilitates such behavior. Given the substantial changes in brain size and organization that occurred during the course of hominid evolution, identifying these behaviors—and associated selection pressures—has been the focus of much research.

Hominid Brain Evolution: Selection Hypotheses

It has long been fashionable to suppose that once hominid encephalization began, brain size steadily increased due to selection for “intelligence.” There are at least three problems with this idea. First, intelligence is inchoate and relative. As a scientific term, it lacks rigor and specificity. It cannot be directly measured. Many animals are intelligent, in the sense that their brains fully enable them to cope with the demands of their particular environments. Invariably, intelligence is assessed from a *Homo*-centric perspective blinding us to the considerable intelligence of other species. This issue aside, intelligence—as applied to humans—is a concept freighted with historical prejudice and modern bias. Although there are researchers who believe in a generalized intelligence (called *g*), these beliefs nearly always revolve around culturally specific and historically recent forms of cognition. Whatever these might be, they rarely are applicable to the kinds of cognitive demands made on hominids in Plio-Pleistocene environments. Second, neither absolute nor relative brain size is a reliable proxy for the behavioral complexity and cognitive plasticity associated with “intelligence.” Rats have small brains (~2 grams) yet have remarkable behavioral repertoires that enable them to adapt to all manner of environments. Among primates, capuchin monkeys have relatively much larger brains than gorillas, without major differences in assessments of intelligence. Finally, intelligence is simply too broad a concept to be useful. Rather than speaking in terms of general intelligence, we should discuss specific skills and abilities for which there may be evidence that is amenable to testing. So parsed, intelligence includes toolmaking, foraging, sociality, language, and culture. Before examining how these and other factors may have exerted selection pressure on hominid brains, it is important to remember that encephalization did not come first—bipedality was the prime mover in hominid evolution.

Although bipedality and the brain are often treated as separate and distinct aspects of hominid evolution, this approach ignores the major impact that bipedality had on the neural organization of hominids. All primates (except one) are quadrupeds of one kind or another. This means that for nearly 55 million years, primate brains have evolved in a manner that subserves the several different forms of quadrupedal locomotion. Standing upright requires substantial changes to this basic primate design. Bipedalism had direct and indirect effects on neural organization. The vestibular system, which plays a major role in balance and orientation, had to be reorganized, along with changes to neural pathways and associated motor regions. Several studies have shown that bipedalism is, over longer distances, an energetically more efficient form of locomotion than quadrupedalism. To maximize this efficiency and aid upright walking, the typically flared primate pelvis had to narrow. This reconstruction resulted in constricted birth canals, which in turn altered developmental patterns in hominids. Hominid infants had to have smaller brains (and softer bones) at birth in order to pass through a narrow birth canal. Having smaller brains at birth delays development. In humans, this delayed development is much longer than it is in other primates. Delayed postnatal maturation (secondary altriciality) has several effects, not the least of which is that it prolongs dependency and enables learning. The cumulative impact of this life-history alteration should not be underestimated. In all likelihood, bipedality accounts for the slightly changed brain-body size ratios first seen in australopithecines.

Bipedalism had another major impact on hominids: It freed the hands for tasks other than locomotion. The earliest hominids almost certainly lacked the fine motor control for hands that we associate with later hominids. Over time, however, hominids would have begun using their hands for novel tasks, including stone throwing, toolmaking, extractive foraging, and gestural communication. All of these require an ability to sequence grasping activities in a deliberate manner, and would have resulted in a significant reorganization of related motor control regions in the brain. Indeed, many researchers hypothesize that activities such as stone throwing and toolmaking laid the neural substrate for the later emergence of language, which also involves finely controlled motor sequencing.

Of course, bipedalism did not just happen. There had to be selection pressure for upright walking. Most researchers agree that upright walking began during a period of cooling and drying that resulted in the retreat of African forests and the appearance of patchy savannah-like environments. This ecological shift resulted in changed foraging patterns, at least for hominids who were no longer restricted to arboreal habitats. Bipedalism enabled hominids to range over larger territories, where foraging opportunities are much broader than they are in the canopy. Several changes in hominid-foraging patterns have been suggested, including opportunistic scavenging, cooperative hunting, tuber

extraction, and shoreline harvesting. Whether early hominid foraging included all or only a few of these, each of these behaviors entail increased caloric intake, which is a major factor in any consideration of brain evolution.

In energetic terms, brains are notoriously expensive organs. Although the human brain constitutes a mere 2.3% of body mass, it consumes approximately 23% of the body's daily energy intake. Given the high-metabolic costs of maintaining neural tissue, there are serious constraints on brain size. Many researchers argue that removal of these constraints was the essential first step in hominid encephalization. There are several variants of this argument, the most well-known of which is Leslie Aiello's expensive tissue hypothesis (Aiello & Wheeler, 1995). Aiello notes that digestive organs are metabolically costly, and that in order to grow larger brains, hominids had to make a trade-off between digestive and neural tissue. The evidence for a reduction in hominid gut size and corresponding increase in brain size is compelling. As hominid brain size began increasing, the shape of the rib cage and thorax changed from the wide and flared hominoid pattern (indicative of a large gut designed to process lower quality foods) to the narrow and barrel-like human pattern (indicative of a smaller gut designed to process higher quality foods). These changes, in turn, are often associated with increased consumption of animal proteins, which could have occurred by hunting or, more likely, by way of scavenging and the secondary processing of carcasses and bones with stone tools.

Another group of researchers argue that this foraging and encephalization shift was associated with what they call the shore-based diet. Under this scenario, early hominids began exploiting the easy-to-harvest marine resources that are concentrated around the shorelines of lakes and rivers. These resources would have included crustaceans, mollusks, frogs, turtles, spawning fish, and birds' eggs. In addition, a wider variety of edible and nutritious plants are available near water, and these presumably were included in the diet. A key feature of this argument is that shore-based diets include considerable amounts of fatty acids (docosahexaenoic acid and arachidonic acid) that are essential for encephalization in mammals. Importantly, these are limiting nutrients for brain development. However, these constraints were removed, and there can be little doubt that a higher quality diet was an important factor in hominid brain evolution. Recognizing this, Richard Wrangham recently has suggested that cooking—which results in much higher availability of nutrients from food—played a significant role in hominid evolution.

All constraint hypotheses have something in common: They revolve around changes in hominid behavior. As a general evolutionary rule, behavior remains constant unless something causes it to change. When environments remain stable over long periods of time, there is little reason for previously adaptive behaviors to change. However, when environments become variable and fluctuate rapidly, formerly adaptive behaviors may become maladaptive.

Organisms with relatively stereotyped and static behaviors that are unable to adapt thus become extinct. With this in mind, several researchers propose that behavioral plasticity in the face of environmental change was an important factor in hominid evolution. During the late Pliocene and throughout the Pleistocene, climactic change became more frequent and severe. Africa in particular experienced environmental perturbations that dramatically altered ecologies and landscapes. These changes would have exerted strong selection pressure for flexible and fluid responses, or an ability to behave in nonstereotypical ways. Because behavioral plasticity is often correlated with encephalization, habitat instability and hominid brain evolution are probably linked.

The Social Brain

In 1976, Nicholas Humphrey published a seminal article titled "The Social Function of Intellect." Humphrey began with what appeared to be a paradox: Primates are among the most cerebral of animals, yet for the most part lead relatively undemanding lives. This thought occurred to Humphrey after spending a few months observing gorillas (and reading primate behavioral literature), all of which suggested that—compared with many other mammals—primate life (and in particular, foraging) was not especially difficult. Humphrey is not alone in this observation. Primatologists routinely confirm that field studies can be tedious, with long days spent watching primates leisurely foraging in trees or on the ground, alternated with long periods of rest and sleep. Given this fact, the question naturally arises: Why are primates so behaviorally sophisticated? For Humphrey, the answer was obvious. Primates are highly cerebral because they are intensely social.

Sociality is a complex evolutionary adaptation. One should not mistake mere aggregations of organisms with sophisticated social behavior. Life in a swarm, flock, or herd is in a limited sense social, but it does not involve the cognitive computations required of highly social mammals such as primates, cetaceans, and some carnivores. Complex social behavior usually involves tightly bonded groups or societies. Maintaining group cohesion while simultaneously tracking and navigating rank orders, member coalitions, shifting alliances, and individual relationships is no easy task, and is one that requires a fair degree of cerebral sophistication. Because relevant information must be constantly updated and stored over long periods of time, complex sociality places tremendous loads on memory and recall. It should come as no surprise, therefore, that all socially complex animals score rather high in various measures of encephalization and behavioral plasticity. Primates are especially notable in this regard.

With these observations in mind, Robin Dunbar (1998) proposed the social brain hypothesis to explain the fact that primates have unusually large brains, given their body size,

compared with other vertebrates. Primates consistently have EQs higher than those of most other taxa. Dunbar began by noting, as many researchers have done, that neocortical areas of the brain are associated with reasoning and consciousness, and that the neocortex has expanded disproportionately during primate and hominid evolution. Operating on the assumption that primate group size is a rough proxy for social complexity, Dunbar measured primate neocortex size and compared it with primate group size. He found a significant correlation between these variables, and concluded that neocortex size acts as a constraint on primate group size.

Sociality does not, of course, always involve cooperation. It often involves group competition, which can create selection pressure for the ability to deceive. Pursuing this idea, Richard Byrne (2000) has found that all primates (except for Strepsirrhines) have at least some ability to deceive. Byrne's Machiavellian intelligence hypothesis proposes that complex cognition in primates arises, in part, from the need to out-compete group members. Apes appear to possess greater deceptive abilities than monkeys, a fact which causes Byrne to argue that absolute brain size—rather than relative brain size alone—is an important factor in primate cognitive evolution. Byrne's hypothesis has two important features that extend beyond the confines of Machiavellian intelligence. First, he notes that social competition has an inherent feedback effect. Because deception engenders counterdeception and the behavior of others is constantly shifting, there may have been spiraling selection pressure for advanced social cognition. This idea is similar to the “red queen” effect that drives predator-prey adaptations in a coevolutionary arms race. Second, advanced deception—such as that seen in apes—requires a theory of mind, or an ability to imagine others' mental states. Significantly, mirror neurons and theory of mind have often been linked. Although the evidence for true theory of mind in other primates remains controversial, researchers agree that theory of mind is a key human attribute that played an important role in hominid evolution.

The Linguistic Brain

There can be little doubt that what separates humans from all other primates is language. Although cases such as Kanzi (bonobo), Washoe (common chimpanzee), and Koko (gorilla) show that intensively trained apes have impressive communicative and lexical skills, they do not possess language as we know it. More importantly, apes neither intuitively learn language (as do human children) nor spontaneously invent it (as did humans). Primate vocalizations and gestural routines are a long way from being languages or even protolanguages. Knowing this, the linguist Noam Chomsky long maintained that human language was so unique that it had no precedents in the

animal kingdom. Chomsky's early approach was anti-Darwinian and essentially held that an innate language module somehow appeared, fully formed, in humans. A less saltational but explicitly Darwinian form of this idea has recently been advanced for the FOXP2 gene. Given the complex and supramodal nature of language, it seems highly unlikely that it simply appeared at some serendipitous moment in hominid evolution. For something like language to have evolved, there must have been more or less constant selection pressure toward it for hundreds of thousands, if not millions, of years. For this reason, many researchers have suggested that hominid encephalization and language are closely connected. It is apparent, however, that simply having a large brain cannot explain language. If it could, we might expect whales and elephants to have language.

Early researchers into brain function and anatomy identified two regions as having special significance for language: Broca's area in the frontal cortex and Wernicke's area in the temporal cortex. While these areas are undoubtedly important, patients with lesions to these regions do not usually experience complete language loss. Total aphasia or loss of language have been reported in patients who experience severe subcortical damage, a fact indicating that language functions are widely distributed in the brain. More recent imaging studies in humans confirm that language cuts across many brain regions and involves multiple connections, some of which appear to be of relatively recent origin. Increased connectivity is frequently cited as a differential aspect of the human brain associated with language. In the end, language defies localization, and there is no “language module” in the brain.

Two leading researchers on brain evolution and function, Merlin Donald (1991, 2001) and Terrence Deacon (1990, 1997a, 1997b), argue that the expansion and reorganization of the hominid brain over the last 2 million years was driven not by language per se, but by specific abilities that eventually culminated in language. In Donald's view, early *Homo* possessed two critical abilities not seen in other primates: fine motor control and voluntary memory access. Together, these abilities allowed for *mimesis*, which is an ability to rehearse and refine body action in a representational manner. Mimetic skill could have operated without language, and would have greatly enhanced social cooperation and learning. In Deacon's view, these changes amount to symbolic thought—an ability to model the world in abstract ways and communicate with others, even without fully developed language. Although Donald and Deacon differ on details, they agree that pre- and protolinguistic skills (such as gesture and prosody) underwrote the unique course of human brain evolution. In support of this view, Robin Dunbar (1998) observes that primate group cohesion depends to a large extent on grooming and hypothesizes that language evolved as a form of social grooming.

The Conscious Brain

In many respects, the human brain is most remarkable for its conscious properties. Precisely what consciousness is defies easy description or explanation. For humans, it is often associated with attention, focus, and awareness. Francis Crick likens consciousness to a searchlight that deals with current tasks and conditions. Purposive intentionality, goal states, future planning, and voluntary decision making are all aspects of consciousness. Given our *Homo*-centric view of the world, many assume that consciousness is a uniquely human attribute. This view is mistaken. While humans possess a type of consciousness that is different, there is no reason to think that other animals are not conscious. Consciousness, in other words, exists along a phylogenetic continuum.

Whether consciousness itself is a direct product of selection or is an emergent feature of neural evolution remains a mystery. We know, however, that mobile organisms face special challenges as they operate in multidimensional environments. Sensory inputs must be coordinated with motor outputs in a stable arena of action. For smaller, slower, and less complex organisms, this coordination does not even require a brain, let alone something akin to consciousness. For larger, faster, and more complex organisms, a brain—and some form of consciousness—appears to be necessary. If this is the case, then it is not unreasonable to suggest that reptiles are minimally conscious and that mammals are moderately conscious. Conscious organisms are aware of the immediate environment, and depending on feedback, are able to adjust behaviors. In this sense, consciousness is a form of error correction and action modulation, and its adaptive utility is obvious. The ability to react rapidly to constantly and rapidly changing environments is critical to survival.

Many researchers refer to *primary consciousness*, which is most often noted in mammals and birds, and *higher-order consciousness*, which is typically associated with humans (and may be minimally present in some apes, elephants, and cetaceans). Primary consciousness revolves around a remembered present and involves episodic memory. Its activation requires an external or environmental stimulus. Higher order consciousness entails introspection and involves both short- and long-term memory. It is self-cueing and does not require external or environmental activation (though this often occurs). Higher order consciousness also entails causation and subjectivity, which is an awareness of self associated with agency. For humans, this aspect of consciousness is self-evident and manifests as a stable identity. For other species, its presence may be indicated by self-recognition in mirror tests. Chimpanzees, elephants, and dolphins all appear to recognize themselves when presented with mirrors.

Given the central role that consciousness plays in our waking lives, it is not surprising that many researchers locate it in a central part of the brain: the thalamocortical

system. The thalamus is medially situated to integrate sensory inputs and motor outputs. It appears to be a kind of switching center, with huge numbers of reciprocal relay cells engaged in recursive and parallel signaling. Gerald Edelman (2003) calls these relay signals *re-entrant interactions* that take place in the thalamocortical *dynamic core*. Significantly, brain wave activity in this core fluctuates in accordance with attention. Because the thalamus is centrally situated, it mediates between subcortical and neocortical processes. Its location, therefore, probably serves as an integrating area for the normally stable platform we call “consciousness.”

The Emotional Brain

Because language and consciousness play a central role in human experience, many philosophers and scientists have assumed that the mind is fundamentally rational. They have, in other words, privileged conscious cognition over other brain processes. Although Friedrich Nietzsche and Sigmund Freud vigorously challenged this assumption with their respective inquiries into “drives” and the “subconscious,” modern neuroscience typically eschews systematic inquiry into affective or emotional states. There is, however, one group of researchers who argue that much of our behavior is attributable to subconscious routines operating outside of language and consciousness. They are the evolutionary psychologists. In its most extreme form, evolutionary psychology holds that most of what humans do is driven by subconscious routines that evolved for specific and narrow purposes during the Plio-Pleistocene. Although there is little neurobiological evidence to support the idea that the brain is divided into modules, softer forms of evolutionary psychology focus on emotions and provide important insights into brain function and behavior.

As is true of consciousness, emotions exist along a phylogenetic continuum. At their most basic level, emotions are bioregulatory urges that govern approach/aversion and appetite/withdrawal behaviors. These urges are often parsed into arousal categories such as seeking, rage, fear, panic, play, lust, and care. Emotions allow animals to register environmental conditions, map body states, and maintain homeostatic balances. Many kinds of organisms—mammals prominently included—possess these abilities. Emotions enable reflexive responses to environmental stimuli and therefore play a major role in behavior. Internal-drive states related to food, sex, and safety are critical to survival and reproduction, the two essentials of evolutionary fitness. These drive states are largely regulated by emotions operating at subconscious levels. For animals possessing only primary consciousness—those locked into the present—emotions are highly adaptive and unproblematic. For humans possessing higher order and reflective consciousness, emotions—while still adaptive—are considerably more complex and are often problematic.

In humans, emotions register initially as drives that are then mediated by more complex cognition (i.e., language and memory). Feelings proper are the result of emotional-cognitive interactions. There is, in other words, an affective coloring to all conscious experience. This is, however, a two-way street—cognitive processes can trigger emotional responses. It should be apparent, therefore, that emotions play a major role in human decision making. What may appear to be purely rational thought processes are nearly always inflected by feelings that originate in the emotional brain. Under various circumstances, emotions and feelings can completely overwhelm executive level or rational cognition. *Sickness and love* provide but two examples, a fact well-known to all great novelists. Pure reason, as such, almost surely does not exist.

In the brain itself, emotions are usually identified with the subcortical limbic system, including the cingulate cortex, amygdala, and hypothalamus. In phylogenetic terms, these are relatively ancient structures that are closely connected with visceral functions. Their combined activity often triggers neuroendocrinal (hormonal) cascades, which can bathe the entire brain in chemicals affecting all aspects of feeling and behavior. The cellular and neuronal activity of the limbic system is regular and consistent. Jaak Panksepp (2003) suggests that these subcortical systems are akin to analog (regular stream) signals, whereas higher cortical systems are digital (intermittent pulse) signals. Operating within the context of the larger brain, these subcortical structures have major impacts on temperamental states, moods, and habits. They also play a role in memory formation, given that emotions often serve as tags for particular events. When similar emotions or conditions are experienced subsequently, the memory flood that sometimes results is a product of this valence tagging.

The Cultural Brain

Among scientists who study the brain, there is an unfortunate tendency to study it in isolation, as if it existed and operated in a box. The brain, of course, is encapsulated within a body, and the body exists in an environment. For humans, this environment is particularly rich: It is called culture. Although other animals possess transgenerational, social learning abilities that give rise to local traditions, the human brain takes these abilities to unprecedented heights. It is often said, with good reason, that the paramount human adaptation is culture.

Although human brains are specifically wired for various tasks at a subconscious level, higher order consciousness enables flexible learning across nearly all domains of thought and action. Human brains are, in a word, plastic. At birth (and compared with other primates), a human infant's brain is grossly underdeveloped. To reach a similar stage of development at birth compared with chimpanzees, human infants would need to gestate another entire term, or

until 18 months. This underdevelopment has several consequences, not the least of which is that it renders human infants utterly helpless and sets the stage for prolonged dependency. During early development, enormous amounts of energy are devoted to the brain. During the first few years of an infant's life, the rapidly growing brain consumes 60% of daily metabolic expenditure, a figure that stabilizes at approximately 20% later in life. None of this growth occurs in isolation: Human infants are constantly attended to and surrounded by conspecifics. Though it may be hard to discern, infants almost immediately begin imbibing this highly social environment. As a consequence, their brains literally develop in a cultural matrix.

As Merlin Donald (1991, 2001) poignantly observes, there is no such thing as an isolated mind. We can no more conceive of a brain independent of culture than we can of a body independent of environment. Brains severed from culture are not normal. Tragic examples of this essential connection are seen in cases where children have been socially isolated and neglected during their developmental years. These abused children typically suffer permanent impairment of linguistic, social, and other skills that most take for granted. Clearly, the brain undergoes profound changes during these early years and cannot develop properly unless embedded in a cultural environment. This enmeshment is so tight and constant that we sometimes underestimate the degree to which our minds are bound by culture. Symbolic thought, considered by many to be the key attribute of the human brain, does not develop as a matter of course. Rather, cultural programming is required before symbolic thinking can occur. Symbols, in other words, originate outside the brain. Cultural learning allows us to decode and manipulate those symbols, but only after they are internalized. Because experience and learning physically alter the brain and its connections, it can be said that culture actually instantiates itself in the brain.

Though we tend to associate "culture" with recent Holocene achievements such as literacy and mathematics, hominid brains and culture have long been locked together in an evolutionary embrace. Unfortunately, our view of Plio-Pleistocene hominid culture is limited by the fossil record of mostly stone tools and bones. While the lithics associated with the Oldowan and Acheulean tool industries can tell us something about the brains and behaviors of hominids, that something is necessarily limited. The hominids who manufactured and transported Oldowan tools certainly understood causation and possessed foresight in ways that chimpanzees do not. The later hominids who manufactured more refined Acheulean forms had further developed this anticipatory cognition and understood symmetry. Other than these kinds of limited insights, however, we do not know precisely what kinds of cultural innovations were fueling hominid evolution. The most likely explanation is that social, technical, and communicative skills were all under selection pressure, with the result being a distinctive form of hominid culture.

Whatever this culture may have been, it surely was more rich and complex than the picture we can paint from stones and bones alone.

Several researchers suggest that the hominid brain and culture formed an evolutionary feedback loop, having a ratchet effect on both. With each behavioral change and cultural modification, selection pressures would have favored those best able to adapt, and those best able to adapt would have possessed the kind of neural plasticity that often leads to further behavioral change and cultural modification. The notion of a hominid brain-culture spiral receives support from the evolutionary theory of niche construction, which posits that organisms can modify their environments in ways that alter subsequent selection pressures. The standard view in evolutionary theory is that selection pressures emanate from the environment to shape organisms who live, more or less passively, in the setting which presents itself to them. Selection, in this view, is a process with causation flowing only in a single direction. With the use of stone, bone, and fire, there came a point at which hominids began to actively alter their environments in ways that influenced subsequent selection. Humans, of course, radically alter environments to suit their needs, with consequences for subsequent behavior. Culture, in this view, widens evolutionary pathways so that causation can flow in two directions.

Conclusion and Future Directions

The human brain has deep evolutionary roots extending back in time to the first vertebrate brain, which appeared during the Cambrian some 500 million years ago. One lineage of vertebrates—the mammals—developed a relatively distinct brain that is roughly homologous across mammalian orders. Except for olfactory reduction and visual enhancement, early primate brains were not notably different from other mammalian brains. Primate brain evolution is marked primarily by emphasis on visual acuity, and only slightly by overall enlargement. Selection for visual acuity in primates most likely was associated with the shift to diurnality, changes in foraging, and complex social behavior.

The earliest hominid brains are not especially enlarged, but show signs of lateral and vascular reorganization that are of uncertain behavioral significance. Gross morphology aside, there can be little doubt that the foraging-related shift to bipedality worked significant changes to the early hominid brain. Bipedality forced changes to motor-control regions and had a major impact on the timing of brain growth and development. It was only after these changes had occurred that the hominid brain began to progressively enlarge. Issues of tempo and mode aside, hominid encephalization was most probably related to behavioral alterations involving sociality, technology, and communication. Considered together, these changes encompassed a distinctive hominid culture.

With the appearance of *Homo sapiens* some 200,000 years ago, the human brain had—in terms of overall size and external appearance—attained its modern configuration. There is no reason to think, however, that the human brain has stopped evolving since that time. Indeed, evidence from genetics suggests that there have been several mutations implicating the brain within the past 40,000 years. Some of these mutations involve size and speech, while other more recent ones involve auditory regions. These latter mutations may be especially relevant to the appearance of fully developed linguistic skills.

Progressivism in evolutionary studies and prejudice within anthropology hampered many early studies into brain evolution. An obsessive focus on size and “intelligence” has prevented many researchers from seeing that primate and hominid brain evolution has been an irregular, mosaic affair involving changes in structure, function, connection, cells, chemistry, growth, and development. Only over the last several decades have researchers begun to consider the brain in an evolutionary context relatively free from cultural myopia. This context has provided promising insights into pathologies ranging from schizophrenia to autism.

With regard to the human brain, it can rightfully be said that never has so much been known about so little. Brains, while small and unimpressive in appearance, are incredibly complex organs. The human brain has approximately 100 billion neurons and over 100 trillion synapses. Although the brain's physical, cellular, and chemical composition is relatively well understood, its ability to give rise to mind is not. In almost every respect, brain research is in its infancy. Consequently, future research possibilities into brains and behavior are nearly limitless. Going forward, anthropologists who hope to contribute to our understanding of the human brain and mind will need to be able to cross disciplinary boundaries and work with researchers in genetics, neurology, biochemistry, biology, zoology, paleontology, psychology, ethology, and philosophy. If we hope to unravel the marvelous mystery that is the human brain, the combined insights from these fields and others will be required.

HUMAN ADAPTATIONS

JILL M. CHURCH
D'Youville College

An adaptation is a feature of an organism that was produced through natural selection to perform a specific function. The *Oxford Dictionary of Biology* defines adaptation as “any change in the structure or functioning of successive generations of a population that make it better suited to its environment” (Hine, 2008, p. 9). Adaptations allow organisms to cope with environmental pressure or stress. Adaptations can be biological (physiological) or behavioral (cultural) and occur in all living organisms; however, this chapter will focus solely on human adaptations.

Human adaptation happens on a variety of levels. In addition to genetic adaptation through the mechanism of natural selection and cultural adaptations (e.g., clothing, shelter, social systems, rules/taboo), humans are capable of three additional forms of physiologic adaptation. Acclimation refers to very short-term changes in response to a stress, such as shivering in the cold or sweating in the heat. Acclimatization occurs over days or months, such as adjusting to breathing thinner air at high altitudes. Developmental acclimatization is a change in body structure over an individual’s lifetime, such as the larger chest size and greater lung capacity of an individual raised at those high altitudes. The ability of humans to respond physiologically or developmentally to environmental stresses is called *plasticity*. Human responses to new environmental conditions often occur in a combination of physiologic and behavioral changes.

Genetic changes would only be seen after the passing of many generations.

Theory

A cohesive theory to explain evolutionary principles evolved in Western Europe, building on knowledge and observations that date back to the 16th century. Many of these ideas were borrowed from Arab, Chinese, and Indian scientists and philosophers. These earlier scholars proposed the concept of evolution, but had no suggestions to explain the theory, process, or mechanisms driving this force.

Charles Darwin, a British naturalist, was the first person to suggest an explanation of the mechanics of the evolutionary process. As he published his theory of natural selection, a Scottish naturalist named Alfred Russel Wallace independently reached the identical conclusion. Since scientific knowledge builds on previous knowledge and theories, it is possible to see the development of ideas that caused these two gentlemen to simultaneously develop the theory of evolution by natural selection.

It was generally accepted throughout the Middle Ages that all forms of life on the planet were static. All species existed exactly as God created them. This belief that a life-form could not change after creation is called the fixity of species, upholding the idea that God created all animals and plants with the features they needed to perform their

tasks. Irish archbishop James Ussher (1581–1656) took this information in the early 17th century and studied the “begat” chapter of Genesis in the Bible. He determined that the earth was created in 4004 BCE. For decades afterward, this date was printed at the beginning of every Bible. The concept of vast geologic time simply did not exist.

As Europeans learned more about the wider world though, doubts about the common mind-set arose. From encounters with Chinese civilization claimed to have occurred before the date given for the creation of the universe to questions about how the inhabitants of the Americas got there after dispersing from Noah’s ark, the literal interpretation of Genesis was being systematically undermined.

It was a scientist named Copernicus (1473–1543) who began the revolution of modern scientific thought. He was a Polish mathematician and astrologer who simplified the Ptolemaic model of the universe by placing the sun at the center of the universe and the earth as an orbiting planet. This radical change to intellectual thought enabled scientists to view the physical universe in new ways. By the early 1700s, the concept of “motion” was widely accepted in the physical universe, but biologists still insisted on the fixity of species. One of the leading naturalists of the time, Carolus Linnaeus (1707–1778), declared that there was a continuum of life from algae to humans but each species was fixed and unchangeable. He developed a well-received classification system called *Systema Naturae* to classify organisms. He isolated common traits and assigned two Latin names to each organism—a generic term (genus) for the group of organisms and a more specific term (species) for the specific plant or animal. The two words together would be the name for that specific life-form.

While Linnaeus’s classification system was widely accepted, he had contemporaries that were vocal in their opposition to his views. Georges Louis Leclerc, Count Buffon (1707–1788), was a leader among his detractors. Buffon stressed the importance of change in the universe. He described the variety and number of minute changes in nature as a system of laws, elements, and forces. He felt the aim of scientists was to discover and explain these forces that drive nature, not simply categorize their result. Both arguments were widely discussed in intellectual circles well into the 19th century.

Erasmus Darwin (1731–1802), grandfather to Charles, was an eccentric scientist, doctor, and poet. He explored a number of evolutionary ideas, but tended to express his ideas in verse, making little impact on general scientific thought. While he believed in the process of evolution, he could not explain how it happened. Another scientist, Jean-Baptiste Pierre Antoine de Monet de Lamarck (1744–1829), was finally able to go one step beyond Buffon and Erasmus Darwin by organizing his ideas into a comprehensive theory of adaptation. Lamarck stressed that organic forms interacted with their environment. Their stability was proportional to their living conditions, and as those conditions changed, life-forms were impacted. In other words, physical

changes were caused by an environmental need. As an organism made a repeated effort to do something, “fluids and forces” would go to that point in the body and develop an organ to eventually fulfill that need. Lamarck also believed that new organs, or appendages, developed this way would be passed on to the next generation. This theory of acquired characteristics, or Lamarckism, is known to be untrue today, but many of his views are as valid today as they were almost 200 years ago.

Lamarck made the concept of evolution popular, but there was vehement opposition to the notion that existing species could develop into new species. Georges Cuvier (1769–1832), a contemporary of Lamarck and a very well-known scientist often called the “Pope of Bones,” was very vocal about his criticism of Lamarck’s views. By this time it was widely accepted, from examinations of the fossil record, that new species of plants and animals had come into existence. Cuvier insisted on the fixity of species, and developed a theory of catastrophism to explain how new species could appear. His theory proposed that a series of natural disasters or catastrophes (like the formation of a mountain chain) would destroy all life in that area, and be reflected in the geological record. Over time, the area would be repopulated by life from surrounding areas unaffected by the disaster. This would explain the appearance of new life-forms in the fossil record of a location without mentioning evolution.

The most influential opponent to Cuvier’s views was Charles Lyell (1797–1875). Lyell was a lawyer with a great interest in geology. He befriended Charles Darwin when he returned to England after his 5-year voyage on the HMS *Beagle*. Lyell’s greatest contribution to science was his three-volume *Principles of Geology*. In this pivotal work, he rejected catastrophism and reaffirmed the principle of uniformitarianism proposed by James Hutton in 1785, namely, that there are no forces working today that were not also active in the past. Lyell showed that the earth’s crust formed through very slow, gradual changes like weathering or erosion by water, wind, and ice. These forces, over the vastness of geologic time, could create the mountains, rivers, deserts, and coasts seen in the present. Lyell believed the earth was hundreds of millions of years old, which gave Charles Darwin a conception of time that made the gradual process of evolution possible.

Another inspiration to both Darwin and Wallace in developing their theories of natural selection was an essay written by Thomas Malthus (1766–1834), an economist. Malthus pointed out that unrestrained human population growth would cause it to double every 25 years, but the capacity for food production would increase far more slowly. Animals in the wild had to struggle for survival, which would restrict the population growth, but humans would have to apply artificial restraints given their limited food resources but infinite breeding capacity. This gave Charles Darwin the missing insight needed to explain selection occurring in nature. He realized that individuals with

favorable characteristics would be more likely to survive, and individuals with unfavorable characteristics would not. Previous scientists looked at a species as a single entity and minor differences within a species as irrelevant. Darwin was the first to realize that the struggle of the individual to survive was the mechanism that made evolution work. This is the process of natural selection by which individuals that share favorable characteristics will increase in number from generation to generation, so greater numbers within the species will share those adaptations better suited to the environment. Over time, successful adaptations will produce enough variation that a new species is formed. Darwin, Wallace, and others finally understood the importance of variation and adaptation and how these drive the process of natural selection, but no one in the 19th century understood how traits are passed to offspring. A contemporary of Darwin, the Augustinian monk named Gregor Mendel, was actually working out the rules of heredity, but his work was not recognized until the early 20th century.

In the early 1900s, the foundations of modern evolutionary theory were in place. Darwin and Wallace had articulated the importance of the process of natural selection in driving evolution, and Mendel's work was rediscovered, establishing the mechanisms for inheritance. One would think that a comprehensive theory of evolution was developed quickly from this knowledge, but for the next three decades rival groups would vehemently argue different viewpoints. Some biologists took the Darwinian view stressing the importance of natural selection in the production of variation, while others stressed random mutations as the source of variation. A combination of these views, called the modern synthesis, was finally developed in the mid-1930s. Biologists working with mathematical models came to realize that both mutation and selection were needed to explain evolutionary change. Mutation alone does not produce evolutionary change, but mutations are the source of variation, which produces different characteristics that natural selection chooses for or against.

A central component of modern synthesis is the relationship between populations and species. A species is a group of populations whose members can interbreed and produce fertile offspring. A species has a geographic range it inhabits, with populations of individuals clustering into smaller areas within it. A population in a remote area with little outside contact may eventually select characteristics specific to surviving in that region which result in measurable physiologic differences from the rest of the species. The accumulation of many small genetic changes over generations results in the differences seen in populations today. From a modern genetic perspective, evolution is defined simply as a change in allele frequency from one generation to the next.

Methods

Anthropologists today know that human variation is the result of a number of evolutionary factors, including

mutation, genetic drift, gene flow, and natural selection. Mutations are random, spontaneous changes in a gene that can be caused by any number of environmental factors. They are the ultimate source of all genetic variation. Genetic drift is also a random factor related to population size. In a small population, some individuals may contribute a disproportionate share of genes to succeeding generations. Gene flow is the exchange of genes between populations. It occurs when people migrate to a new area (either temporarily or permanently) and interbreed with another population. Finally, there's natural selection, the principle mechanism of evolutionary change. It is the process by which individuals with advantageous characteristics for reproduction in a specific environment leave more offspring in the next generation with the same trait, increasing the proportion of their genes in the gene pool over time.

Cultural adaptations have also played a significant role in human evolution. Cultural adaptation refers to nonbiological responses of individuals or groups to alleviate environmental stress. It is an important mechanism that allowed humans to survive and colonize relatively inhospitable areas until physiological adaptations could occur. All the evidence to date suggests that hominids evolved in the hot savannas of East Africa. Humans today cope better with heat than they do cold, illustrating the long-term adaptations to heat that developed in our ancestors. As humans migrated to colder environments, they invented fire, clothing, and shelter to survive.

Throughout the course of human evolution, people have settled in almost every climatic zone of the world. Using a variety of adaptations, they have adjusted remarkably well to living in extremely hot or cold temperatures, exposure to solar radiation, very dry or humid air, thin atmosphere, and broad seasonal fluctuations in climate. For populations to cope with the challenge of new habitats, they must undergo changes through a combination of natural selection and physiological plasticity. The interaction between both processes is so intertwined it is difficult to isolate either.

General build and skin color are the most obvious adaptations. Ancient Greeks took this knowledge one step further by associating physical characteristics with the environment in which people lived. People from the interior of Africa had the darkest skin and it was assumed that the tropical sun was the cause. Similar associations were made in other animals. The average size and shape of indigenous individuals had a relationship to the temperature, while nose size and shape correlated to humidity. A zoologist by the name of Constantin Wilhelm Lambert Gloger first commented on this phenomenon in 1833. Gloger's rule states that within a species of endotherm (warm-blooded mammal), skin pigment tends to be darker in warmer climates at lower latitudes or lower altitudes, and lighter in color in colder climates at higher altitudes or higher latitudes.

Adding to Gloger's rule, a 19th-century zoologist named Carl Bergmann studied the relationship between body size and temperature in a variety of mammal species,

explaining his findings in terms of heat loss. Bergmann's rule (developed in 1847) states that if two mammals have similar shapes but different sizes, the smaller one will lose heat more rapidly. This makes the smaller animal better adapted to living in warm climates. Larger animals lose heat more slowly and would be better adapted to colder climates. The reason for this relationship is that heat production is a function of the total volume of an animal while heat loss is a function of total surface area. A final aspect of Bergmann's rule factors the shape of a mammal into the relationship between heat production and loss. He states that two differently shaped animals with the same volume will produce the same amount of heat, but a linear shape would have a greater surface area and dissipate heat more rapidly. Therefore, mammals living in hot climates will have linear body shapes and those in cold climates will have stockier body shapes. Another zoologist, Joel A. Allen, applied these principles to body limbs and other appendages. Allen's rule (developed in 1877) predicts that mammals in hot climates will have longer and leaner limbs and those in cold climates will have shorter, bulkier limbs.

The Bergmann and Allen rules apply to adult humans, but evidence to date suggests that a combination of genetic and environmental factors influence the relationship between climate, growth, body size, and body shape. When children grow up in a climate that differs from that of their ancestors, they tend to grow as indigenous children do.

Measuring the size and shape of the human head has long been a focus of racial classification. In the 19th century, a Swedish anatomist named Anders Retzius developed a measure of cranial shape called the cephalic index. This index is derived from two measurements: the total length of the head and its maximum width. The width of the head is divided by the length, and the result is multiplied by 100. The cephalic index among human populations ranges from 70 to 90. These values only apply to the average for a population. There is a certain amount of variation within a population, and the numbers for different populations do sometimes overlap.

As this data was compiled and compared geographically, a pattern emerged. Populations in colder climates tend to have wider skulls relative to length than those in hot climates. This correlation fits with the Bergmann and Allen rules. Rounded heads, those with a high cephalic index, would lose heat more slowly and be advantageous in cold climates. Narrow heads lose heat faster and would have the advantage in hot climates.

Another variation with a strong relationship to climate is the nasal index. This index is determined by dividing the width of the nasal opening by the height of the nasal opening, and multiplying by 100. Typical values for humans range from 64 to 104. In the past, stereotypical racial views associated wide noses (large nasal indices) with African populations, but in actuality, there are some African peoples with wide noses and others with long, narrow noses. Instead, the nasal index has a direct relationship to the temperature and humidity of an area. Populations in

cold climates tend to have narrow noses, because high, narrow noses can warm more air before it reaches the lungs, which is advantageous in the cold. High, narrow noses also have greater internal surface area to moisten air in dry climates, either hot or cold. Wider noses are found in areas of high humidity.

Applications

The study of human variation and adaptation is useful in a variety of careers. The broad field of biological anthropology, also called physical anthropology, studies the mechanisms of biological evolution, genetic inheritance, human adaptation and variation, and primatology. The objects of study range from fossils and bones to living populations. In addition to researching and teaching in the anthropology department of a college or university, there are many situations that require the study of human adaptation.

A key opportunity to study human adaptations appears in biomedical research. Biomedical scientists focus on issues related to public health, including growth and development, nutrition, aging, disease, genetics, epidemiology, physiology, and forensics. Anthropology's theoretical bases of evolution, human adaptation, human variation, and their relationship to cultural influences are very relevant to biomedical practices. A growing number of biological anthropologists are therefore transferring their skills and interests to research careers in schools of medicine and in private biomedical research facilities.

Museums also have anthropologists on staff. Specialists in various subfields are needed to manage collections and prepare exhibits in addition to conducting research. Skills in educating visitors about the relationship between biology and culture and explaining the importance of the collection to the public are an important part of a museum's mission. Anthropologists also write grants to secure funding for museums to support additional research.

Another critical application of the study of human variation and adaptation occurs in the military. Knowing how troops will react to extended exposure from a variety of environmental stressors is necessary for the training and preparation of soldiers. Working in full body armor and gear requires specific adaptations, whether in extreme heat, cold, or high altitude. Psychological stress over long periods of time will also result in physiological changes to the body. This stress can come from a variety of sources, such as exposure to combat or the isolation of working in very remote places like submarines or arctic research stations.

There has been a great deal of research in the last several decades about human adaptation to conditions in space. Physical and psychological adaptations are necessary to endure long periods of time in a weightless environment. The majority of the data to date comes from missions of relatively short duration, making it difficult for scientists to extrapolate the effects of long-term exposure.

In addition, virtually all studies have been on physically fit, male cosmonauts. The effects of space on average individuals, children, and the elderly are completely unknown. Hence, there is a great deal of work to be done in this field as humans contemplate future space colonization, and researching the ability of humans to adapt to these extreme living conditions will play a vital role.

Comparison (Global)

Environmental conditions vary greatly around the world. Over thousands of years, human beings have adapted to living with extreme heat, extreme cold, high altitude, dietary limitations, and more. While human populations have a variety of cultural or behavioral methods to combat exposure to environmental stressors for rapid acclimation, the actual physical changes in over hundreds of generations can be seen in those native to a region. While demonstrating direct effects of natural selection is difficult, humans do show physiological differences in response to their environment. The question is whether these changes were due to adaptation through natural selection, or would any population of humans have the same physiological ability (plasticity) to adjust to that environment, given enough time?

Ultraviolet Radiation

Skin color is the best understood relationship between physical characteristics and climate. As the ancient Greeks hypothesized, there is a correlation between skin color and solar radiation. A pigment called melanin in the dermal layer of the skin is responsible for its color. Levels of melanin in a population are a genetic characteristic, but exposure to ultraviolet light will increase the amount of melanin in the skin of all populations at the same rate, regardless of the initial pigment level.

Ultraviolet light is strongest at the equator due to the way sunlight reaches the earth and weakens toward the poles. It is also stronger in the Southern Hemisphere than in the Northern Hemisphere. The distribution of human skin color around the world illustrates past evolutionary adaptations. It is believed that as hominids evolved in Africa, they developed more sweat glands and less hair to adapt to the hot climate. Darker skin would have been beneficial as protection from the damaging effects of ultraviolet radiation. As some human groups migrated out of Africa, lighter skin was selected for areas away from the equator.

Dark skin in areas of high solar intensity provides a number of benefits. Melanin blocks ultraviolet radiation, so the darker an individual's skin, the more protection against skin cancer. Some scientists reject this benefit as a selection factor however, because skin cancer generally affects individuals past reproductive age. If someone dies after the reproductive years have passed, it would not impact the process of natural selection.

Protection against sunburn has also been suggested as a beneficial adaptation. During the thousands of years of human civilization prior to the development of antibiotics, severe sunburn could lead to skin damage and exposure to dangerous infection. However, this benefit would have a minimal impact on an entire population.

The most likely advantage to darker skin in equatorial regions involves the damage ultraviolet radiation can cause on the levels of folate in the body. Ultraviolet light destroys folate, and deficiency of this mineral in an individual can lead to both birth defects and decreased reproductive capacity. As humans migrated farther from the equator, the dangers of ultraviolet exposure were reduced. This does not explain why light-colored skin evolved though, only that it *could* evolve.

The most widely accepted model for the adaptation of lightly pigmented skin focuses on the ability of the human body to synthesize vitamin D. Vitamin D deficiency can cause poor bone development and bone diseases like rickets. These disorders can affect fertility and mortality. Modern humans receive enough vitamin D through vitamins or food additives (like fortified milk), but in the past, people obtained the vast majority of their vitamin D from sunlight. As human populations migrated away from the equator, their darker skin blocked too much ultraviolet radiation. Lighter skin would then be a beneficial adaptation, resulting in healthier individuals.

Hot Climate

Because humans evolved in tropic or subtropic zones, they are genetically well adapted to hot, dry climates. They are one of very few mammals that can remain moderately active during the hottest part of the day. This is due to having the most efficient process of heat reduction in mammals—the ability to sweat.

Thermal sweat is produced by eccrine glands, which release a watery solution with virtually no fat or protein content, and very little salt. Most other mammals capable of sweating depend on apocrine glands, which produce a solution full of fats, proteins, and salt. These substances evaporate very slowly, reducing the rate of heat loss. Humans only have these glands on the face and hands. The Inuit, natives of arctic regions, demonstrate a unique adaptation here. The Inuit sweat less on their trunks and extremities, but more on their faces. This is an advantageous feature in the arctic, where moisture accumulating on clothing would be a hazard.

Human skin is covered by more than 1.5 million sweat glands, which can produce copious amounts of sweat over the entire body. Combined with the relative lack of body hair, sweating provides a very efficient cooling system for humans.

Humans also have a number of behavioral adaptations to living in hot climates. Clothing is important to protect individuals from solar radiation and the hot, dry winds of the

desert. Typical desert clothing is lightweight and loose. This allows air to circulate near the skin and rapidly evaporates sweat. The layer of air between the body and clothing also adds a layer of insulation. Desert shelter is usually compact to minimize surfaces exposed to the sun. Light colors on the outside reflect heat. Doors and windows are minimal and kept closed during the day to keep the interior cool.

Heat stress in humid, tropical environments requires a modified set of behaviors. Humidity retards the evaporation of sweat, so clothing tends to be minimal to increase the likelihood of evaporation. Shelter is open, often lacking walls entirely, to maximize the circulation of air. Lastly, behavior is modified. People will be most active very early and very late in the day, taking a long break during the most intense midday heat.

Cold Climate

Modern humans have a very low tolerance for cold, lacking the insulation of fur and hair. Exposure of the skin to temperatures as warm as 75° F causes constriction in the blood vessels of the skin. Temperatures in the 60s increase heat production in the body, resulting in shivering. Subcutaneous fat gives a little protection. It has low heat conductivity and helps retain core body heat, protecting internal organs.

If an adult submerges a finger into freezing water, blood immediately stops flowing to the area. Continued exposure would cause the body to force blood to the area in a cyclical fashion. Expansion and constriction of the blood vessels may be adaptive because this would keep heat loss to a minimum. Once temperatures drop below the freezing point though, the appendage would freeze without the heat caused by circulation. Therefore, the most adaptive response would depend on the length and severity of exposure to the cold.

There are measurable differences among populations exposed to this type of cooling. Men of black African descent have a much lower average of finger temperature in ice water. European men have a better physiological response, and men from the arctic and high altitude populations have the most effective response. The different levels of tolerance are due to vasodilation—the body constricts and relaxes blood vessels automatically, cycling the blood flow to the affected appendage.

Cultural adaptations to cold stress involve clothing and shelter. The Inuit, again, have adapted effectively to life in a polar environment. It is not enough to wear a great deal of heavy clothing to stay warm. Working hard in those conditions would cause an individual to overheat, and wet clothing in the arctic is hazardous. The Inuit instead wear layers of clothing that capture pockets of insulating air between them, much as the desert dwellers do. Their clothing is also designed with flaps and openings that can be adjusted as needed to prevent sweat buildup.

Inuit shelters are also highly specialized. Homes are designed with an underground entry that is curved to block

incoming wind. The main living area inside is constructed on a higher level than the fireplace to maximize access to the heat and minimize drafts. When the Inuit are out hunting or fishing for long periods of time, they build igloos. These temporary shelters have thick walls of snow and ice, which provide efficient insulation. The reflective surface of the walls also helps to retain heat.

The Quechua Indians living in the cold, dry highlands of Peru do not have such effective temporary shelters. The temperature inside their temporary structures is often much the same as outside. Their most effective protection against heat loss is in their heavy, warm bedding—woven from the fur of the llamas and alpacas they herd.

High Altitude

There are a number of stresses associated with living at high altitudes. Low oxygen levels, cold, strong ultraviolet radiation, and sometimes, poor nutrition combine to create an inhospitable environment.

Oxygen deprivation, or hypoxia, is common at high altitudes. While the amount of oxygen in the air remains fairly constant more than 60 miles above the earth's surface, barometric pressure decreases rapidly with an increase in altitude. The air is less compressed at high altitudes, making oxygen less concentrated. With this, there is less oxygen available to the hemoglobin in the blood. Hypoxia can then result in increased respiration, hyperventilation, and loss of appetite or weight loss. Memory, sensory abilities, and hormone levels may also be affected.

The thinner air results in higher concentrations of ultraviolet radiation, loss of rapid surface heat, and low humidity. Hypoxia is not only a danger to human life; it reduces plant and animal life as well. Trees cannot grow at altitudes over 13,000 feet, and the limited availability of plants and animals can be a source of nutritional stress.

Scientists have studied high- and low-altitude populations of Peruvian Indians and found two main differences. Chest dimensions and lung capacity are greater in all ages of the high-altitude group, and they have a shorter average height. Studies in other high-altitude areas around the world show similar chest and lung growth patterns, but not all groups reflect relatively short stature. Nutrition in the developmental years has a great influence on adult stature, and a limited diet appears to play an important role in the growth and development of Peruvian populations.

Water

There are no human populations living under water, but there are groups that, for thousands of years, have lived by the sea. Tribal groups found in Southeast Asia are referred to as "sea gypsies," known for their exceptional diving and swimming ability. One such tribe, the Moken, live along the coasts of Burma and Thailand. Moken children are expert divers, gathering shells, clams, and sea cucumbers

from the sea floor. While most humans have poor vision under water (due to human eyes losing the ability to focus, making everything blurry and small objects very difficult to see), the Moken children can see twice as well as European children under water. A study done by Anna Gislén and her colleagues (2003) found that the pupils normally dilate under water because it is darker, but the pupils of the Moken children constrict for improved focus. It is not clear if this is a genetic adaptation in this population, or if it is an example of human acclimatization. Given their traditional lifestyle, the ability to accommodate under water may have been selected for strongly.

Nutrition

There are vast differences in the types and availability of food resources around the world. During human infancy, childhood, and adolescence, much of the energy provided by nutrients is devoted to growth. Too few calories can result in a reduction in size and a delay in maturity. Too many calories, on the other hand, can result in fat accumulation and acceleration in physical maturity. Neither result is ideal. Inadequate nutrients can impact basic biological processes and lead to disease susceptibility.

Food acquisition changed little through most of the course of human evolution. Humans were hunters and gatherers starting at least 2 million years ago, until the development of agriculture about 12,000 years ago. In general, hunting provided the smaller portion of the calories in a diet and the greater portion came from tubers, fruits, and seeds, but in any case, local environment shaped diet. Groups living near water would exploit fish and seafood while those in arid regions relied on other sources for nutrients. An exception is the Inuit, as having so little vegetation available for consumption resulted in the bulk of their diet coming from meat and fish.

The development of agriculture had a profound impact on human development. The domestication of crops provided an increased concentration of food, which expanded permanent settlements and increased population growth more rapidly. These factors, in turn, increased the spread of disease. Climate, resources, and level of technology all influenced food quality and quantity.

One of the best-known genetic adaptations to diet is illustrated in the adult human ability to digest lactose, the sugar that is found in cow's milk. The body creates an enzyme called lactase to break down this sugar for digestion. While infants and young children in all human populations can digest milk, the gene encoding to produce lactase shuts off during childhood in some populations. If too much milk is ingested after this happens, it ferments in the large intestine, causing severe gastrointestinal distress. In many African and Asian populations today, most adults are lactose intolerant, but in European and Middle Eastern populations, adults tend toward lactose tolerance.

What would cause this variation? In hunter-gatherer societies throughout the Paleolithic, milk was generally not available after children were weaned. Perhaps the body continuing to produce an unneeded enzyme affected the digestion of the new foods in the growing child's diet, making it a selective advantage to have the production of lactase turn off after it was no longer needed. Many European populations are lactose tolerant, and are at least partially descended from peoples in the Middle East who also exhibit lactose tolerance. The Middle Eastern groups tended to be pastoral or agricultural, raising cows, goats, and other milk-producing animals. They undoubtedly consumed milk and milk products throughout their lives. Selection pressures in this environment would favor lactose tolerance.

The rise of agricultural societies created an increase in food production, but resulted in more restricted diets. Agriculturalists tend to rely on one or very few staple crops, resulting in less dietary variety which can lead to undernutrition, starvation, or malnutrition. Undernutrition and starvation result from a lack of calorie intake to thrive, but malnutrition results when diets lack a critical vitamin, mineral, or protein. In underdeveloped countries, protein malnutrition is the most common form, resulting in a disease called kwashiorkor, which causes swelling, anemia, hair loss, and general apathy. A related syndrome called marasmus is caused by a combination of protein and calorie deficiency.

Malnutrition and starvation have a profound effect on reproduction. Malnourished mothers suffer from high rates of premature delivery, prenatal mortality, and delivering children with birth defects and low birth weight. Infants that do survive face retarded growth and development, along with decreased resistance to infectious and gastrointestinal diseases.

In modern times, industrial societies are coping with the result of too much food being readily available. Combined with an increasingly sedentary lifestyle, food overabundance is a source of environmental stress. If more calories are ingested than needed to maintain an active and healthy body, the excess is deposited as fat. Obesity is a growing problem in Westernized societies, making people susceptible to heart disease, high blood pressure, and diabetes.

Disease

Throughout the course of human evolution, disease has exerted a great deal of pressure on human populations, with a variety of causes and effects. Disease can be hereditary (e.g., sickle-cell anemia), metabolic (e.g., vitamin deficiency), degenerative (e.g., heart disease), from malignant cells (e.g., cancer), or infectious (e.g., malaria). Cultural factors are as critical as physiologic causes in the spread of disease.

Before urbanization, disease impact was limited. Small groups of people were constantly moving around a region with little contact between groups to spread disease. Large

settlements with high population densities greatly accelerated the spread of airborne infections such as influenza, smallpox, and measles. The domestication of animals also introduced greater risks. The type of animal raised, sanitary conditions, and the proximity of animals to humans influenced exposure. Cultural behavior also contributes to the spread of disease: Practices such as ritual cannibalism, sharing ceremonial pools, having multiple spouses, and other activities can add to the risks.

Changing the environment also influences the development of disease. Clearing forested land in tropical regions for farming leads to open pools of standing water. These still pools of open water in a warm climate stimulate mosquito breeding, creating the ideal conditions to spread malaria. Crowded, unsanitary urban conditions repeatedly expose large numbers of humans to a host of easily spread infectious diseases. Changing patterns of land use, population density, birth rates, and access to medical care all impact the environment and other species that cohabitate with us. Large numbers of animal species are endangered or extinct as a direct result of human modification of the environment.

While many species suffer from human urbanization, other species—namely viruses, bacteria, and other pathogens—may thrive. In the past, infectious disease would decimate human populations. The bubonic plague swept through Europe in the Middle Ages and wiped out a large percentage of the population. Today, cultural adaptations in the form of modern medicine protect us from past diseases, but sometimes give rise to new pathogens. The overuse of antibiotics and antibacterial health and hygiene products has caused natural selection to occur in bacteria species. Bacteria resistant to these products tends to reproduce, creating very resistant “superbugs” that are very difficult to eradicate.

Future Directions

Human beings are still evolving. Evolution is a process, not a task with a final endpoint or finished result. Evolution is increasingly complex due to our biocultural nature, with human adaptability primarily based on our culture. We can change our behavior to adapt to a new situation faster than we can respond physiologically. We can also direct our cultural evolution while we cannot control the path of natural selection.

When one considers the vastness of geologic time, our population explosion is extremely recent. The implications are complex and little understood. The extent of our agricultural technology assures we have not yet reached the limits of food production. Medical technologies have (on average) reduced infant mortality rates and increased life expectancies, though social and political factors greatly influence both.

What are the potential effects of dramatic population increases? A likely result is increased genetic diversity. As

more individuals are born, the rate of new genetic combinations increases. As the individuals mature and reproduce, the gene pool of the species increases in diversity. Increasing diversity increases adaptive ability, which would be beneficial to the species.

However, there are also a number of troublesome consequences. Humans can no longer rely on gathering enough naturally growing plants for food. We are increasingly reliant on highly industrialized agriculture. High-yield crops and farmed livestock, both bred for specific characteristics, are the norm. These engineered crops are often treated with pesticides, hormones, fertilizers, and more. There is also increasing reliance on manufactured goods. The long-term impact of industrialization can only be speculated on though, since evolutionarily, the Industrial Revolution is still in its infancy.

Conclusion

In this chapter, we have defined various types of biological and cultural adaptations to the environment. In the past, human populations were viewed in terms of race. This chapter reviewed the development of evolutionary theory, ending with the modern synthesis of genetics and evolution.

Culture plays a critical role in the human ability to adapt. We have considered physiological and behavioral adaptations to various environmental conditions, including exposure to ultraviolet radiation, heat, cold, high altitude, nutritional availability, and the influence of disease.

Clearly, population growth is one of the leading influences on current human adaptation. One result is increasing population density in inhabited regions. Urban centers have millions of people in close daily contact. Evolutionarily, these situations are brand-new, so it is difficult to predict how we will adapt. Scientists have noted correlations between the level of development of a region and instances of heart disease, hypertension, cancer, and neurological disorders. As generations reproduce, will humans select for characteristics to resist these diseases? Humans will also have to adapt to new environmental stresses they have created themselves. In addition to crowding, noise pollution, and exposure to artificial radiation, the greater consumption of resources leads to waste, pollution, and environmental degradation. Fossil fuels used for energy are affecting the environment. Deforestation also contributes to global warming. Even if the planet were undergoing a normal warming cycle, human activity appears to be tipping the balance toward a catastrophic, global climate change.

It takes a long time for humans to undergo genetic adaptation, and the characteristics that are selected for cannot be controlled. It stands to reason that all humans in our modern global society have to agree to work together to protect and adapt to the always-changing world we inhabit.

We must integrate evolutionary, biological, and anthropological knowledge in order to understand ourselves and our place in nature. By using collaborative investigative methods and critical thinking, we surely have the capacity to change the world for the better.

HUMAN GROWTH AND DEVELOPMENT

BRITTENY M. HOWELL

Northern Kentucky University and Gateway Community and Technical College

Physical anthropology, developed in the 19th century before Darwin's theories of natural selection and Mendel's work on genetics, is one of the oldest subfields of anthropology. Physical, or biological, anthropology was originally defined as "the natural history of the genus *homo*" by its principle founder, Paul Broca (1871). In 1918, Aleš Hrdlička defined physical anthropology as the study of man's variation, including racial anatomy, physiology, and pathology (p. 4). Today, biological anthropology includes the study of the mechanisms of biological evolution, genetic inheritance, human adaptation and variation, human growth and development, primate behavior and morphology, and our hominin ancestry.

Many anthropologists specializing in human growth and development are found in departments of medicine, health sciences, and anatomy (Stein & Rowe, 2005, p. 2). However, it is not just biological anthropologists who study growth and development. The development of medical anthropology as a subfield has, among many other contributions, brought attention to the relationships among growth, development, and culture. There are also countless specialties in the health care professions that concentrate on human growth and development studies.

Human growth and development is an extensive field of study. A thorough investigation of the field would include a study of measurement, mathematical models, assessment strategies, birth weight standards, fetal growth, breast-feeding, weight and height ratios, childhood maturation,

disease, and treatments, to name just a few components. Here, anthropometry as a means of quantifying human growth will be discussed, along with measurement, rates of growth, and fetal and childhood development. The history of anthropometry will also be discussed at length because it is integral to human growth and development studies. In addition, the use of statistical models, anthropometric instruments of body measurements, and standards of measurements are all important developments in the field. With this, the current and new directions of the discipline will be introduced.

Last, the chapter will cover how malnutrition is a major barrier to proper growth and development and how anthropologists use anthropometry to assess malnutrition. The four major classifications of malnutrition will be addressed, along with malnutrition's effect on growth and development, how culture can contribute to malnutrition, and examples from around the world of chronically malnourished populations. In its many forms, malnutrition remains a global health challenge around the world and an obstacle to proper growth and development (World Health Organization [WHO], 2004).

Anthropometry

Anthropometry, defined as the measurement of the body and its proportions, is one of the oldest branches of

biological anthropology. Frenchman Alphonse Bertillon first defined anthropometry in 1883 as an early system of classifying individuals. The beginnings of forensic anthropology are rooted in anthropometry because it was understood that certain measurements of the body and the skeleton could distinguish individuals.

Anthropometry as a scientific endeavor entered mainstream anthropology in the 19th century as a reliable, quantitative way to study the human body. While anthropometry has a wide variety of uses, here we are concerned with this methodology in determining health and patterns of growth and development. Anthropometric data consist of important metrics of growth and development such as stores of fat, muscle, and even calcium in the form of bone mineral. Anthropometry is a dynamic field as changes in lifestyles, nutrition, and ethnic composition of populations can lead to changes in body dimensions around the world. A major challenge for anthropologists, then, is the troubling issue of setting standards suitable for people across the globe with very diverse diets and cultural practices. To assist, a *standard* defines a recommended pattern of growth that is associated with specific health outcomes (Butte, Garza, & de Onis, 2007, p. 154). Anthropologists are continuously updating the standards and searching for new measurement techniques.

Anthropometry is important for measuring growth and health status because it is generally noninvasive. The standardized methods and relatively inexpensive medical instruments of anthropometry are also used around the world. Since anthropometry measures the body's surfaces rather than the precise growth and development of cells or organs (Johnston, 1998, p. 27), it is only one of many tools that can be used in diagnoses. This is an important distinction to make, because while abnormal nutritional status begins with cellular changes, chronic malnutrition is later manifested in altered body measurements (Devlin & Horton, 1988; Waterlow, 1986).

History of Anthropometry and Growth Studies

Human growth and development have been studied for centuries, possibly as early as 2000 BCE with ancient Sumerian references to the stages of human gestation (Boyd, 1980, pp. 2–4). By the end of the 18th century, the field of medicine had well-established vital statistics of birth and death, as well as standards of body measurements, especially those of fetuses and neonates. In 1806, Sir Charles Bell, a Scottish anatomist and surgeon, published *Anatomy and Philosophy of Expression*, which detailed the changes in proportions of the human face and head from birth through adulthood. This was remarkable work for the time because it disregarded classical ideas of facial proportions and focused on the underlying structures of the face and head (as cited in Boyd, p. 313).

Georges-Louis Leclerc de Buffon's *Natural History: General and Particular*, translated and updated in 1812 by William Smellie, contained the first comprehensive study of human growth rates from birth to maturity and served as an integral treatise on rates of growth in the 19th and early 20th centuries. This book underwent hundreds of editions and is considered by many to mark the beginning of modern anthropometry (Hrdlička, 1918).

In 1833, Lambert Adolphe Quetelet, a statistician and astronomer, published an article accompanied by drawings that acknowledged the differences between modern rates of growth and those body proportions idealized by ancient Greek and Roman sculptors. Quetelet also took into account that people's rates of growth may vary around the world and that people with certain diseases, such as dwarfism, may grow at different rates. Quetelet's 1835 landmark work, titled *Sur l'homme et le développement de ses facultés, ou essai de physique sociale*, marked the origins of the systematic and quantitative study of rates of human growth and development. His theory of anthropometry was based on the notion that the distributions of anthropometric data follow the laws of chance (Boas, 1982, p. 77). Quetelet also developed a simple but revolutionary measure that classified people's weight compared with an ideal weight-to-height ratio. The Quetelet index, more commonly called *body mass index* (BMI), is the most widely used measure of malnutrition and obesity worldwide (Eknoyan, 2008, pp. 47–51).

Sir Francis Galton was another important figure in the development of anthropometry. Like Quetelet, he began as a statistician and branched out into measuring human growth and development. Galton started an anthropometry laboratory in which he published research from 1874 until the turn of the century. His innovative research during this period included the use of "fingerprints" in criminology studies, a technique already in use in Bengal, India.

Fetal and Childhood Growth

The study of fetal and childhood growth is almost as old as the study of growth and development itself. An early article titled "Foetus" published in the *Dictionnaire des Science* (1816) by Murat reported the length of fetuses during their 9-month gestation. Quetelet used Murat's values and in 1835 constructed an equation for the total period of fetal and childhood growth (Boyd, 1980, p. 303). However, the study of child growth rates was still considered underdeveloped at the turn of the 20th century. Hrdlička stated in 1918 that the study of fetal and childhood growth was far from complete despite the progress of neonate studies in America. He recognized that studying child growth and development had an impact on the health of individuals later in life and that anthropometry was especially helpful in detecting and treating individuals with abnormal growth or pathological development (Hrdlička, 1918, pp. 20–21).

In 1876, Galton had discovered what appeared to be a correlation between weight and height for 14-year-old boys: As their height increased by an inch, their weight increased by 4 pounds (Galton, 1876, pp. 174–180). Growth status and rates of growth in children are related to later growth, composition, and proportions of the body in those individuals. These growth measures can be associated with current and future risk factors for serious diseases, such as the various forms of malnutrition.

Population Growth

Investigators of human growth and development did not recognize the degree of population differences for quite some time. Louis René Villermé was the first statistician of public health in the early 19th century to note that the height of a population correlated positively with the productivity of the soil. He found that stature was greater and rates of growth were faster in wealthier countries. Villermé may have been one of the first scientists to recognize a correlation between malnutrition and growth stunting of different populations.

Emmanuel Le Roy Ladurie also crossed an important threshold as one of the first historians to systematically investigate the geographic variation and the socioeconomic correlates of human height in 19th-century France. In a series of publications beginning in 1969, he showed that the physical stature of French soldiers born in the late 1840s correlated positively with their education and wealth. Those who were able to read and write were 1.2 cm taller than their illiterate counterparts. It was presumed that literate men came from wealthier families and spent more time and money on education and less at manual labor than did illiterate people (Komlos, Hau, & Bourginat, 2003, p. 1).

During the late 19th and early 20th centuries, anthropologists were preoccupied with measurements of skulls, cranial capacities, and facial angles of both the dead and the living, which were often used to reach racist conclusions. In fact, much of the history of anthropometry is published in books and articles about race and evolution. William Stanton's 1960 work highlights the history of anthropometry in America in the context of race, evolution, and religious debates.

In 1842, Anders Adolf Retzius introduced an equation of head-width to head-length ratios to distinguish the dolichocephalic (long-headed) from the brachycephalic (short-headed), which remained the main cephalic index used through the 20th century. Many Native American skeletal remains were unearthed and beheaded for such measurements, often used to conclude their smaller cranial capacities or differing cranial dimensions indicated aboriginal inferiority (Wade, 2000).

Instruments to measure cranial angles and capacities were in heavy use in the late 19th century by biological anthropologists. These instruments included sliding calipers, craniographs, stereographs, goniometers, a number of

instruments for studying the interior of the skull, and osteometric boards. Many of these were developed and/or modified by physician Paul Broca (as cited in Hoyme, 1953, pp. 418–419), the most prolific scientist of cranial measurements in the 1860s and 1870s.

The emphasis on cranial measurements declined in popularity in the late 1800s, and many anthropologists shifted to studying the total physical type of man. They attempted to describe and compare tribes and races as biological units, and define the normal physical status of man, “preferably the white race” (Hrdlička, 1918, p. 9). Additionally, Hrdlička stated that the paramount scientific aim of biological anthropology was the complete study of the “normal white man living under ordinary conditions” (p. 9). Contemporary anthropologists believed that “the yellow-brown or black man would serve equally well, if not better, were we of his blood and were he as readily available” for anthropometric study (Hrdlička, p. 18). At this time, “abnormal” ethnic and racial composition and admixture of populations was considered a messy situation that could not be properly studied. Some studies in the early 20th century, however, were without implications of racial inferiority. These studies provided the research essential for anthropometry to become a legitimate field of study that contributed to the larger study of human growth and development of populations (Hoyme, 1953, pp. 422–423).

Despite this change in status of biological anthropology and anthropometry, Hrdlička wrote that not many institutions were devoted to instruction of anthropometry and complained that the more “attractive” subfields of anthropology—namely archaeology and ethnology—were diverting average anthropology students away from anthropometric studies. He stated that progress of anthropometric studies at the turn of the century was stalled due to a lack of trained professionals and interested students, and that “a new competent physical anthropologist is almost an accident” (Hrdlička, 1918, p. 11).

Franz Boas, credited as a pioneer of the four-fields approach to American anthropology, was also well versed in German mathematics and applied his research to human growth rates from 1883 to 1912. He is most well-known for his research with Eskimo and Inuit populations, but he also collected anthropometric data on the Cheyenne, Cherokee, Oglalla, Omaha, Chippewa, and Winnebago tribes as well as European migrants, among others (American Philosophical Society, 2006).

Although anthropometric data between populations were gathered in the 19th century, it has been only recently that these data were systematically collected around the world. Documenting and analyzing the growth patterns of people around the world can tell us much about adaptability and the complex human-environment interactions. The greatest differences found in human growth and development are largely attributed to environmental factors, as they are between industrial and nonindustrial nations, and between wealthy and poor

groups within nations. For example, developing countries tend to exhibit low birth weight.

Current and Future Trends in Anthropometry

Today, many anthropologists specialize in biological or anthropometric studies. Current trends in anthropometry seek to understand the genetic component of human growth and development that may account for interpopulation growth differences. Anthropometric instruments and measurements have been standardized for international reference. These measurements are referred to as either *standards* or *references* in the literature. A reference describes the growth pattern of a defined population that is not necessarily associated with good health (Butte et al., 2007, p. 154). A growth reference is a table or chart that is meant to account for differences of age and sex in anthropometry (Cole, 1998, p. 80). A challenge to using a growth reference is the variability in rates of growth that occur in school-age and pubescent children. The “peaks” of weight and height are obtained over a wide range of ages, and thus a reference tends to flatten out the median curve, especially during puberty. Also, modern anthropologists are concerned with the validity of international standards because, even after socioeconomic factors are controlled for, there remain differences in rates of growth between populations of the world (Ulijaszek, 1998).

To combat some of the challenges of using international standards for all children around the world regardless of their current health status, growth charts have been made for children suffering from specific diseases. Growth charts currently exist for such diseases as achondroplasia, Marfan syndrome, sickle cell disease, and Turner syndrome that allow the growth of affected children to be judged in relation to others with the same disease (Roche & Sun, 2003, pp. 66–67). Identifying unusual growth patterns in children given their primary diagnosis can help to identify comorbidity, children with more than one disease or illness.

Height and weight are highly heritable traits, and limited data are available for interpopulation effects of genes on growth during childhood and adolescence. In an attempt to eliminate genetic or cultural bias, the WHO Multicentre Growth Reference Study of 2006 collected primary growth data from 8,440 children from Brazil, Ghana, India, Norway, Oman, and the United States. The resulting growth curves constituted new international standards for growth and development for children from birth to 5 years old (WHO Multicentre Growth Reference Study Group, 2006). Growth rates vary more for children over age 5 between populations. The current WHO growth reference for older children and adolescents is based on 1977 data and growth charts that are in need of updating. Cole (1998) states that growth references need to be updated every 10 to 15 years to capture secular trends in height and weight (p. 82). In order to produce international growth

and development standards for older children, Butte et al. (2007) outline a number of factors that need to be considered with new data collection. Samples of healthy children from around the world must take into account the environmental influences on growth of children and adolescents: proper nutrition, lack of endemic infections, socioeconomic status that does not limit growth, low levels of environmental pollution, and populations without high levels of psychosocial stress (p. 155).

Three-dimensional body imaging, an emerging trend in anthropometry, was first developed in 1973 using light sectioning. These early attempts were laborious, time-consuming, and not entirely accurate. Today’s computer three-dimensional systems have dramatically increased the usability of 3D body scans for surface anthropometry. There are currently at least four body-imaging systems in use in the United Kingdom, the United States, and Japan. The primary use of body-imaging technology is to identify distortions of body shape, such as those related to skeletal pathologies like scoliosis or facial abnormalities. Body imaging can also be used for producing prosthetics or measuring arthritic swelling and tumors, among other important applications (Jones & Peters, 1998, pp. 30–33). However, 3D body imaging has its limitations. First, the human body has external and internal factors that are always changing its form. These small-shape changes cause the computers to record an error factor that is even affected by skin and body-hair pigmentations. Additionally, no current medical computer system is able to record 100% of the body’s surfaces. Despite these current limitations, 3D imaging may become more useful in the future as technology becomes better able to handle the unique challenges of measuring the human body.

Malnutrition

Now that we have discussed how to measure the body, let us discuss conditions in which measuring the body is important for diagnosis. Anthropometric measurements are compared with international standards in order to identify diseases such as malnutrition. Malnutrition is defined as a medical condition that is caused by improper diet. Nutrition is a multidisciplinary science including food science, physiology, biochemistry, genetics, epidemiology, anthropology, and psychology. Nutrition studies are relatively young compared with growth studies and biological anthropology, which developed over the past 150 years. Today, there are four recognized manifestations of malnutrition: overnutrition, secondary malnutrition, micronutrient malnutrition, and protein-energy malnutrition:

1. *Overnutrition* occurs when nutrients are oversupplied relative to the amounts required for normal growth, development, and metabolism. The term can refer to obesity brought on by general overeating, as well as the oversupply of a specific nutrient.

2. *Secondary malnutrition* is not a direct result of the person's diet but describes an illness or condition that prevents absorption of nutrients, increasing excretion, or causes the body other damage that is triggering a response to increase its required nutrients.
3. *Micronutrient malnutrition* is caused by lack of sufficient micronutrients, such as vitamin A or zinc, in the diet that can impair normal growth and development, as well as make the individual susceptible to diseases.
4. *Protein-energy malnutrition (PEM)* is caused by underfeeding and is expressed in two forms: kwashiorkor and marasmus. Kwashiorkor is caused by a diet consisting of carbohydrates with insufficient protein intake and is identified by the potbelly-like appearance of sufferers that is caused by edema and an enlarged liver. Kwashiorkor usually presents at age 2 to 3 years and lasts for a few weeks, resulting in either recovery, if one is given proper nutrition, or death. Marasmus presents as a result of low caloric intake and is also referred to as wasting, where the sufferer has an emaciated appearance. Marasmus, more common than the fatal kwashiorkor, often develops before the child is 1 year old due to lack of breastfeeding and lasts several months.

Micronutrient and PEM malnutrition are both classified as primary malnutrition, or undernutrition. Within the category of undernutrition, varying degrees of severity are expressed as either first-, second-, or third-degree malnutrition with third degree being the most severe. In addition, some authors also use the terms *acute* and *chronic* undernutrition to refer to the length of time the sufferer has experienced periods of undernutrition. Case studies used in this chapter discuss second- (acute) and third-degree (chronic) malnutrition in populations in various regions of the world.

Effect of Malnutrition on Growth and Development

Deficiencies in protein and calories are more severe than the specific nutrient deficiencies mentioned above because protein and calories are essential for growth, health, activity, and survival. Calories provide the energy the body needs for involuntary functions such as blood circulation, breathing, and maintaining body temperature. Protein is needed in the diet because the body does not produce enough amino acids to build essential proteins—it is essential for building cells, carrying nutrients to and from the body's cells, and developing antibodies.

Anthropologists can assess malnutrition visually in a number of ways. Radiographs can indicate the presence of lines of arrested bone growth. These lines are generally believed to be caused by undernutrition. They are identified as dense lines that form at the epiphyses of long bones and can continue to form parallel lines down the bone shaft if periods of undernutrition are chronic and recurring. They occur most often in the bones of the leg, particularly the distal tibia. Regular occurrences of

dense lines may be an indication of repeated periods of undernutrition or seasonal food shortages (Walimbe & Gambhir, 1990).

Dense lines on the leg bones were first detected and described by Ludloff in 1903, but in 1921 Stettner was the first to interpret them in terms of arrested growth. Asada (1924) and Harris (1933) induced line formation in experimentally starved laboratory animals, and it was Harris's research that dubbed them *Harris lines*. The precise mechanism of line formation remained obscure until the research of Park and Richter in 1953 (as cited in Mays, 1985, p. 207). They were able to show that periods of undernutrition cause the bone growth to form transversely, instead of in normal, vertical columns. The impact of Harris lines on bones was articulated by Scrimshaw, Taylor, and Gordon (1968), who stated that Harris lines can result in permanent stunting of the skeleton (pp. 56–57) and result in short-statured individuals.

Park (1964) has stated that Harris lines do not form with a mere slowing of growth; arrested growth needs to be complete to form Harris lines (p. 823). In addition, after growth arrest, sufficient recovery from undernutrition is needed to restore bone growth (Mays, 1985, p. 209). Marshall's 1968 longitudinal study has found there is a significant correlation between periods of malnutrition/infection and the presence of Harris lines. Mays states that the probability of line formation is significantly increased by a period of nutritional stress or disease, but there is not a simple, direct correlation where Harris lines always indicate undernutrition.

Another way to assess undernutrition is by visual inspection of teeth. Dental hypoplasia can be identified as striations on the teeth that indicate severe periods of undernutrition. Dental hypoplasia is the loss of thickness of surface enamel due to periods of arrested growth during the development of the teeth; it can be viewed as a line or a groove in the tooth, called *linear enamel hypoplasia (LEH)*. LEH can be present in adult or deciduous (baby teeth) dentitions. Like Harris lines, LEH indicates a recovery from malnutrition, in that the tooth shows a period of arrested growth in the form of a groove or line and the recovering period of normal enamel deposition below the LEH. Researchers sometimes use dental hypoplasia analyses to assess adults who have experienced childhood undernutrition and its recovery and to document famine cycles.

Most commonly, individuals can also be assessed by anthropometric measurements of skin-fold thicknesses, BMI, and weight:height, weight:age, and height:age ratios. These ratios can be interpreted differently by researchers, and many studies have differing parameters to determine malnutrition. Today, the various WHO standards tend to be the reference point that anthropometric measurements are evaluated against. The WHO standards indicate measurements of healthy individuals, and deviations from these standards can aid in malnutrition diagnoses.

Consequences of Malnutrition

Comorbidity refers to the presence of one or more diseases in addition to a primary disease in an individual. Undernutrition lowers resistance to infectious diseases resulting in comorbidity. Of most concern to malnourished children of developing countries are diarrheal disease and pneumonia. Tuberculosis, malaria, measles, whooping cough, and intestinal worms follow. Measles is another concern, which results in extremely high mortality rates in the developing world because of malnutrition at weaning age and lack of vaccinations. In developing countries, childhood death rates due to measles can be up to 83 times higher than in the United States.

There is another manifestation of undernutrition called nutritional growth failure, or *stunting*. Stunting appears as children, and then later adults, come to lie outside the normal range of body weight and/or height for their age. Short-term undernutrition is indicated by wasting, and long-term, chronic undernutrition can result in growth stunts (McElroy & Townsend, 1996, p. 220). While growth stunting does not present itself with kwashiorkor or marasmus symptoms, individuals are likely to suffer from physical underdevelopment and mental impairments.

Culture and Malnutrition

Culture plays an important role in dictating food consumption, as well as defining and treating nutritional illnesses. Since food is a basic necessity that is often part of a frequently repeated family routine, attitudes and usages centered on food are intimately connected with individual and family life (Black, 1943, p. 142). Acceptable foods to eat, dietary restrictions, religious fasting, healing rituals, and many other cultural factors may hinder proper nutritional status. For example, African mothers often put children affected by diarrheal diseases on a prolonged starvation diet that causes acute forms of malnutrition, also making them susceptible to other infections (Konczacki, 1972).

Differences in the nutritional status of children in Mexico are attributed largely to cultural food styles and/or available income of a household. In many studies, it has been concluded that nutrition is better in rural *mestizos*, individuals of mixed native and Spanish ancestry, than rural Indians and worst in urban *mestizos* (Balam & Gurri, 1992; Malina, Himes, Stepick, Guitierrez Lopez, & Buschang, 1981; Muñoz de Chávez et al., 1974). Rural Indians and *mestizos* may both be extremely poor, but nutritional differences may lie in the narrow scope of foods used by more “traditional” Indian families, who rely mainly on staples such as maize and beans. However, in Mexico, Baer (1998) states that women are contributing more to household income and are thus making more important spending decisions. As this area is largely reliant on imported and store-bought foods,

the mother’s education level is thought to be directly related to the dietary status of her children. Baer goes on to state that the imported foods in the local stores are unfamiliar and that women do not know their nutritional value—a problem exacerbated by local advertising of these unfamiliar and high-priced foods as being “healthy” regardless of their nutritive qualities (p. 5). Baer’s study concluded that people of low income in the Sonoran region consume greater amounts of beans and grains while the higher income households consume more fruits, vegetables, dairy, and meat (p. 43). These findings are consistent with areas where there is a high prevalence of malnutrition and diet is restricted to local or ethnic foods such as maize and beans. These foods do not contain sufficient amounts of protein or calories. However, this is not to say that all “traditional” foods are deleterious.

In addition to providing food, in many societies the family also delivers most of the health care. Studies have shown a positive correlation between poor health outcomes and the level of stress in the home (Loustanaou & Sobo, 1997, p. 24). This implies that stressed families of malnourished individuals may not be seeking or have access to outside health care. In the following examples, it becomes apparent that different forms of malnutrition are prevalent in different areas of the world due to cultural norms of food consumption and recognizing malnutrition.

Examples of Malnutrition Worldwide

Protein-Calorie Malnutrition in Mesoamerica

In 1988, 14.2% of children under age 5 in Mexico were considered underweight, and 22.8% of them were short for their age, as stated by Long-Solis and Vargas (2005). These authors also stated that short stature is a sign of chronic malnutrition and higher risk of disease. They also conducted a survey in 1999 and found that the percentage of underweight children dropped to 7.5 and those considered to be short for their age was down to 17.7%, reduced by 22%. In addition, the authors found that half of the indigenous children surveyed were considered to be too short for their age, or stunted, with implications on their nutritional status (Long-Solis & Vargas, 2005, p. 165).

Malina et al. (1981) researched undernutrition in Oaxaca because it is among the poorest states in Mexico, with high child mortality rates. They analyzed children by weighing and measuring stature, arm circumference, and the triceps skin fold of 1,410 children 6 to 14 years of age. Excluding the children of wealthier families, the authors found that in categories of weight and stature, the rural *mestizo* children were healthier than the rural, indigenous Zapotec children. In addition, urban *mestizo* and indigenous children were found to be smaller and more underweight than the rural *mestizos*. This study shows that the move to cities does not necessarily lead to improved growth status (p. 269).

However, within chronically malnourished areas, there exist children with good nutrition; not every child in the community will be undernourished. Muñoz de Chávez et al. (1974) examined the epidemiology of good nutrition in these areas to find factors that lead to some children being better nourished than others in families of similar size and economic status. It was found that large family size was not a factor because many well- as well as ill-nourished children were from families of the same size. The difference lies in the composition of the family; those with more working adults had better nourished children while families with more children than adults did not have good nutrition (p. 224). The families with more working adults had greater income and were observed to have spent more of their earnings on food than the families of undernourished children. In addition, in support of Baer, this study found that families that were more “indigenous” had more undernourished children than the “occidentalized” families. Maize and beans were the staple foods in the families with more traditional cultural views, while the families that had more Western concepts and culture actively sought out other food items for their children (p. 225).

Secondary Malnutrition in Africa

Individuals suffering from certain diseases may become susceptible to undernutrition due to the nature of their illness. In many parts of Africa, adults and children have been found to have high rates of secondary malnutrition due to HIV infection. The undernutrition is due to decreased nutrient intake, malabsorption, and altered metabolic rates due to HIV infection. Secondary malnutrition of this nature has even been identified as the cause of death in AIDS patients due to the depletion of body mass (Gramlich & Mascioli, 1995, p. 2).

In fact, HIV-infected African children were 17 times more likely to suffer from undernutrition than uninfected children (Mgone et al., 1997). In South Africa, marasmus, or wasting, was more strongly associated with HIV-infected children than kwashiorkor. This study also found that HIV-infected children had higher rates of mortality than uninfected children (Yeung, Wilkonson, Escott, & Gilks, 2000, p. 108).

Micronutrient Malnutrition in Asia

Micronutrient malnutrition can occur in any population in which the local diet lacks one or more essential nutrients for proper growth and development. In Southeast Asia, many people subsist on a diet lacking in green and yellow fruits and vegetables that contain vitamin A. The symptoms of vitamin A deficiency begin with impaired vision and night blindness, leading to xerophthalmia and total blindness. Xerophthalmia is an ocular condition that leads to opaque spots on the eye and degeneration of the cornea. Additionally, individuals suffering from micronutrient

malnutrition may also exhibit signs of undernutrition such as wasting or stunting.

Vitamin A deficiency is considered a significant public health problem in India, Pakistan, Bangladesh, Indonesia, and the Philippines. A study in India estimated that the prevalence of xerophthalmia in children under age 6 was 8.7%. A study among children in Yemen showed that night blindness was found in 0.5% of the children. In northeastern Thailand, the prevalence of night blindness in rural areas was 1.3%, and among children of the Orang Asli of Malaysia night blindness was found in 16.0% of the children (Ngah et al., 2002, p. 88).

Overnutrition in the Western World

Overnutrition often refers to being overweight or obese, the general condition of overeating foods high in calories, surpassing the amounts needed for proper growth and development. Overweight is defined by a BMI of between 25 and 29.9 (kg/m²), and obesity is defined by a BMI greater than 30. Overnutrition is a growing problem in developed countries. In 2006, Dr. Barry Popkin from the University of North Carolina stated there were now more overweight people worldwide than undernourished people. He reported to the International Association of Agricultural Economists that the number of overweight people had topped one billion (of which 300 million are obese), compared with 800 million undernourished.

In 2003 and 2004, 17.1% of U.S. children and adolescents were overweight and 32.2% of adults were obese. Approximately 30% of non-Hispanic white adults were obese, 45.0% of African American adults, and 36.8% of Mexican American adults. Among adults age 20 to 39, 28.5% were obese, 36.8% of adults age 40 to 59 years were obese, and 31.0% of those age 60 or older were obese in 2003 and 2004 in the United States (Ogden et al., 2006, p. 1549). In England, rates of overweight and obesity are also growing, with 23.1% of men and 24.8% of women classified as obese in 2005 (The Information Center, 2006).

Overnutrition and excessive body weight in developed countries is brought on by a host of conditions. Increased sedentism, lack of exercise, increased use of packaged and processed foods, fast-food consumption, poor diet choices, and general overeating are all contributing factors. Excessive body weight is associated with various diseases such as cardiovascular diseases, type 2 diabetes, sleep apnea, certain types of cancer, and osteoarthritis. As a result, obesity has been found to reduce life expectancy.

Conclusion

This chapter examined human growth and development through two perspectives: anthropometry as a means of quantifying growth and development, and malnutrition as a major obstacle to proper growth and development

worldwide. The long history of anthropometry began in 1883, contemporaneous to the development of physical, or biological, anthropology. Anthropometry benefited the field of anthropology as it provided a quantifiable way to measure the human body and its parts.

Many scientists played a part in the development of anthropometry as a scientific endeavor, including Quetelet, Broca, Boas, Galton, and Hrdlička. These individuals developed mathematical and statistical models of human growth rates, developed the instruments of anthropometry, and set standards for anthropometric measurements and population studies. These “founding fathers” of anthropometry helped pave the way for anthropometry as a widely accepted means of measurement of the human body worldwide. But of course, this was not a totally smooth transition. The history of anthropometry was marred by a period of racist thinking and conclusions. The fields of anthropometry and biological anthropology have since distanced themselves from those racist ways of thinking and have developed into reputable fields of scientific inquiry. Today, anthropometric measurements and methods are widely accepted and practiced, and can even be used to diagnose abnormal growth patterns such as those characteristic of malnutrition.

A major barrier to proper growth and development is malnutrition. Malnutrition comes in four major forms: (1) overnutrition, (2) protein-calorie malnutrition, (3) micronutrient malnutrition, and (4) secondary malnutrition. Taken together, malnutrition remains a formidable obstacle to proper growth and development worldwide, and much of the earth's population suffers from one type of malnutrition or another. Protein-calorie malnutrition is referred to as undernutrition and manifests as wasting or stunting. Chronically stunted populations, like those of Mexico, provide an example of where culture and diet may play a part in the prevalence of undernutrition.

Micronutrient malnutrition refers to a condition where individuals are not receiving adequate amounts of the vitamins and minerals the human body needs for proper growth and development. In Asia, populations that subsist mainly on rice and have low intakes of green and yellow fruits and vegetables tend to be deficient in vitamin A. Vitamin A deficiency leads to blindness and remains a problem in certain areas of India and Southeast Asia.

Overnutrition tends to be a disease of the developed nations but is now found all over the world in people with abundant food resources. The United States remains one of the fattest countries in the world, where overindulgence has led to high rates of cardiovascular disease, diabetes, and cancer.

There are many ways to approach a synthesis of human growth and development. Much of the literature in the field today is housed in medical journals. However, biological anthropologists remain at the forefront of developments in anthropometric techniques and instruments. Anthropologists are also leaders in the study of

how culture and population differences play a part in proper growth and development around the world.

HUMAN BIOCULTURAL DIVERSITY

BRITTENY M. HOWELL

Northern Kentucky University and Gateway Community and Technical College

ANDREW SHOONER

University of Cincinnati

This chapter focuses on human diversity as seen in both culture and biology. Of the innumerable ways humans can be culturally diverse, this chapter briefly discusses just a handful of characteristics such as religion and belief, social organization, gender, sexual orientation, and even the cultural constructs of race and ethnicity. In addition, a few features of human biological diversity will be discussed such as skin, hair, and eye color and body structure and stature.

Skin color, hair texture and color, nose form, stature, and even eye color are just some of the observable aspects of human biological diversity that have served as adaptations to environmental and geographic conditions. Anthropologists strive to teach physical diversity in terms of *geographic clines*, gradual changes in physical characteristics over a geographical area. In certain geographical areas, there tends to be a co-occurrence of physical traits such as skin color, and these are often explained as human adaptations to the environment.

Lastly, human groups construct ideas of race differently. This chapter will conclude with a brief history of the concept of race in the Western world and its impact on society. The ways in which race can be constructed by each culture vary dramatically. From the very narrow ideas of four races in America to the over 500 racial classifications of Brazil, the race concept is very much in the eye of the beholder. This chapter aims to provide a broad overview of only some of the ways in which humans are culturally and biologically diverse.

Cultural Diversity

Humans express themselves in a myriad of ways—through customs, traditions, sexual orientation, religion, and many more. As such, these expressions of cultural diversity are much more prevalent than are expressions of biological diversity. *Culture* refers to the set of learned behaviors, beliefs, attitudes, values, and ideals that are characteristic of a particular society (Ember & Ember, 2009, p. 23). Since many characteristics of culture, such as customs, traditions, language, kinship, politics, and subsistence strategies, are discussed elsewhere in this text, this section of this chapter aims to briefly address aspects of cultural diversity such as religion, belief, gender roles, sexual orientation, and social organization.

Religion and Belief

It is often stated in anthropology that concern for a higher power is a cultural universal (Kottak & Kozaitis, 2008, p. 85). *Religion* has been defined anthropologically as the “belief and ritual concerned with supernatural beings, powers, and forces” (Wallace, 1966, p. 5). For many, religion is a formal institution involving regular worship in groups. With its group nature, religion creates a community of shared beliefs. The solidarity that participants experience is an important social function, but just as religion forms bonds between people, it is also divisive.

People have a sense of belonging to a religious belief system, often to the exclusion of others. Religious diversity is defined by the different ways people interact with deities and the supernatural, the types of religious practitioners that are sanctioned, and the way religion is used as an adaptation to external forces.

Communication With the Supernatural

The *supernatural* refers to the existence of entities outside the visible universe. People in every human culture believe there are supernatural forces that affect their daily lives. The founder of the anthropology of religion, Sir Edward Burnett Tylor, stated that people invented the supernatural as a way to explain events and conditions for which they had no reference to explain any other way. People needed to explain their existence, the meaning of death, and even dreams, but had no other explanation for these phenomena. He posited that the earliest forms of religion were *animistic*, involving the belief that humans, animals, and nature were imbued with spirits (Tylor, 1871/1958). This also means the earliest religions were probably *polytheistic*, in which people believed in more than one god. *Monotheism*, belief in a single god, developed later.

People around the world interact with supernatural beings and deities in different ways. These strategies include prayer, dreams, visions, rituals, and sacrifices (Wallace, 1966, pp. 52–66). Ember and Ember (2009) simplify the difference between these strategies. Prayer refers to asking the supernatural to do something on one's behalf, while rituals and sacrifices are thought to be sacred acts that will please and compel the supernatural to act (p. 195). The latter strategy is termed *magic*, supernatural techniques meant to accomplish specific goals (Kottak, 2008, p. 183), while manipulating the supernatural for harm against others is referred to as *witchcraft*. Witchcraft is often used to explain tragic or unforeseen accidents and illness in cultures such as the Azande of Zaire or populations in Papua New Guinea. Violating a taboo or acts of carelessness are recognized causes of illness or death, but witchcraft is used to explain the otherwise unexplainable.

People in cultures that believe in witchcraft also tend to believe strongly in revenge and retaliation for bewitching each other. Some anthropologists have stated that belief in witchcraft may be an adaptive mechanism that acts to level society and purge marginalized individuals from the group. People who are particularly successful and acquire much wealth are often accused of invoking witchcraft to cause their peers to fail so that they may triumph. Accusing wealthy individuals of using sorcery for ill-gotten gains often strips them of their wealth and acts to level society again (Whiting, 1950).

Shamans are intermediaries between the human and spirit worlds. These part-time religious specialists are also often associated with healing. Common techniques of the shaman include dreams and *trances*. Trance involves the

use of an altered state of consciousness in which communication with the supernatural is possible. Individuals may obtain trancelike states through exhaustive dance or running, taking alcohol or hallucinogenic drugs, or deprivation of food, water, or sleep. It has been stated that 90% of the world's societies practice religious trance (Bourguignon, 1973). Shamans are also quite common around the world, and the ability to communicate with the supernatural and cure the sick is the shaman's primary responsibility. The belief that illness is caused by the supernatural is prevalent worldwide. In 1980, George Murdock compared 139 societies and found that only 2 did not contain the belief that gods or spirits could cause illness.

Religion as an Adaptation

The purpose of religion is more than just explaining the unexplainable. Religion serves the emotional needs of people as well. People can take comfort in the fact that there is an omnipresent and all-powerful deity watching over them. A belief in the afterlife or a "better place" can also help people cope with emotions experienced due to terminal illness and death. Anthropologists recognize that all religions act to reduce anxiety and uncertainty. According to Malinowski (1931/1978), when humans face much uncertainty and danger they turn to magic. He hypothesized that when people lack control, magic and spirituality alleviate psychological stress.

Human societies around the world are divided into many major and minor religions and belief systems. The largest world religions are Christianity, Islam, Buddhism, and Hinduism. Of course, there are many others not mentioned here as well as numerous divisions within religions. Religion is a major factor in human cultural diversity because people around the world see religion as part of their identity, as something that defines them to the exclusion of other belief systems. Because people tend to be emotionally attached to their belief system, religion is often a form of conflict that divides groups of people.

Gender and Sexual Orientation

To understand diversity in gender and sexual orientation it is important to distinguish between sex and gender. *Sex* is a biological and anatomical classification referring to the chromosomes present in an individual; females have two X chromosomes and males have one X and one Y chromosome. Men and women also differ biologically in primary and secondary sexual characteristics. Primary sexual characteristics are genitals and reproductive organs, while secondary sexual characteristics are often breasts, voice differences, and hair distribution (Kottak & Kozaitis, 2008, p. 145). But there are other differences in male and female biology beyond sexual characteristics. *Sexual dimorphism* refers to those nonsexual differences such as height, weight, muscle mass, lung capacity, and endurance. Today, there is

quite a bit of overlap in these areas but these differences existed to a greater degree throughout human evolution.

As opposed to sex, *gender* refers to the cultural construct that defines acceptable male and female behavior. These gender roles vary widely across the globe. Anthropologists have identified recurring themes in gender divisions of labor, but gender roles differ with the environment, economy, and political system of societies (Kottak & Kozaitis, 2008, p. 146).

Because gender differences exist in societies, often gender stratification develops. *Gender stratification* is the unequal distribution of power between males and females that reflects their different positions in the social hierarchy.

In many societies, gender stratification favors males. According to many anthropologists, gender divisions of labor progressed into gender stratification favoring men when many societies abandoned foraging in favor of farming (see Diamond, 1987, 1998; Kottak, 2009). Previous foraging subsistence valued the work of women because their vegetable food-gathering and small-animal trapping provided a majority of the daily caloric requirements (Diamond, 1987, 1998; Lee, 2003). The shift to agricultural lifestyles involved long days of hard manual labor, in which male biological differences were favored. As men became the primary food producers, there was a shift of women and domestic tasks to an inferior status. Also, in many societies, males are granted access to the public sphere and the outside world, which gives them experiences and power over females who do not possess access to such experiences (Rosaldo, 1980; Kottak, 2009, p. 228).

However, the gender roles and expectations are too great for some. Individuals sometimes feel they do not belong to their sex or gender. In some societies, there is a place for these people whose sex and gender do not correspond, individuals who feel they are neither man nor woman.

The Third Gender

The “two-spirits” Native North Americans constitute a third gender, often referred to as *berdache*. The two-spirits has been identified in over 150 North American tribes in the historical and ethnographic literature. An interesting feature of the berdache identity is that it could include both males and females. Berdache are known for preferring work of the opposite sex and engaging in homosexual relationships with nonberdache individuals. The two-spirits identity is believed to be the result of supernatural forces that come to them in visions or dreams. The community to which berdache belong often regards them as being neither male nor female, but they are distinguished from typical male and female gender roles. Many Native North American tribal groups also attributed fertility and sexual powers to berdache shamans (Roscoe, 1998).

In the Middle East, the country of Oman has a third gender called *xanith*. A xanith is anatomically male but takes on gender roles that are in between those of males and females. While men wear white and women wear bright

patterns, xaniths wear unpatterned, pastel clothing. They also have medium-length hair and intermediate social roles. Gender roles are strictly defined in Oman and women are not to leave the home without permission. A xanith, though, may come and go as he wishes as well as interact with both men and women socially. Xaniths may have sexual relationships with women or men, or choose to remain unwed. If a xanith is involved in a relationship with a man, he will be allowed to retain his male public status as a man as long as he is also married to a woman and can prove he consummated that marriage (Wikan, 1982).

The *fa’afafine* are a third gender specific to Samoa, in the South Pacific. These individuals are born male but are raised as females. The literature suggests there are two ways in which parents may choose to raise their son as a *fa’afafine*. First, and traditionally, sons became *fa’afafine* because the couple had plenty of sons and not enough daughters. Traditional gender divisions of labor prohibited men from doing domestic work, and raising a son as a *fa’afafine* served as an adaptation to having too few daughters. Other sources state that, more recently, sons may choose to be raised and treated as *fa’afafine* because of homosexual or effeminate tendencies (Mageo, 1992). *Fa’afafine* are not always considered homosexuals or transvestites, because they retain characteristics of being both male and female; they do “women’s work” as well as sometimes taking a wife and having a family.

In contrast to *fa’afafine*, *hijras* are third-gender individuals of India, a group that includes hermaphrodites (individuals born with both male and female genitalia), eunuchs (castrated men), and homosexual men. Due to the relatively few humans that are born truly hermaphroditic, Nanda (1999) believes that most *hijras* are men who have undergone the emasculation procedure or homosexual men who have retained their genitalia. Many *hijras* state that they were born as neither man nor woman, even if they had undergone the emasculation procedure, and are united in their belief that “no greater insult is possible than to describe them as males” (Lal, 1999, p. 127). In fact, *hijras* dress and behave as females but do not try to pass themselves off as females; they make themselves known to be *true hijras*, neither man nor woman.

Hijras belong to a special caste of devotees to the mother goddess Bahuchara Mata and are traditionally employed as performers in special ceremonies, such as weddings and the blessing of newborn children. According to Hindu belief, and much like Native American berdaches, these third-gender individuals have the power to bring fertility and prosperity in traditional ceremonies. Although the presence of *hijras* at ceremonies is believed to be auspicious, Indians are somewhat fearful of these sexually ambiguous individuals because they also have the power to bring infertility and misfortune on families that do not pay them enough. Additionally, many *hijras* are homosexual prostitutes, which decreases their respect, and those *hijras* that make a living as street performers receive much public scorn and ridicule (Nanda, 1999).

All of the societies with a third gender discussed here are considered to have some form of institutionalized homosexuality. Sexual orientation is generally divided into four forms: (1) *heterosexuality*, sexual attraction to the opposite sex; (2) *homosexuality*, attraction to the same sex; (3) *bisexuality*, attraction to both sexes; and (4) *asexuality*, no sexual attraction to either sex. Although all four forms exist in many parts of the world, they are defined differently by each culture. For example, in the societies mentioned above, a form of institutionalized homosexuality exists within the purview of a third gender.

Institutionalized "Homosexuality"

An extreme example of institutionalized homosexuality can be found among the Etoro of Papua New Guinea. Here, masculinity is considered an achieved status whereby adolescent boys need to acquire the characteristics that will make them men. Particularly, this includes the acquisition of semen from older men. Beginning around age 10 and continuing into adulthood, males are inseminated orally by older men, usually their maternal uncles (Kelly, 1976). It was considered inappropriate for two youths to engage in this activity because it is believed they are draining each other's semen supply, and thus shortening their life spans.

It is also important to note that a number of Papuan societies practice *female avoidance*. Femininity is believed to be an ascribed status—something one is born with and does not need to acquire through deeds during the lifetime. This innate femininity is also considered highly polluting. Males in these regions live in communal housing with other men, hide ritual and sacred objects from women, limit all interactions with females, and even have a taboo against heterosexual intercourse. Sex with women is believed to sap the life force from men and is only to be practiced for procreation. Viewed in light of these dramatic circumstances of female avoidance, institutionalized homosexuality does not seem so surprising. The Etoro are exhibiting homosexuality not as something driven by their hormones or genes, but as a cultural tradition (Creed, 1984).

Discussions of gender roles and sexual orientation need to be viewed in light of a number of cultural characteristics, such as religious beliefs, and social and political structure. Particular practices and belief structures can often be better understood by how they trace their descent, how power is structured, and how these relations came to be.

Sociopolitical Organization

Human cultural diversity is also expressed by human social and political organization. Elman Service (1962) is well-known for his sociopolitical typology that divides human groups into the four categories of band, tribe, chiefdom, and state. A *band* is a kin-based society where all members are related through blood or marriage. Band-level societies engage in nomadic or seminomadic foraging,

or hunting and gathering. This type of society is usually egalitarian, where people enjoy relatively equal political, economic, or social status. This does not mean that all people in band-level societies are equal; egalitarian bands do have status differences based on gender and age. Bands are also based on reciprocity, an economic system that governs exchange between social equals, which serves to forge and solidify relationships. The Khoisan of southern Africa are famous examples of band-level societies that retained many "traditional" features up until the 1970s (Lee, 1979, 2003).

Tribes are sedentary or seminomadic societies living in villages that practice small-scale agriculture such as pastoralism and/or horticulture. Like bands, tribes are also organized by kin groups, although tribes claim common descent through clans and lineages. Also like bands, tribes lack formal government, but many tribes possess a village head or "big man." A big man is like a village leader that has influence in more than one village. The Yanomami of the Amazon forest and the Masai of East Africa are examples of tribal societies.

Chiefdoms are also kin-based societies. Although they do possess permanent government, kinship, marriage, descent, age, and gender are factors that divide people in chiefdoms into social classes. A person's status can be determined by achievement or ascription. Achieved status refers to the social position one holds due to hard work, perseverance, skills, or other actions and activities achieved during one's lifetime. An example of an achieved status would be an occupation, since no one is born a doctor and that status must be earned. An ascribed status is one that is assigned at birth and generally cannot be controlled or changed, such as gender and nationality. Wealth, power, and social status can be either achieved or ascribed in chiefdom-level societies. An example of a chiefdom is the Cherokee of North America.

State-level societies are political units with formal governments based on codified law with law enforcement. States also have economic, or fiscal, systems that are needed to support the large population and government officials. Compared with bands, tribes, or chiefdoms, states are large and urban based, and they exist as today's nation-states. Any contemporary country is a state-level society.

Even though Service's (1962) classification system seems clear-cut and functional, this is no longer the case. Anthropologists recognize that no category except the state truly exists today as a self-contained form. All forms of social organization exist within the larger nation-state and are subject to its laws and regulations (Kottak, 2009, pp. 108–125).

Cultural diversity exists in many forms. Diversity is expressed in the way people worship, the way they adhere to or reject gender roles and norms of sexual orientation, and even the way they are socially organized. These are just a few of the ways in which humans express diversity; others include language, kinship structures, values, marriage, folklore, ethnicity, and music, which are discussed in further

detail throughout this text. Now we turn our attention from human cultural diversity to biological diversity.

Biological Diversity

In addition to the many ways people can be culturally diverse, there also exist some biological differences. Again, human biological diversity is far less pronounced than the infinite ways in which people express themselves culturally. Anthropologists explain physical differences in human appearance in terms of *geographic clines*, a term coined by Sir Julian Huxley in 1938. Clines are gradual shifts in *phenotypes* over a geographical area. A phenotype is an observable trait or characteristic, such as skin, hair, or eye color, nose form, or stature. Biological anthropologists recognize that human expression of certain physical characteristics shifts with geographic and environmental conditions. These gradual shifts in phenotypes are not clearly delineated, and they do not separate “races” of people. Phenotypic variations are known to be adaptations to environment and geography.

Human Adaptations

Over the course of human evolution, human physiology has adapted to a number of environmental factors such as amount of UV light exposure, extreme hot and cold climates, and availability of nutritious food. Many human biological traits have taken about 4 million years to develop while others are more recent in human history. As *Homo sapiens sapiens* migrated out of Africa, they began to inhabit a wider variety of climate zones. Humans were able to adapt to many environmental conditions within the last 500,000 years of their existence. This section of the chapter aims to describe the most common environmental obstacles and how human biology was able to adapt and even flourish under these conditions.

Skin Color

Humans manufacture most of their vitamin D by absorbing and then synthesizing UV light through the skin. However, the ultraviolet light emitted from the sun that reaches the earth is unevenly dispersed. Areas around the equator are exposed to higher levels of the sun’s UV light than far northern or southern areas, and this UV light dispersal is roughly latitudinal. The UV light distribution on the earth’s surface is quite uneven and is even considered inadequate for proper vitamin D production in some regions.

Melanin is a pigment compound found in the skin. Melanin granules range in color from brown to black and protect the skin from overproduction of vitamin D. Individuals exposed to high levels of UV light express high levels of melanin in the skin, resulting in dark skin color. Individuals living in environments with little to no UV

exposure are characterized by low levels of melanin in the skin and express light skin color. In other words, the amount of melanin in the skin is related to the amount of daily exposure to UV radiation (Frisancho, 1993, p. 154).

Skin color is darkest near the equator, in regions where melanin production in the skin is elevated due to the amount of sunlight. These high levels of melanin protect the body from sunburn. Additionally, increased melanin production prohibits overproduction of vitamin D. As one moves farther away from the equator, either north or south, the clines of skin-color variation contain less melanin, resulting in lighter skin. Light skin is able to better manufacture vitamin D without much exposure to UV sunlight (Frisancho, 1993, pp. 166–167). This being said, individuals living in extreme northern or southern latitudes may still experience ill health due to vitamin D deficiency.

In the 17th through 19th centuries, many children in northern European countries suffered from rickets, a vitamin D deficiency disease. Rickets is characterized by muscle weakness, projections above the ribcage, and skeletal malformations such as bowed legs and narrow pelvis. This corresponded to a time in history when middle- to upper-class Europeans prized milky-white skin and outdoor activities were seen as “lower class.” Thus, outdoor activities were avoided unless the skin was completely covered up. Scientists then began to notice a link between rickets and sun exposure and ran some experiments to determine if this was the case. In 1919, Huldschinsky exposed children with rickets to radiation from a lamp and found that the children were cured of the disease in a few months. A few years later, in 1921, Hess and Ungar exposed children with rickets to sunlight in New York City for a few months and also found that they were healed of their lesions. Vitamin D deficiency has also been found in women in the Middle East due to cultural mandates that women be shielded from view in public. The practice of covering the skin with dark clothing in this region has led to hypocalcemia, low calcium levels in the blood, in women, which also affects the health of their children through breastfeeding (Dawodu et al., 1998).

Another factor affecting skin color is disease. Recessive genes can cause albinism, or hypomelanism, which is characterized by a lack of melanin in the skin, hair, and eyes. People born as “albinos” have white hair and skin and eyes with pink or pale-blue irises because their cells lack the ability to produce melanin. Albinism can be severe or quite mild, but individuals who cannot produce normal levels of melanin are at higher risk of skin cancer, astigmatism, optic nerve hypoplasia, and photosensitivity.

Hair and Eye Color

Ultraviolet light exposure affects not only melanin in the skin but also hair color and texture and even eye color. This is due to variation in melanin content of hair and eye pigment. Most humans have brown or black hair

that contains more melanin than red or blond hair. Likewise, different eye colors contain a different density and distribution of melanin: Blue eyes contain the least amount and dark brown eyes contain the most melanin.

Generally, dark or light skin, eyes, and hair co-occur as an adaptation to the environment. Light hair, skin, and eyes help people of northern regions produce adequate amounts of vitamin D for survival where little UV radiation reaches the earth's surface. By the same token, large amounts of melanin in the skin, hair, and eyes protect these features from overexposure to high levels of UV light in equatorial environments. However, this generalization has a few exceptions. Many European children are born with blond hair that darkens with age. Additionally, Aboriginal Australians have dark skin and eyes but light or even blond hair.

It is important to note that eye and hair color are not entirely defined by geographic clines. There are complex patterns of genetic inheritance that affect eye and hair color. Researchers know that there are many genes that affect these traits as well as admixture among the world's populations (Molnar, 1998, pp. 246–247).

Body Shape and Stature

Another environmental factor that has affected human evolution is climate. Human physiology is quite remarkable in its ability to adapt to extremely hot or cold conditions. Body build and stature appear to have been altered in order to acclimate to environmental conditions. Although generalizations can be made that body shape and stature follow geographic clines, there are a few notable exceptions. It is imperative to remember that other factors such as diet, disease, and complex genetic inheritance and variation also play a role in determining body shape and stature.

According to Fourier's law of heat flow, we know that the amount of radiant heat that can be lost in an object depends on the ratio of surface area to body mass. Researchers also know that about 67% of the heat lost in a human at rest is due to radiation (Stein & Rowe, 2000, p. 408). Taking these two facts into account, one can see how humans with a higher surface area:body mass ratio would be better at radiating heat from the body. Conversely, humans with a low surface area:body mass ratio would be better able to retain, or conserve, that body heat. We would expect to find tall and slender individuals with a higher surface area:body mass ratio in hot climates and short, stocky people with a low surface area:body mass ratio in cold climates. A good example is the Nuer of equatorial Africa. The Nuer are part of a larger group of tall East Africans, referred to as Nilotes, that all exhibit long, slender bodies with long limbs. These features are adaptations that allow their bodies to dissipate and dispel large amounts of body heat in their hot climates. Conversely, the Inuit of the Arctic exhibit short, stocky bodies with short limbs that allow them to retain body heat in their cold climates. The high amount

of subcutaneous fat that makes them "stocky" acts to insulate and help retain body heat.

Of course, there are a few exceptions to this theory. Most notably, the Mbuti Pygmies of the Congo live only a few hundred miles from some of the tallest people in the world, the Tutsi (Hiernaux, 1977). How could the world's smallest population live so close to one of the world's tallest? A possible explanation for this has to do with the humidity in the hot, steamy forests that they inhabit. The pygmy body form is completely different than that of their tall, heat-dissipating neighbors; however, they are well suited to a hot, wet climate. The high humidity of the forest makes heat loss due to radiation and sweating ineffective. Instead, pygmies compensate with a reduction of internal body heat production. This is possible with a reduction in metabolism and muscle mass, which are accomplished with weight reduction. They are light and small because they are not producing as much body heat as their tall neighbors. While their neighbors can thermoregulate with sweating, pygmies had to adapt a different mechanism to acclimate to the hot and humid regions they inhabit (Molnar, 1998, pp. 198–200). Further evidence to support this hypothesis is that "pygmoid" populations around the world, such as Negritos of the Philippines and New Guinea, exhibit a similar body form and inhabit similar high-humidity regions.

As has been demonstrated in the preceding sections of this chapter, humans display a wide range of both cultural and biological variation. However, the cultural variation of humans is much greater and more complex than their biological variation. Cultural variation includes such differences as religion, beliefs, gender, sexual orientation, and socioeconomic status in society. Cultural features can also be widely dispersed throughout the world's populations. In contrast, much of humanity's biological variation can be explained as adaptations to geographic clines. Such features as skin color, hair and eye color, and body form and stature have helped people acclimate and thrive in different areas of the globe.

While the biological facts seem to point to adaptation to environmental conditions, other factors, such as diet, disease, and inheritance, play a role in the expression of human variation. Additionally, cultural constructs of these physical differences are quite different around the world. Many cultures rely on the concept of human races to explain physical differences. Unfortunately, the concept of race in the Western world has largely ignored biological explanations for human differences and historically has aimed to classify people into discrete categories. Grouping people based on phenotypes has led to prejudice, discrimination, and segregation.

Race in Western Culture

The concept of race in Western science has changed dramatically over the last 200 years. At the beginning of the

19th century, European thought about race was influenced by two significant forces: the doctrine of Christianity and the rational philosophy of the Enlightenment. The Judeo-Christian creation story reinforced the belief that all of mankind is descended from a single couple, Adam and Eve. The theory that all humans are descended from a single pair of ancestors is called *monogenesis*.

Since before the medieval period, the perception of the universe known as *scala naturae* was strongly integrated into both religious and scientific European thought. *Scala naturae*, or the “great chain of being,” was a perspective that fit the natural and supernatural world into a hierarchical structure that paralleled medieval European society itself. *Scala naturae* placed God at the top of the universal order, nobility at the highest levels of humanity, and the peasants at the bottom. The Christian church and the medieval state used *scala naturae* as a philosophical source of authority. Following this system meant never questioning one’s station in the great chain, much less the validity of the structure as a whole. Even into the Enlightenment of the 18th century, this perspective had a strong following.

The Enlightenment

As Europe’s exploration and colonization expanded throughout the world in the 18th century, its society became increasingly aware of human cultural and biological diversity. Scientists of the time worked to put this diversity into a rational order. Carolus Linnaeus was an 18th-century biologist best known for his work creating a classification system, or taxonomy, of organisms. Contemporary biology’s current taxonomical system is based on his work. Linnaeus included humans in his taxonomy, separating mankind into distinct races, and attributing certain traits to the races as a whole. The development of racial types by Linnaeus in 1758 is perhaps the beginning of the model of race we still experience in contemporary Western culture. Another very important Enlightenment typologist was Johann Blumenbach. In his text, *On the Natural Varieties of Mankind* (1776), Blumenbach divided humanity into three major races, as well as two connecting minor races. At the center of this continuum was the “ideal” Caucasoid (Europeans). The Malaysian minor race connected the Caucasoid to the African race, and the Aboriginal Indigenous Americans connected them to Asians. There are several important aspects to Blumenbach’s approach. He argued for the influence of climate on race type, which explained how such gradation of variation could occur. The gradations of race that he observed, and his environmental explanation for the emergence of race, reinforced the possibility of a single origin of humanity.

Polygenism

European society considered its exploitation of cultures on other continents as bringing positive changes to inferior

racess. In America, however, the exploitation was not kept in far-off colonies, but was a part of everyday life. American society subjugated both the American Indians who were being driven from the land, and the African slaves being used to develop the economy. In this context, some thinkers proposed that these other races were not descended from the same ancestors as Europeans, but were instead effectively different species.

Gould outlines two key players in the American school of polygeny: Agassiz the theorist and Morton the empiricist (Gould, 1996, p. 74). Louis Agassiz was a Swiss-born comparative paleontologist and biologist at Harvard who never produced any evidence to back up his radical polygenist claims. As Gould describes, Agassiz appears to have arrived at the polygenist conclusion from visceral reaction to close contact with black slaves in America. He made subjective, racist observations and claimed them to be objective philosophical inquiry. Despite the abstract nature of his work, Agassiz was still an important figure in the polygenist-monogenist debate.

Samuel Morton (1839), an American physician and natural scientist, focused his efforts in support of polygeny on practical craniometry. He believed bigger skulls equated to bigger brains, which indicated greater intelligence (Wolpoff & Caspari, 1997). Morton sought hard scientific data to build a comparative body of evidence for inherent racial distinctions. To do this, he compared a large number of human skulls from many different populations throughout the world. His comparisons observed smaller volumes in American Indian than in Caucasian skulls. Another observation he saw as important was made in his study of Egyptian skulls, *Crania Aegyptiaca* (1844). He found a clear distinction between the white ruling class and the “Nubian” working class of ancient Egypt. Using a world chronology based on a literal interpretation of Christian scriptures, Morton dated these white Egyptian skulls to soon after creation, or around 4000 BCE. Such a find reinforced the concept of the original diversity of races, and argued that race was beyond the influence of environment, as Blumenbach had postulated. Besides conclusions brought about by his literalist-scriptural view, Morton’s more empirically based conclusions, derived from calculating cranial capacity by filling skulls with mustard seed and measuring how much the skull could hold, also produced what could only be described as bad science. His samples were chosen from both men and women, without any concern over characteristics that vary between men and women (sexual dimorphism). Also, he excluded samples that he deemed anomalous, despite the clear bias inherent in such manipulation.

At the same time that Morton was conducting racial studies biased toward fitting observable data into preconceived notions of race, scientists like Charles Darwin were working sufficiently outside the influence of *scala naturae* to produce new explanations for human diversity. Darwin’s *On the Origin of Species* (1859) implied, as a matter of

logic, that humanity is a product of divergence from a previous species altogether. Darwin's work also credited the influence of randomness; all biological variation did not follow some predestined chain of being, but rather was subject to unpredictable variability. This is a critical distinction that served to completely overturn much of the philosophy of science up to that point. If Darwin's work served to completely outmode the issue of polygenism versus monogenism, it also set in motion what would become the contemporary challenge to the concept of race as a whole.

Race as a Social Construct

Biology since Darwin has still included concepts of race determined by culture and its understanding of genetics. Despite increasingly strong arguments against scientifically definable race, the concept has not disappeared from biological study. The Race, Ethnicity, and Genetics (REG) Working Group of the National Human Genome Research Institute (2005) highlights the lack of genetic diversity among so-called races when compared with other animal species. Of the genetic variation that does exist among humans, only 5% to 15% occurs between groups on different continents (p. 521).

Grouping populations into racial or ethnic categories due to a small part of their phenotype can confuse issues that have a much more complex genetic background. While doing broad population studies does require some generalizing terms, the most specific, unambiguous types should be used. Overall, the type of study being done should determine such classifications. Clearly, how scientists have approached race over the last 200 years has been determined by a variety of forces. Researchers like Samuel Morton serve as examples that science is inevitably a product of the society that produces it. In "Darwin's Influence on Modern Thought," Ernst Mayr (2000) argues that such a relationship can exist between a scientist's work and the culture that produced it.

Conclusion

Humans vary culturally and biologically. It must be noted, however, that humans express far less biological diversity than cultural diversity, and many of these variations can be explained as adaptations. Humans striving to explain the inexplicable, to understand death and the nature of life, have invented belief systems to help them cope with the world around them. People use these beliefs and traditions to alleviate anxiety, to obtain hope, and to create equality among the believers.

In their quest to understand the world, people have classified all that is around them, putting types of animals, plants, and even people into categories they can understand. In so doing, humans have created ideas of racial groups and even gender roles and divisions that are not based on

biological realities. These classifications have often served to benefit one group and subjugate others. In many cultures, these human divisions are not accepted by all and subgroups have emerged. In Samoa, Papua New Guinea, and Native North America, third and fourth genders have emerged as a way for some people to deal with the gender divisions and inequalities that had been instituted.

People are also divided into different socioeconomic categories. Elman Service's (1962) typology aimed to order all humans into bands, tribes, chiefdoms, or states. It is well understood that these categories no longer exist as self-contained entities, but humans continue to keep themselves divided. Racial classifications have also served to group people together often under the assumption of biological differences. Anthropologists now understand that many human biological traits serve as adaptations to the environment. Traits used to classify people into races are actually advantageous characteristics for their environment. Despite this new knowledge, people continue to use racial classifications as a way to organize the people around them. Although the history of the race concept in Western culture has come a long way, it is apparent there is still a long way to go.

RACE AND RACISM

PAUL F. BROWN

Minnesota State University, Mankato

In 1977, 43-year-old Susie Phipps, a white woman living in Louisiana, decided to apply for a passport in order to take a cruise. Since she didn't have a previous passport, she went to the Division of Vital Records in New Orleans to obtain a copy of her birth certificate. In addition to her parents' names, her date of birth, and so forth, her birth certificate also listed her race, a common feature on birth certificates at the time of her birth. Much to her shock and dismay, her race was listed as "colored." Apparently, she took this news so badly that she was forced to retreat to her bed for three days. She claimed there had been a terrible mistake. She was white, she said, had white children, two white husbands, and lived in a white neighborhood.

In 1982, Susie Phipps sued the state of Louisiana to get her racial designation changed to "white." During the ensuing trial, a number of scientific experts, including physical anthropologists, were called to testify. Without exception, they all stated that there was no scientific way to determine a person's race, and that the concept lacked scientific validity. The judge, as it turns out, was in complete agreement with the scientists and yet he ruled in favor of the state and threw out the suit. Why?

It turned out that Susie Phipps was the great-, great-, great-, great-granddaughter of a black slave who eventually married a Frenchman by the name of Joseph Greggerie Guillory, Phipps's great-, great-, great-, great-grandfather. According to a Louisiana law passed in 1970, any person with at least 1/32 "Negro blood"

was black. Therefore, the judge ruled that Susie Phipps, a woman who had lived her entire life as white, whose race on her children's birth certificates was listed as white, whose friends and family members saw her as white, was legally black. Culture, it seems, trumped science.

This story underscores the ongoing confusion and tension in our society over the very meaning of race, its validity as a concept, and its application. Anthropology is not immune from this tension. Since Sherwood Washburn's (1963) "new physical anthropology" of the 1950s, most anthropologists have rejected the concept of race as a scientifically valid means of describing human biological differences. Nevertheless, the notion of race still persists within both anthropology and the public. In order to sort out this confusion, we need to understand exactly what is meant by the term *race*, and how it is understood and used by different segments of society. This seemingly contradictory view of race is made explicable through an analysis of the history of the concept, beginning with its use by the ancient Greeks and continuing through the development of science in Western thought. Our ongoing ambivalence toward the concept of race is evident in the ways in which we, as anthropologists, teach our students about race in particular, and biological variability in general. Race epitomizes the tension within modern anthropology between those who focus on our diversity and those who emphasize our sameness.

According to the *Oxford English Dictionary* (1989), *race* is defined as

each of the major divisions of humankind, having distinct physical characteristics; . . . a group of people sharing the same culture, language, etc.; an ethnic group; a group of people or things with a common feature; a distinct population within a species; a subspecies. (Vol. 13, p. 69)

This definition includes references to both cultural and biological characteristics. This mixing of the biological with the cultural is a basic component of racism and has a long history in Western thought. In addition, the definition implies that different races are identified with essential, inherent tendencies or behaviors.

History of the Concept of Race

Greek Essentialism

The notion that different races not only look different, but also behave differently as a result of their physical differences, can be traced back in Western thought at least as far as the writings of the ancient Greeks, particularly to the humoral model of existence proposed by Hippocrates (460–377 BCE) in his *Discourse on Airs, Waters, and Places*.

In Hippocrates's humoral model, all living things are imbued with an *essence* that determines their physical characteristics and nature. The essence of an organism not only determines its physical traits, but also, in the case of animals, determines temperament (aggression, passivity, etc.), intelligence, and behavior. The essences are the product of the exact combination of qualities, elements, humors, and associated temperaments. All living things have the four humors of yellow bile, blood, black bile, and phlegm; it is the exact ratio of these humors in an organism that ultimately determines its physical traits and temperament. Once the first member of a particular group arises, a template is created from which all descendants are derived. For example, a dog is a dog because it contains dog essence. The first dog arose in a particular part of the world and the qualities and elements of this dog resulted in a preponderance of one of the four humors with its corresponding temperament. Once the first dog came into being, all subsequent dogs inherited the same essence, thus determining their dog features and behaviors. These essences are immutable; thus all dogs will remain basically the same indefinitely in physical composition and temperament. All living things were also listed along a scale, the "great chain of being," which ranked organisms from the most godlike (humans) to the least godlike (insects, etc.).

The humoral model was also used to explain humans. Unlike dogs, however, the Greeks saw humans as made up of a number of distinct groups, each with its own physical features, temperaments, and corresponding behaviors. Thus, some humans, because they originated

in an environment characterized by the qualities of "hot" and "moist," resulting in the element "air" and the humor "blood," have the temperament of bravery, aggression, and militancy; others, who originated in a region where "moist" and "cold" qualities resulted in a predominance of the element "water" and the humor "phlegm," are passive and lethargic. All descendants of these original human types would inherit these same immutable features and temperaments from their parents.

Different human types were also ranked differently along the great chain of being. Thus, some people were inherently superior or inferior to others. During the medieval period in Europe, the Greek humoral model was kept mostly intact; the only significant change was in terms of origins. Instead of influential environmental factors such as air, water, heat, cold, and so forth, the church substituted the God of Genesis as the creator of all living things. However, the basic-essentialist assumption that different types of animals, including different human groups, were unchangeable remained the same. The medieval Europeans also adopted the notion of the great chain of being, ranking different types of people into higher and lower groups. This ranking was held to be unchangeable; one's position on the hierarchy was assumed to be part of God's divine plan.

"Scientific" Racism

One of the first Europeans to explicitly apply the humoral model to different racial types was Jean Bodin (1530–1596). In his *Methods for Easy Comprehension of History*, Bodin associated people of different skin colors with different humors. Thus, whites (Europeans) had a predominance of the humor phlegm; yellow-skinned people (Asians) had a predominance of yellow bile; blacks (Africans) were assumed to have more black bile; and red-skinned peoples (Indians) were associated with the humor blood. Following the Greek model, Bodin also associated a particular temperament with each of these peoples based on their predominant humor. Indians (red skin, blood) were savage and warlike, while Africans (black skin, black bile) were lethargic and slow-witted. Asians (yellow skin, yellow bile) were cunning and devious, and Europeans (white skin, phlegm) were reflective and rational. Thus, the relationship between racial features and behavior, which was commonly assumed in the minds of most Europeans, became officially established in Western thought thanks to the work of Jean Bodin.

Following Bodin, the work of Carolus Linnaeus (Carl von Linné, 1707–1778) lent further scientific credibility to the racist association between race and behavior, including things like personality, intelligence, and morality. In his famous work, *Systema Naturae*, Linnaeus created the first formal system of taxonomy, the classification of plants and animals. Expanding on the work of John Ray, Linnaeus extended scientific nomenclature to all known life-forms, including humans. Organisms were grouped into categories

(taxa) based on similarities in the form and function of traits. However, this was not an evolutionary scheme. All species were viewed as permanent and immutable. Each was made by the creator in its present form and would remain so indefinitely. This applied as much to the different types of humans as it did to any other organisms. While Linnaeus put all varieties of humans into the same genus and species, *Homo sapiens*, he did assign different races to different subspecies categories. Thus, Africans were given the name *Homo sapiens afer*, while Europeans were called *Homo sapiens europaeus*. In keeping with Bodin's use of the Greek humoral model, Linnaeus assigned different temperaments or behavioral characteristics to each racial subspecies. For instance, *Homo sapiens afer* was "ruled by caprice." He described African women as "women without shame, [whose] breasts lactate profusely." *Homo sapiens europaeus*, on the other hand, was described as "rational" and "ruled by customs." Because of his reputation among the naturalists of his day, Linnaeus gave scientific credibility to the idea that people could, indeed, be divided up into races, and that these different races possessed different inherent and unchangeable abilities and potentials. Furthermore, these races could be ranked in terms of behavior and ability: Europeans (whites) were the highest, followed by Asians (yellows), then Indians (reds), and finally Africans (blacks).

Blumenbach's Skulls

Linnaeus's work sparked a great deal of interest in classifying all manner of plants and animals, including humans. Among those who were caught up in the taxonomy frenzy was a naturalist by the name of Johann Friedrich Blumenbach (1752–1840). He, too, assumed that people could be easily and accurately divided into essentialist racial categories. However, unlike his contemporaries, Blumenbach wasn't content to merely create racial typologies without reasonable data to support them. He looked at skin color and rejected it as the basis for racial types, noting that greater color variability existed within types than among them—an observation that turned out to be quite prophetic. Instead of looking at externals, such as skin color or hair texture, Blumenbach focused his work on the many characteristics and landmarks of the skull, taking dozens of measurements and observations. These data led him to create five racial types. While still essentialist in character, his work was less subjective than his contemporaries. In fact, some of the measurements Blumenbach developed are still used by forensic anthropologists today in order to establish the biological affinity of human remains. Because of his pioneering work in osteometrics, some people refer to Blumenbach as the father of physical anthropology.

Polygenesis: Beyond Racial Typologies

An underlying current that ran throughout much of the research on race was that different races represented, at the

very least, different subspecies or perhaps even separate species of humanity. The latter view is known as *polygenesis*, the belief that different races have entirely separate biological lineages. Perhaps the most explicit use of polygenesis in explaining different racial types is found in *Types of Mankind* (1854), by Josiah Nott and George Gliddon. Nott and Gliddon argued that each racial type had its own independent evolutionary line proceeding through a series of animals to its modern racial form. Among other things, this work gave scientific legitimacy to the common belief that races should not crossbreed; the result was dangerous to both parties involved. It also made it easier to justify the ranking in the chain of being for the races since they were actually separate species.

The Darwinian Revolution

In 1859, Charles Darwin published *On the Origin of Species*. The impact of this work on the thinking of people about life was monumental. The belief in the fixity of categories in nature, having existed at least since the Greeks, was shown to be incorrect. Instead, Darwin described a world in constant flux. The effects of natural selection reshaped every generation. Our taxonomic categories were fleeting and arbitrary; there was nothing essentialist or permanent about them.

These ideas transformed the way we look at the world; however, there were some notable exceptions. Darwin himself couldn't imagine how racial features could in any way be considered as promoting fitness. After all, what possible difference could the color of one's skin or the shape of one's nose make to survival and reproductive success? Darwin's failure to consider racial features as part of the adaptive process in humans led him to assume that these characteristics were not merely irrelevant but also permanent. It is hard to miss the irony that the very person who overthrew the notion of fixity in animals added to the prevailing ideas that racial types were permanent. It wasn't until his volume *The Descent of Man* (1871) that Darwin himself finally recognized the possibility of adaptive value in different racial traits. By then, of course, the damage had already been done and, consequently, the publication of Darwin's *Descent* had little impact on racist views.

Francis Galton and Eugenics

The failure of Darwin's work to overthrow the essentialist views of race gave rise to a number of so-called evolutionary schemes to address the race "problem" in England. One of the most insidious of these was *eugenics*.

Francis Galton, a cousin of Darwin's, began the eugenics movement in the 1880s as a way of addressing what he called "the race-destroying problem of heinous blood." Like most racial essentialists, Galton firmly believed that superior behavior was determined by superior biology, and that

those individuals who behaved “poorly” did so because of inferior biology. He believed that if the “superior races” (i.e., upper-class British) could produce more offspring than the “inferior races” (the lower classes), England could do away with all manner of ills (e.g., crime, prostitution, insanity, and drunkenness). However, he observed that in spite of their superior biology, the upper classes reproduced at a slower rate than the lower classes. The reason for this circumstance, he reasoned, was the tendency of upper-class men to seek out heiresses as marriage partners. It was the “bad blood” in such families that caused the lower rates of reproduction among wealthy families.

Galton assumed that upper-class families with “good breeding” would surely have produced male heirs to titles and lands; heiresses would only be found in families of lesser breeding who were incapable of producing male offspring. Not only did these inferior families fail to produce male heirs, but also they had less reproductive success overall compared with families of “good blood.” Thus, heiress blood was “race destroying.”

Galton’s solution to the problem was “positive” eugenics, the deliberate matching of children for marriage from families of good blood. Galton reasoned that if a registry could be created listing superior families, then prospective brides and grooms for one’s children could be selected from this list, assuring healthy and plentiful offspring for the upper classes, and reducing the likelihood that the superior races would be degraded by marriage to people from the inferior races. And since behavior follows biology, the greater the number of children produced from these matches, the greater the number of properly behaved people in society.

These registries proved difficult to construct; genealogies were often vague, lacking in completeness and hard to verify. Galton’s response to this setback was the promotion of “negative” eugenics: the active reduction in fertility among the lower classes. Social programs were established that prohibited certain people from marrying, and in extreme cases (i.e., prostitution, criminal behavior, insanity, “feeble-mindedness”) people were involuntarily sterilized. This was all done in the name of improving society. Since crime and other similar behaviors were caused by inferior biology, the only way to solve the problem was to reduce the number of people of inferior biology in society. Eventually, the majority of the population would be comprised of people of good breeding, thus creating a utopian society in which bad behavior was eliminated.

By the early 1900s, eugenics spread from England to other European countries and to the United States. In the United States, class distinctions were less marked than in England, so ethnicity replaced class as the main marker of social/biological rank. Each new wave of immigrants to the United States was assigned the bottom rung of the latter. Thus Italians, Irish, Jews, and Germans each took their turn as the most despised group.

Eugenics received much support from the new science of genetics that had sprung from the 1900 rediscovery of

Gregor Mendel’s work. Heredity was being seen more and more as something relatively fixed and immutable. This idea of “hard” heredity gained favor as the notions of “soft” heredity, based on the work of Jean-Baptiste de Lamarck, were discredited. Environmental influences on behavior were minimized as the pendulum swung strongly to the “nature” side of the nature-nurture debate. People are the way they are in their ethnicity and behavior because of their genes. Change was only possible through the long, slow process of mutation.

Franz Boas

The first real challenge to the claims of the eugenicists came from the work of Franz Boas, the father of American anthropology. Boas was the subject of scorn and even censure from his scientific colleagues for questioning the connection between race and behavior. The “hard” heredity of the eugenicists implied that one’s behavior (ethnicity or culture) was essentially determined by one’s biology. In the absence of any real adaptive explanations of so-called racial features, it was assumed that racial features and their associated behaviors were fixed. This represented a clear example of preevolutionary, essentialist thinking.

In a landmark article on eugenics published in *The Scientific Monthly* in 1916, Boas systematically lays out the problems with the eugenicist argument. He begins by saying how wonderful it would be if we could, indeed, rid humanity of all ills through the control of reproduction in the same way that desired characteristics are bred in domesticated animals. He follows this with a series of brilliant syllogisms pointing out that no firm connection between biological features and any sort of temperament, intelligence, or behavior had been established, only assumed. He also argues that even if such a connection did exist, then we would be hard-pressed to decide which features would be considered desirable under all conditions, and which may be subject to fad and fancy. Imagine, he said, selecting for a type of personality or talent that may be considered important today, only to have such a trait become less desirable in the future. Furthermore, the future may bring problems that call for certain behavioral traits that aren’t necessarily seen as useful today. By reducing biological variability, we reduce our adaptability.

The most prescient part of Boas’s argument is his discussion about the role of the environment, both physical and cultural, in shaping behavior. This is where he lays the foundation for anthropology’s separation of biology and cultural behavior. Culture, he argues, is not biology dependent. Indeed, it is wholly the product of one’s social and physical environment, along with the specific history of the society to which it belongs. This is such a part of the anthropology worldview today that we take it for granted. However, in 1916, this was seen as revolutionary, even heretical. It was a “rejection of modern science.” “Modern science,” of course, meant eugenics in particular, and genetics in general.

Boas was not content with merely suggesting hypothetical views to counter eugenics. He was first and foremost a scientist, and he recognized the importance of empirical evidence to support his ideas. He soon began a study of recent immigrants to the United States. He began by looking at Sicilian immigrants in terms of two factors: (1) cranial features, such as cephalic index, and (2) cultural behavior. He had two major goals in mind. First, he wanted to test the assumption held by the eugenicists that racial features, such as the cephalic index (a simple index derived by comparing the length of the skull with the width of the skull), were permanently linked with behavior. Second, he wanted to examine the connection between environment and behavior. He tested his idea that biology and culture were independent by comparing the cultural behavior of immigrants and their children upon arrival in the United States with their behavior after 10 years in residence. His findings were surprising, even to Boas. As he expected, the behavior of the Sicilians after 10 years in the United States was markedly different than their behavior upon arrival. This cultural change was most profound among the children, many of whom behaved in ways identical to children whose families had been in America for generations. Clearly, cultural behavior was the product of the environment, and was independent of biology.

The part of the study that was most unexpected, even to Boas, was that even the biology was subject to change. Cephalic index, once thought to be a static identifier of race, also changed among the Sicilian immigrants. Again, the most profound changes occurred among the children. Even biology, it seemed, was subject to modification from the environment.

Sherwood Washburn and the New Physical Anthropology

Boas and his students separated the racist connection between biology and culture for all of anthropology. However, physical anthropologists continued in their efforts to categorize human biological diversity. This search for “types” was not unique to physical anthropology. Cultural anthropologists described “Apollonian” and “Dionysian” cultural types, while archaeologists constructed any number of typologies based on pottery design or lithics. All of these involved the creation of an archetype through the arbitrary selection of characteristics deemed essential to a particular type, and the subsequent search for cases that fit the archetype. As in all essentialist approaches, the defining characteristics of a particular type were fixed and stable.

In the 1950s, physical anthropologist Sherwood L. Washburn changed the way we look at biological diversity. He argued that the search for racial types is not scientific, and actually ignores the dominant paradigm in all of the life sciences—evolutionary theory. One of the most important implications of evolutionary theory is that life is

in a constant state of flux. There are no static, unchanging elements. Even the taxonomic category of species is a temporary designation of a breeding population. In applying this to physical anthropology, Washburn (1951) said, “[Anthropology] must change its ways of doing things to conform with the implications of modern evolutionary theory. . . . There is no way to justify the division of a breeding population into a series of racial types” (p. 298).

Racial Typologies: Essentialist View

Racial types, like all essentialist concepts, are based on the assumption that certain core features exist almost exclusively in one type and not in another; each type is discrete and relatively stable. This is precisely why Washburn recognized that racial typologies are nonevolutionary in their form. All humans belong to a single species, *Homo sapiens*. Any biological differences we can observe among individuals or breeding populations (demes) must have arisen after the dawn of our species. This is evidence that humans, like all species, are in a constant state of change, in terms of both our biology and our culture. So-called racial traits, therefore, may have come about as adaptive responses to the different environments humans encountered as we expanded out of Africa some 100,000 years ago. This shifts our focus in physical anthropology from searching for static, essential features of racial types, to evolutionary explanations of biological diversity.

The American Anthropological Association (AAA) (2007) permanent Web site on race, *Race: Are We So Different?* (<http://www.understandingrace.org>), shows why essentialist views on race are arbitrary and nonscientific. Take, for example, *stature*. If we observe three people of different heights, as illustrated in Figure 7.1, we can easily divide them up into three types: short, medium, and tall.

However, as we add more and more people to our sample, we quickly realize that our essential types are arbitrary and lacking in scientific validity. As our sample size grows, as shown in Figure 7.2, we see that what we thought were fixed types actually are part of a graded continuum from short to tall, with no obvious or justifiable points to divide one type from another.

A similar situation exists with attempts to divide people up by skin color. If we start with three, as shown in Figure 7.3, we can easily create a typology comprised of light skin, medium-color skin, and dark skin.

Here, we see three actual groups: the Chöpi, the Jirel, and the Dutch. Each is supposed to represent a skin-color type. However, as Figure 7.4 shows, we encounter the same problems that we did with stature when we expand our sample size to include many more people from around the world.

Once again, we can find no scientifically valid point to draw our lines to separate this continuum into skin-color types.

What these examples illustrate is that the biological differences we observe in people today represent *clines*, not types. Clines are gradual, usually continuous changes in the representation of traits from one area of the world to another. Skin color is an excellent example of a cline. As we move from the tropical areas of the world, where we find the darkest skin shades, to more northerly latitudes, skin shades get progressively lighter and lighter. There are no breaks or jumps in skin shade where one might reasonably draw a line.

Washburn pointed out in his presidential address at the American Anthropological Association meeting in 1962 that because “races” are open-ended systems that blend seamlessly into one another, the number of races one proposes depends on the purpose of the classification (Washburn, 1963). In other words, unless one specifies why a particular group does or does not have a particular trait, the classification has no meaning and leaves open the possibility of creating an almost limitless number of races.

Recent genetic research demonstrates that there are very few genetic characteristics that are unique to any particular breeding population. Rather, the majority of genetic varieties (alleles) are found in all human populations. The difference is in the frequency in which they are distributed from one population to another. Again, skin color provides a good example of how this works.

Pigmentation in the skin is determined by the amount of melanin. Melanin is produced by *melanocytes*, cells located in the bottom layer of the skin’s epidermis. The more melanin produced, the darker the pigmentation. All people, no matter what their skin shade, have about the same number of melanocytes. The differences come from how active the melanocytes are. The activity of the melanocytes is determined by the action of two genes that turn on the chemical activity that produces melanin. The differences in skin shades aren’t due to discrete differences in biology from one group to another. Rather, the biological mechanism for pigmentation is found in all groups. As we move from the tropics to Scandinavia, the melanocytes produce less and less melanin. Surprisingly, all of this is related to the amount of ultraviolet radiation striking the earth (more at the equator and less at the poles), the synthesis of vitamin D, and the absorption of calcium.

Finally, racist views of humanity have been discredited through worldwide comparisons of DNA. The old essentialist view separated people into distinct groups genetically with only the slightest amount of overlap between groups, as seen in the Venn diagram in Figure 7.5. However, the actual genetic picture looks quite different. As shown in Figure 7.6, humanity is all about overlap in DNA. The most salient feature about our species in terms of biological variability is our sameness. The differences are only minor adjustments to different environments made by our ancestors as they moved around the globe.

A couple of other quick points about racial typology: In addition to the fact that most biodiversity exists in the form of clines, we should also note that the traits used to categorize

people into races are often arbitrary. Everything from skin color to the shape of the nose has been offered as “essential” elements of a race. Furthermore, the traits that are used to define races often don’t go together. A particular skin shade will vary independently of nose or ear shape. This is something that Blumenbach realized over two hundred years ago.

While physical anthropologists have abandoned the search for racial types, they certainly haven’t lost interest in human biodiversity. On the contrary, Washburn’s advice to use evolutionary theory to explain the frequency and geographical distribution of different phenotypes has led to the creation of a vigorous and productive research agenda in physical anthropology. Such topics as lactose tolerance among certain adults, the persistence of sickle-cell anemia and related conditions, differences in immune responses, and differences in lung and vascular capacities in certain parts of the world are just a few of the many issues being investigated today in biodiversity studies.

Race and Intelligence

Despite decades of research on intelligence by modern psychologists and other scientists, some segments of our society still cling to the persistent belief that some “races” are inherently more intelligent than others. If this were merely the view of white supremacists or other hate groups, then it could be easily ignored. Unfortunately, publications from some academics purporting to show racial differences in intelligence continue to show up on a regular basis. These publications tend to rely on two things to “prove” their case: IQ scores and standardized-test scores.

Modern psychologists are quick to point out that what one measures in an IQ test is as much about social environment as it is about innate intelligence. If intelligence were only genetically determined, then a person’s IQ should remain stable throughout life. However, we know that IQ can change depending on the social or intellectual environment in which one lives. Furthermore, psychologists recognize that all instruments such as IQ or aptitude tests contain a certain amount of cultural bias that will tend to favor test takers from the same cultural background. In order to compare two *groups* in terms of intelligence, we would first need to show that the individuals who comprise those groups are essentially identical in terms of background, cultural affiliation, and social experiences. It’s fairly easy to demonstrate that certain groups in our society, because of discrimination, have not shared equally in terms of wealth, education, and other benefits.

In the same presidential address mentioned above, Washburn (1963) described a study that compared the standardized-test scores (mean scores) of blacks and whites in the North and the South. It found that black children in the North scored better than white children in the South. Rather than accept the obvious conclusion that Northern schools were expending more educational effort

than Southern schools, those who saw things in racialist terms argued that all the “bright” black children had migrated to the north, so these represented an innately more intelligent group than the white children in the South. However, Washburn (1963) pointed out that the mean score of Northern whites was also higher than that of Southern whites. Washburn quipped, “Are we to believe that the intelligent Whites also moved to the North?” (p. 529).

Should We Abandon the Concept of Race?

Human traits exhibit continuous grading rather than discrete boundaries, making it scientifically impossible (or at least invalid) to group people into meaningful units called races. Furthermore, a person’s biological ancestry is the result of fluid adjustments over time to changing environments. The traits we might use today to classify people into races may be quite different or even absent in the future. Given these facts, should we simply discard the concept of race from anthropology? The resounding answer in the anthropological literature is “yes and no.” In order to untangle this paradox, we need to look at who is using the term *race* and exactly how they are using it.

Forensic Anthropology

Most anthropologists have no quarrel with the notion that race has no biological validity in terms of defining distinct groups based on physical attributes. However, there is one area in physical anthropology where the idea of classifying people into types is still very much alive and well: forensic anthropology.

Forensic anthropologists are charged with identifying individuals in a medicolegal context. They are called upon by law enforcement to help identify human remains that are too skeletonized to be analyzed using conventional soft-tissue methods of identification. Their skills are used in homicide cases, disasters such as plane crashes or fires, and any situation where osteological analysis may shed light on the deceased. Forensic anthropologists examine skeletal remains to determine age at death, sex, and any signs of trauma or disease that might affect the skeleton. In police cases, they look for any unique characteristics that may help in identifying the deceased, and they attempt to determine time, manner, and cause of death.

While anthropologists may balk at the idea of putting people into racial boxes, this sort of information is of great value to law enforcement. An obvious question one would ask, when trying to determine the identity of a person whose skeletal remains have been found, is about race: Was the individual black? White? Asian? It falls on forensic anthropologists to try to provide this information. The way they do this is through the careful measurement of dozens of features of the skeleton, in particular the skull. Decades of analysis of skeletons of people of known ancestry have enabled forensic anthropologists to identify

a constellation of osteological features that vary by ancestry. No single feature is sufficient to make a designation about ancestry, but taken together these features are highly predictive of a person's biological affiliation. Dr. George Gill (2000), a forensic anthropologist, reports an accuracy level of over 80% using new and traditional methods. The anthropology department at the University of Tennessee, Knoxville has taken the osteometric information from many thousands of individuals of known ancestry and put together a useful program called FORDISC, a computer program that can help individual researchers assign biological affiliation to a specimen of unknown ancestry. While FORDISC has been criticized for providing false identifications, most of these cases have been shown to be the result of user error and not due to the program itself.

Conclusion

Outside of the rather narrow confines of forensic anthropology, shouldn't we abandon the outmoded and dangerous term *race*? If we simply stop talking about race and instead talk about individuals, then couldn't we achieve a race-blind society and put an end to racism? After all, race is not a valid way to describe human biological variability, and, at best, it is simply a cultural construction.

Dr. Alan Goodman, former president of the American Anthropological Association and a noted authority on the concept of race, firmly supports the idea that race is not a valid way of conceptualizing human biodiversity, but he also rejects the notion that "race" is a mere cultural construct that has no real impact on people's lives. He calls race "a lived experience" that can have devastating effects (Goodman, 2006). People discriminate based on appearance. This includes such things as skin color. But overwhelmingly, discrimination is based on cultural or ethnic indicators such as language, dress, social habits, and so forth.

We tend to separate people into ethnic categories, but we often use racial terms to identify these categories. Thus, one talks about "black" culture or "white" culture as if the color of one's skin is somehow connected to one's behavior. While the connection is clearly not genetic, it is real nonetheless. An example can be found in the 2008 presidential election when then-candidate Obama was criticized by some leaders in the African American community for not being "black enough." Clearly, they were not talking about his skin color, but rather his lived experiences as a person of color. Obama didn't go through the "typical" black experience of discrimination and the social injustice that goes along with it, because he was raised by a white family in biologically and ethnically diverse Hawaii.

Using racial labels like "black" or "white" as shorthand for ethnic experiences may be useful and even necessary for Americans when talking about race. However, it also keeps alive the centuries-old essentialist notions about race and behavior. As long as we keep using biological terms to describe cultural characteristics, it may be inevitable that

we will continue to see the connection between the two as inexorable. Can we find a way to talk about the social injustice caused by racism without using racist terminology? That remains one of the biggest challenges facing our society today.

DNA AND GENETIC ENGINEERING

JOHN K. GRANDY

Lee Medical Associates, Dunkirk, New York

Anthropology has studied humankind in numerous capacities: morphologically, culturally, archaeologically, and philosophically. However, the knowledge gained by understanding the DNA molecule has increased our knowledge of humankind on a genetic and molecular level. In addition, with the completion of the Human Genome Project in 2003, the entire human genome has been sequenced and is now available for analysis. This is important to anthropologists because it allows the field to go beyond the bones and into the DNA.

Genetic engineering may provide scientific ways to explore the chemical record provided by DNA. Anthropologists will be able to view and explore the past, the present, and conceivably the future of any species, including our own, by the scientific examination of DNA. In addition, understanding DNA and genetic engineering will potentially provide anthropologists with analytical data to explain our genetic relationship to other primates. This type of data will serve to strengthen and further clarify earlier DNA homology studies that have already provided empirical evidence of our close genetic relationships to chimpanzees and gorillas. In the future, this technology can be used to determine our genetic relationship to Neanderthals and Cro-Magnons.

The genetic study of *Homo sapiens sapiens* is possible because the DNA molecule provides a chemical record of humankind's genetic makeup and evolutionary history as a process of time. This chemical record will allow examination because DNA is present in every cell in the body and is

universal to all life-forms on this planet. All current conglomerations of DNA in all living species are a result of genetic variation and natural selection within populations throughout ongoing organic evolution.

An Introduction to Biotechnology and Genetic Engineering

The two terms *biotechnology* and *genetic engineering* are used somewhat synonymously. However, the two have different origins and initially they had slightly different applications. Biotechnology, by conventional definitions, is the intentional alteration of other living things (i.e., plants and animals) for the purpose of benefiting humankind. This has been done throughout the history of our species. In fact, the word *clone* is Greek for "twig," because small sprouting twigs were removed from mature trees and planted in order to grow new trees.

Examples of early biotechnology include breeding animals that have desirable characteristics in order to increase the chances of producing offspring with those characteristics. It was noted even as far back as ancient times that if a fast male horse was bred with a fast female horse, most of the offspring would be fast.

Another example of early biotechnology would be the intentional pollination of specific crops that are more disease resistant and yield better fruition, while purposely not pollinating other crops lacking those desired characteristics.

Historically this method of biotechnology was limited to controlling what type of particular male specimen bred with a particular female specimen in an attempt to procure

favorable genetic characteristics in the resulting offspring. In many ways, these practices were an early form of eugenics (see Box 8.1).

BOX 8.1 EUGENICS AND EUTHENICS

Eugenics is considered the use of genetic measures, such as selective breeding, to make improvements to the genetic characteristics of a population. The word *eugenics* was originated by Sir Francis Galton (1822–1911), in his book *Hereditary Genius* (1869/1990). Positive eugenics is the encouragement of individuals within a population, with desirable and beneficial characteristics, to propagate through breeding. Conversely, negative eugenics is the discouragement or intentional prevention of the procreation of individuals in a population with undesirable, or subjective and nonbeneficial, characteristics.

Euthenics is the improvement of an individual's (or organism's) functioning, efficiency, and well-being by modifying environmental factors that are controllable. Examples of controllable environmental factors are living conditions, medical treatment, and education. Positive euthenics is the proactive method of improving an individual's quality of life. Examples of positive euthenics would be vaccinating against debilitating diseases and the potential use of genetic engineering to correct genetically inherited disease. Conversely, negative euthenics is the intentional or unintentional degradation of controllable conditions that subjects a population to a poorer quality of life. Examples of negative euthenics would be pollution, overpopulation, lack of education, lack of access to medical treatment, and disproportionate distribution of vital resources.

Euthenics differs from eugenics in that the focus of improving the individual is done after birth has already occurred, whereas eugenics strives to improve the probability of giving birth to an individual with desired genetics through selective breeding habits (i.e., before birth). Note that positive and negative euthenics affects an organism after it has been born and does not focus on selective breeding or the discouragement of two individuals breeding together. Another way of looking at this concept is that eugenics is a pregenetic attempt to improve an organism. Conversely, euthenics is a postgenetic strategy to improve an organism's well-being.

The concept of proliferagenics is the utilization of both eugenics and euthenics to improve and proliferate the genome and the well-being of a species. This idea focuses on improving pregenetic natural selection and then applying postgenetic euthenics to maximize the vitality of a species's genome.

Genetic engineering is similar to biotechnology in that there is an alteration of an organism's characteristics. In contrast to biotechnology, the process of genetic engineering denotes the intentional alteration of the actual DNA by using applications of new scientific technology that make changes at a molecular level. This means that a change is made in the actual genetic constitution of a cell by introducing, modifying, or eliminating specific genes by applying modern molecular-biologic techniques.

Another distinction is that biotechnology has traditionally been applied to agriculture for improving food products and livestock, whereas genetic engineering has more applications in medicine and anthropology. However, modern biotechnology has integrated genetic-engineering techniques as opposed to just utilizing breeding strategies to achieve those improvements. Due to the fact that biotechnology currently applies genetic-engineering techniques, the two terms are now frequently used interchangeably.

An alternative way to view the effects that biotechnology and genetic engineering could have on a modern population requires the natural manipulation of individuals through human intervention (using eugenics

and euthenics or proliferagenics). The desired or beneficial genetic results can now be accelerated with genetic engineering.

From a historical perspective, humankind long ago began to alter the process of natural selection of animals and plants to yield beneficial results. Now, with the advent of genetic engineering, humankind has the ability to accelerate that process even more. In fact, one can speculate that humankind may eventually possess control over its own evolution.

The possibility that humankind may have direct control over its own evolution, by using genetic engineering and DNA nanotechnology, is known as *emerging teleology*. Emerging teleology is the theory that scientists can direct evolution by using genetic engineering and DNA nanotechnology—a technique that uses molecular recognition to create self-assembling branched DNA complexes, which in turn yields the engineering of functional systems at a molecular level. This concept of emerging teleology was first proposed by philosopher and anthropologist H. James Bix in 1991.

In conclusion, we have to ask ourselves, what is genetic engineering expected to accomplish for humankind?

Or what has genetic engineering accomplished for humankind already? As mentioned earlier, understanding DNA can potentially help anthropologists to better understand the genetic relationships among species. Currently, several genetic-engineering techniques are already in use. Modern genetic-engineering applications include the use of genetically modified cells or microorganisms that can accomplish three major benefits:

1. Cells or organisms can be engineered to produce medically beneficial substances. The most common example of this is the production of insulin (see Box 8.2).
2. Genetically modified organisms can be engineered that will help in the study of human diseases. An example of this is the use of “knockout mice,” which has helped scientists to understand diseases like cancer (see Box 8.3).
3. Gene therapy allows the possibility of curing genetically inherited diseases by making corrections to the genetic defect at the level of the gene responsible. This can be achieved by inserting the correct gene(s) or by deleting the defective gene(s).

In 1987, the FDA approved the use of the first genetically engineered vaccine, which was used for Hepatitis B.

BOX 8.2 INSULIN

In 1978, a biotechnology company called Genentech produced the first synthetic human insulin. This synthetic insulin was produced by bacteria called *Escheria coli* using recombinant DNA techniques, which inserted a human insulin-producing gene into *E. coli*. This was the very first genetically engineered product made for human consumption and was approved for use by the Food and Drug Administration in 1982. The insulin-producing *E. coli* is an example of a transgenic organism. A transgenic organism is an organism with artificially inserted DNA from a different organism.

Prior to this, insulin was obtained from pigs and cows (bovine insulin actually differs from human insulin by three amino acid sequences). This type of insulin was associated with many allergic reactions and side effects. The genetically engineered insulin is identical to human insulin because it is manufactured by a human gene inserted into a bacterium; therefore, it is associated with fewer side effects and allergic reactions.

BOX 8.3 KNOCKOUT MICE

A knockout mouse is a mouse that has been genetically engineered to have a particular gene (or genes) turned off or “knocked out.” Knocking out or inactivating a particular gene can provide a research model, which can then provide information on what that gene normally does functionally. This is important because it is now known that 85% of human genes are shared with mice. Therefore, information about a particular gene in a mouse can be extrapolated to provide provisional information in relation to many human genes.

The first knockout mouse was engineered by Mario R. Capecchi, Martin Evans, and Oliver Smithies in 1989, for which they received a Nobel Prize in Medicine in 2007.

Knockout mice (also known as transgenic mice) can provide models to study genetic diseases (e.g., cystic fibrosis and neurofibromatosis). These knockout mouse models are known as disease analogues, which are used to create genetic databases that are collected by experiments on knockout mice. Results of the Mouse Genome Project (MGP) were published in 2001, and because humans share many genes in common, it is possible to accurately compare these similar sequences of genes to study disease.

This technology could be very significant in anthropology for the study of primates. It is conceivable that knockout chimpanzees or gorillas could be engineered.

Although these three major benefits offer the potential to help millions of people—and already have—controversy will ultimately arise over the direct, nonmedical application of genetic engineering to enhance normal physiological functions in humans.

Genomics is the study of the genetic makeup of a species. A genome project of a species is a comprehensive identification and classification of a species’s genetic makeup. Genome projects of several microorganisms have been completed including many viral and bacterial

genomes (e.g., *Haemophilus influenza* and *Mycoplasma genitalium* genomes were sequenced and completed in 1995). In addition, the Mouse Genome Project was completed in 1996 and the Human Genome Project was completed in 2003. Currently, other primate genome projects are underway, including the Chimpanzee Genome Project and the Neanderthal Genome Project.

In order to understand and conceptualize how understanding the DNA molecule and genetic engineering will impact many areas, including medicine and anthropology, one needs to first appreciate the history leading up to this marvelous technology. In addition, we need to stop and think about how the DNA molecule was discovered and what new technology enabled humankind to accomplish that important discovery. Finally, we need to be aware of the ideas that were proposed to be responsible for the phenomenon of inheritance before the discovery of the DNA molecule.

Early Concepts of Inheritance

Before the DNA molecule was discovered, there were only ideas and theories about heredity and inheritance. The most enduring dogma was the idea of “pangenesis,” which held that all of the cells throughout the human body shed *gemmules*. These *gemmules* were believed to be able to collect in the reproductive organs periodically before fertilization and reproduction.

The term *pangenesis* came from the Greek word *pan*, meaning whole or encompassing, and *genesis/genos*, meaning birth/origin. Pangenesis was found in Greek writings in the 5th century BCE and was advocated (and in some ways espoused) by Hippocrates (460–370 BCE). This idea was accepted by fellow Greek thinkers Plato (428–347 BCE) and Aristotle (384–322 BCE). However, Aristotle later attempted to refute pangenesis with his idea of *entelechy*.

Aristotle proposed the concept of *entelechy* to explain the manner in which an organism inherits and expresses its traits, which according to this idea are determined by a “vital inner force.” He also noted the idea of “having one’s end within,” meaning that an organism’s essential potential can be actualized by its own vital inner force, or *entelechy*. Aristotle also believed that this vital force was possessed by males in their semen and that females merely possessed the raw material to be formed.

Pangenesis and *entelechy* were both prevalent and accepted as facts throughout the Middle Ages by great thinkers such as Albertus Magnus (1193–1280), his student Thomas Aquinas (1225–1274), and Roger Bacon (1220–1294). In the later part of the Middle Ages, a physician named Paracelsus (1493–1541), also known by the name Philippus Theophrastus Aureolus Bombastus von Hohenheim, proposed that semen was actually an extract of the human body, which contained all of the

organs in what he called an “ideal form.” He believed that this was the biological link between parent and offspring. He was close.

Jean-Baptiste de Lamarck (1744–1829) proposed a theory that he called inheritance of acquired characters through use and disuse. In his theory, he proposed that changes in an organism’s physiology (over the course of its life span) were acquired and modified through the use of a particular function and then became a permanent and adaptable modification in what he called the germ-line. According to Lamarck, this modification was impressed on the parent form and then transmitted to the offspring, who would, as a result of this process, express this modification as a permanent characteristic that could be altered subsequently through use or disuse.

The acceptance of pangenesis and *gemmules* appeared as a provisional hypothesis by Charles Darwin (1809–1882) in his publication *On the Origin of Species* (1859), and later again in *The Variation of Animals and Plants Under Domestication* (1868). However, Darwin was unaware of the DNA molecule (which was not yet discovered) or of the works of Gregor Mendel (which were published during Darwin’s lifetime, and received but never read by him); therefore Darwin continued to comprehend his theory of evolution according to those concepts of his time—pangenesis and *gemmules*.

Thus, before any scientific explanation could account for the phenomenon of inheritance (or evolution), there were several unfounded ideas that were accepted. These ideas were mainly pangenesis, *gemmules*, and *entelechy*. Later theories such as the use and disuse of acquired characteristics were proposed and gained some popularity, but no theoretical model existed that could scientifically or mathematically account for how characteristics were inherited.

Gregor Mendel: The Father of Genetics

Gregor Johann Mendel (1822–1884) was a monk and a mathematician, and known as “the father of genetics” because his seminal works inspired others to study the phenomenon of inheritance. In 1857, he began conducting experiments using pea plants, *Pisum sativum*. He bred particular plants together and then he meticulously recorded the characteristics of the resulting offspring.

Mendel’s term *character* was a description of what we now call a phenotype (see Box 8.4). Typical characters that Mendel studied and measured were the height of the plants and the color of the pea plant’s flowers. Each character possessed different traits; for example, height was measured as tall, normal, or short; and color was measured as white, pink, or red. Therefore, traits were different varieties of phenotype (i.e., the measurable or observable characteristics of the plants).

BOX 8.4 GENOTYPE AND PHENOTYPE

The study of genetics uses the terms *genotype* and *phenotype*. An organism's genotype is the actual genetic constitution, or its DNA. The term *phenotype* is used to describe the observable, tangible, and measurable physical properties of an organism. The phenotype of any characteristic is a result of the interaction between the organism's genes with each other and also with those genes' interaction with the environment over time:

$$\text{Phenotype (expressed characteristics)} = \text{Genotype (genes/DNA)} \times \text{Environment} \times \text{Time}$$

A phenotype has a genetic and environmental component that affects how it is expressed. The genotype contains the information that is expressed.

Mendel's experiments demonstrated that the traits of a character were distributed in a mathematically predictable pattern. He used these mathematically predictable patterns to devise two important laws known as Mendel's laws, which he called the law of segregation and the law of independent assortment.

In general, the first law, which was the Mendelian law of segregation (of genetic factors), was hypothesized by Mendel to mean that each trait (e.g., height or color) must have two "factors." Mendel would later call these factors "alleles." One factor, or allele, was inherited from each parent, one from the mother and one from the father. Although two alleles are inherited, only one of the alleles was expressed, and therefore, according to Mendel, they were segregated. Today it is known that *gametes* are sperm and egg cells, which combine their genetic material during fertilization.

Mendel did not know the underlying biological process in cell replication and division at that time. However, it is now known that during the cell cycle, the DNA replicates itself and divides, yielding two identical cells, each with two sets of chromosomes, known as diploids. This process is known as mitosis. In addition, a specialized version of mitosis takes place with the production of the gametes, in which the gametes, known as haploids, have one set of chromosomes each. This process is known as meiosis. When the two separate gametes (or haploids) are joined during fertilization—one from the mother and one from the father—to form a zygote, the alleles (i.e., the DNA) then recombine.

During the course of his experiments, Mendel found that each allele was either dominant or recessive for a specific trait. He elaborated that there were three possibilities. First, if the two alleles were both dominant, then the trait inherited was considered to be *homozygous dominant* (AA). Second, if the two alleles were both recessive, then the inherited trait was considered to be *homozygous recessive* (aa). Third, if the two alleles were different, one dominant and one recessive, then the inherited trait was considered to be *heterozygous* (Aa), or a hybrid. The homozygous dominant, homozygous recessive, and heterozygous combinations could be crossbred and those

results could be used to mathematically predict the probability of what type of offspring would result.

The Punnett square was devised by British geneticist Reginald Punnett (1875–1967), who published the first textbook on genetics, *Mendelism* (1905). He used these Punnett squares to predict the mathematical probability of the outcome of a particular breeding experiment. The results of the Punnett square could be used to predict the probability of possible genotypes of the offspring in a particular cohort given the genotype of the maternal allele and the makeup of the paternal allele.

Mendel's second law, the Mendelian law of independent assortment (of genetic factors), is where he hypothesized that the inheritance pattern of one trait does not affect the inheritance pattern of another trait (i.e., they assort independently). He justified this with his concept that alleles segregate during gamete formation and then recombine independently of one another. He was incorrect in this assumption. It is now known that there is a multigene interaction and what is known as the blending of inherited traits. This was proven in the early 1900s by Thomas Hunt Morgan (1915/1978) and his colleagues in experiments involving fruit flies.

In essence, Mendel's second law worked with pea plants because they are much simpler organisms, genetically, than mammals. In addition, the characteristics that he was measuring were not complicated. However, Mendel himself speculated that these laws may only apply to certain species, but he didn't know why, because the DNA molecule had not been discovered yet. This is the reason why Mendel and others at his time could only study what was being expressed genetically. They did not understand or appreciate the genetic material itself.

In Example 1 (see Figure 8.1), a trait that is homozygous dominant (YY) is crossed with a trait that is homozygous recessive (yy). This example yields 100% heterozygous/hybrid offspring (Yy). In Example 2, two hybrid traits are crossed. This example yields 50% heterozygous offspring, 25% homozygous dominant offspring, and 25% homozygous recessive offspring. This is a classical and simplified example of Punnett squares.

Example 2

Figure 8.1 Punnett Squares

In addition to the two laws that Mendel devised, there are three other elements that made his work significant. First, he demonstrated the value of conducting controlled experiments. Second, he was a mathematician and applied mathematics to analyze and interpret his data. Third, he published his results, which is probably the most significant of all because his findings were not widely acknowledged during his time. However, his works were rediscovered after his death and had a profound effect on the study of inheritance and genetics. His work was of particular significance because this was the first successful mathematical model that had been proposed to explain inheritance.

Hugo DeVries: The Mutation Theory of Evolution

Hugo Marie DeVries (1848–1935) was a Dutch botanist and is considered to be one of the first geneticists. He is known for his mutation theory of evolution, which was chiefly influenced by Gregor Mendel's laws of heredity, which he rediscovered in the 1890s, and Charles Darwin's theory of evolution.

DeVries's (1905/2007) mutation theory of evolution speculated that new varieties of a species could appear in sudden, single jumps as opposed to slowly changing over time. His theory proposed that differences in an organism's phenotype could change rapidly from one generation to the next; this also became known as *saltationism*. He based this theory on his experiments, which involved hybridizing plants. One particular observation was made by DeVries during these experiments that influenced and compelled his mutation theory of evolution. Occasionally an offspring appeared that had different characteristics than both the parents and was also different from the other offspring. Based on this finding, he postulated that new varieties of species could appear in nature spontaneously. By this, he in essence proposed that a mutated gene could equal a new species (i.e., mutation equals speciation). This was opposed to Darwin's theory of gradualism.

DeVries's mutation theory of evolution was supplanted in the late 1930s by modern evolutionary synthesis, initiated by Julian Huxley (1887–1975). Huxley first introduced

this theory in his book *Evolution: The Modern Synthesis* (1942). At this time, he attempted to rationalize a unification of several biological specialties (e.g., genetics, systematics, morphology, cytology, botany, paleontology, and ecology) in order to postulate a more rational account of evolution. Julian Huxley's work was stimulated by population genetics and served to clear up confusion and miscommunication between specialties existing at that time. In addition, modern evolutionary synthesis defended the notion that Mendelian genetics was more consistent with Darwin's gradualism (and natural selection), as opposed to DeVries's hypothesis of the mutation theory.

The mutation theory of evolution proposed by DeVries had nothing to do with what we currently acknowledge as genetic mutations. The current definition of a mutation is the process by which a gene undergoes a structural change to create a different form of the original allele, which results in a completely new allele. Therefore, spontaneous changes can occur in the DNA that can (but sometimes do not) cause changes in an organism's physiology. This change does not give rise to the sudden appearance of a new species; rather it can produce a modification of the erstwhile species. This was later supported by genetic research done on white-eyed and red-eyed fruit flies by Thomas Morgan and colleagues (1915/1978).

DeVries was known for another accomplishment that arose from his experiments when he speculated that the inheritance of specific traits of an organism occurred through a transfer of particles, which he termed *pangenes* (derived from the word pangenesis). The term *pangenes* was shortened 20 years later by Wilhelm Johannsen (1857–1927) to *genes*. The term *gene* is currently defined as a basic unit of inheritance.

There was some debate that surrounded the "rediscovery" of Mendel's work. In DeVries's publication on the topic of inheritance, he mentioned Mendel in a footnote but took credit for the concept of particles of inheritance with his idea of pangenes. It was Carl Erich Correns (1864–1933), a German botanist and geneticist, who pointed out Mendel's priority, which DeVries eventually publicly acknowledged.

As it turned out, Carl Corren was a student of Karl Wilhelm von Nageli (1817–1891), a famous Swiss botanist, who had corresponded with Mendel regarding his findings years earlier. Corren was familiar with Mendel's work as a result of this association. An even stranger twist to this was that when Nageli and Mendel were collaborating, Nageli had actually discouraged Mendel from doing any future work studying genetics, for what he considered religious and ethical reasons.

Morgan and Muller: The First Genetic Experiments

Thomas Morgan (1866–1945) was a geneticist who performed experiments on fruit flies (*Drosophila melanogaster*).

He chose to conduct experiments on fruit flies because they required few resources, reproduced quickly, had observable characteristics that could be measured, and had only four chromosomes, which made them ideal for genetic research.

As a result of his experiments in the “fruit-fly lab,” Morgan established that genes were arranged in a line on what is known as a chromosome, which is present in every living cell. Since genes were believed to be responsible for inheritance and were now shown to exist on chromosomes, this became known as the chromosomal theory of inheritance, which had been alluded to prior to Morgan but had not been supported scientifically. He also noted that there was recombination of inherited characteristics resulting from the exchange of genes between two chromosomes of a pair, which he called “crossing over.” This of course disproved Mendel’s second law of independent assortment.

Morgan collaborated with three of his very important students: Hermann Muller, Alfred Sturtevant, and Calvin Bridges, all of whom continued performing genetic research on fruit flies. Collectively, from around 1908 to 1914, they were able to establish that chromosomes carry genes, those genes are distinct physical objects that are arranged on the chromosomes, the genes also could change place on the chromosomes, the genes could be mutated, and those mutated genes could be reliably inherited in future generations.

Morgan’s experimental proof that genes were discrete physical objects carried on chromosomes and they govern the patterns of inheritance was of major significance. Prior to this, the gene was a speculation with no scientific evidence to support it. Morgan’s research also illustrated that the sex of a species was inherited just as all other characteristics are inherited. He became aware that it was the chromosomal differences between the sperm and egg cells that correlated with the determination of gender. This was proven by his famous experiments with white-eyed male fruit flies and red-eyed female fruit flies.

A significant discovery, made by Hermann Muller (1890–1967), was that mutations could be caused by exposure to high-energy radiation. This technique enabled them to perform those significant genetic experiments, and to give validity to the chromosomal theory of heredity. Hermann Muller received a Noble Prize for physiology and medicine for his discovery that X-rays induced mutations. He was also the first to visualize genes as the origin of life. The reason he believed this was because genes (or chromosomes) can replicate themselves. He further speculated that all of natural selection and evolution acted at the level of the gene.

Prior to Morgan and Muller, the first proof that chromosomes carried hereditary material came from American physician and geneticist Walter Sutton (1877–1916), based on his research on grasshopper cells. Sutton was the first to speculate that the Mendelian laws could be applied to the chromosomes at a cellular level, which is now known as the Boveri-Sutton chromosome theory. However, it was

Morgan’s genetic research that provided enough reproducible scientific data to support the chromosomal theory of heredity, which became generally accepted by around 1915 (even though some geneticists, such as William Bateson, continued questioning it until about 1921).

The Discovery of the DNA Molecule

In the early 1920s, it was generally accepted that genes were arranged on chromosomes and that this is how the inheritance of characteristics arose. However, no one was sure what chromosomes were chemically made of or how they worked.

In 1928, a British scientist named Frederick Griffith (1871–1941), who was influenced by Mendel’s hypothesis of units of inheritance, theorized that a molecule of inheritance must exist. He began conducting experiments on *Streptococcus pneumonia* and proposed that an inheritance molecule existed and could be passed on from one bacterium to another by a process called transformation. Griffith’s research on transformation proved how an inheritance molecule could be transferred from one bacterium to another; however Griffith never discovered what the inheritance molecule was. Nevertheless, his work in turn inspired others to continue looking.

During this time, it was known that genes were arranged on chromosomes responsible for the phenomena of inheritance, but no one was able to prove their makeup. This dispute narrowed down to proteins, lipids, carbohydrates, and nucleic acids. The popular belief was that the inheritance molecule was protein because there were more proteins in existence, whereas only four nucleic acids were known (later a fifth nucleotide would be discovered in RNA). Some postulated that it was proteins and nucleic acids that made up the inheritance molecule, but there was no scientific proof to support any of these arguments.

Friedrich Miescher (1844–1895) discovered nucleic acids in 1868, while studying white blood cells. He called them *nuclein* because they were located in the nucleus, but no proof existed to support the fact that nucleic acids were responsible for the inheritance of characteristics.

In the early 1940s, a scientist named Oswald Avery (1877–1955) rediscovered Griffith’s work on transformation. Avery had the advantage of newer technology and advances in cellular biology. Avery had begun to conduct experiments that selectively destroyed different components (carbohydrates, proteins, lipids, and deoxyribonucleic acids) of a virulent bacterium, which he injected into a mouse. If the mouse died, he concluded that the bacterium had maintained its virulence (i.e., it was able to replicate its virulence). During his experiments, he found the bacteria were able to maintain their virulence when the carbohydrates, proteins, or lipids were destroyed. However, the bacteria were unable to be virulent when their deoxyribonucleic acids were destroyed. Therefore, Avery was the

first scientist to prove that the genetic material responsible for inheritance was composed of nucleic acids.

Avery's findings were very significant because they proved that genes, which are made out of nucleic acids (i.e., deoxyribonucleic acids or DNA), are responsible for the genetic inheritance of all organisms' characteristics. However, at this time, no one knew what DNA's structure was or how it functioned.

In 1952, Erwin Chargaff (1905–2002) published results based on his experiments involving the isolation of nucleic acids from three microorganisms: *Serratia marcescens*, *Bacillus schatz*, and *Hemophilus influenza* type C. He was able to separate the nucleic acids using a technique called adsorption chromatography. He discovered that DNA was composed of two purines, adenine (A) and guanine (G), and two pyrimidines, thymine (T) and cytosine (C).

In addition, Chargaff also pointed out that in any section of DNA, the number of A residues was always equal the number of T residues and that the number of C residues were always equal to the number of G residues. This became known as Chargaff's rule. Later, Watson and Crick (1953) would correctly propose that A and T actually pair together and that G and C pair together (due to hydrogen bonding), which is known as Watson-Crick base pairing. By analyzing the chemical structures of these molecules, Watson and Crick pointed out that A and T both have two hydrogen bonds available, which is why they pair together. C and G have three hydrogen bonds available, which is the reason they pair together. Therefore, Watson and Crick were able to find the molecular explanation of Chargaff's rule (A=T and C=G), but they went a step further with Watson-Crick base pairing to explain why this is true.

Shortly after Chargaff was making his discovery, another significant discovery was being made by scientists Maurice Wilkins (1916–2004) and Rosalind Franklin (1920–1958). Their research illustrated that the DNA molecule had a helical shape and was made up of two strands that were connected by ladderlike rungs. They were able to prove this by studying crystallized X-ray patterns of DNA.

On April 25, 1953, Watson and Crick published an article proposing a molecular structure of DNA. They had incorporated the findings of Chargaff, Wilkins, and Franklin, as well as their own, to propose that the helical strands were the sugar-phosphate backbone and that the ladderlike rungs were pairs of nucleotides (A=T and G=C). Therefore, Watson and Crick established that the molecular structure of DNA was in fact a double helix. This was significant because they were then able to explore and propose a model to explain how DNA worked.

It should be pointed out that the structure of DNA was discovered based on the research and results of many scientists. Watson and Crick definitely made this significant discovery, but they gained much insight from the works of Chargaff, Wilkins, and Franklin.

Chromosomes: Compact DNA

A *chromosome* is a long, single piece of DNA that contains several genes; in some species 10 to 40 genes and in other species thousands or more genes can be present in just one chromosome. In eukaryotes, the chromosomes are organized structures that consist of DNA and special structural proteins called *histones* that wind, coil, and compact large DNA sequences so that they fit efficiently in the nucleus. The chromosome does not always stay condensed, but periodically relaxes and uncoils for replication and for the transcription of proteins. *Topoisomerase II* is a DNA-nicking-closing enzyme that allows the uncoiling of the DNA supercoils during DNA replication and translation.

In prokaryotic cells, the DNA is either organized in clusters with no nucleus or into small circular DNA molecules called *plasmids*, which do not contain histones. In viral genomes, very simple chromosomes are found and can be made out of DNA or RNA, which are short, linear or circular chromosomes that usually lack structural proteins.

In all animals, DNA in the chromosomes is packed by histones into globular aggregates known as a *nucleosome*. The amino-acid sequence of histones shows almost 100% homology across all species, which illustrates their importance in maintaining chromosomal integrity, structure, and function. In addition, it is now known that the genes that code for histones have no introns.

The DNA strand is wound up and packed with eight histones to form a nucleosome, or what is sometimes called "beaded strings." These units are further coiled into what is called a solenoid, which contains five to six nucleosomes. The solenoids are then condensed into a chromatin fiber, which has histone H1 holding the core together. The chromatin fiber then folds into a series of loops that are held together by a central scaffold (made of nonhistone chromosomal protein), and this configuration is called a looped fiber. The looped fiber is then coiled to form the fully condensed heterochromatin of the chromosomes.

The coiled and condensed heterochromatin pairs up with an identical copy of itself, and each of the two are referred to as a *chromatid*. Two identical chromatids are attached to each other by a *centromere*. The centromere divides both chromatids into a long arm and a short arm. During cell division, microtubules attach to the centromere and align the chromosomes in the center of the dividing cell. The chromosomes are then split, yielding two identical cells—each with its own set of chromosomes. This process is known as *mitosis*.

All four arms of the chromosome (two long arms and two short arms) have a specialized cap known as a *telomere*, which has several functions (e.g., preventing the ends from sticking together). The chromosomes also show a distribution of two types of bands. G-bands are A-T rich regions and R-bands are G-C rich regions.

DNA Structure: The Double Helix

As mentioned earlier, the DNA molecule is composed of two purines (A and G) and two pyrimidines (T and C), and all four are nitrogenous bases. These nitrogenous bases are attached to a deoxyribose sugar, which is attached to a phosphate group to form a nucleotide (see Figure 8.2).

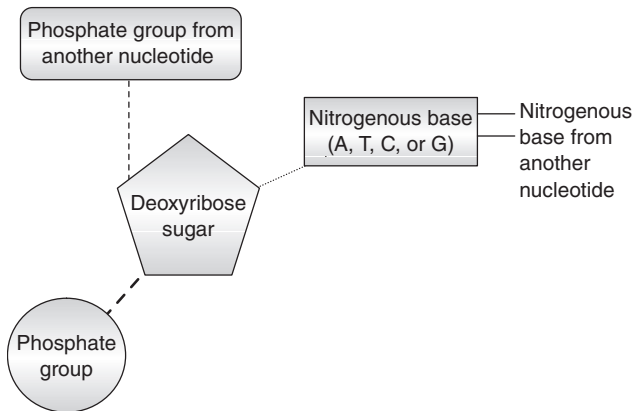

Figure 8.2 Nucleotide

In DNA, a nucleotide is any of the four nitrogenous bases attached to a deoxyribose sugar, which, as explained, is attached to a phosphate group. Because there are four different nitrogenous bases (A, T, G, and C) in DNA, there are four different nucleotides. The deoxyribose sugar can bond with a phosphate group from another nucleotide to form a chain. The nitrogenous base portion of the nucleotide can bond with the nitrogenous base from another nucleotide.

Nucleotides attach side by side to make long strands of DNA. They are able to attach in this fashion by the phosphate group of one nucleotide to the deoxyribose sugar of another nucleotide. This strand is formed in what is known as the 5 prime to 3 prime direction and opposite of this strand is a complementary chain which goes in the 3 prime to 5 prime direction. The original strand is attached to the complementary strand by the hydrogen bond discussed earlier: A=T and C=G. Therefore if the original strand is

5 prime-ATGCTC-3 prime,

the complementary stand is

3 prime-TACGAG-5 prime.

When Watson and Crick proposed the structure of the DNA molecule, they stated that the molecule was a double helix held together by ladderlike projections. The backbone of the helix is the deoxyribose sugar and phosphate group. The ladderlike projections are the base pairs A=T, G=C, T=A, and C=G.

DNA Replication

One of the phenomenal characteristics of the DNA molecule is that it not only stores genetic information but replicates itself. This process is simply known as *replication*. Replication starts when the double strand is opened up by a *helicase enzyme*, which exposes the base sequences. While the base pairs are exposed along the template strand, a new strand of DNA (a complementary strand) is synthesized by DNA polymerase.

Replication occurs continuously from the origin of one strand, called the leading strand, which follows the 3 prime to 5 prime direction. The other strand on the DNA molecule replicated is called the lagging strand and does not replicate continuously, but rather in small sections (~100–200 bases), which are called *Okazaki fragments*. These fragments are linked together by DNA ligase. The leading strand replicates a complementary strand with DNA polymerase delta, while the lagging strand makes a complementary strand using DNA polymerase alpha.

The process of replication results in two identical copies (called daughter duplexes) of the original strand of DNA. Each daughter duplex contains one parental strand from the original DNA molecule and one newly synthesized strand. This is known as a semiconservative model. In 1958, Matthew Meselson and Franklin Stahl used a scientific technique with radio-labeled nitrogen bases to prove that the DNA molecule replicates using a semiconservative model.

In healthy cells, there is a set of postreplication-repair enzymes and base-mismatch proofreading systems. These systems remove and replace mistakes made during replication (e.g., a wrong base being inserted into a growing strand). Occasionally, a change in the nucleotide sequence takes place; this is known as a *mutation*.

In 1977, two scientists, Richard Roberts and Phil Sharp, discovered that there were many regions in the DNA that did not code for anything. Roberts and Sharp called these noncoding interruptions *introns* (short for *intervening sequences*), and the sections that are coding regions are referred to as *exons*. They also found that mRNA, which was thought to be an exact copy of a transcribed section of DNA during protein synthesis, was actually missing these intron regions.

Introns are believed by some to be “junk DNA” or filler sequences. However, others believe that the extra sequences may stabilize the DNA molecule, or that the introns may be genetic remnants of evolution (vestigial DNA) and may have been expressed in the past but now lies dormant. In addition, it is conceivable that introns may have a function that presently eludes us.

The RNA Molecule

RNA (ribonucleic acid) is a small, single-stranded nucleic acid that is involved in protein synthesis. Single-stranded

RNA (and in rare cases double-stranded RNA) are also found in viruses. Besides being single stranded, RNA differs from DNA in two other important ways. First, DNA contains deoxyribose sugar in its backbone, whereas RNA contains ribose sugar. Secondly, in RNA there is no thymine; rather it is replaced with a different nitrogenous base called uracil, which pairs with A on the DNA molecule during protein synthesis (U=A), just as thymine does.

In the early 1980s, Thomas Cech did a significant amount of research on RNA. At that time it was believed that only proteins could act as biological catalysts. Cech was able to prove that RNA could function as a biological catalyst as well. He even discovered what he called *ribozymes* (later classified as species of RNA), which take part in the synthesis of mRNA, tRNA, and rRNA. Currently nine types of RNA have been identified:

1. *Heterogeneous nuclear RNA* (hnRNA) is transcribed directly from DNA by an enzyme called RNA polymerase. This form of RNA contains all the coding regions (exons) and noncoding regions (introns). Then, hnRNA is processed to yield mRNA for protein synthesis.
2. *Messenger RNA* (mRNA) is the modified version of hnRNA, which has had all of the introns removed, and possesses only the coding regions, which contain a code (the triplet code or codons) that is used for transcribing proteins.
3. *Transfer RNA* (tRNA) is transcribed from coding sequences on the DNA molecule by RNA polymerase III. This type of RNA possesses an anticodon on one of its ends, which matches a particular section of mRNA. On the other end, tRNA has an amino acid attached. In a basic sense, tRNA serves as an adaptor between mRNA and amino acids during protein synthesis.
4. *Ribosomal RNA* (rRNA) exists as several species of rRNA, which are categorized by their sedimentation coefficients that are recorded in Svedberg units (S). A ribosome is composed of two subunits: a large subunit (5S, 5.8S, and 28S) and a small subunit (18S). The ribosome's function involves holding mRNA in place while the corresponding tRNA attaches amino acids together during protein synthesis.
5. *Small nuclear RNA* (snRNA) is found in RNA-protein complexes called spliceosomes. Their function is to remove introns from hnRNA to produce mRNA. In the disease systemic lupus erythematus, the body produces antibodies to snRNA molecules.
6. *Small nucleolar RNA* (snoRNA) functions in site-specific base modifications in rRNA and snRNA. These modifications include methylation and pseudouridylation.
7. *Signal recognition particle RNA* functions by recognizing particular signal sequences on some proteins and assists in transporting them outside the cell, a process known as exocytosis.
8. *Micro-RNA* (miRNA) is believed to control the translation of structural genes. They are proposed to do this by binding to the complementary sequences in the 3 prime untranslated regions of the mRNA.
9. *Mitochondrial RNA* replicates and transcribes independently of the other nuclear DNA and RNA.

However, mitochondrial DNA exists as a double-stranded loop (or circle) with an outer, heavy strand and an inner, light strand. Both strands are transcribed by mitochondrial-specific RNA polymerase to produce 37 separate mitochondrial RNA species (mitochondrial rRNA, mitochondrial tRNA, and mitochondrial mRNA).

Many scientists believe that RNA existed before DNA. This is mostly because small forms of RNA can support life (e.g., a virus). However, a virus needs to infect other cells to replicate itself and this is why viruses are known as “obligate intracellular parasites.” Small species of RNA (explained above) are also able to perform biologic activities independently (e.g., they are responsible for protein synthesis from strands of DNA). However, the DNA molecule is a far more stable repository for genetic information and it produces RNA. Therefore, the question of how RNA can exist without DNA to produce it arises. Finally, there is the possibility that both molecules arose at the same time, forming a symbiotic relationship.

Transcription: DNA to RNA

The question now arises, how does DNA make RNA? *Transcription* is the process by which DNA makes a copy of a section of itself; that copy is RNA and is used for protein synthesis. In the DNA molecule, there are genes known as structural genes that code for proteins. Transcription begins when protein transcription factors attach to a promoter site on the DNA molecule. Next, RNA polymerase Pol II attaches to the transcription factors and then “unzips” the double helix. The complex of transcription factors and RNA polymerase Pol II move downstream (3 prime to 5 prime) along the template strand of the DNA, unzipping it as it moves forward and reconnecting the back portion of the double helix, and forming what is called a *transcription bubble*. During this process, nucleotides are linked together to form a complementary RNA copy of the coding strand of DNA. This is an exact copy of the DNA called hnRNA.

The hnRNA molecule is modified into mRNA, through ribonucleoprotein complexes called spliceosomes, which are several snRNA molecules that remove introns from hnRNA. The new mRNA molecule is then transported from the nucleus to the cytoplasm, where it will be used to make a peptide or peptides, which are used to make proteins and enzymes.

Translation: Protein Synthesis

Translation is the process in which a strand of mRNA in conjunction with tRNA and rRNA produces peptides and polypeptides. The old central dogma of molecular biology was that DNA makes mRNA, and mRNA makes proteins.

The current theme is that DNA makes hnRNA, and that becomes mRNA (with the help of snRNA), which works with tRNA and rRNA to make polypeptides that are used to make proteins.

On a strand of mRNA, nucleotides pair up in sets of three (e.g., AUG and AAA, which are called triplet codons or codons). Each codon corresponds to an amino acid (e.g., GCA = alanine). There are 64 possible combinations of codons, but several codons represent the same amino acid (e.g., GCA, GCC, GCU, and GCG all represent alanine). Three of the codons—UAA, UAG, and UGA—represent a “stop” signal on the mRNA. AUG represents methionine, which is a “start” signal. The codons make up what is known as the genetic code. It works on the basis of tRNA, which contains and anticodon on one end and an amino acid on the other end.

A strand of mRNA is composed of a start signal (AUG), a coding region of codons, and a stop signal. Translation takes place in the cytoplasm within the endoplasmic reticulum. This process takes place in three main steps:

1. *Initiation:* During this phase, the small rRNA subunit (which contains initiation factors) and tRNA, with the methionine (MET) amino acid, both attach to the start signal (AUG) on the mRNA. Then the large rRNA subunit attaches to the mRNA. When the small and large subunits are attached together they are referred to as a ribosome.
2. *Elongation:* After initiation is complete and the first tRNA is attached to the strand of mRNA, a second tRNA attaches to the mRNA on the next codon. The second tRNA will correspond to that codon (e.g., the mRNA codon ACG would have tRNA with the anticodon [UGC] and the amino acid threonine [THR] attached). The existing MET amino acid on the mRNA would then form a bond to THR. This bond is a peptidyl transferase reaction, which creates a peptide bond between MET and THR. After that, a third, fourth (and possibly more) amino acids will be connected in this fashion, yielding an elongated chain of amino acids. This process continues throughout the entire coding message of the mRNA molecule.
3. *Termination:* In this final phase, elongation continues until a stop codon is reached and enters into the ribosome (rRNA large and small subunits). When this takes place, a release factor disconnects the amino acid chain (called a peptide or polypeptide), and the ribosome splits into a small and large subunit, both of which separate from the mRNA molecule.

After translation is completed, posttranslational modification occurs, which involves the removal of methionine and peptide cleavage.

DNA Sequencing

DNA sequencing is a scientific method for determining the order of the nucleotide bases in an unknown strand of

DNA. The original method was devised in the early 1970s by Walter Gilbert and Allan Maxam, and called Maxam-Gilbert sequencing. Their method was very labor-intensive and involved the use of hazardous chemicals. In 1975, Frederick Sanger developed a quicker, more reliable, and less hazardous method of DNA sequencing called the Sanger method or chain-termination method. This method involves the use of dideoxynucleotides (ddATP, ddTTP, ddCTP, and ddGTP), which are different from normal nucleotides in that they lack a hydroxyl group. Because they lack a hydroxyl group, they interrupt and stop the normal sequence being produced in the complementary strand from the template DNA, which causes a termination in the chain. This termination takes place at that dideoxynucleotide's spot (A, T, C, or G). This method is sometimes called the dideoxynucleotide DNA sequencing method, or chain-termination sequencing.

Utilizing this technology, a strand of unknown DNA can be taken, amplified using PCR (PCR is a process that rapidly replicates a piece of DNA), and sequenced. The single-stranded DNA of unknown sequence is used as the template and a complementary strand is made using radioactively labeled nucleotides. Next, the radioactively labeled complementary strand is placed in four separated mixes, each containing DNA polymerase and one of each of the four dideoxynucleotides. The four separate mixes are then run through a polyacrylamide gel electrophoresis in four separate rows, which separates the small fragments of DNA. These four rows of fragments correspond to the particular dideoxynucleotide used. From this, a deduced sequence of the original template strand can be made. Currently a method using automated sequencing, which uses fluorescent markers instead of radioactively labeled markers, is used.

The groundbreaking technology of PCR and DNA sequencing made sequencing a genome a reality. Without this technology, the Human Genome Project would have taken several decades to complete or may have even been unattainable. DNA sequencing also has applications in diagnostic testing and forensics. It can also be used to identify a specific pathogenic mutation that causes a particular genetic disease.

The Human Genome Project: Living in the Postgenomic Era

The Human Genome Project (HGP) was completed in 2003. It had originated as an international project initiated in 1990 by the U.S. Department of Energy and the National Institute of Health. This project had six major goals:

1. To identify all 20,000 to 25,000 genes in the human genome.
2. To determine all of the sequences of the chemical base pairs that constitute the entire human genome. The approximate number of chemical pairs is estimated at

around 3 billion. It is known that there is a large amount of repetition of these base pairs, and therefore an exact number of chemical base pairs at this time can only be estimated.

3. To store all of this information and make it available in databases.
4. To make improvements on computer-based tools for data analysis of biological problems. The field that

currently deals with these issues is called bioinformatics (see Box 8.5).

5. To transfer these related technologies to private biotechnology and genetic engineering sectors to stimulate further research and product development.
6. To address the legal, social, and ethical issues that will appear as a result of the completion of the HGP and also the application of genetic engineering.

BOX 8.5 BIOINFORMATICS

Bioinformatics combines the mathematical, statistical, and computational methods that are directed toward solving various biological problems. It involves the manipulation, searching, and data mining of DNA sequences. Without the field of bioinformatics, it is unlikely that the Human Genome Project or any other genome project would have been completed or that the information attained could be analyzed in a timely fashion.

The completion of the HGP is significant for the field of anthropology because it will improve the study of topics such as germ-line mutations and assist in determining our genetic relationship with Cro-Magnons and Neanderthals, as well as establish the relationship between those two species. The Neanderthal Genome Project was launched in 2006 and upon its completion the Cro-Magnon Genome Project is likely to ensue.

With the completion of the HGP, there are many anticipated improvements in anthropology, medicine, energy, and the environment. However, many ethical and legal concerns will arise as well.

The Origin of Genetic Engineering

The first experiments involving genetic-engineering techniques were made possible by seminal works of three individuals: Paul Berg, Stanley Cohen, and Herbert Boyer. All three scientists were separately working on research and experiments involving DNA. Eventually, they collaborated, using all of their techniques to coordinate the very first experiments involving removal of a gene from one species and inserting it into the genome of another species.

During the years 1972 to 1973, Paul Berg at Stanford University was the first scientist to complete a successful gene splicing experiment. This research involved the removal of a gene from a viral genome called Simian Virus 40 (SV40), which was a monkey virus. He was initially interested in studying a particular gene because he found that SV40 could cause cancer in mice. The advantage of studying a viral genome was that it was very small—approximately a few hundred genes. This allowed him to easily identify and isolate this gene. He then attached this gene to the DNA of a lambda virus (known as a biological vector), which would then insert this gene into another cell. This was the very first time that a gene or genetic material from one organism, in this case a virus, was removed and spliced into the DNA of another organism, in

this case a second virus. The new DNA, which had its original DNA along with the spliced DNA, would continue to function as normal and is known as recombinant DNA.

Recombinant DNA is the artificial or synthetic production of DNA, engineered by combining one or more strands of DNA from one source and attaching it to the strand of DNA of another source. This process yields a novel strand of DNA, known as recombinant DNA, that would normally not have existed. The recombinant DNA can then function normally, replicating itself and producing its sequenced products as all other DNA normally does.

Stanley Cohen was another scientist at Stanford University. His initial research was investigating how the genes in plasmids could make bacteria develop resistance to antibiotics. He implemented techniques allowing him to remove a plasmid, which was a small ring of DNA, from one bacterium and insert it into another bacterium. Once the plasmid was inside the other bacterium it could then produce the products that it normally made in the original bacterium. This process happens naturally between bacteria and was originally observed by Fredrick Griffith, who called it called transformation. However, Cohen was able to intentionally and selectively make this process take place.

Herbert Boyer, a scientist at the University of California, was doing research on a bacterium called *Escherichia coli* (or *E. coli*), which is normally found in the human intestine. His research involved the use of restriction endonucleases (RE), which were originally discovered by Werner Arber, Daniel Nathans, and Hamilton Smith (they received a Nobel Prize in 1978 for isolating RE). It was discovered that bacteria produce RE to defend themselves against viruses, which work by snipping viral DNA into smaller pieces rendering the virus ineffective. Today there are over 800 RE that are used in laboratories for gene splicing and the production of recombinant DNA. The RE attach to very specific sites on the DNA and can be used to isolate and remove specific sections of DNA. After this technique was refined, Boyer later went on to genetically engineer human insulin (see Box 8.2), which

was the first genetically engineered product approved by the FDA in 1978.

In 1973, the first animal gene was cloned, using the techniques refined by Berg, Cohen, and Boyer. Using Boyer's RE, Cohen's technique for removing plasmids, and Berg's splicing techniques, they were then able to successfully remove and fuse a segment of DNA, which contained a gene from a frog (*Xenopus*) with the DNA of the bacterium *E. coli*.

In a basic sense, the frog gene was removed using RE, then spliced into a plasmid, and then inserted into *E. coli*. After the resulting DNA was inserted into *E. coli*, the frog gene was transcribed, producing a specific frog protein that was not previously produced by *E. coli*. This was the very first time that an animal's gene was removed, inserted into a bacterial genome, and the product of that animal gene successfully produced.

The transfer of DNA from one organism into another organism is possible because DNA is universal among all organisms and cells on this planet. This means that the DNA in a bacterial cell is made up of the same components as the DNA in a human cell. The organism (*E. coli*) that successfully receives DNA from another organism (the frog gene) is known as a *transgenic organism*.

Modern Genetic Engineering

The fundamental steps in genetic engineering include the isolation of the DNA, the amplification of the DNA, and the transfer of that DNA into another cell. It is a very complicated process, but a simplification has been made here in order to establish an understanding of the process.

The DNA section of interest is called *donor DNA* and needs to be isolated from the rest of the DNA. This is done using restriction enzymes, which cut up the DNA into fragments. The restriction enzymes are very specific and cut the DNA at very specific points. Therefore, the DNA of interest can be located and removed.

After the desired section of DNA is isolated, it then needs to be amplified because the amount originally acquired is usually not enough to be effectively transferred. The donor DNA is amplified by a process called the polymerase chain reaction (PCR), invented by Kary Mullis. PCR is a process that rapidly replicates a piece of DNA by using *Taq* DNA polymerase.

Finally, the isolated and amplified DNA needs to be introduced into the host cell. This is accomplished with biological vectors and nonbiological vectors. Biological vectors are either plasmids or viruses, which were used in the original genetic engineering experiments by Berg and colleagues. Nonbiological vectors include electrochemical poration, biolistics, microinjections, and recombinase-mediated cassette exchange (RMCE).

As mentioned, the DNA in all organisms and cells is made out of the same material (nucleotides and sugar

phosphates). This is why it is possible to transfer DNA from one organism's cells into another organism's cells and this is also why DNA is able to produce its products normally within the new cell after this process is complete.

There are two types of genetic modifications; one involves the addition of genetic material and the other involves the deletion of genetic material or the products it expresses. Deletion is done in one of two ways: knockout and antisense genes.

Gene therapy is classified in one of two ways:

1. *Germ-line gene therapy*: This is a genetic modification done on the sperm or the egg (germ cells), which are known as a haploids because they only contain one set of chromosomes, whereas all other cells in the body (somatic cells) contain two identical sets of chromosomes (two chromatids connected by a centromere). When this type of gene therapy occurs, the defective genes are no longer inherited (i.e., the genetic change is passed on from one generation to the next).

2. *Non-germ-line gene therapy*: This is a genetic modification that is performed on the somatic cells as opposed to the germ cells. This is also called somatic gene therapy. When this type of gene therapy occurs the genetic disease can still be inherited by future generations. This is because the DNA from somatic cells is altered and these cells are not used for reproduction; therefore the defective genetic material in the haploid germ cells will continue to be passed on to future generations.

In addition to modifying germ cells and somatic cells, the techniques of genetic engineering can also be used to genetically clone species. *Cloning* is when two (and sometimes more) individuals or cells are produced from one genome.

On July 5, 1996, two scientists, Ian Wilmut and Keith Campbell, cloned the first animal from an adult somatic cell by using a technique called nuclear transfer. The animal was a ewe they named "Dolly." This showed that one cell could be removed from the body of an animal and be used to re-create a second, identical individual animal.

Individualized Medicine

Other projected use of genetic engineering is the possibility of individualized or genetic medicine. *Individualized medicine* is a futuristic style of medicine in which treatment will be tailored to the unique genetic needs of the patient. This is also known as personalized medicine. There are two major fields involved with the development of individualized medicine—pharmacogenetics and pharmacogenomics. Pharmacogenetics is an aspect of genetic medicine that studies the genetic sensitivity and differential response of a medication for a patient population. Pharmacogenomics is

another aspect that is geared toward the manufacturing of pharmaceuticals with methods of genetic engineering.

In the near future, these two fields will change the way medicine is practiced. It is conceivable that during a typical office visit less time could be spent on deciphering somatic complaints and performing a physical exam, and more time on examining the genetics of the patient.

DNA Consciousness

There is the possibility that the DNA molecule may in fact have a form of consciousness of its own, known as *DNA consciousness* or molecular/chemical consciousness (Grandy, 2006b, 2009a). This form of consciousness would of course be very different from neurological consciousness or human consciousness. In fact, DNA consciousness may underlie our very own conscious process.

This is a realistic possibility considering certain families of gene clusters; *Hox* and *Pax* genes are responsible for and oversee the development of our neurological consciousness. If those genes are altered or deleted, neurological consciousness does not develop.

Other ideas that support DNA consciousness are that the DNA molecule replicates itself, produces proteins freely, communicates chemically with other parts of the cell, and interacts with the external environment of the cell. It performs all of these functions independently. In addition, it is the first known molecule to discover itself (i.e., through *Homo sapiens sapiens*).

Genetic-engineering techniques may help us to explore this area by enabling scientists to explore how DNA interacts with itself, other molecules, and the environment; how it is able to freely self-replicate, and how it *knows* when and when not to produce certain products.

Future Directions

The future applications of genetic engineering are numerous indeed. Most of the immediate impact will be seen in the fields of anthropology and medicine. In medicine, there will be improvements in clinical therapeutics and individualized medicine. This will improve life spans and harness the potential to halt or reverse the aging process.

In anthropology, the completion of genome projects will assist in establishing genetic relationships between humankind and other species. In addition to studying our evolution, we could potentially control our evolution. Therefore, emerging teleology could become a reality.

The potential to alter human genomes could create the first transgenic *Homo sapiens* and provide the appearance of new species on this planet and elsewhere, a concept known as *transhumanism*. This could also give rise to new species such as *Homo sapiens futurensis* (the human of the

future as proposed by Birx) or *Homo sapiens genomicus* (the transgenic human as proposed by Grandy).

It is also conceivable that genetic engineering could potentially equip our species with genes that could improve our ability to survive in outer space. This could give rise to *Homo sapiens extraterrestrials*. During space travel, there is also the likelihood of encountering alien microorganisms as well as new types of diseases and ailments secondary to space exposure (Grandy, 2009d). This would open a new area of space medicine.

Ethical questions and fears will arise as well. We should be very cautious while considering the modification of our genome because we only understand a small fraction of the interworkings of the DNA molecule. Currently, scientists do not know how altering or modifying a gene in a genome as complicated as the human genome could affect us or future generations. Other ethical concerns will be raised; for example, what are good genes and what are bad genes? Who will make that determination? Originally, nature was in charge of deciding these issues. However, humankind began circumventing natural selection long ago without being prepared to address these questions.

In addition, our environment is not as dangerous (in a predatory sense) as it once was, and advances in medicine have increased human life spans while also allowing individuals—who would normally have died and not passed on their DNA to future generations—to survive and pass on inferior genes. This has given rise to a weaker gene pool or a failure to improve the species (Grandy, 2009c). Genetic engineering could potentially be a remedy to this situation. However, questions will arise over the nonmedical use of genome improvement.

With all of these possibilities on the horizon, we should always stop to remember the many great scientists and their pioneering research that made this a possibility. We should also keep our own humanity in mind as we attempt to tamper with something that we are only beginning to understand.

PART II

ARCHAEOLOGY

ARCHAEOLOGY

ROBERT BOLLT (1971–2010)

Honolulu, Hawai'i

Archaeology is the study of human cultures through the study of material and environmental remains. The word, derived from ancient Greek, means “the study of antiquity.” Archaeology is one of the four sub-fields of anthropology, together with biological anthropology, linguistic anthropology, and social/cultural anthropology. Archaeological remains can take many forms, two of the basic ones being artifacts (any object altered by human hands) and faunal remains, or midden (food remnants such as bone and shell). Artifacts can be anything from simple flaked stone tools and pottery sherds to the most elaborate and priceless objects found in such treasure troves as the tomb of Tutankhamun. These finds constitute the *archaeological record*, which archaeologists then piece together to interpret as much as they can about the cultures they are studying.

Archaeology can be further subdivided into prehistoric archaeology and historic archaeology. Prehistoric archaeology refers to cultures that did not develop writing. Historic archaeology, or text-aided archaeology, is assisted by documentation such as the cuneiform of the ancient Near East, Egyptian hieroglyphic documents and inscriptions, and so forth. These often help immensely when it comes to dating a site or sites accurately. A site is the place in which archaeological remains exist, and different archaeologists have different definitions of what constitutes a *site*; this can vary from an entire human-modified landscape, to a city, a house foundation, or a buried fire pit.

Archaeologists can work in a variety of institutions, from universities and museums (which usually require the archaeologist to hold a PhD) to cultural resource management (CRM) organizations and firms, which are responsible for making sure that sites are not destroyed in the wake of modern development such as construction. Many archaeologists working in this important area do not necessarily need higher degrees, with a BA or MA often being sufficient. Although archaeology is not a “hard science,” like chemistry, biology, or physics, it usually employs hard scientific methods for greater accuracy, which will be discussed in more detail below. Archaeologists now commonly work together with palynologists (who study the pollen record to reconstruct past environments), geologists, and other specialists. As technology advances, so do the tools available to archaeology that could not even have been imagined when it was first recognized as a discipline in the late 1800s.

The Fundamentals of Archaeology

To begin with, how are archaeological finds preserved? This depends entirely on the environment. The best-preserved organic finds are in arid places such as the deserts of Egypt, frozen places such as Siberia, and waterlogged swamps and bogs where the anaerobic environment minimizes decay. Stone is virtually eternal, and metals such as copper, bronze,

tin, and iron tend to oxidize and deteriorate. Gold, however, preserves intact, but, because of its intrinsic value, golden objects are often the rarest—either plundered in antiquity and melted down, or else stolen in past or modern times.

Archaeology can involve the excavation of a single site, such as a house or camp, or the survey of an entire settlement, which studies the spatial relationships between human occupation and activities. *Settlement pattern* archaeology works on the basis that no settlement exists in total isolation, and examines the relationship between settlements and the surrounding environment. The archaeological study of warfare examines the interrelationship between settlements, and evidence includes such things as fortifications and the remnants of palisades. Objects such as bullets, musket balls, arrowheads, and sling stones are also clues, as are skeletons that have suffered trauma.

Burials are often the richest archaeological finds in terms of preserved artifacts in the form of grave goods, which often hold great aesthetic value. Usually, archaeologists work with broken fragments of artifacts such as stone tools or pottery, which were discarded as garbage by the people who used them; intact finds outside of burials are very rare indeed. Burials also prove invaluable insights into ritual practices and the biology of the individuals, including nutrition, average mortality rates, disease, and so forth. Burial excavation, however, is an increasingly sensitive issue, and often forbidden by the modern populations whose ancestors are interred.

Underwater archaeology, of shipwrecks and structures, offers its own difficulties but can yield tremendous finds that have lain undisturbed for hundreds, if not thousands, of years. Special training and equipment is required for such work, and preservation measures are essential for objects that have been underwater for so long. Such conservation can often take years before the objects are ready to be exposed to air and thus avoid disintegration.

Archaeologists also try to understand the subsistence strategies of the people under question, analyzing the food remains to determine their diet. This is essential in understanding the origins of human food production, including staple crops such as wheat and barely in the Old World, and corn and potatoes in the New World, as well as the domestication of animals. In sum, archaeologists have a very wide array of choices and research questions. Now let us examine how archaeology developed as a discipline.

Archaeology: Historical Beginnings in the Western World

The first historically recorded personage to have expressed an interest in the remains of the past was the last king of the Neo-Babylonian (or Chaldean) Empire, Nabonidus, to who reigned from 556–538 BCE. He actively had people excavate and search for the inscriptions of previous kings and rebuilt the ruins of ancient Babylon. This interest in the past is, to our knowledge, the first such example of

“archaeology” on record. The Greeks—and later, the Romans—relied on myths and legends (many of which could have been grounded in fact) to chronicle their countries’ prehistoric or undocumented past, of which the Trojan War is one such example. However, they never sought material proof of these events.

The willingness to accept the present as distinct from the ancient past continued throughout Europe until the Renaissance, when scholars and artists “rediscovered” their classical roots in antiquity. The first great scholar to look to the past as an inspiration was the Italian humanist and poet Francesco Petrarca (known commonly as Petrarch), who lived from 1304 to 1374 CE. His use of the Italian language later influenced writers such as Dante and Boccaccio, who were largely responsible for codifying it as the standard. Petrarch studied the classical past to find perfection in his present, a pursuit that spread to other scholars throughout Italy and then beyond. For example, Boccaccio (1313–1375 CE), a friend of his, wrote essays on the classical past as a result of Petrarch’s influence. The first scholar credited with the study of the archaeological monuments of ancient Rome was the pioneering clockmaker Giovanni de’Dondi (1318–1389 CE); his father, Jacopo, was also a pioneering clockmaker, hence perhaps the interest in time.

In the 15th century, the first true *proto-archaeologist* emerged; he was the Italian humanist and antiquarian Ciriaco de’ Pizzicolli (or Cyriacus of Ancona [1391–1453/55]). (An antiquarian is someone who collects and studies objects for their own sake, not necessarily making an effort to understand the cultures that produced them.) Having studied Latin in Rome, Cyriacus began by translating inscriptions on monuments and then took his interests a great step further, by traveling throughout the eastern Mediterranean, and observing, describing, recording, and illustrating archaeological remains, which eventually filled a six-volume work called the *Commentarii*. He went as far as southern Italy, Dalmatia, Epirus, the Morea, Egypt, Chios, Rhodes, Beirut, Anatolia, and Constantinople. He documented and mapped the ancient city of Eretria, a Greek *polis* active in the fifth and fourth centuries BCE on the island of Euboea off of mainland Greece. He also described the remains of the Bronze Age citadel of Mycenae on mainland Greece hundreds of years before Heinrich Schliemann excavated the site for the first time (discussed in a subsequent section). Cyriacus’s fascination with inscriptions and ancient documents drove him to amass a large collection, which he eventually incorporated into his *Commentarii*, which was unfortunately destroyed in a fire shortly after his death sometime between 1453 and 1455, but was circulated in manuscript form.

Pompeii and Herculaneum: The Nursery of Western Archaeology

Italy was also the scene of the first subsurface archaeological discoveries proper. In 1599, the architect

Domenico Fontana was digging a new course for the river Sarno when he accidentally discovered the remains of the cities of Pompeii and Herculaneum, buried by the ash of Mount Vesuvius's eruption in 79 CE. A century and a half later, workmen building foundations for the King of Naples's (Charles of Bourbon) summer palace happened upon the ruins of Herculaneum. Charles, who later became King of Spain, used the recovered antiquities to reinforce Naples's importance. A Spanish military engineer, Rocque Joaquín de Alcubierre, then rediscovered the ruins of Pompeii in 1748.

The first true and organized excavations of Pompeii and Herculaneum were undertaken under the direction of the Swiss architect Karl Jacob Weber (1712–1764) through the patronage of King Charles III of Naples. He produced finely illustrated folios, *Le Antichità di Ercolano esposte* (the Antiquities discovered in Herculaneum), which circulated throughout Europe and brought awareness of these great finds to intellectuals throughout the continent. The Spanish architect and military engineer Francisco La Vega took up where Weber left off in 1764 under the patronage of Ferdinand, the Bourbon King of Naples. Vega's brother Pietro, also a military engineer and cartographer, continued the excavations, also under Ferdinand's patronage.

From 1860 to 1875, the Neapolitan archaeologist Giuseppe Fiorelli (1823–1896) directed the excavations at Pompeii. Fiorelli pioneered the method of excavating and studying sites layer by layer, digging from the top down rather than the previous method of finding the streets and revealing the houses from the bottom up. As a result, he established a school to train people in these archaeological techniques. It was also Fiorelli who invented the process of casting the incinerated bodies of the city's victims by pouring plaster into the cavities left within the hardened lava. Additionally, he mapped the city's topography, dividing it into subsections, and his work helped preserve the city itself. In 1863, he became the director of the Naples National Archaeological Museum (founded by King Charles III of Spain in the 1750s), and then director general of Italian Antiquities and Fine Arts in 1875, a position he held for the rest of his life.

Following Fiorelli's work, the Italian archaeologists Michele Ruggiero, Giulio De Petra, Ettore Pais, and Antonio Sogliano worked on the city, restoring many of the houses' roofs in order to preserve the fragile mosaics and wall paintings that are so identified with the city. Another important archaeologist to work in Pompeii was August Mau, who in 1882 developed a classification for the decorative styles of the paintings. In the early 20th century, Vittorio Spinazzola carefully excavated houses in order to understand how they had been buried, and then to reconstruct their facades as they had been before the catastrophe. In sum, the work done at Pompeii set an example of archaeology for the Western world and opened up new horizons of thinking.

Egypt: Napoleon's Intellectual Triumph

Napoleon Bonaparte launched his Egyptian Campaign in both Egypt and Syria in 1798. His goal was to protect French trade interests and undermine British access to its Indian colonies. The campaign was unsuccessful overall, and in 1801 he was forced to withdraw and surrender to the British. The campaign was, however, an intellectual triumph as it heralded the discipline of Egyptology, which is so vast that it is considered a separate field from archaeology or anthropology. Napoleon did something that no military leader had ever done before: He brought along a large group of scholars, the savants, in order to record and collect as much as possible of the Egyptian monuments and antiquities. Prior to this, illustrations of Egyptian monuments were often highly fanciful, drawn by people who had never even seen them.

The savants amassed a tremendous amount of information, and an Egyptology craze swept throughout France and England. When Napoleon's forces eventually surrendered to the British in 1801, they were forced to turn over a number of antiquities, including the most famous of all, the Rosetta Stone, which eventually provided the key to the decipherment of the Egyptian language, being a triple inscription written in hieroglyphic, hieratic (a late cursive form of hieroglyphs), and ancient Greek (the only one which could be read). It took over 30 years to crack the code, despite constant efforts. In 1822, the French scholar and linguist Jean-François Champollion (1790–1832) succeeded, opening up an entire new world of written history.

Beyond the Bible: The Western World Discovers Its True Antiquity

Despite the developments in archaeological thought that began in the Renaissance and continued into the 19th century, the West still considered the world and humanity's origins to be grounded in the Old Testament. Nothing in the discoveries of classical antiquity challenged or refuted anything in the Bible, as the events took place centuries after the Old Testament's accounts and then contemporaneous with those of the New Testament. The world was considered to have been only around 6,000 years old, due in great part to the meticulous calculations of the Archbishop of Amagh, James Ussher (1581–1656), who was also primate of all Ireland and vice chancellor of Dublin's Trinity College. Using all available accounts in the Bible and other manuscripts, in 1650, he arrived at the conclusion that God created the world on Saturday, October 22, 4004 BCE. As Ussher's theological and scholarly credentials were beyond any doubt, his calculation was accepted universally. However, beginning in the mid-19th century, discoveries began to be made that were seemingly incongruous with the view that humanity's origins were so recent.

One notable challenge to the belief in humanity's recentness was made by the French geologist and naturalist Jacques Boucher de Crèvecœur de Perthes (1788–1868), often known as Boucher de Perthes. In the 1830s he discovered Paleolithic hand axes in association with long-extinct mammals in the gravels of the Somme River valley. Being rightly convinced that the axes were made by humans, he devoted his time to the study of *antediluvian man*, but did not make his findings public until 1846, followed by the publication of a three-volume work, *Antiquités Celtiques et Antédiluviennes* (Celtic and Antediluvian Antiquities), the first such work that proposed that humanity existed far earlier than commonly supposed, a view that received little serious attention. Many believed that the tools were what today are called *geofacts*, or stones that have been modified by natural events. Some even considered them meteorites, or the products of supernatural creatures. It took more than another decade before additional experts confirmed that the tools were indeed made by humans and that their association with extinct mammal remains was beyond question. Similar finds were made in southern England and France, notably the hand axes at the site of the gravel pits of St. Acheul near Abbeville (from which we derive the term *Acheulian*, early Paleolithic, stone tools).

In the late 1850s and early 1860s, scholars finally began to accept the antiquity of humanity. In 1859, Charles Darwin published *On the Origin of Species*, which, although it did not directly deal with the subject of human evolution and the antiquity of humanity itself, revolutionized scientific thinking. Sir Charles Lyell (1797–1875), a lawyer and the foremost geologist of his day (and also a great influence on Charles Darwin), published *The Geological Evidence for the Antiquity of Man* in 1863, in which he discussed glaciers, evolution, and the age of the human race during the Quaternary Period (1.805 ± 0.005 million years ago). Researchers into humanity's origins could at last go beyond the Bible and recorded history to delve far deeper into the past than ever thought possible.

Mythology Comes to Life: The Quest for the Trojan War

Perhaps no other archaeological endeavor has been as surrounded by mystery and controversy as the search for Troy. Heinrich Schliemann (1822–1890) was a German entrepreneur. Born into a relatively poor family, he struck off on his own as a young man and made considerable money in St. Petersburg in the 1840s. From there, he made a fortune in California during the Gold Rush. During all this time, he educated himself in the classics. He then returned to Russia where he made an additional fortune in indigo, and then, during the Crimean War, on sulfur, saltpeter, and lead, which he sold to the Russians to make ammunition.

Schliemann basically retired from active business in the 1850s and began traveling avidly. He developed a passionate

interest in archaeology that, combined with a love for Homer's *Iliad* and *Odyssey*, led him on a path to disprove the skeptics of the academic world. The skeptics, for the most part, believed that these epic poems largely recounted myths and legends. In 1868 Schliemann began excavating the mound of Hissarlik in northwestern Turkey, a site that had been previously identified as the site of Troy (which had been rebuilt many times over since the Trojan War's supposed date of around 1200 BCE). The city was a classical one in the Greco-Roman era, visited by such people as Alexander the Great. An expatriate Englishman and amateur archaeologist, Frank Calvert (1828–1908), had excavated parts of the site prior to Schliemann's arrival. Calvert advised Schliemann to dig slowly and carefully. However, as archaeological methods were still in their infancy and the discipline was not yet a professional field, when it came to excavating tells (mounds composed of superimposed cities, rebuilt one on top of the other over thousands of years), Schliemann had little learning to go on. His impatience and limited knowledge led him to blast his way through the later cities, recording little about what was found, until he reached what he thought must have been Homer's Troy. To his dismay, it was a small and primitive settlement without any of the riches he had expected to find. What in fact had happened is that he dug too deep, too quickly, and had actually destroyed much of what composed the city (or cities) contemporaneous with Homer's Troy, which lay around five cities (now called Troy VIIa and VIIb) above Schliemann's (now called Troy II).

Schliemann's published works followed, but the academic community was still skeptical given the nonresemblance of Troy II to Homer's great city. Schliemann's countermeasures appear to have been less than honest, as he seemingly conjured out of nowhere a cache of golden jewelry that he dubbed "Priam's Treasure" and had his new wife, a young Greek woman named Sophie, photographed wearing the "Jewels of Helen." Where and when these jewels were found remains a mystery surrounded by inconsistencies in Schliemann's own writings and those of Sophie. He also smuggled some of his finds out of Turkey, breaking the arrangement he had with the Turkish government, which then refused him further permission to dig; the objects still remain the subject of controversy. However, Schliemann learned from his mistakes and went on to excavate Mycenae (the kingdom of Agamemnon) in the Peloponnesian peninsula, the nearby Mycenaean-era (ca. 1200 BCE) city of Tiryns, and then Orchomenos on the Greek mainland. His methods had advanced considerably by the 1870s and his finds were spectacular, although the golden treasures he found, especially the so-called Mask of Agamemnon at Mycenae, proved to be hundreds of years earlier than the accepted date of the Trojan War and perhaps even proto-Greek. He returned to Troy in the late 1870s and early 1880s, dismayed by the knowledge that he had in fact destroyed much of what he set out to find, and died before he was

able to continue work there. Despite his much-criticized methods, Schliemann remains a pioneer in archaeology, perhaps the most famous and controversial of them all. Since his time, excavations have rarely ceased at Troy, and show little sign of ever losing the interest of the world.

Egyptology Resurrected: The Discovery of the Tomb of Tutankhamun

The image that most people have when the word *archaeologist* or *archaeology* is mentioned is that of a man opening up an Egyptian tomb full of golden treasures and containing the mummy of a king. In fact, this event has only really occurred once in Egyptian archaeology, but it captured the world's imagination more than any other find in the discipline's history. The man responsible for this was Howard Carter (1874–1939), an English Egyptologist who began his training in Egypt at the age of 17. He studied Egyptian art and inscriptions and later became a student of the renowned archaeologist William Flinders Petrie (1853–1942), who excavated sites in Britain and all over the Near East. Carter assisted in excavating the grave site of Beni Hassan that contained the tombs of the royalty of the Middle Kingdom, and later went on to discover the tomb of Queen Hatshepsut (looted and without her mummy) in Deir el-Bahri. In 1899 he was engaged by the Egyptian Antiquities Service, a post from which he resigned 6 years later because of a quarrel that spiraled of out control between a group of French tourists and local Egyptian site guards.

In 1907, Carter had the fortune to gain the patronage of the 5th Earl of Carnarvon (1866–1923), an English aristocrat with an avid interest in antiquities. Carnarvon funded Carter's quest for the undiscovered tomb of King Tutankhamun, a short-lived king of the New Kingdom, and son of the "heretic" King Akhenaten. Carter hoped that this would prove the one most intact tomb left in Egypt that had escaped the tomb robbers who had been active ever since the reigns of the kings themselves. Carter spent years searching for it in vain in the Valley of the Kings, and Carnarvon was about to pull his funding by 1922, when Carter convinced him to finance one more season. Their gamble paid off, and on November 4, 1922, the steps leading down to the tomb were found. Carter held off (supposedly) looking inside the tomb until Carnarvon came to Egypt for the revelation.

Amid great fanfare Carter made a small hole in the doorway of the tomb, and when Carnarvon asked if he saw anything, Carter uttered the most famous phrase in archaeological history: "Yes, wonderful things." Part of the tomb had been disturbed in antiquity, but the contents were intact. Priceless objects of gold, ebony, and alabaster filled the chambers, and the king's mummy was there within its sarcophagus. Tutankhamun's golden mask is perhaps the most famous Egyptian piece of art in the world, which could only be removed by severing the king's head because it was stuck

to his face by the resin used for preservation in the mummification process.

Carter spent years removing and cataloguing the objects, which are housed in the Egyptian Museum in Cairo. The world was gripped by the story, and became even more so when the "Curse of Tutankhamun's Tomb" weaved its way into popular culture because of the death of Lord Carnarvon shortly after the tomb was discovered. Carnarvon, in poor health at the time, nicked a mosquito bite while shaving and died shortly thereafter of blood poisoning in 1923. The "Mummy's Curse" has ever since, and forever will be, a part of archaeology's—and especially Egypt's—mystique, although wholly unfounded since Carter himself died of lymphoma 17 years after opening the tomb. The living mummy, a concept completely absent in ancient Egypt, became a horror movie icon beginning in the early 1930s, which it remains to this day and will no doubt continue to do for as long as movies and literature exist.

The Development of Archaeological Theory in the 20th Century

Let us now turn to the internal growth of archaeology as a discipline in the 20th century. During the past 100 years, archaeology evolved from what could be broadly termed in many cases a methodological antiquarian approach, to a refined social science. Essential to understanding how archaeology is practiced today is its history as a branch of anthropology. While various universities differ from country to country in having separate anthropology and archaeology departments, few archaeologists would deny that the discipline is inextricably linked with anthropology as a whole, that is, the study of humanity.

We may refer to this as anthropological archaeology, which had its roots in early 20th-century America. While European archaeologists were primarily studying their own roots in their own countries, or the cultural roots of the Western world in countries such as Greece, Italy, and those of the Near East, American archaeologists had to contend with a different situation. The origins of the Native American Indian populations were, in the 19th century and even into the 20th, largely unknown. Furthermore, the evolution of such complex civilizations as the Aztecs and Maya in Mexico and Central America, and the Inca in Peru, was a puzzle. In North America, archaeologists began to see the connection between modern populations of Native Americans and the archaeological remnants of their past. They reasoned that by studying what was left of Native American culture, that is, its ethnography, the ancient past might become illuminated. It is important to keep in mind that the American archaeologists studying American archaeology were dealing with cultures and civilizations completely alien to their own European ancestry. This latter point has never ceased to be a subject of controversy between the Native American populations and the American archaeologists who study their ancestors.

In the early to mid-20th century, archaeologists practiced what today we call culture history. Its goal was not necessarily to reconstruct the society under study, because not enough excavation had yet occurred to provide sufficient bodies of material evidence to examine the anthropology of the cultures themselves. Culture history was concerned with documenting the development of material culture within and between cultures to understand changes and the diffusion of ideas between them. Culture history was, and still is, essential in certain cases in which sufficient material data does not exist. It is the foundation onto which more subtle hypotheses and broader theories can be superimposed.

Culture history came under its first major attack when Walter Taylor (1913–1997) published *A Study of Archaeology* in 1948. He mercilessly criticized his senior colleagues in archaeology professing they were practicing anthropology; to Taylor, they were doing no such thing. One of his main accusations was that his colleagues were simply collecting artifacts and documenting spectacular ruins, such as those of the Maya, without getting to the heart of the cultures themselves. Taylor called the classification and description of one artifact after another and the development of timelines an exercise without a greater purpose. Understanding chronology and changes in material culture was essential, but archaeologists, Taylor maintained, had to probe deeper to get at how the people actually lived. He advocated less extensive excavations in favor of more intense ones aimed at completely understanding each individual site. Instead of simply documenting only the more spectacular finds, archaeologists should also do the less glamorous work of studying faunal remains, and so forth. However, it was some years before his revolutionary views were embraced and put into practice, even by Taylor himself.

Taylor's mantle was not really picked up until the 1960s and 1970s, when the archaeologist Lewis Binford spearheaded what was later termed *new archaeology* and then redubbed *processual archaeology*. Binford and his students advocated using scientific methods to test hypotheses about the cultures they were studying and, as Taylor had advised almost two decades prior, not to rely upon the artifacts themselves to tell the story. They argued that one must study the environment of the region under question to explain how humans adapted to their external conditions, which might be called cultural evolutionism. The name *processual archaeology* derives from the idea that cultures change according to evolutionary processes.

At the root of processual archaeology is the paradigm of *cultural materialism*, which is based on the importance of tangible, material factors, such as environment, population density, subsistence strategies, and technology, to explain the processes by which cultures adapt and evolve. As such, processual archaeology concentrates on broader evolutionary implications rather than simple historical ones, ultimately to formulate generalized “laws” to explain human

society as a whole. (As such, the role of the individual is downplayed.) Ideally, such processes should be scientifically predictable so that hypotheses can be tested. Ethnohistorical research, which was far closer to true anthropology than how archaeology was practiced up until the advent of processual archaeology, was seen as critical to gain perspectives on the past. Processual archaeology, which associated itself with the other social sciences such as political economy and sociology, tried to be as scientifically objective as possible when observing and reporting data.

In the 1980s, some archaeologists, especially in Great Britain, decided that processual archaeology had serious drawbacks and developed what was called postprocessual archaeology. Postprocessual archaeology emphasized the political ramifications of research, examining itself from a detached, third-person point of view to demonstrate that how archaeological research was presented was just as critical as the research itself. The postmodern viewpoint rejected the processual idea that universal laws could apply to humanity. Furthermore, the roles of the individual, families, social classes, and the like were brought back to the forefront in opposition to the generalist universal viewpoint of processual archaeology. Postprocessual archaeology also claimed that strictly empirical and scientific observation was not possible and, in attempting to practice processual archaeology, archaeologists trapped themselves into a single closed-minded perspective. There are of course many other archaeological paradigms, but these major trends serve to demonstrate the complex evolution that the discipline has undergone in the past century. Now, in the late 20th and early 21st century, processualism and postprocessualism have backed off from their former extremist viewpoints, leaving archaeologists more freedom than to adhere dogmatically to one school of thought or another.

The Basics and Growth of Archaeological Methods

Archaeological methods have evolved alongside modern technology. From the picks, shovels, and blasting materials of the 19th century, far subtler and less destructive approaches have been increasingly refined. Archaeological excavation is a destructive process; once a site is dug, it no longer exists, and we must essentially rely on the archaeologists' word as to what was found, where, when, and how. Therefore, taking notes is essential so that any given site should theoretically be able to be “re-excavated” by future archaeologists seeking data that was perhaps not originally published, or to offer reinterpretations of said data. Consequently, archaeologists make the effort to preserve and conserve as much of the excavated material as possible, placing it in a repository such as a museum for safekeeping.

The technology the archaeologist uses depends entirely on his research questions. These research questions, or hypotheses, which processual archaeology advocated, still

lie at the heart of archaeological research. Archaeologists no longer dig a site simply to collect as many artifacts as possible, but choose and dig a site to answer specific questions. Ground-penetrating radar can prove useful in locating significant anomalies underground, but it will be many years before subsurface “photographs” can be taken. It is unlikely that such technology will ever replace excavation. Excavation itself, however, remains almost as basic as it has always been, utilizing picks, shovels, and sometime bulldozers and backhoes to get at deep cultural layers. The simple handheld trowel, commonly used for cementing and plastering, is the primary tool of excavation, used in order to damage as few finds as possible and to find as many as possible in situ so that their exact location within the site can be recorded before they are removed. Brushes and finer tools such as dental picks are also used.

The archaeologist seeking a site that is not visible on the surface is taking a chance. He must either dig a series of test pits or trenches to locate cultural deposits, or else rely on local knowledge or the chance that someone before located the site either accidentally or intentionally. The metric system is used universally now, and a typical unit is a 1 × 1 meter square, which can then be expanded and the site eventually mapped onto an easily readable grid. Tape measures and line levels are standard tools, and many sites can be excavated without any electronic technology. On the other hand, an archaeologist seeking to understand the settlement pattern of a past society might concentrate less on subsurface excavation and more on mapping as many structures as possible in relation to the surrounding environment, such as the proximity of food resources and relations to other settlements in the vicinity. Modern conveniences such as aerial survey, satellite imagery, and the Global Positioning System (GPS) provide improved accuracy for this kind of work. Transits and theodolites are still used, but total stations, which use laser technology, can pinpoint positions in three-dimensional space far more accurately and the data are fed into computers. Technology such as portable three-dimensional scanners can virtually record anything from an artifact to a monumental structure, thus preserving these in computerized form. For archaeologists concerned with human remains, CT scans offer unparalleled insight into the biology of populations. Egyptian mummies that had to be unwrapped in the past can now be left intact and seen in full through this method. Archaeologists must, however, beware of the overuse of these modern marvels and not let their research be led astray by flashy technical displays.

Another important development in methodology is the increasing multidisciplinary approach to research. Archaeologists now collaborate more than ever before with other disciplines. This could be with palynologists to learn about ancient vegetation; with geologists to learn, for example, where the stone or clay used for toolmaking and pottery originated, thus permitting the documentation of

patterns of exchange between regions; and with geomorphologists to aid in the interpretation of sediment formation. Archaeologists may also work closely with experts in various branches of zoology and marine biology, and increasingly with geneticists. These are but a few examples of how archaeology has expanded to acquire as much information as possible about a given site and to address very specific research questions.

Dating Archaeological Finds

Once scholars had rejected the biblical timeline in the 19th century, other means of dating archaeological sites were needed. The observation of stratigraphy, which simply means that lower strata are older than the successive higher strata, was an early form of relative dating. The concept of the Three Ages also took hold. Scientists subdivided advances in technology into the Stone Age, the Bronze Age, and the Iron Age—terms that are still used today. The Stone Age was then divided into the Paleolithic, or Old Stone Age, which dated from human ancestors’ earliest flaked stone tool use around 2.5 million years ago, to the advent of agriculture, pottery, and ground as well as flaked stone tools representing the Neolithic, or New Stone Age.

The simplest method of dating a site is by historical records, or evidence of writing. An Egyptian monument that contains the date that such-and-such a king constructed it can be correlated with reasonable accuracy to our modern calendar, though becoming increasingly open to a margin of error the further back in time we go. Similarly, we can date a site if a simple object such as a coin with the portrait of, say, a Roman emperor is found within; if the stratigraphy is intact in which the coin is found, the layer cannot predate the production of the coin, thus providing a baseline date.

In the 20th century, significant advances in dating were made. Dendrochronology, or tree-ring dating, analyzes the patterns of annually produced tree rings of long-lived species. These growth rings vary in thickness depending on climate fluctuations. By looking at the patterns of living species of a given tree, scientists can gradually overlap extant patterns to older ones until a match to the piece of wood under question is found. In such a way the exact year the tree was felled can be determined, and thus the year in which a wooden tool or wooden structure was made. These rings can be preserved for many hundreds of years given the right arid conditions such as in the American Southwest. Thermoluminescence (TL) dating is used for ceramic objects of fired clay. Clay contains low levels of radioactivity, which traps the electrons within until the clay is fired, when the electrons are then released as light. The analysis process involves reheating the object to measure the amount of electron light that it emits, thus revealing how long it has been since the object was originally fired. Radiocarbon, or ¹⁴C (Carbon-14) dating, is a technique that

was developed in 1949 and is indispensable to archaeologists who excavate sites without pottery or wooden artifacts. Radiocarbon dating can only be used on organic matter, that is, something which has once been alive. Bone, shell, plant matter, wood, and charcoal (burned wood) can now be dated with a standard deviation of around ± 30 to 50 years. The technique has been, and still is, becoming increasingly refined since its inception, when the fluctuation in cosmic rays was not used to calibrate dates.

Radiocarbon dating works as follows: every living thing absorbs Carbon-14, a carbon isotope that is generated by cosmic rays. When the organism dies it stops absorbing the isotope. The isotope disintegrates at a known rate, having a half-life of 5,730 years. By measuring the amount of Carbon-14 left in the sample, it is possible to estimate when it died. Thus, we can obtain an approximation of when a tree was felled (and thus killed) to be used as firewood, or when an animal was killed to be eaten. This technique has, in certain areas of the world where dendrochronology is possible, been refined even further and the dates more accurately calibrated. The only drawback to radiocarbon dating is that the Carbon-14, present in a very limited quantity, is impossible to detect beyond around 40,000 years.

Accelerator mass spectrometry (AMS) radiocarbon dating, a technique developed in 1983, has the advantage of needing a much smaller sample (around 1,000 times smaller) than previously required. Small objects such as seeds can therefore now be dated, which is especially useful for the study of early human food production. AMS dating works by counting the number of Carbon-14 atoms left over in the sample, rather than measuring the decay events themselves. This technique also cannot be used for objects more than around 40,000 years old. For sites older than around 100,000 years to volcanic rocks 2 billion years old (beyond the purview of archaeologists, naturally), a technique called Potassium-Argon (K-Ar) dating is used, which was developed in the 1950s.

Early fossilized hominid remains are often found in association with roughly contemporary volcanic stone formations. The element potassium (K) is found throughout the earth's crust and has a long half-life (1,250 million years), thus allowing the dating of such material. Potassium contains a small amount of radioactive potassium-40 (^{40}K) atoms, which decay at a given rate. For every 100 potassium-40 atoms, 11% become the inert gas argon-40. Argon-40 is only able to escape from molten rock. When solidified, the argon-40 can no longer escape. Mass spectrometry is used to count the number of argon-40 atoms in ratio to the potassium-40 atoms. By determining how much of the original potassium-40 has decayed, this allows an estimate of how much time elapsed since the lava solidified. Aside from historical records and stratigraphy, archaeologists have to turn samples for dating over to specialized laboratories. This can prove very costly, especially when a large number of dates are needed. The scientific methods used for dating

these materials are a good example of how archaeology, which is not a hard science, works in collaboration with hard scientific methods to provide the most empirical and accurate data possible.

Future Directions

As we move forward into the 21st century, archaeology has lost none of its significance and wonder since its inception as a formal academic discipline in the late 19th century. There are still unexcavated cities and settlements all over the world, from the jungles of Mesoamerica to the sands of Egypt. Future archaeologists, therefore, have nothing to worry about in terms of finding new discoveries. It is just as difficult to imagine the tools that will become available to future generations as it was for the earliest archaeologists to envision those of today. Cultural resource management (CRM) increases in importance, and its practitioners are more than ever before becoming recognized as authorities equal to their colleagues in academia. With the never-ending expansion of the human population and the necessity of building more and more houses and buildings, and of finding farms and pastureland to grow more food, archaeological sites all over the world are in peril, and some would say that archaeologists are racing against time in some areas to salvage what they can for posterity. A site, once lost, can never be recovered.

In addition to development and urban expansion, the problem of illegal excavations and looting continues as it has done for hundreds, if not thousands, of years. Today's antiquities' markets are always selling or auctioning off pieces of the past whose provenance is unknown, most likely looted from a grave. Without provenance the artifact itself can tell us only a fraction of what it could have if found in a proper archaeological excavation. Most such objects acquired by museums in the great age of collecting during the 18th and 19th centuries are the results of such activities, and nowadays the countries of origin are increasingly demanding the repatriation of many such artifacts. This is a very thorny issue, and is unlikely to be universally resolved, as many of the objects were acquired before there were any laws governing the exportation of antiquities from countries such as Egypt. Modern collectors fuel the illegal trade in artifacts, but we must remember that the looters themselves have far different motives from the wealthy collectors to whom their finds are ultimately sold. A poor Peruvian farmer, for example, who finds a series of graves with goods such as pottery and other valuables, may sell them to a middleman and make enough money to feed his family for years. They are, after all, dealing with the graves of their own ancestors, and, in some ways, are more entitled to these objects than foreign archaeologists.

This is not to advocate looting or pot hunting, but merely to remind us that cultural sensitivity is a key requirement of archaeologists, who must increasingly

work in conjunction with the local governments and landowners in whose countries they are guests. Cooperation is essential, and archaeologists should always keep in mind that their findings must not only be published, but also relayed to the very people that hosted them; not only the government, but even the towns and villages that supported their efforts. After all, it is their past, and it belongs to them. The archaeologists' responsibility is to reveal and interpret their findings to the world.

EXCAVATION AND PRESERVATION

CHANG-HO C. JI AND ROBERT D. BATES

La Sierra University

Excaavation and survey are central topics in archaeology, and they constitute the main if not the only way in which the discipline of archaeology collects new data (Roskams, 2001). Our objectives in this chapter are to explore the development of modern archaeological fieldwork and to project a picture of the discipline's future. To this end, this chapter is structured in the following manner. First, we review the historical development of archaeological excavation and survey. Subsequently, we explain the organization of typical excavation and survey projects and their activities in the field. Third, we focus on specifying core claims and criticisms pertaining to processual archaeology and its response to the challenges. Fourth, we suggest an integrated paradigm approach to excavation and survey for future fieldwork, incorporating the identified fundamentals and merits of both processual and post-processual archaeology. Finally, we close by discussing central issues on conservation and preservation and developing an agenda for future discussion.

Development of Archaeological Theory and Method

Archaeology has a rather short history as an academic discipline. This also holds true for excavation and survey. During the 17th and 18th centuries, public interest in ancient ruins and history first began to evolve, and the

19th century saw an upsurge in explorations of ancient ruins. However, it was near the end of this century that true scientific excavation methodology was adopted (Renfrew & Bahn, 2008).

Several archaeologists have contributed to the early development of scientific fieldwork. Augustus Pitt-Rivers introduced a scientific, precise recording system into the discipline through his excavation of Cranborne Chase in southern England. He was concerned with not only discovering spectacular treasures, but also recovering "everything," recording and describing all items, no matter how ordinary they were. One of Pitt-Rivers's contemporaries was William Petrie, who devised his own method of *sequence dating* in order to accurately date multiperiod settlements in Egypt and Palestine. The most influential of the early excavation methodologists, however, was Mortimer Wheeler, who brought a strict grid-square system into the archaeological discipline through his famed excavations in England and India. Later, Kathleen Kenyon brought Wheeler's method to the Middle East and made it the standard tool of modern scientific excavation projects (Joukowsky, 1980). However, in recent years many European excavators have shifted toward the total-excavation techniques of Philip Barker (1996) involving the exposure of large areas of a site and giving careful attention to site drawing and preservation.

About the same time that Wheeler was developing his grid-square system to study Old World history, Alfred

Maudslay, Max Uhie, and Alfred Kidder were putting the New World on the archaeological map with their excavations in Peru, Mexico, and the southwest of the United States (Renfrew & Bahn, 2008). In addition, Kidder developed a regional approach to the study of archaeological sites. He recognized the vital link between a particular archaeological site and its surrounding areas, and suggested the employment of reconnaissance methods as a way to create a more detailed regional survey to explore cogent relationships. Several other methodological and theoretical developments also contributed to the birth of scientific field archaeology including underwater archaeology (George Bass), prehistoric archaeology (Gordon Childe), preservation and conservation of cultural heritage, collection and classification of anthropological data (Franz Boas), historical critical archaeology (Martin Hall and Stephen W. Silliman), urban archaeology (Sheppard Frere), ecological archaeology (Julian Steward and Grahame Clark), invention of radiocarbon dating (Willard Libby), and computerized recording systems.

Development is a building process. A discipline grows larger as the radius of significant theoretical and methodological perspectives expands and as the achievements of earlier periods are integrated into those of the next era of development. Likewise, in field archaeology, the 1960s was marked by induction of the “new” archaeology (hereafter processual archaeology) into the discipline under the leadership of Binford (1972) and Clarke (1968). According to O’Brien, Lyman, and Schiffer (2005), any discussion pertaining to modern excavations and surveys must address the issues raised by processual archaeology.

In the past, traditional field archaeology was largely concerned with how to explain the past and how people had lived; processual field archaeology attempted to explain the past based on an explicit theoretical framework, as well as to make valid generalizations based on sampling data. Processual archaeology advocated deductive field reasoning in that researchers began with advancing a hypothesis, collected data to test it, and reflected on whether or not the theory was confirmed by the outcome of the study. In contrast, traditional field archaeology was typical of an inductive approach in that archaeologists became involved in “piecing together the past” based on observation of a limited number of related events or archaeological sites and data. The research methodology of processual field archaeology usually employed quantitative data collection and centered on answering specific research questions, rather than attempting to address general issues with verbal and narrative data.

One important outcome of the processual archaeology movement was the growth of field projects that included well-defined research objectives and sophisticated regional surveys. That is to say that regional surveys had come of age as an important part of archaeological research under the auspices of processual archaeology. Researchers for the first time began to systematically conduct intensive field

surveys and selective soundings coupled with sophisticated statistical sampling strategies and improved conservation methods. The influence of the movement was also reflected in the development of world archaeology. A case in point was the field research dealing with the origins of human species and activities, such as Braidwood’s fieldwork in the Middle East for the origins of agriculture and Louis Leakey’s efforts in Africa to understand the early phases of human history.

Applications: Elements of Excavation and Survey

The overall method of excavations used by modern archaeological projects is still closely allied with the original template developed by Wheeler and Kenyon. Even so, the readers must be aware of the fact that there are many variations to this standard and oft-practiced methodology depending on research aims, field conditions, and technical and ideological factors (see Barker, 1996; Roskams, 2001).

Modern excavation teams are composed of a variety of personnel. In general, project directors are responsible for managing an excavation. They develop research goals by studying relevant documents, old maps and drawings, and previous work on the site. Project directors also conduct pre-excavation surveys of the site by examining aerial photographs, studying geophysical surveys, and walking the site. Once the excavation begins, they supervise the excavation in the field, oversee the budget, and guide the publication of the excavation results.

Field supervisors are trained archaeologists who work under the project director. They are responsible for a single area or field of excavation. Their responsibilities are broad and include devising fieldwork strategies for their squares; establishing a coherent stratigraphic picture of the finds from the field; organizing square supervisors and workers into an effective work force; supervising excavations; coordinating balk drawing and field photography; collaborating with the project directors, architects, and other specialists in the field; and keeping the records of the excavation results and findings. They are assisted by square supervisors who excavate and record the single-square data and organize the work of volunteers and paid workers in the square. In charge of initial extracting and recording of raw data, the square supervisor’s work is vital to the success of excavation.

The proper scientific methods for conducting an archaeological excavation and recording archaeological data are found in excavation handbooks and field manuals (e.g., Barker, 1996; Blakely & Toombs, 1982; Collis, 2001; Herr & Christopherson, 1998; Joukowsky, 1980; Kipfer, 2007; Roskams, 2001). These field manuals and handbooks allow project directors to choose a recording method that best represents the archaeological goals of the project. Before an excavation can begin, a surveyor must establish

the location of each square according to the general grid pattern of the site. Then, supervisors and volunteers prepare the squares prior to the actual excavation by removing debris from the square, setting up a benchmark for taking levels, and reviewing the final records of the previous seasons if a formerly excavated square is reopened. When the excavation does begin, volunteers and workers use a variety of tools such as hand picks, trowels, hoes, dustpans, brushes, ladders, and sieves according to the methodologies outlined in the handbook.

To maintain control within an excavation, archaeologists using the Wheeler method establish balks between squares. A balk is a cross section of the excavated areas within a square. In order for the balks to be useful, they must be trimmed regularly. A hand trowel or pick is used to create a vertical surface that reveals the various soil layers, architectural features, or intrusive elements. Usually, the square supervisor will label the various features in a balk with locus tags. Then the various layer and other features are drawn on a cross-section map called a balk drawing. At the end of the season, these cross sections are photographed to keep a permanent record of their location.

Archaeological discoveries, no matter how small, must be handled with great care in order not to lose any data. Pottery pails must be labeled appropriately in order to process them while avoiding pottery contamination. Pottery sherds need to be washed of soil debris so they can be analyzed. Floral, faunal, and bone samples must be placed in paper bags to prevent the introduction of mold spores. Radiocarbon samples are usually placed in aluminum foil to prevent contamination, while the contents of jars and bowl are processed through flotation to separate soil granules from seeds or other organic material.

Each discovery—from the smallest grains of sand to the architecture within a square—must be recorded accurately. The basic unit of an excavation is a locus, which represents an area being investigated within a square. Locus numbers are assigned to each area and generally recorded on individual locus sheets; these may represent soil, architectural features, or installations. In order to identify pits, burials, foundation trenches, surfaces, and other features, careful excavation is necessary. When archaeological data are collected correctly, new discoveries can be synthesized into existing historical evidence for the evolution of adequate site history and general sociohistorical theories of the site and its vicinity.

Apart from excavations, another important technique for understanding how an ancient settlement originated and thrived is the regional survey (Banning, 2002). Surveys are used as either ad hoc or pre-excavation preparation activities. Two of the most common survey methods are salvage surveys and reconnaissance surveys. A salvage survey looks for and documents as many ancient sites as possible before they are destroyed by modern and natural events and developments. A reconnaissance survey is usually employed when a field archaeologist intends to locate potential excavation sites or to acquire a broad picture of

settlement history in relation to the site under consideration for excavation. Following the birth of processual archaeology, archaeologists extended this line of work to develop more extensive and intensive regional surveys. They now can acquire large-scale perspectives on changes in settlement, occupation, and land use through time.

A survey team is regularly made up of four to eight persons, including a field director, an artist, a photographer, and volunteers, although its size and personnel may vary depending on the survey goal and resources of the project. Ideally, the purpose of a survey strategy is to undertake an intensive survey of all parts of the research area in a systematic manner. For example, from 1996 to 2000, Ji (2007) undertook an intensive systematic survey of the entire area of the Dhiban Plateau in Jordan, an area approximately 250 sq. km. The survey area was divided into about 250 parcels of 1 km × 1 km using a 1:50,000 scale Universal Transverse Mercator map. Each square was then assigned a sequence number. To increase the precision in locating the selected parcels, a Global Positioning System (GPS) device was used and each 1 × 1 sq. km was then surveyed in a systematic way, employing a series of 200 m spaced traverses; that is, each square was divided into five 0.2 × 1.0 km sectors through which the survey team walked or drove systematically. In this way, no part of the area was either under- or overrepresented in the survey. When a survey square contained previously known or conspicuous archaeological ruins, these sites were examined first and then their vicinity explored. At each site, a major effort was given to the collection of pottery sherds and artifacts on the surface. The survey team recorded and took photos of each archaeological feature in the site, while artists made field sketches of the site and any significant features. In addition, off-site features (e.g., rock-cut installations, cisterns, tombs, quarries, terraces, water channels, caves) were located and documented. Surface soil was also collected at some selected sites for geological and landscape studies.

In addition to the survey techniques used on the Dhiban Plateau, the *non-site* or *off-site* survey is also used to survey large areas. Thomas (1975) conducted the first non-site survey in the Reese River Valley of central Nevada. Here, Thomas collected artifacts across 140 spatial units (each 500 × 500 m in size), instead of surveying sites, to study how hunter-gatherers dovetailed their economic activities into the environment in the Great Basin area. Similar to Thomas's study was Foley's research (1981) in Kenya, where he studied the relationship between an off-site artifact distribution and the formation of central sites in the area. These surveys heralded the advance of landscape archaeology (see subsequent section), an approach that considers the distribution of material remains such as potsherds, fishing holes, stone tools, hunting grounds, seasonal shelters, and pathways as an investigation in their own right, with their own ends (Tilley, 1994).

A more recent example of non-site survey is Christopherson's random-square survey (Herr & Christopherson,

1998) in the Madaba Plains in Jordan. Here, the surveyor first divided his project area into about 2,000 survey plots, each measuring 200 × 200 m, and then randomly selected 100 out of these squares, roughly 5% of the total area of the region. Christopherson then used a GPS device to locate the random squares. Christopherson's project shows how Thomas's and Foley's early efforts led to the current evolution of a survey method fully grounded in the analysis of spatial units such as random quadrates (see Banning, 2002).

Beyond Processual Archaeology

The concept and movement of processual archaeology grew in popularity in the early 1970s, but soon it came under attack from multiple quarters. Some structuralist scholars argue that ideas and symbolic concepts of past societies are critical in understanding their actions and determining which cultural elements of their civilization survive and thrive (Arnold, 1983; Glassie, 1975). Along with this, some argue that archaeologists should study the structure of ideas in the minds of the ancients who made pottery and artifacts. Recurrent patterns on the material cultures are reflective of human and social thoughts behind the design elements. Hodder and Hutson (2004), on the other hand, viewed all data and knowledge as subjective and thus any attempt to find objective knowledge as illusive (see also Shanks & Tilley, 1987). Here, there is no such thing as objective hypothesis testing. Archaeology, in this perspective, is intrinsically linked with history, and field research needs to be primarily designed for historical inquiries rather than to promote a general sociological and cultural theory for different societies. On the other hand, neo-Marxist archaeologists emphasized the ideology of the elites and their desire to control the society as significant in shaping changes and developments of the society (Leone, 1984). This view emphasized ideology as a powerful force within ancient societies. Accordingly, archaeologists should give relevant attention to the weight of ideology not only in the process of data interpretation, but also at the stages of research design and actual fieldwork.

Processualist archaeologists responded to this wave of criticism by creating a new approach to landscape studies (Roskams, 2001). Formerly, a landscape was nothing more than a physical environment where archaeologists carried out reconnaissance in search of ancient evidence of archaeological sites. It is now perceived as a cultural construct that warrants a careful analysis in relation to an excavation site. The emergence of contextual data collection is also notable, demanding that archaeologists provide detailed, contextualized information in relation to their finds to promote fuller social explanation of the archaeological data.

Postprocessualist challenges, however, were most evident in the area of interpretation and theory evaluation as

it ushered in a cognitive-processual approach to archaeological data (Renfrew & Bahn, 2008). This new interpretive framework is different in several ways from the functional approach of conventional processual archaeology. The new processual archaeology now recognizes both ideology and internal conflict as important forces within past societies. Similarly, material culture is defined as having had an integral place within the construction of the early societies, helping later generations understand the cognitive and symbolic aspects of those societies. The new framework also gives increased attention to the historical approach of traditional archaeology, seeking to explain the ideological and socioeconomic evolution of early societies in their context of cyclical change and underlying long-term trends. Cognitive processualist excavators and surveyors continue to reject the extreme relativism of postprocessualist archaeology and Hodder's critical theory, but acknowledge the linkage between fact and theory as more ambivalent and complex than previously presumed in the 1960s and 1970s.

To Renfrew and Bahn (2008), cognitive processualists currently focus their research agenda in two main directions: (1) inspecting the bearing of symbols in social changes and transformation structure and (2) examining the conventional areas of research interest such as agriculture development and state formation. For example, the work of Flannery and Marcus (1983) in the Oaxaca Valley, Mexico, examined the evidence for religion and social division in addition to traditional issues such as diet, state formation, environment, and technology. Their ethnographic research shows some gender division of work areas in the household. The excavations also yielded evidence for ritual activities at the community and household levels. People were buried according to certain religious beliefs; variations in grave size and quality pointed to the presence of distinctive class division among those who were buried in the valley. The structure of social transformation is another current focus in that some processualists actively incorporate various new concepts such as positive feedback, punctual equilibrium, catastrophe, and self-organizations. The incorporation of these new concepts is designed to generate more effective and complete formal models of social change and cultural transformation. Within these models, human ideas and symbolic elements of human society bear prominent roles.

Future Directions of Archaeological Fieldwork

All archaeological inquiries ultimately involve a decision to describe something from the past—to ask questions and seek answers about earlier societies, requiring that data of some kind be collected, that the data be analyzed in some way, and that the researchers come to some conclusion or interpretation. However, fieldwork is not necessarily

a uniform application of the scientific method. Depending on research paradigm, substantive variances can exist between the types of questions, the form of data collection and analysis, and the meaningful conclusions that field archaeologists can draw with validity.

A question then arises as to how many paradigms currently exist in the discipline of archaeological fieldwork. Renfrew and Bahn (2008) advanced four major models: (1) structuralism, (2) critical theory, (3) neo-Marxism, and (4) cognitive-processual archaeology. Others see at least several methods of carrying out fieldwork including functionalism, Marxism, feminism, phenomenology, evolutionism, historicism, and cultural-historicism (Johnson, 1999; Trigger, 2006).

Most archaeologists, however, would agree on the salience of two broad research paradigms behind archaeological fieldwork: inductive and deductive (Roskams, 2001). The inductive paradigm proceeds from particular facts or empirical data to a general conclusion; the deductive paradigm involves essentially the reverse process—setting a hypothesis and then testing this assumption with data in order to arrive at a conclusion. The 20th century began with the rule of an inductive approach to archaeological fieldwork and ended with the ascendancy of a deductive approach. This change unfolded during the first half of the century but became dramatically embodied with the movement of processual archaeology in the 1960s and 1970s. The development of this phenomenon, however, was not a case of a deductive approach replacing an inductive approach. An inductive approach to fieldwork is still very much prevalent and it has strong support from many quarters of traditional and postprocessual archaeological communities.

Whether archaeological excavations and surveys can be “purely” deductive/processual or “purely” inductive/traditional/postprocessual, and as such be guided by one of two opposing approaches, remains uncertain, however. For example, archaeologists with a specific research agenda on the development of Iron Age religious rituals may uncover a variety of architectures and artifacts related to periods other than the Iron Age. In this case, the excavators have moral and academic obligations to gather all the data, albeit unrelated to their research focus, in a systematic manner and eventually describe and explain what has happened across all the periods in their field reports. This example illustrates how one field project can consist of deductive/processual and inductive/traditional components, although in this case the emphasis of the fieldwork may remain weighed toward one end of the continuum if the excavators continue to center their excavation efforts and resources on the collection of Iron Age cultic data.

In addition, archaeologists should be aware of the danger of the domination of one single paradigmatic view. Research projects that grow out of only one specific perspective tend to illustrate some part of the fieldwork while ignoring the rest. Indeed, what would occur if advocates of deductive processual archaeology paid more attention to

the broad range of historical issues and questions that traditional field archaeologists have generated for them? And what if inductive historiographic archaeologists spent more time exploring the range of socioeconomic phenomena that processual archaeology has sought to define and test?

The discipline of archaeological fieldwork may need to move beyond inductive/traditional versus deductive/processual archaeology arguments because both research paradigms are useful and important. In this context, it is encouraging to note that a mixed-paradigm approach to social science has recently gained favor as an alternative to the exclusive reliance on either a deductive or an inductive framework (Creswell, 2003; Johnson & Onwuegbuzie, 2004). For archaeology, a case in point is cognitive-processual archaeology, which seeks to incorporate the research questions of traditional and postprocessual archaeologists about ideology, internal conflicts, historical events, and chronology without giving up their positivist views on theory and data. By doing that, cognitive processualists attempt to bridge the schism between traditional and processual archaeology, as well as to eschew the incompatibility distinctions of those who assert fundamental discrepancies between inductive and deductive research.

In the 21st century, however, archaeologists may need to go further by adopting a more integrated paradigm. This approach is more appropriate for field archaeologists whose primary goal is not to search for a simple corroboration of processual, traditional, Marxist, or historiographic archaeology but rather to expand their understanding. In other words, the aim of integrated research is not to supplant either the inductive/traditional or deductive/processual archaeology paradigm, but rather to draw from their strengths and minimize the frailties of single-paradigm field studies. Its logic of inquiry requires the skillful use of both induction and deduction in order to uncover and rely on the best of a set of explanations for understanding one's results (de Waal, 2001). To this end, excavators and surveyors must collect multiple forms of data using divergent strategies and methods in such a way that historical and socioeconomic questions are both best and most fully answered through different data sets.

In an integrated fieldwork model, researchers first need to decide whether to give the inductive/traditional and deductive/processual archaeology components equal eminence or to give one paradigm the dominant position (see Johnson & Onwuegbuzie, 2004, pp. 19–20). A second dimension to consider is time ordering of the inductive/traditional and deductive/processual phases within or across research, with the phases operating in a simultaneous or consecutive manner. Another dimension to cogitate is where integration would take place: at the stage of research question, data collection, analysis, or interpretation.

Due to these multiple assorted dimensions, the potential number of manners in which archaeological research can integrate inductive/traditional and deductive/processual methods is immense. For example, a variety of research

paradigm models can evolve depending on how inductive/traditional and deductive/processual paradigms are arranged along the research procedure of research objective, data collection, and data analysis. Figure 10.1 presents six integrated designs, which may be called across-research-process-paradigm designs. For another example, once a researcher employs an integrated paradigm approach, he or she should make two principal decisions: whether or not to operate chiefly within one paradigm and whether to blend the two paradigms

simultaneously or sequentially. Figure 10.2 illustrates nine of many possible designs that can be constructed based on these decisions. We can easily come up with more creative and more sophisticated fieldwork designs than those illustrated in Figures 10.1 and 10.2. For instance, archaeologists may choose to increase the number of repetitions between deductive and inductive data collection and analysis or formulate a fieldwork design that combines both integrated paradigm design features in Figures 10.1 and 10.2.

SOURCE: Adapted from Johnson and Onwuegbuzie (2004). Figure prepared by Chang-Ho Ji.

NOTE: Bold letters in table denote high priority or weight, and nonbold letters denote lower priority or weight.

A key point is that the potential for variation is limitless. A variety of integrated methods, research designs are feasible; excavators and surveyors can be innovative, rather than constrained by one dominant orientation once integrated methods research is employed. In integrated methods research, excavators and surveyors should be able to generate designs that more adequately and efficiently address their research questions than the routine conventional fieldwork where one operates completely within either an inductive/traditional or deductive/processual paradigm orientation.

Revolutionizing the archaeological community to ensure that the research designs of all field projects are predominantly integrated-paradigm oriented is an ambitious goal. Yet, the discipline as a whole is apparently transitioning from a strictly hypothetico-deductive method of processual archaeology to a future of an elastic field archaeology that is more inclusive, synthetic, and diverse in scope. For fieldwork paradigms, as stated above, it could mean the integration of inductive/traditional and deductive/processual excavations and surveys. In regard to field technique, it also could lead to incorporating various new technologies into excavations and field surveys (Roskams, 2001). Many important advances have indeed been made

in relation to information technology, ranging from (but by no means limited to) geographical information systems to statistical software programs, geophysical engineering, and aerial and satellite photography. If excavations and surveys are to be truly cutting-edge, then archaeologists must incorporate these techniques and use them for data collection and presentation. There is little doubt that information technology will have a major impact on archaeological fieldwork in the coming decades.

Finally, there are potential problems that field archaeologists should avoid; each is a trap that relates to the complexity and technical bases of fieldwork itself. First, archaeologists should avert the “a priori purposeful” trap because fieldwork is not a latent activity and because the process of excavation and survey demands that archaeologists let research goals and designs evolve with them. Good field research needs working goals, hypotheses, and designs that are not static. Second, excavators and surveyors should be careful not to engage in the “evaluative” trap by interfering with the normative dispute over the inductive/traditional and deductive/processual paradigms and because both processual archaeology and postprocessual archaeology are consequences of rather similar vigorous scientific processes. The archaeological fieldwork paradigm is, therefore,

“both” or “relative” rather than “good” or “bad.” Finally, field archaeologists should avoid the “verification” trap. The goal of archaeology is not merely to “interpret the past but to change the manner in which the past is interpreted in service of social reconstruction in the present” (Shanks & Tilley, 1987, p. 195). It is fundamentally “a political practice” under the influence of dominant political and ideological forces (Palus, Leone, & Cochran, 2006, p. 86). Archaeologists must be aware of the political conditions and the wider ideological battle over power and their influence on archaeological scholarship. Scientific fieldwork may yield knowledge about the nature of an ancient community, but it cannot comment on what are “true or false” political, ideological, or religious claims.

Conservation

Once an integrated model has been selected and the artifacts have been excavated, archaeologists face the problem of how to prevent the artifacts from further deterioration while they are being studied. When artifacts are *in situ*, they chemically interact with the environment around them. In dryer climates like Egypt and Chile, some artifacts are less likely to be affected by their surroundings. In moist climates like northern England or the Amazon, deterioration can accelerate through contact with bacteria, insects, animals, salts, or minerals, depending on the type of artifacts. Even the most stable artifacts, such as highly fired ceramics or stone bowls, can develop stains and calcification that make them difficult to analyze. Once artifacts are removed from their *in situ* environment, they begin to interact with their new environment in ways that may be harmful to the artifacts. Removing some types of artifacts, then, can cause permanent damage (Cornyn, 1990).

Artifact conservation is a relatively new phenomenon; its basic purpose is to stabilize artifacts without a negative effect on the archaeological evidence (Banning, 2000, p. 126; Pye, 2001, pp. 9–10). Some archaeologists use an aggressive approach that attempts to remove all corrosion, especially from metal or glass objects that might continue to deteriorate with oxidation. Unfortunately, this approach may render the artifacts useless for certain types of archaeological analyses such as noninvasive spectrography, archaeometry, metallurgical testing, or UV and ultraviolet examination. It may also prevent the application of future technologies for the study of the artifact. Therefore, most archaeologists prefer a less invasive approach that interferes as little as possible with the archaeological evidence preserved on the artifact. Archaeologists should always attempt to create an environment that will not accelerate deterioration.

There are several principles that should be considered when dealing with artifacts. First, wherever possible, archaeologists should consult a conservator throughout the process of conservation. Conservators are professionals who are trained in the art of preserving artifacts and can

help create guidelines for their collection, handling, cleaning, repair, and storage. Many specialize in specific material such as bronze, glass, or textiles and should be consulted before entertaining the use of any invasive conservation methods on these materials. Second, most artifacts are fragile; before beginning conservation a plan should be outlined identifying any problems with the artifacts, the objectives for dealing with those problems, the types of conservation techniques that are available, and any risks to the artifacts. It may be that some artifacts have more immediate needs and will benefit from conservation, while others may not need immediate attention or may not benefit at all from conservation (Banning, 2000, pp. 126–127).

Third, all conservation projects should include accurate and well-maintained records. A system for assessing and recording information about each artifact and exactly what conservation methods will be used should be in place prior to conservation. Labels should be securely attached, reliable, and stable. A database or other computer program can be used to record artifacts’ information and should be backed up regularly to ensure long-term preservation. Fourth, any conservation project should be a collaborative effort. Archaeologists, curators, and other specialists may have very different criteria for determining if an artifact should receive special conservation methods. An archaeologist might treat an object because it contributes to an understanding of the stratigraphic sequence within an excavation, a curator might see an artifact for its value as a display piece, and a specialist might need to preserve organic residue for further testing. All interested parties should work together to stabilize an artifact without negatively impacting its archaeological contribution (Pye, 2001, pp. 34–35).

While protecting artifacts from further decay is an important consideration, there may be ethical issues to consider before undertaking a conservation project. Most excavated artifacts belong to the host country. Although archaeologists may take them from that country to be studied outside of the region, they are expected to return the artifacts in a timely manner as specified in the permit. Even artifacts excavated by nationals may be claimed by indigenous peoples if they were found on native lands or have ritual significance. Such groups may have a stake in whether or not a conservation project is undertaken, and archaeologists and curators may need to consider whether conservation is worth the expense if in the end the artifact is returned to the host community. In any event, culturally sensitive artifacts and human remains need to be treated with respect. It is no longer acceptable to display burial artifacts or the bones of someone’s ancestors without permission from or consideration of the interests of indigenous peoples. Wherever possible, excavated sacred remains need to be repatriated—museums and universities with bone collections likely collected in the 19th century should create appropriate protocols for the return of these artifacts to their respective cultures. Archaeologists should

always seek to respect the laws of the host countries as outlined in the permits and any international laws and conventions that may apply.

Preservation

Where conservation seeks to stabilize artifacts, archaeological preservation attempts to maintain artifacts in that state indefinitely. Until recently, archaeological preservation was the responsibility of museum curators and specialists. In the past, archaeologists were only interested in what data artifacts could contribute to their understanding of a culture or a civilization. For archaeologists, conservation served the purpose of maintaining an artifact in a state that would allow it to be studied in depth for as long as was necessary. Once the scientific research was completed, artifacts were put into the care of museum curators and archaeologists were no longer involved. Likewise, archaeological sites were turned over to cultural resource managers, indigenous populations, or antiquities authorities to decide whether resources should be allocated for long-term preservation. In recent years, archaeologists have begun to see the value of preserving artifacts not only for their own research or that of future scholars, but also for the contribution to informing and educating the general public (Pearce, 1990, pp. 1–3).

Several factors have contributed to the need for archaeologists to preserve not only artifacts, but also the sites from which they were excavated. Recent destruction of archaeological sites in Iraq and the vandalism of the Iraqi National Museum have served as a wake-up call to those who have a vested interest in archaeological preservation (Emberling & Hanson, 2008). Widespread looting throughout the world has emphasized how fragile archaeological and cultural heritage sites are becoming. With little protection from local authorities, many ancient sites are seriously threatened. Even archaeological sites currently being excavated are at risk of vandalism, forcing archaeologists to re-evaluate their preservation strategies.

Although archaeological and cultural heritage sites are increasingly threatened, archaeology as a discipline has gained widespread popularity. Movies and documentaries have glamorized the role of the archaeologist, and some archaeologists have become pseudo-celebrities, appearing in numerous television shows and documentaries. Television channels such as Discovery, National Geographic, the History Channel, and others have inspired many people to take an interest in archaeology. Many shows have highlighted the threats that historical sites face and brought the need for action into the public conscience. In addition, historical tourism has also risen in popularity. For more than a century, visitors have flocked to exotic sites such as the Giza Plateau in Egypt, the Acropolis in Athens, and the ancient city of Machu Picchu in Peru. Most of these sites are well guarded and well preserved to prevent looting or destruction from

overuse. However, smaller sites (especially those en route to larger sites) are also attracting visitors and becoming tourist destinations. These sites are frequently unguarded and do not have the resources for long-term preservation. Archaeologists and cultural resource managers have found that attracting visitors to an archaeological site, even a small one, can help reduce looting and vandalism. Unfortunately, most small sites do not have the budget for the long-term preservation needed to prepare them for the general public. In order to preserve a historical site, archaeologists must engage the local community in the process. When local communities are involved in the management of a cultural resource, they often recognize the financial value that tourism brings and frequently take pride in hosting an archaeological site in their community (Hodder, 2004, pp. 164–166).

Conclusion

The future of archaeology is intimately related to the cultural heritage sites that archaeologists investigate and that now hang in the balance. On one hand, American audiences continue to be fascinated by what archaeologists do and what they discover. Although the media has portrayed archaeology in a sensationalist manner, it has provided a medium for archaeologists to correct misunderstanding, introduce new discoveries, and inspire a new generation of archaeologists. However, it has also come at a price. The added attention has not gone unnoticed by desperate communities who see cultural remains as a potential resource. In the face of poverty, many communities near cultural heritage sites have turned to looting as a way to survive. Little is being done to combat the destruction of archaeological sites throughout the world, and the appetite for looted antiquities has not abated. One can hardly blame these individuals and communities for taking advantage of this resource. Unfortunately, this destruction is so severe that some sites may never be excavated scientifically again. Indeed, the future and sustainability of any site lies in developing strategies that engage the local communities in the archaeological process. Local communities must become involved in all aspects of the archaeological process—from its planning and excavation to its management and security. These communities need to be encouraged to take ownership and pride in their cultural heritage and its archaeological sites. Only then will archaeology have a future.

ARTIFACTS, BURIALS, AND RUINS

GREGORY D. MUMFORD

University of Alabama at Birmingham

In the 21st century, archaeology faces many challenges as field archaeologists balance traditional, current, and emerging concepts and techniques. They must apply these to site selection, excavation, recording, conservation, and analysis, for both individual artifacts and their broader matrix in mortuary through occupational contexts. This chapter outlines the broad range of traditional to current approaches for studying artifacts and their contexts, and incorporates selected issues and potential solutions for future archaeology.

As in many fields of study, the archaeology of diverse study areas/periods (e.g., Egyptology, classics, Mesoamerica) has splintered into numerous specialties (e.g., Egyptian archaeology, Egyptian language) and subspecialties (e.g., Old Kingdom Egypt, New Kingdom pottery). Such experts also rely on other fields and specialists for input (e.g., geology, paleobotany, zooarchaeology). This increasing diversification has challenged archaeologists to communicate more effectively than in the past—among themselves and with other disciplines, especially in cross-cultural studies and broader global issues (e.g., the 4.2 K BP event: a global climatic change that affected world cultures differently around 2200 BCE). To anticipate, remain competitive, and deal effectively with a seemingly infinite range of field-specific to site/period-specific requirements, current and future generations of archaeologists must now deal with an ever-growing and indispensable toolkit of varying expertise, technology, and analytical tools.

Archaeology also faces such major and increasing obstacles as global warming, population growth, a worldwide economic recession, political turmoil, urbanization, agricultural expansion, site destruction, and looting. These and other factors impact archaeological remains, whether by exposure of previously submerged, and naturally protected, waterlogged sites, or the targeting of sites for looting and destruction (e.g., the March 2001 destruction of the Bamiyan Buddhas and the 2003 looting of the Iraqi National Museum in Baghdad).

Rediscovering Our Past

The emergence of social stratification and inclusion of wealth in burials has been accompanied by persons interested in retrieving such items, initially mainly for personal gain, and in more recent centuries for material and intellectual enrichment. One of the earliest “archaeologists” was an Egyptian prince, Khaemwaset, who served King Ramesses II (ca. 1279–1213 BCE) and investigated and restored various ancient monuments (Kitchen, 1982, p. 107). King Nabonidus of Babylonia (ca. 555–539 BCE) was another pious individual who investigated, restored, and collected antiques from past monuments. In Europe, the Renaissance (14th–17th centuries CE) marked a revived interest in antiquities: wealthy persons collected antiquities for display in their homes; more meticulous

investigators studied and researched various monuments, such as Stonehenge (William Stuckley, 1687–1765 CE) and the Great Pyramid in Egypt (John Greaves, 1602–1652 CE) (Lehner, 1997).

Although digging began in the early to mid-1700s at sites such as Herculaneum and Pompeii, the first scientific excavation is generally credited to Thomas Jefferson's 1784 investigations of a burial mound on his estate in Virginia. The landmark publications of geological stratigraphy and evolution, including James Hutton's *Theory of the Earth* (1785), Charles Lyell's *Principles of Geology* (1833), and Charles Darwin's *On the Origin of Species* (1859), guided early archaeologists' concepts regarding the formation and antiquity of the archaeological record. During this period, Jacques Boucher de Perthes's discovery and publication (1841) of human hand axes alongside the remains of extinct animals slowly began to convince fellow scholars that humanity had appeared much earlier than the 4004 BCE date calculated by some theologians. C. J. Thomsen published the notion of a *Three Age System* between 1836 and 1848 CE, dating European artifacts to successive ages of Stone, Bronze, and Iron, which remain the basis for many relative chronologies across the world.

This *Age of Discovery* paralleled a resurgence of interest in the ancient civilizations of Egypt, Syria-Palestine, Anatolia, Mesopotamia, the Aegean, and elsewhere. The Napoleonic expedition to Egypt from 1798 to 1800 included over 100 scholars and discovered the Rosetta Stone, which Champollion deciphered in 1822, thereby enabling the translation of innumerable hieroglyphic texts. Botta and Layard led French and British expeditions to Mesopotamia in the 1840s, but cuneiform remained unreadable until Henry Rawlinson deciphered it in the 1850s (Lloyd, 1980). John Lloyd Stephens explored Mayan ruins in Central America in the 1840s, but Mayan texts remained undeciphered until the 1960s. In the 1870s and 1880s, Heinrich Schliemann rediscovered Homer's Troy at Hissarlik in Western Anatolia (Bryce, 2006). Archaeological skills matured during this period, most notably demonstrated between 1887 and 1898 by General Pitt-Rivers, whose excavations and full publications of Wor Barrow remain a peak achievement in archaeology.

The early to mid-1900s witnessed further developments in archaeology. W. M. F. Petrie introduced a more meticulous approach to excavating and recording in Egypt and is famed for inventing seriation dating at a predynastic cemetery at Naqada. He placed separate pottery groupings in relative chronological order by tracing the gradual devolution of a wavy-ledge handle on a particular longer-lived vessel form. Gordon Childe initiated revolutionary approaches to assessing the origins of cultures in prehistoric Europe, arguing for indigenous factors behind changes in material culture. Sir Mortimer Wheeler applied a grid-square technique of excavation, using vertical soil sections to trace and record stratigraphic layers and phases in relation to architecture at ancient settlements in India.

New scientific techniques for dating the past emerged after World War II, including radiocarbon dating in 1949. The increase in this and other technologies was paralleled by new theoretical and practical approaches to designing, implementing, and analyzing the excavation of sites, beginning with the *New Archaeology* (i.e., processual archaeology) in the 1960s. This approach was pioneered by Lewis Binford and others, who attempted to explain change and the processes of change in past cultures by using deductive reasoning, designing research questions, testing hypotheses, and quantifying data. This approach was modified in the 1980s and 1990s, using interpretive, or postprocessual, archaeology. This essentially emphasized that each past culture and circumstance requires a specific research design.

Mortuary and Occupation Contexts

The absolute most crucial point in archaeology remains defining and recording the context of all materials and artifacts as fully and accurately as possible. A *site* can be defined as a place containing traces of human activity that may range from a discarded or lost item along a trail (e.g., a jar) to an ancient city. It is the context that enables one to maximize reconstructions of past lifeways from innumerable components spanning microcontexts (e.g., a vessel's contents), to medium-scale matrixes (e.g., a chamber/dwelling, an altar/shrine, a body/tomb), and much broader-scale coverage of sites, regions, polities, cultures, continents, and the globe. To maintain this context, it is necessary to isolate and identify all (surviving) materials from a single depositional sequence, or a *locus*. A locus might reflect an individual act of depositing garbage in a midden, placing an offering on an altar, or interring a body.

By distinguishing contemporaneous materials from earlier worn, or broken, debris within such deposits, archaeologists can begin to make more meaningful assessments about the significance of artifacts within and across a single time frame. It becomes much trickier, however, to link multiple spatially separated deposits the further apart such loci lie within a structure or site, or between sites and across regions. For instance, the emergence of certain material cultural traits in one location may appear later in a more distant region. On the other hand, some artifacts may be retained longer as heirlooms (e.g., royal name seals), thereby generating an unnatural life span for an object that becomes less useful for dating.

Social Groupings

Any assessment of past settlements, burials, and artifacts will almost inevitably be guided by the nature of a given society. Past cultures and site types can be subdivided broadly according to several basic categories of social organization: hunter-gatherers (bands), segmentary

societies (tribes), chiefdoms, and early states (complex societies) (see Renfrew & Bahn, 2008). These social groupings often display distinct types of occupation, burials, and artifact types in the archaeological record that enable their differentiation, while other aspects may be more generic. In general, site complexity and social hierarchy increase continuously from prehistoric hunter-gatherers to early and modern complex state societies.

Hunter-Gatherers (Bands)

Archaeologists have applied systematic and unsystematic surface surveys to detect past hunter-gatherer sites: seasonally occupied base camps, transitory camps, wild vegetation gathering areas, animal migration routes and hunting zones, kill sites, butchery sites, and lithic sources and production sites. Ethnoarchaeological studies have been especially helpful in reconstructing past activities. For example, studies of the Kalahari !Kung San bushmen, Australian aborigines, and other bands reveal that most bands of hunter-gatherers number around 25 persons, with members rarely exceeding 100 people. Their mobile lifestyles and high infant mortality discourage large families. The !Kung San hunter-gatherers also have distinct patterns in their seasonal summer camps, displaying several hut clusters placed closer together according to kinship ties within an extended family. Each hut also has a hearth and an activity area per band member.

When examining ancient seasonal campsites, it is often impossible to distinguish single-occupation phases, which have frequently merged into an admixture of artifacts, bones, and other debris among various features (e.g., hearths), and hut circles. In such circumstances, archaeologists obtain a long-term idea of activity patterns, while a meticulous collation of conjoining bone and stone fragments aids in isolating a series of contemporary activity patterns across a site. For example, Lewis Binford resided among the Nunamiut Eskimo in Alaska to clarify the more generic seasonal movements and the use and discard patterns by modern hunter-gatherers in order to comprehend better the formation process behind past hunter-gatherer sites and material culture assemblages. His study isolated such generic hunter-gatherer actions as bone-fragment discard patterns.

Site catchment analysis represents a more recent approach to comprehending past hunter-gatherer territories. Ethnographic and archaeological research has demonstrated that the further the base camp, the less apt mobile bands are to exploit resources directly. A two-hour walk constitutes the general radial limit, but may extend between 5 and 10 km depending upon the traversability of the surrounding terrain. One study of a typical hunter-gatherer group's range (i.e., site exploitation territory), in the Amboseli region of Kenya, examined every 10 m square grid unit in a 600 square km area. The project collected a sample of 8,531 stone stools, and it was estimated that a band of 25 persons had discarded 163,000 artifacts

per year: a daily average of 18 items per person. The artifacts used by mobile hunter-gatherers tend to be less cumbersome and easily carried, often negating the adoption of such things as pottery containers.

Ethnographic and archaeological evidence also aid in clarifying the seasonal availability of food in relation to its exploitation by and the movements of hunter-gatherer bands. For instance, late Paleolithic hunter-gatherers at Wadi Kubaniya (northwest of Aswan) apparently collected tubers as a staple food (mid-October to mid-August), relied more on fish and mollusks when these sources were obscured during the flood season, and supplemented their diet with seeds and dom palm fruit in briefer periods (November to February and March to April, respectively) (see Midant-Reynes, 2000).

Separate hunter-gatherer bands are also known to meet occasionally for rituals, celebrations, competitions, and other shared activities. A recent example is an early Neolithic, nonresidential, *cultic* center at Gobekli Tepe in Anatolia, which has at least 20 circular structures with carved animals and insects.

In hunter-gatherer cave sites, where occupation layers are much better defined, it is possible to trace changes in hunting and gathering patterns over time. These can be influenced by changes in climate, sea level, and coastline location. For example, at Elands Bay Cave in South Africa, distinct modifications occur in a hunter-gatherer group during the late Ice Age to Neolithic period, ca. 11,000 to 3,000 BCE. The sequence of faunal debris and cave art revealed a gradual switch from hunting mostly open grassland fauna to exploiting mainly marine species in response to rising sea levels and an encroaching coastline and estuary.

Hunter-gatherers' burials also provide further information about their mortuary customs and past lifestyles. For instance, some seasonal hunter-gatherers in the Levant practiced defleshing (excarnation) followed by the eventual placement of disarticulated bones in a regional burial ground (Mazar, 1990). Neolithic males from Niger exhibit abnormally high lesions (i.e., mechanical stress, or joint disease) on their arms and feet, reflecting hyperactivity in specific muscles associated with running and probably operating bows and other projectiles in hunting. In contrast to settled populations, prehistoric hunter-gatherer bodies in temperate climates and open grassland tend to be free of parasites.

Segmentary Societies (Tribes)

Segmentary societies (tribes) are often recognizable in the archaeological record through traces of farming; animal husbandry (e.g., meat from livestock); exploitation of secondary products (e.g., milk, wool); a mostly sedentary lifestyle; household craft production (e.g., simple pottery); and a slightly more complex social organization, albeit a generally egalitarian lifestyle. A less visible affiliated

group includes nomadic pastoralists, who rely primarily on livestock. In general, a segmentary society may number up to a few thousand persons, and usually resides in either isolated dwellings (i.e., a *dispersed* settlement pattern) or small villages (i.e., a *nucleated* settlement pattern). Of the latter housing pattern, some villages represent *agglomerate settlements* with residential and other units placed adjacent to one another in a tightly packed community (e.g., Catal Hoyuk) (Hodder, 2006). Housing may vary widely, from more makeshift wattle-and-daub structures, evidenced via postholes, to sturdier mud-brick buildings. James Hill's ethnographic study of Pueblo Indian artifact distributions revealed three types of room use in similar structures to Catal Hoyuk: storage areas, cultic chambers, and domestic quarters (i.e., sleeping, interacting, cooking and consumption of food). He found further gender-oriented room usage, but did not incorporate architectural components into this assessment.

In general, many segmentary societies have a designated burial ground (e.g., long barrows in Wessex), albeit displaying relatively equal ranking in burial goods and status. Estimates reveal that an average barrow could easily be completed by an extended family of 20 persons working for 50 days. A careful scrutiny of funerary goods and burial types associated with different age and gender groupings suggests slight differences in ranking within the limited hierarchy. For instance, compiling a frequency distribution (i.e., a histogram) for the quantities of various artifact types from burials of infants to elderly people would enable one to gauge the role played by *ascribed status*. In other words, one can determine the quantity and quality of goods associated with key age-groups that could not have earned a sufficient income prior to their interment. Other types of this social organization lack central cemeteries, and may place bodies under various structures, including houses (e.g., Neolithic Palestine).

Many communities contain a focal point, such as a public monument, or ritual center of sorts, maintained by religious elders. For example, segmentary societies represent the most likely social grouping associated with the early megalithic monuments in Europe (Cunliffe, 1994). Renfrew and Bahn (2008, p. 204) calculated that an early Neolithic causewayed enclosure in Wessex (ca. 4000–3000 BCE) required about 250 persons working for six weeks (100,000 labor hours) to complete it. This falls well within the capabilities of a segmentary society. Excavations at these monuments also reveal evidence for public feasting, another component generally associated with such peoples. Adjacent segmentary societies may also contain various shared and distinct traits: Ethnoarchaeological studies at Lake Baringo (Kenya) have revealed that some modern regional cultures distinguish themselves by specific ear decorations, while sharing other items of material culture. Hence, this cautions archaeologists that certain cultural markers may or may not survive to differentiate population groupings.

Chieftoms

In chieftoms, physical remains tend to reveal a more visible hierarchy in settlement patterns, housing types, and burial wealth. Although chieftoms lack urban centers, the chieftain's settlement generally dominates the surrounding villages, which may contain a collective population of 5,000 to 20,000 or more persons. An example of this is the 14th- to 15th-century CE site at Moundville in Alabama. This type of social grouping is normally made up of multiple families (lineages), which are dominated by one family whose relations tend to hold various ranks under the chieftain. This social organization often contains warriors and some form of defense (e.g., a palisade). The central settlement is permanent and generally characterized by one or more cultic installations (shrines/temples), frequently affiliated with the chief's duties; the central settlement has elite residences for the chieftain, his entourage, and specialized craftsmen. There is also normally a redistribution of produce and finished products (similar to taxation) from outlying villages to the central village; the chieftain would redistribute choice items among his entourage. In more hierarchical societies, the surrounding landscape might yield more intensive farming, plowing, and possibly the subdivision of fields into smaller plots. Settlements also yield evidence for local-craft specialization (e.g., metalworking).

Another focal point for chieftoms may include a large-scale monument, such as the late Neolithic mound of Silbury Hill (ca. 2800 BCE) and Stonehenge. Renfrew and Bahn (2008, p. 205) suggest the former structure took 3,000 persons about 18,000,000 labor hours and 2 years to build; using an identical number of workers, Stonehenge would have required 30,000,000 labor hours in a 4-year period to complete.

Regarding burial assemblages, the chieftain and other members of society have much richer funerary goods than the average community member. For example, a chieftain's remains from ca. 550 BCE at Hochdorf, in Germany, rest in a wooden chamber with a wagon, a large cauldron, gold-decorated drinking horns, and other luxury items (Cunliffe, 1994, p. 347). Christopher Peebles's cluster analysis of 3,000 burials from Moundville (Alabama) also revealed a good example of a ranked segmentary society. The wealthiest burials occurred within and beside the mounds. They yielded specific artifacts, such as copper axes and ear spools, associated with mostly male burials; additional high-ranking males and children are nearby. The next social stratum in this cemetery is located a bit farther away from the mounds: These burials contain both genders and similar funerary items, with the exception of copper. Those of the lowest social ranking are buried along the periphery of the site, having few burial goods.

Early State Societies

Early state societies display greater diversification in social stratification, craft specializations, government, and

settlement patterns, with populations ranging from at least 20,000 to several million or more people. Such societies and their hierarchies are sufficiently large and too complex to be kin-dependant: They often contain serfs (agricultural laborers), craftsmen, officials, priests, and an elite and ruling family. There tends to be greater differentiation between rulers and religion, with the ruling elite residing in palaces separated from temples. In ancient Egypt, however, despite having a distinct residence and secular duties, the pharaoh retained close symbolic and functional ties in many aspects of religion, temples, and cults, acting as a mediator and chief priest for the populace. Early state religions are also mostly polytheistic with multiple temples or shrines, sanctuaries, and cult figures. A few monotheistic religions emerge, including the consolidation of Jewish monotheism and the Torah during the Babylonian exile (586–539 BCE) and the exiles' return to Jerusalem and rebuilding of the (Solomon's) Temple (Stern, 2001).

A distinct centralized government and capital emerges in early complex societies, displaying palatial residences, administrative offices, temples, public buildings (e.g., granaries, water reservoirs, wells), industrial areas for different crafts, and residences for the elite and lower classes. Some large centers also contain substantial public ceremonial areas: arenas for competitive games and sports (e.g., Greek Panhellenic games, Roman hippodromes and coliseums, Mayan and Aztec ball courts); structures for public performances (e.g., Greek and Roman theaters); and areas for the receipt of materials and products from long-distance expeditions, regional-foreign tribute, and the dispersal of rewards (e.g., Egyptian New Kingdom temple and palace forecourts, podiums in the desert near el-Amarna). Many agricultural resources and finished products are sent as taxation, and sometimes as tribute, to the capital for redistribution within it and to the population in general. In many state societies, writing evolves for facilitating administration, communicating across distances, formulating religious doctrine, and expressing other ideas (e.g., laws, king lists, literature).

Aside from their own immediate hinterland, state capitals usually dominate complex settlement patterns containing a ranked hierarchy of provincial centers, towns, villages, hamlets, and farmsteads. Provincial capitals and outlying towns often have 5,000 or more residents, and frequently represent a microcosm of the capital city, but have less emphasis on, or an absence of, certain features, such as major temples and palaces. In central place theory, such settlements are placed in a theoretical and idealized landscape containing neighboring identical hexagons, each of which encloses a central town surrounded by equidistant villages and hamlets. Although few real landscapes approximate this pattern, settlement-pattern studies often incorporate site hierarchy (and Thiessen polygons) in computerized simulation models to assess the significance behind the dispersal and spacing of different settlement sizes and types across widely varying landscapes.

The boundaries of both small and large states and empires are sometimes discernible by the dispersal of particular structures and artifacts. Some states built roadways or other transportation networks between outlying quarries and settlements (e.g., Rome, the Inca, Egypt) and established elaborate systems of frontier forts and walling systems (e.g., Hadrian's wall in Britain, the Great Wall of China, Egyptian Middle Kingdom forts in Nubia). The Roman empire's northeastern frontier had a distinct Celtic buffer zone between its monetary market economy and a nonmonetary and marketless economy in Germany. The Celtic region yielded both Roman coins and Germanic products, facilitating trade between two different economies.

Early state societies display many types of burial practices and frequent socioeconomic stratification in their burials. Ancient Egyptian pharaohs received distinct and elaborate burials, especially during the Old and Middle Kingdoms (2700–2200 BCE and 2050–1650 BCE). Their large pyramidal tombs had adjacent royal cult temples, a priestly staff, and associated estates for revenues (Dodson & Ikram, 2008). In contrast, the Egyptian elite and middle classes received a broad range of much smaller and less elaborate subterranean burial chambers and rectilinear superstructures (mastabas) with fewer funerary possessions.

Early complex societies also had varying customs regarding the treatment of the body (e.g., cremation, inhumation, mummification, exposure, secondary burial, and other practices). In Egypt, only the middle and upper classes could afford mummification, with three main gradations of techniques and quality; the poorest Egyptians often received a simple pit-grave burial with minimal if any possessions (Grajetzki, 2003). The location and orientation of the deceased's remains also varies widely in early states. For example, the ancient Egyptian elite often preferred burial on the Nile's western side (associated with the setting sun and land of the dead), and usually arranged bodies in an extended position, with the head to the north and face to the east toward the rising sun (associated with rebirth).

Preparations for death also vary widely per society. Middle- and upper-class Egyptian tombs and their furnishings yield a wide range of specific items: an appropriate tomb complex that could function as a *dwelling* for the spirits of the deceased and family members (some tombs include bathrooms); substitute model workers (shabtis) to work in the place of the tomb owner(s) during the afterlife; statuettes to house the deceased's *ka*-spirit in case the actual body perished; lists, models, depictions, and physical offerings of food to sustain the deceased during the afterlife; papyri and other media recording spells to aid the deceased in bypassing diverse netherworld obstacles and attaining a successful afterlife; various garments, textiles, furnishings, and other possessions for the deceased's comfort in the next life; and a professional mortuary cult, or family members, contracted to maintain the deceased's tomb complex and mortuary offerings.

Early complex societies also have differences between age-groups and gender in burials. In New Kingdom Egypt (1550–1069 BCE), elite male burials often have a set of three successive coffins placed in a rectilinear sarcophagus versus a set of two for females; the husband's coffins also generally hold a papyrus document enabling the deceased to achieve successful entry to the underworld. The stark difference between the funerary furnishings for various social strata is also emphasized by the thousands of artifacts found in the relatively minor and virtually intact burial of Tutankhamun (1336–1327 BCE), in contrast to contemporary, simple pit graves for peasants who lacked possessions.

Artifacts

The aforementioned social groupings and contexts have yielded many different types and quantities of artifacts. Various definitions have been applied as to what constitutes an *artifact*, ranging from all inclusive concepts indicating an item of any size that has been used, altered, or manufactured by human beings (e.g., a pyramid), to more size-specific notions: Renfrew and Bahn (2008) define an artifact as “any portable object used, modified, or made by humans; e.g., stone tools, pottery, and metal weapons” (p. 578). Archaeological organizations, protection agencies, and the public also vary widely regarding the specific age and definition for an (archaeological) artifact or *antique*. A 100-year benchmark is often used (e.g., the Egyptian Supreme Council of Antiquities). In reality, however, any item used, modified, or made by a human becomes an artifact upon the moment of its initial manufacture or application.

Today, especially in light of the increased global construction and destruction in our urban and rural landscapes, archaeologists should consider all artifacts and time periods equally important within a given site or site component under excavation. For instance, the “modern” debris ignored in excavations 100 years ago are now “antiques.” The following discussion outlines some of the more pertinent aspects of the life cycle of various artifacts (and related contexts), from their raw state to trade and transportation, production, usage, discarding and reuse, preservation, excavation, dating and analysis, and “final” context.

Materials and Sources

Biased preservation tends to place artifacts into organic and inorganic materials, ranging from single material to multicompositional items with specific macro- and micro-climatic conditions assisting in their preservation. The materials composing artifacts also become increasingly complex from prehistoric to recent societies. Aside from humans, human ancestors’ (and even some animals using natural cobbles/stones and pieces of bone, shell, and wood

as “tools”) earliest and longest-lived artifact is represented by stone tools (from 2.5 million years ago to the present). Despite the application of a broad range of sedimentary and igneous stones for utensils, flint forms a particularly popular material.

The desirability of flint for tools is emphasized by the intense effort put into mining it in Neolithic Europe and at other times and places. For example, the flint mines at Grimes Graves in Britain (ca. 2500 BCE) contain around 350 vertical shafts that were cut between 9 and 15 meters in depth to reach a subterranean layer of high-quality flint. This single mining site may have produced over 28 million flint axes. A similar effort was expended in the Neolithic flint mines at Rijckholt, in the Netherlands, which may have provided 153 million axe heads based on the excavated sample of mines within this area. The labor and technology invested to obtain such axe heads included excavation tools (e.g., stone and antler picks), soil and rock removal devices (e.g., ropes and baskets), mining technology (e.g., ladders, scaffolding, and tunnel supports), support systems (e.g., supplying food to the miners), and artisans (e.g., shaping axe heads and applying wooden handles and bindings).

More labor-intensive and large-scale techniques appear in various prehistoric to early state quarries and mines. For instance, Egypt quarried large to colossal pieces of granite at Aswan to make or embellish statuary, pyramids, temples, and other structures (Arnold, 1991). This quarry's famous unfinished obelisk measured 42 meters in length, weighed about 1,168 tons, and was quarried by a methodical application of dolerite balls to pound a channel around and under the obelisk. Other societies exhibited a similar dedication to building monuments (e.g., an Inca stone quarry at Rumiqolqa in Peru and a statue quarry at Rano Raraku on Easter Island). Assessing the full range of unfinished artifacts represents one of the best analytical techniques for understanding ancient mining, quarrying, and construction processes. Otherwise, various devices are available, or emerging, to enable a detailed examination of artifact surfaces and interiors (see next section).

Other materials required much less labor to obtain. For example, many past societies used raw and locally available faunal and floral components, such as wood, bone, and shell. These may appear unaltered as artifacts (e.g., cowry shell money, game pieces) and in architecture (e.g., driftwood construction, prehistoric bone shelters). More complex and modified organic materials could be processed further by physically shaping or heating such materials (e.g., timber-frame housing, bone-inlaid wooden furniture, perforated shell necklaces).

Trade and Transportation

Various prized materials and products have been transported from sources that range from the immediate hinterland to destinations hundreds to possibly thousands of

kilometers away. Such items could be obtained via direct exploitation, or through other means, from direct trade between adjacent regions to indirect down-the-line trade. An example of down-the-line trade occurs in the Near East: During the Neolithic, obsidian is exported from two distinct sources in central Anatolia and Armenia to two slightly overlapping contact zones in Syria-Palestine and Syria-Mesopotamia; Ethiopia supplied Egypt with obsidian from the Predynastic to Ptolemaic-Roman periods (Nicholson & Shaw, 2000). In periods of socioeconomic and political strength, early states dispatched long-distance expeditions to obtain raw materials directly: Egypt obtained turquoise from South Sinai and sent maritime missions to Punt in eastern Sudan to trade for aromatics and African products.

Recent and improving scientific techniques permit us to pinpoint the sources of various materials and theorize about the relations between different regions. A microscopic examination of pottery and stone thin sections helps identify specific minerals and their characteristics, narrowing down their probable source areas. Trace-element analysis, and in particular Neutron Activation Analysis (NAA) and inductively coupled plasma mass spectrometry (ICP-MS), provide more precision in detecting sources for pottery fabrics, obsidian, and other stones. Isotopic analysis, including lead isotopic analysis, is best applied to isolating the sources for lead, silver, and copper items. In some cases archaeological and textual-pictorial evidence identify the means by which such materials are transported: Djehutyhotep's tomb in Egypt illustrates laborers dragging his colossal statue on a sled. In other circumstances the routes and means of transportation are inferred (maritime trade between islands).

Means of Production

Past peoples have applied numerous techniques to make artifacts using diverse and composite materials (e.g., stone, bone, antler, shell, leather, wood, plant and animal fibers, pottery, faience, glass, and metals). Production centers and incomplete products are ideal for clarifying the different stages in the manufacturing process for a given artifact. Stone tools often incorporate flint knapping using stones or antlers to strike blade flakes from a core, sometimes removing smaller flakes to create a serrated edge. Lithics and other tools, in turn, are often applied to manufacture items from bone, antler, leather, and wood.

Further insight into stone tool production is gained by replicating a given artifact by flint knapping, or, if possible, by refitting flakes and pieces extracted from the original flint nodule. Past uses for plant and animal fibers often involved stripping or shearing the fibers from their source, and spinning and weaving them into textiles, garments, and other products. Identifying fiber types and weaving techniques yields much information on the manufacturing process. For pottery, past cultures gathered different clays for specific applications and augmented them by adding a

grit and straw temper (for strengthening). Clay was mostly used to make containers by adopting such techniques as pressing clay over a mold, coil building and paddling, and using a slow or fast wheel. The completed unbaked product would be fired using various firing kiln types and temperatures. Ancient potsherds can be refired until a change is noted, using a scanning electron microscope, in order to determine the original firing temperature. A petrographic analysis of a potsherd thin section identifies the fabric composition. The production of faience, glass, and metal items is equally complex. In early copper technology, naturally occurring copper could be cold-hammered, or heated and hammered into shape (annealing); copper ores could also be smelted, melted, or cast in open or more complex molds (e.g., *lost wax* technique); coppersmiths often combined (i.e., alloyed) copper with some tin to produce bronze. Thin sections of metal items also enable a metallographic examination to discern more details about the manufacturing process.

Usage

It is often difficult to extrapolate the general, if not the specific, usage of a given artifact. In some cases, certain stone items are debated as being entirely natural (geofacts) versus human-made/used artifacts. Microwear analysis aids this process of elucidating the potential uses of stone tools. For instance, experimental archaeology has revealed microwear distinctions between stone tools used to cut bone, antler, hide, meat, wood, or other nonwoodlike plants; other wear patterns may indicate whether a stone tool was used for piercing, cutting, or scraping. Similar wear pattern analyses also illustrate the potential applications for bone, antler, shell, leather, and floral artifacts. Plant and animal fiber artifacts, such as garments, retain traces of wear, stretching, damage, mending, and other use history. Such observations can determine whether a garment was made for or placed unworn in a burial, or if it had been used in daily life (Barber, 1991). Residue analysis assesses the contents and hence usage of such things as pottery containers. Ethnographic studies may clarify further our comprehension of past artifact usages by observing how recent and ideally similar populations use identical artifact types. Such studies must be used with extreme caution, however, if extrapolating back in time to a different people and time period.

Discarding and Reuse

All artifacts are ultimately discarded or lost. Some items are made for a specific and very brief use (e.g., an ancient Egyptian bread mold), while others are produced to last for "eternity" (e.g., Tutankhamun's gold funerary mask). Aside from ornate items produced for purposeful destruction (e.g., in a potlatch), most short-term, functional items exhibit a minimum amount of craftsmanship

to enable them to function sufficiently. Artifacts may break accidentally, or through regular wear and tear, only to be discarded on the spot or in an adjacent midden. In other situations, particularly valued, or sentimental, items may be repaired: Egyptian predynastic pottery displays repair holes for lacing; chipped statuary and masonry are also often patched. Already “discarded” antiques may regain a value: ancient Egyptian jewelry, statuary, and other valuable commodities often appear in later contexts as trade items; Early Dynastic and Middle Kingdom stone vessels were exported as “antiques” to a late Bronze Age site at Amman (Jordan) from 1400 to 1200 BCE. Some artifacts retain their value as heirlooms for decades to hundreds of years (e.g., Egyptian cultic and royal statuary dedicated to the Karnak Temple [ca. 2000 BCE to the Roman period]). In many cases, long-lived and valuable materials are reused, smelted, or recut for new purposes. For instance, the Assyrian ruler Sargon II (721–705 BCE) led a campaign into the Levant and removed cypress wood beams from the destroyed palace roof of Ursa. Likewise, the Egyptian New Kingdom royal tombs in the Valley of the Kings were systematically robbed for their gold, silver, and other valuables to replenish the state during the impoverished Third Intermediate Period (1069–664 BCE). Other reuse is evidenced by the sarcophagus lid from Merenptah’s burial reused in a Dynasty 21 burial at Tanis in northern Egypt. Older rubbish is also often reused for diverse purposes: Earlier potsherds often get mixed into the clay for mud-bricks, and subsequently become introduced into later contexts through the disintegration of mud-brick structures.

Preservation

The greatest impact upon past material culture assemblages is the inherent biased preservation of inorganic materials versus more frequently lost organic materials, especially in temperate climates. However, in sub-zero conditions (cold climates), arid regions (dry climates), and water-logged circumstances (wet sites), organic materials are often well-preserved, enabling a far more realistic assessment of prehistoric to more recent artifact assemblages. For instance, the permafrost in southern Siberia has preserved many organic remains in steppe burials, including tattooed human skin, clothing, food, animals, and other items. The arid conditions in Egypt’s adjacent deserts have helped preserve human bodies, skin and hair, wooden furnishings, textiles, and papyrus documents. Wet sites, which lack oxygen, also yield well-preserved organic materials (e.g., bog bodies). The artifacts from wet sites emphasize just how many artifacts may be lost from temperate conditions, with organic items frequently numbering in the thousands and forming 75% to 90% of some assemblages.

Along with climate conditions, certain natural disasters provide exceptional circumstances for preserving organic materials. The 79 CE eruption of Vesuvius engulfed Pompeii in ash, thereby aiding the physical preservation of

many organic substances and the formation of encasing *molds* that retained the exterior morphology of many otherwise disintegrated items (Zanker, 1998). Early excavators poured plaster into such hollows to obtain casts of the exterior features, clothing, and other aspects of the victims and artifacts; more recently, injection of a clear liquid fiberglass enables the observation of both the exterior interface and the interior remains of artifacts and skeletal debris in these hollows.

Detection, Excavation, and Conservation

The available methods for detection, excavation, recording, and conservation have improved dramatically in archaeology over the past few centuries. Remote sensing and other techniques yield increasingly detailed images of artifacts and features beneath the soil, or within contexts that either cannot be excavated or are preferably left undisturbed or undestroyed (e.g., mummified bodies, cartonnage coffins). For example, fiber-optic cameras and similar devices enable a microscopic to macroscopic examination of ancient human remains and larger features (e.g., ancient Egyptian sealed boat burials at Giza [Lehner, 1997]). Diverse satellite-, aerial-, and ground-based remote sensing and other technologies detect sub-surface architecture, large features, and some artifacts. The technology includes diverse satellite imagery (e.g., Landsat, QuickBird); aerial remote sensing (e.g., Light Detection and Ranging [LIDAR], side-looking airborne radar [SLAR]); acoustic and seismic methods (e.g., bosing, sonar); electromagnetic devices (e.g., ground penetrating radar [GPR]); electrical resistivity; magnetometer surveys (e.g., fluxgate and alkali-metal vapor instruments); metal detectors; and smaller-scale, nondestructive technologies (e.g., X-rays, xeroradiography, computerized axial tomography [CAT scanner], magnetic resonance imaging [MRI], fiber-optic endoscope).

Although physical excavation should remain a viable technique for recovering artifacts and their broader contexts, the development and refinement of many nondestructive remote sensing technologies offers increasing alternate means to obtain ever more accurate, high resolution three-dimensional images and interior cross sections of archaeological sites, features, and artifacts. If such technology becomes sufficiently detailed and inexpensive for archaeology, then a point at which excavation becomes largely reduced to specific sites and circumstances is likely, leaving the retrieval of selected artifacts, features, and physical samples for salvage purposes, or further physical and visual analysis.

Dating and Analysis

The introduction of radiocarbon dating, dendrochronology, thermoluminescence, potassium-argon dating, and other techniques enables the placement of absolute dates on past

strata, features, and material culture assemblages, including refinement of date ranges previously assigned to more historical periods (e.g., pharaonic Egypt). The growing compilation of long and accurate sequences of annual tree-ring dates (dendrochronology) across the globe, especially in less temperate zones with contrasting seasons, promises to narrow the absolute date ranges currently available through high precision, calibrated radiocarbon dating. The latter technique currently yields date ranges from a few decades to over a century in accuracy. The ongoing refinement of other dating techniques, such as cation-ratios, should refine the dating of rock art and other more elusive contexts that lack better-dated or well-associated artifacts.

Archaeology has also developed increasingly better approaches to analyzing the data from survey and excavation work. Aside from formulating artifact typologies and providing simple descriptions of excavation results, more recent investigations emphasize assessing and explaining broader and more diverse aspects of the past, such as the nature of and changes to the past climate, environment, and landscape, land use, subsistence, health, diet, and beliefs in association with ancient settlements, burials, and their artifact assemblages. To clarify some of these aspects of past lifeways, archaeologists examine such things as textual-pictorial evidence (if present); fecal matter; stomach contents; bones (e.g., teeth, collagen); utensils and containers (e.g., associated with food preparation, consumption, and storage); microbotanical remains (e.g., pollen analysis, fossil cuticles, phytoliths, diatom analysis, rock varnishes, plant DNA), macrobotanical evidence (e.g., seeds, fruits, plant residues, wood); microfauna (e.g., insectivores, rodents, bats, birds, fish, land and marine mollusks, worms); and macrofauna (e.g., large animals). The refinement and emergence of new technology should only improve our abilities to assess human material culture, lifeways, behavior, and many other aspects.

Final Context

From an optimistic perspective, many excavated artifacts have reached their “final destinations,” namely in private and public storerooms or display cabinets. Most artifacts are displayed in isolation, however, being removed from, and conveying limited visual and written information about their original contexts. Ideally, archaeological site publications, electronic databases, archives, libraries, and other media should relay and preserve indefinitely the temporal, spatial, and inherent significance of each artifact and its original and varied past contexts. However, aside from the “obliteration” of a given artifact, such as pulverized stone, recycled metal, or decomposed organic materials, the “life cycles” of more durable artifacts in current archives and museum collections are actually still in transition. However, such happenings as the looting of the Iraqi National Museum and history’s lessons on the inevitable rise and fall of past and present civilizations

emphasize just how transitory museums can be, leaving open the future contexts and fate of already excavated and displayed artifacts.

Conclusion

In a world fraught with increasing threats to our past global heritage, archaeologists must liaise more effectively with other specialists and the public to optimize the long-term preservation of material culture assemblages and their contexts. One way is to pursue the full publication of excavation and survey results both on a global scale and in a durable format to survive potential local, national, and international disasters affecting and threatening our global community. The emergence of diverse and high-memory electronic storage media and the World Wide Web have also begun to permit the less expensive publication and dissemination of immense quantities of archaeological records and data previously not feasible for most archaeologists. Yet, such rapidly emerging and changing technologies also require either the maintenance of specific machine-readable devices, or the continual transfer of electronic data into new media to keep pace with both emerging and obsolete technologies (e.g., microfiche). Ironically, archaeology is entering into an increasingly more complex world, ripe with expanding technological opportunities, but now also facing rapidly growing and innumerable threats to archaeological sites and materials. Today’s archaeology is becoming more salvage work and highly selective in nature, especially with the opportunities afforded by more accurate remote sensing technologies. Are the more adventurous and romantic days of archaeology over? Is the more traditional archaeologist (“Indiana Jones” to many) doomed to hang up his hat, don a lab coat, and take a “desk job”? Only time will tell.

AZTECS, INCAS, AND MAYANS

FRANCES F. BERDAN

California State University, San Bernardino

The Aztecs, Incas, and Mayans are considered to have developed the most complex civilizations in Latin America during pre-Columbian times. They were not the only complex civilizations in this region, generally called Nuclear America (the area of most complex civilizations in pre-Columbian America), nor were they the first. (See Figure 12.1.)

Nonetheless, the Aztecs, Incas, and Mayans have been primary subjects of intense archaeological, ethnohistoric, ethnographic, and art historical research—and many controversial issues have surrounded each of them. These issues, for example, have ranged from the extent of Aztec human sacrifice, to the meaning of historical kingships among the Inca, to the causes of the ancient Mayan collapse. While some of these issues are unique to one group, others are shared; taken together, a look at all three of these civilizations highlights these commonalities. Common issues include matters such as their rise to statehood, their styles of political integration, the role of ethnicity, the role of ideology in political and social change, and the nature of writing in each civilization. Similarly, methodological issues have arisen in the investigation of all three groups, especially in terms of the integration of archaeological, ethnohistorical, epigraphic, and ethnographic research.

Figure 12.1 Aztecs, Incas, and Mayans

Aztecs

Background

The Aztecs were the last of the great civilizations to emerge in Mesoamerica in pre-Columbian times. Their precocious predecessors had developed intensive agricultural techniques, planned urban settlements, successful styles of statecraft, vast commercial networks, social hierarchies, warfare, and polytheistic religions with intense theatrical ceremonies. A hybrid culture, the Aztecs (or Mexica) were originally one of many nomadic groups that migrated south from the northern Mexican deserts from at least the 12th century CE; they settled in the Basin of Mexico and rapidly acquired the cultural attributes of the local peoples. In the year 1325 they established their city of Tenochtitlan, and by 1430 they had become sufficiently powerful to gain dominance within the Basin by forming an important military alliance with two neighboring city-states. They spent the next 90 years forging a conquest empire extending throughout much of central and into southern Mexico. Their political and military dominance abruptly terminated with the Spanish conquest in 1521.

Theoretical Issues

Complexity, City-States, and Urbanism

As victims of the theory of unilineal evolution, the Aztecs were denied the status of “civilization” until well into the 20th century. Lacking iron tools and alphabetic writing, they were considered “barbarians” at a tribal level of social complexity, and their empire was viewed as a confederacy of tribes. However, by the mid-20th century, scholars were well on the way to revising this view, recognizing that Aztec life was highly specialized, intensely hierarchical, politically centralized, and religiously complex (Bernal, 1980, pp. 143–144). This view has since been consistently reflected in a number of ethnographic-style studies of the Aztecs (e.g., Berdan, 2005; Clendinnen, 1991) as well as works with a greater emphasis on art history (e.g., Townsend, 2000) and archaeology (e.g., Smith, 2003).

However, this did not mean that the debates about Aztec social complexity were over; they simply became more refined and focused. As documentary evidence was amassed to support a caste-like view of Aztec social and political hierarchies (especially toward the end of the empire’s history), archaeological research cast a somewhat different light on the noble-commoner chasm. For instance, research in commoner settings in Morelos (just to the south of the Basin of Mexico) has revealed that commoners were perhaps not so desperately separated from their elite overlords. Indeed, remains of material goods (such as fine polychrome ceramics and bronze goods) previously thought to be restricted to nobles have been found in commoner dwellings (Smith, 2003, p. 136). Commoners’ access to a wide range of imported goods along with documentary evidence for

extensive market activity suggests some material affluence and a strong commercial economy, balancing the view of a more politically controlled economy (D. Carrasco, 1999). Both perspectives are essential to an understanding of overall imperial dynamics, and—although it is clear that rulers and nobles set themselves visually and effectively above the remainder of the population—questions of the degree of the noble-commoner division, and the extent and potency of the political power of the Aztec elite, continue to be debated.

Decades of intense settlement pattern surveys have contributed to a better understanding of the spatial arrangements of Aztec communities (Sanders, Parsons, & Santley, 1979; Nichols, 2004). Historical sources clarify that there were a large number (50 or so) of city-states in the Basin of Mexico alone (Gibson, 1964; Lockhart, 1992). These were distinct territorial and political units consisting of a main settlement and surrounding related communities, often small hamlets. Each city-state boasted its own dynastic ruler, founding legend, patron deity, and market, and often an economic specialization and primary ethnicity. Unless conquered by some more powerful city-state, city-states were politically autonomous. Recognizing these city-states as the essential building blocks of Aztec political structures, a particularly important focus of research has been delineating the boundaries of these units and unraveling their internal and external relations (Hodge, 1994). One significant finding allows the linkage among settlements within a city-state as based more on social and political obligations than on strict geography—city-state boundaries were not always territorially neat, but were often based on historical relationships that superceded geographic contiguity.

The mid-1900s saw a shift in emphasis from questions about the formation of states, urbanism, and the development of social stratification to questions about the lives of Aztecs in rural settings. George Vaillant’s partial excavation of a noble palace was the extent of Aztec household excavations up until the groundbreaking Basin of Mexico regional settlement pattern survey (Sanders et al., 1979). More recently, excavations by Michael E. Smith (2003, 2008) in Morelos have tackled a range of lifestyles, from commoner houses to noble dwellings; these studies provide valuable insights into matters of social stratification, standards of living, and the effect of imperial conquest on provincial inhabitants.

Tenochtitlan, the Aztec (Mexica) imperial capital, has been long considered “urban” due to its inordinate size and overall monumentality. But can (or should) the other city-states in the Basin of Mexico be considered urban? The vast demographic divide between Tenochtitlan’s 200,000+ population and the estimated 10,000 to 25,000 population for the next largest settlements in the Basin have typically resulted in nonurban designations for these smaller communities. Smith (2008) recently argued convincingly for the “urban-ness” of these settlements based more on function than on strict population size. Yet arguments persist regarding the nature of these cities. David Carrasco (1999) argues for the primacy of religious functions in these urban

settings, while Smith (2008) proposes the supremacy of political over religious roles in defining the nature of these cities. Few such cities have been excavated in any representative fashion, since in almost all cases Spanish cities were built directly atop the Aztec ones.

The Nature of Empire and Empire Building

One persistent problem in understanding the nature and extent of the Aztec empire is its relative “invisibility” in the archaeological record. It has been often enough repeated that without an extensive ethnohistoric record documenting Aztec conquests and tribute, the idea of an Aztec empire would be unsupportable. Yet Aztec material remains are found in some abundance at a major fortress (Oztoma in the south) and administrative center (Quauhtochco in the east), and linguistic evidence suggests the presence of Nahuatl (Aztec)-speaking peoples scattered throughout the documented imperial domain.

Excavations at and around the Aztec Great Temple (Templo Mayor) in downtown Mexico City (Tenochtitlan) since 1978 have solidified the vision of the Aztecs as a powerful empire (Matos Moctezuma, 1988). Not only did the structures themselves require extraordinary control over massive amounts of labor and building materials, but also the nearly 140 offertory caches throughout that ceremonial precinct have yielded thousands of culturally revealing artifacts. Taken together, some 80% of the artifacts in these offerings originated from outside the Basin of Mexico, an indication of the extent of tributary control and/or commercial wealth of the Aztec polity (López Luján, 1994). They also represent the highly significant investment in religion made by the Aztec political rulers and the interconnectedness between politics and religion in Aztec life.

The Aztec empire might best be described as hegemonic—a loose arrangement of conquered city-states required to yield to Aztec rule and to pay tribute on a regular schedule. If submissive, local rulers were typically left in place. In effect, relatively little changed in the provinces beyond the presence of haughty tribute collectors, the siphoning off of local production as tribute, and the occasional imposition of an imperial governor or garrison. The usual approach to understanding the nature and workings of this empire has been a top-down approach: what were the imperial goals, what was the imperial income, how did the emperors wage war, and so on. Yet a more recent approach entails a more bottom-up approach: understanding the effects of imperial conquest on the subjugated city-states (Berdan et al., 1996). This approach has also yielded a more refined understanding of imperial politics and strategies. These were not random conquest pursuits, but rather well-considered strategies of empire formation involving distinctions between *tributary provinces* with predictable tribute payments and “strategic provinces” that protected hostile borderlands and secured crucial trade routes.

Additional approaches reveal the strategies used by conquered peoples to gain the best possible advantage in these asymmetrical political and military situations. In concept,

this is not unlike recent trends in history and ethnohistory in understanding the roles and creative strategies used by native peoples in Mesoamerica under Spanish colonial rule (e.g., Berdan, 2007; Lockhart, 1992). These issues involve agency, and elevating decision-making processes to a more important role in imperial developments and changes.

The Extent of Human Sacrifice

Few issues sparked the Western imagination during the Age of Exploration more than the presence and idea of human sacrifice. The records of human sacrifice among the Aztecs derive primarily from ethnohistoric documents (pictorial and textual), but recent excavations have also revealed evidence for individuals sacrificed with their skulls strung on skull racks or their remains buried in offerings. The presence or absence of human sacrifice is no longer an issue, but its scale is.

Human sacrifice was deeply embedded in the Aztec way of life. It was supported by a complex mythology, and Aztec beliefs demanded that the people “pay their debts” to their gods with their most precious offering—human blood. Calendrical ceremonies (often using deity impersonators) and the almost constant autosacrifice by temple priests resulted in relatively low numbers of sacrificial deaths. However, it is the imperial sacrifices, following massive military campaigns, which are at issue here. Documentary sources suggest that thousands of captured enemy warriors were sacrificed in single ceremonies, one document recording a number of 80,400. These extraordinary figures are highly unlikely, but the numbers are not easily resolved, either historically or archaeologically.

Writing

In 1963, Ignace Gelb gave little credence to Aztec writing, describing it as a forerunner to actual writing. Since then, numerous ethnohistorians, art historians, and archaeologists have produced research that has revised this view and generated interesting arguments regarding the nature and use of “writing without words” (see especially Boone & Mignolo, 1994; Boone, 2000, 2007). This was not alphabetic writing, but rather a system meshing pictographic, ideographic, and phonetic symbols. A great many books were produced on native paper (*amatl*) treating economic, demographic, cartographic, historic, dynastic, and religious matters. Almost all of these, however, fell victim to the Spanish conquest and its attendant spiritual conquest.

Detailed studies of native and native-style codices such as the *Matricula de Tributos*, the *Codex Mendoza* (Berdan & Anawalt, 1992), and the *Codex Telleriano-Remensis* (Quiñones Keber, 1995) have stimulated arguments about the extent of phoneticism in Aztec glyphs, the application and use of symbols, and regional expressions of the writing system (Boone, 2000; Lacadena, 2008). These issues continue to be energetically debated.

Methodological Issues

Meshing Archaeological and Ethnohistoric Information

Ethnohistoric sources on the Aztecs are especially abundant and varied. They include native pictorial codices, indigenous narratives, accounts of Spanish conquerors, relations of Spanish friars and administrators, and everyday colonial records written in Nahuatl. These have become more and more available over the past half-century. A particularly significant milestone was the translation and publication, beginning in 1950, of the 12-volume Nahuatl “ethnographic” works of the Franciscan friar Bernardino de Sahagún (1950–82). This was followed by facsimile reproductions of several codices as well as translations of a wide range of colonial Nahuatl documents (e.g., Anderson, Berdan, & Lockhart, 1976; Lockhart, Schroeder, & Namala, 2006).

This plethora of historical sources has illustrated that until recently, reconstructions of Aztec life have depended almost entirely on the documentary record. With the spectacular Templo Mayor discoveries and the general increase in Aztec archaeological research, the problem (or better, opportunity) arises of meshing these types of information into a more complete and accurate reconstruction of Aztec culture and society. This profitable research direction is exemplified by studies such as that of Guillem Olivier (2003), which links textual sources on religion with physical artifacts. Art history (e.g., Umberger, 1996) and ethnoarchaeology (e.g., Parsons, 2006) are also making complementary contributions to rounding out this picture.

Chronology

Chronological issues involve (1) correlating ethnohistoric and archaeological dates and (2) developing chronologies with meaningful divisions, particularly a chronological scheme that delineates the Aztec imperial period. Regarding the first issue, ethnohistoric dates tend to be very specific while archaeological dates fall within a “range.” Thus, correlations between historical and archaeological dates are necessarily imprecise. Yet some significant insights have been gained by pursuing such chronological correlations. For instance, the year Two House (or 1325) records historically as the founding date for Tenochtitlan, the Mexica (Aztec) capital city, and the documents clarify that their new little island setting was uninhabited. But archaeological evidence indicates that the site was indeed inhabited. Concerning the second chronological issue, recent research questions focus on the impact of imperial power in conquered cities and regions. For instance, did imperial conquest affect the local standard of living? Did imperial conquest reroute established trading networks? Did imperial conquest upset the local political arrangements? Questions such as these require a chronological scheme that separates preconquest from postconquest times. Such a scheme has been developed by

Michael Smith (2003, 2008) for some Aztec sites in Morelos, providing a valuable model for future research.

Demography

The central issue in understanding Aztec demography is, quite simply, how many people there were. This is largely a methodological issue, since an understanding of Aztec demography rests on incomplete and ambiguous information. Spanish conquerors offered highly variable population figures, and colonial censuses only became widespread later in the 16th century when the native population had already been decimated by epidemic diseases. Nonetheless, time-of-conquest population estimates have been made based on this historical information and on archaeological surveys. The resulting estimates range widely: from 920,000 to 2.96 million for the Basin of Mexico alone (Smith, 2003, pp. 57–59). While the lower estimates are most likely, this area of research remains problematical.

The Problem of Generalizing

There has been a tendency in Aztec studies to make broad generalizations from specific pieces of information. This has derived, at least in part, from the fragmentary nature of the documentary and archaeological databases. Ethnohistoric documents, for instance, derive from specific locales and describe the specific histories, social arrangements, royal successions, economies, or other matters as they pertain to the locale in question (Boone, 2000). To what extent is it valid to generalize from these specific cases? Put another way, how extensive was cultural and social variation within the Aztec domain? Tenochtitlan is a good case in point. Because only scattered and uneven information exists on other Aztec cities, there has been a tendency to describe these other centers in terms of Tenochtitlan. Yet Tenochtitlan was atypical in its extraordinary size and unique in several of its features (such as a walled ceremonial precinct and a gridlike layout [Smith, 2008, p. 68]). It does not serve as a good prototype for other Aztec-period cities. Other examples of variation abound in matters as diverse as rules of royal succession, calendrical designations, glyphic writing conventions, the presence and meaning of noble houses, and the layouts of rural settlements. This suggests caution in making broad generalizations, at least at this time.

Future Directions

New data continues to be uncovered on the Aztec civilization. This includes the ongoing excavations in Tenochtitlan’s Templo Mayor precinct, excavations at neighboring Tlatelolco, and several archaeological projects in “the provinces.” In addition, more documents continue to be translated, and more artifacts photographed and described

by art historians and archaeologists alike. There seems to be an almost endless supply of data yet to be mined.

Scientific procedures providing compositional analyses and sourcing of materials are becoming more and more common, and should continue to be extremely useful in matters such as identifying trade networks and delineating political spheres of influence.

Based on these data and methods, more probing questions are being asked and more sophisticated interpretations have emerged. These include matters such as the nature of urbanism; the intertwining of specialization, trade, and tribute; the affect of Aztec conquest on the provinces; strategies used by conquered peoples; and the application of models such as world systems to the Aztec situation (e.g., Smith & Berdan, 2003). Also still on the table, since the beginning of Aztec studies, is the very definition of Aztec, which continues to be debated. In tackling these issues, the trend is toward more interdisciplinary research, especially blending the skills and approaches of archaeologists, ethnohistorians, and art historians, as well as potential contributions from ethnographic analogies.

Incas

Background

The height of the Inca empire coincided roughly with that of the Aztec empire. Histories record that the empire began in 1438 with the ascendancy of the Inca Pachacuti, and ended with Francisco Pizarro's Spanish conquest in 1532. In less than 100 years the Incas created the most extensive empire in the pre-Columbian Americas. The Inca empire encompassed six present-day countries, was approximately 4,000 kilometers long, traversed several of the world's ecological zones, and contained scores of ethnic and language groups. It is estimated that Inca control extended over some 10 million subjects divided into 80 provinces.

They called it *Tawantinsuyu*, or "the four parts together." Their universe was conceived as centered at their capital city of Cuzco, high in the Andes, and their imperial realm radiated out from Cuzco encompassing four directional domains. At Cuzco, the relatively small Inca lineage/ethnic group—estimated at 15,000 to 40,000 persons—achieved local, regional, and super-regional military dominance and held its diverse conquered peoples together through aggressive and sophisticated administrative strategies. They were remarkably successful in building an empire that involved the mobilization of enormous armies; required diverse strategies in confronting, dominating, and integrating a heterogeneous constellation of ethnic groups; and entailed the implementation of complex management policies to control and channel imperial labor and resources into elite Inca hands.

Evidence of their skills and artistry remain: their spectacular stonemasonry in extant buildings, their cunning

artistry in fine crafts and weavings, and their engineering prowess in roads (totaling 30,000–40,000 kilometers) and records of woven suspension bridges and hanging baskets designed to traverse deep, wide watercourses. In addition, they produced complex knotted cords called *quipu* (*kipu*), which are still not fully understood by scholars, and may have served as a form of writing. This was a way of life with a rich mythology and exquisite artisanship, where royal mummies advised the current ruler who mounted ambitious military expeditions and conquests throughout most of western South America.

Theoretical Issues

Inca History

Ethnohistoric documentation of Inca dynastic history comes from the Spanish, native, and mestizo worlds. From the Spanish world come six eyewitness accounts, an array of 16th- and 17th-century Spanish chronicles (e.g., Cieza de León, 1959; see Rowe, 1946), and large numbers of 16th-century administrative and legal documents. From the indigenous and mestizo worlds come historical accounts from Inca descendants and those of mixed heritage but deeply embedded in native life. These include two especially important documents, an extensive commentary by Garcilaso de la Vega (1966) and a lengthy illustrated letter by Felipe Guaman Poma de Ayala (1987). These documents have been variously subjected to questions and critiques of authenticity, reliability, bias, special interests, and embellishments.

In general, these ethnohistoric accounts of Inca history paint a picture of named royal personages progressively expanding the Inca imperial domain. One approach to interpreting these histories (the historicist approach) concludes that the documents accurately represent a linear, sequential history of Inca dynastic rule (Rowe, 1944, 1946). While advocating this view, historicists also recognize that Inca rulers had a propensity to recast history and historical events in their personal favor. An alternative to the historicist viewpoint has been forwarded by others who propose that the Spanish chroniclers misunderstood the nature of Inca rulership and molded the Inca information to fit into their known Spanish categories, resulting in the presentation of a Spanish-style monarchy of sequential dynastic rulers. These scholars (e.g., Zuidema, 1990; Rostworowski, 1999) suggest a *structural* model where rulership mirrored Inca lineage structure, and a *diarchy* model where two royal Incas ruled simultaneously, one from Upper Cuzco and the other from Lower Cuzco (representing a moiety system). These positions continue to be debated.

The Integration of Empire

Early conceptions of the Inca portrayed them as an enormous, exquisitely organized monolithic empire—the state oversaw all aspects of daily life, the religion was a

state religion, and the empire exercised intensive and pervasive control over its conquered subjects. Everything was very tightly controlled, all very neat and tidy. This view fostered “an image of uniform and ubiquitous control” that current scholarship no longer accepts (D’Altroy, 2003, p. 86). Instead, variation in Inca policies and local adaptations has emerged as a prominent, alternate theme.

The Inca brought a great many diverse ethnic groups under their imperial umbrella. It might be anticipated that they did not deal with all of these groups in the same manner, and this indeed appears to have been the case. However, the nature and extent of this variation is not fully understood and is still being explored. The two essential categories of information on the Inca, ethnohistoric and archaeological, are also inconclusive on this matter of the development and integration of the Inca empire. Ethnohistoric information is more complete for the northern extent of the empire, and weaker for the south; for whatever region, the documentary sources are singularly Cuzco-oriented and provide a top-down perspective on Inca-provincial relations.

Another perspective derives from the provinces, and asks questions of local responses and adaptations to Inca arrival, domination, and economic exploitation. Archaeological investigations have been especially productive in illuminating this bottom-up perspective. Particularly significant regional archaeological research (which also relies on historical sources) has been that conducted in the central highland Peruvian site of Huánaco Pampa (e.g., Morris & Thompson, 1985). Additional archaeological research has been conducted at other imperial sites, yielding an emerging picture of considerable variability in local histories and responses to Inca conquest, as well as the differential implementation of Inca imperial policies (see D’Altroy, 2003, pp. 249–262; articles by John Murra, Craig Morris, Franklin Pease, and others in Collier, Rosaldo, & Wirth, 1982).

Methodological Issues

Chronology and Archaeology

Large-scale chronological schemes for Andean prehistory began with the pioneering work of Max Uhle (1903), who provided the basis for subsequent sequential categories, especially the one devised by Rowe (1965). Under these chronological frameworks, the Inca empire falls within the final stage, or the Late Horizon (Inca-style phase to Uhle). This period, spanning the years 1438 to 1532, is useful in delineating the period of general Inca dominance, yet it is still too gross a category for scholars attempting to discern the effects of Inca subjugation on specific conquered regions and ethnic groups. This dating dilemma is not aided by methods of radiocarbon dating, which identify broader time spans than that experienced by the Inca empire.

Nonetheless, a great deal can be learned from archaeology. Scientific archaeological research among the Inca is still

relatively young, dating from the 1930s and not intensifying until the mid-1900s. Archaeological investigations in provincial areas can be enlightening by identifying Inca architecture and/or ceramics. But questions surround the meanings of these Inca indicators: Were they actually built or brought by the Inca as conquerors? Were these Inca objects and symbols copied by a local elite seeking prestige? Did the ceramics and other portables travel through exchange? While there are many productive archaeologists pursuing these and other Inca-related questions (especially in the provinces; see D’Altroy, 2003, p. 23), a nagging problem continues to be the difficulty in “trying to match the material objects in the archaeological record with the peoples [ethnic groups] mentioned in the Inca histories” (McEwan, 2006, p. 199).

The Elusive Quipu

Scholars have long marveled that the Inca could create and administer so vast an empire without a writing system. It is clear that they did not have an alphabetic system in the European manner—but what about other visual communication devices? Coded messages woven into textiles and painted onto wooden boards have been suggested as such devices, but the most persistent candidate for a writing system is the *quipu*. The quipu was an arrangement of dyed, knotted cords whose configuration conveyed specific information or messages to those who knew how to decode (or read) them. Whatever the information embedded in the quipu, the quipu-reader required a considerable amount of memorized knowledge. Lacking that knowledge, modern scholars must rely on cunning and inevitably controversial interpretations to unravel the types and extent of information contained in the many extant quipu (estimated at 600).

As they are currently understood, the quipu were particularly well-suited to recording specific information such as censuses, tax receipts, land measurements, harvests, and herd counts. It has been proposed that they could also have been used for more abstract purposes such as recording myths, stories, histories, and poetry. Progress in decoding the quipu began in 1923 when Leland Locke recognized a decimal-based system in the quipu. Ascher and Ascher (1981) followed, suggesting a more complex system based on the hierarchical ordering of information. Since then, Gary Urton (2003) has proposed that some quipu may have been based on a binary system resulting in up to 1,500 possible symbol combinations. Despite the current high interest in the topic, the uses, contexts, variations, and translations of quipu continue to puzzle investigators.

Future Directions

Questions persist concerning the development and nature of Inca empire building. The Inca gained military and political control over a geographically vast and ethnically diverse world in an extraordinarily short period

of time—less than 100 years. Did they draw on earlier models of statecraft?

There is a clear recognition of variation within the Inca empire, from both top-down and bottom-up perspectives. This involves variation in how the Inca approached and treated different provinces and ethnic groups, and how the different groups responded and adapted to the Inca presence. Archaeologically, the Inca imperial core, the region around Cuzco itself, has not yet been completely surveyed and therefore is imperfectly known (D'Altroy, 2003, p. 23). Farther afield, how can Inca conquests be recognized archaeologically? How can the impact of Inca conquest as well as the responses by the conquered peoples be measured in the archaeological record? Can effective chronologies be developed to date Inca conquests in particular areas, or indeed even the beginnings of the empire itself (McEwan, 2006, pp. 198–199; D'Altroy, 2003, p. 47)? Where possible, a meshing of ethnohistoric and archaeological (and to some extent ethnographic) sources of information can be particularly useful in reducing ambiguities in both types of sources and in unraveling the specifics of imperial dynamics and local ethnic variations.

Energetic debates continue on the nature and workings of the Inca state and empire. What was the nature of Inca kingship? How intense was the role of royal Inca mummies in imperial expansion—to what extent did their continuing control of resources serve as incentives for expansion and control of more and more external resources by each succeeding king (Conrad & Demarest, 1984; D'Altroy, 2003)? And how important was the role of ideology in serving the state and propelling the empire to such remarkable achievements?

Mayans

Background

Mesoamerican prehistory is traditionally divided into three periods: preclassic, classic, and postclassic. The Mayans of southern Mexico and northern Central America thrived during all these time frames. Of these periods, the classic is the most popularly known, most abundantly researched, and also the most enigmatic.

By the classic period, Mayans had developed extensive planned cities and other settlements, constructed massive masonry religious and political structures, erected impressive commemorative monuments, used a complex of calendars based on sophisticated astronomical knowledge, fashioned fine crafts using raw materials obtained through intricate trading networks, warred with their neighbors, maintained a strict social hierarchy, and supported kings who wielded great power locally and occasionally regionally. They accomplished all of this between approximately 250 CE and 900 CE in the rather unlikely rainforest setting of present-day southern Mexico, northern Guatemala, Belize, and adjacent areas. Comprising as many as 80 separate

political entities, most of this rainforest civilization declined during the 9th century and generally collapsed by 900. Following that collapse, Mayan civilization continued and even resurged in highland Guatemala, Belize, and northern Yucatan where Spanish voyagers encountered major centers in the early 16th century.

Theoretical Issues

Supporting and Sustaining Mayan Civilization

Early Western scholars looking at the ancient Mayans faced an enigma. How could a complex civilization develop in a rainforest environment? Rainforests were considered to only allow a slash-and-burn style of agriculture, by its very nature extensive and resulting in low population densities. This, in turn, led to interpretations of classic Mayan sites (in the southern Mayan lowlands) as empty or vacant ceremonial centers with low population densities (see Thompson, 1970).

However, intensive archaeological research (especially settlement surveys) since the 1960s and 1970s produce a demographic picture that did not agree with these assumptions. Population estimates at major classic Mayan centers have yielded numbers of up to 100,000 (for Tikal and Calakmul), and a widely dispersed population with inter-site densities of nearly 200 persons per square kilometer (Culbert & Rice, 1990). It thus became difficult to continue to consider these centers as “vacant ritual centers,” and they became elevated to urban status with large resident populations and centralized political, economic, social, and religious functions.

How, then, were these large cities and complex polities sustained and supported in their rainforest setting? The suggestion was that traditional slash-and-burn cultivation, as revealed in the ethnographic record, was insufficient to support such high population numbers and densities; this stimulated a search for more intensive agricultural methods and other food production strategies (see Harrison & Turner, 1978). Demarest (2004, pp. 127–146) suggests that the classic Maya mirrored their rainforest environment by building their agricultural systems and settlement patterns around themes of diversity and dispersal. Slash-and-burn systems were combined, variously at different sites, with household gardens, terraces, and raised fields and other hydraulic adaptations. The ancient Maya also made use of the considerable wild resources available in the rainforest. Combined, it appears that these food production activities were capable of sustaining the farming households as well as providing sufficient surpluses to support a demanding elite and other urban specialists.

Kingship, Politics, and Warfare

In 1841 John Lloyd Stephens published *Incidents of Travel in Central America, Chiapas and Yucatan*

(with Frederick Catherwood's illustrations). This popular publication sparked further explorations into the ancient Mayan world—explorations that became more and more scientific in approach. These included, importantly, the explorations, detailed reports, and precise images of Alfred Maudslay (1899). Taken together, these and other investigations and reports spawned early romantic visions of the Maya as a peaceful, tranquil people (e.g., Thompson, 1970). This was reinforced by the fact that in these early days, only calendric-related glyphs had been confidently translated. It was not until the 1950s and 1960s that additional hieroglyphs were translated, especially those documenting the great deeds of exalted divine kings of major Mayan cities (e.g., Proskouriakoff, 1960). These translations have progressed to the extent that now the major corpora of hieroglyphs consist of historical texts, and entire dynasties have been reconstructed (Martin & Grube, 2000).

These advances in hieroglyphic translations have been coupled with major scientific archaeological research projects beginning in the 1920s. Two important examples are the Carnegie Institution of Washington research projects at Chichén Itzá, Uaxactun, and Copan (1920s–1950s), and the University of Pennsylvania projects at Tikal (1950s–1960s); these and other major projects have provided groundbreaking archaeological results and encourage a continuing avalanche of research, especially on the classic Maya.

These and subsequent projects along archaeological and epigraphic fronts have dramatically transformed scholarly understanding of the Maya. The Maya are no longer viewed as strictly star-gazing, peaceful intellectuals. They clearly were brilliant astronomers, engineers, and artisans, but they were also ambitious kings, powerful warriors, and everyday people sowing crops, making pots, and trading for profit. In short, current research characterizes the ancient Maya as organized into forceful state-level polities with hereditary divine kings. These cities engaged in warfare with their neighbors, resulting in occasional actual conquests. Some scholars suggest that superstates had developed, although this is still controversial. Scholars are in general agreement, however, in recognizing a wide range of variation among the Mayan polities—in size, in subsistence, in history, in internal and external relations, and in the reasons for their demise and collapse.

Not all scholars have agreed with this interpretation of Mayan civilization consisting of states and urban centers. A classic example is the proposal by William Sanders and Barbara Price (1968) that the Mayans represented a chiefdom level of political and social organization, and that any increase in complexity was due to contact with the central Mexican urban center of Teotihuacan. Today, however, this view has been put aside by most Mayan scholars.

Environment or Ideology

The magnificent architecture and sculpted monuments left behind by the classic Maya and recorded by

early explorers and more recent scholars have led to a well-deserved appreciation of the artistic skills of the ancient Mayans. Lofty temples and sculptures impressed early investigators, much as they were surely intended to impress contemporary Mayans. These wonders of art and architecture have contributed to the notion of the Mayan elite as intellectual priests focused on matters of religion and cosmology. On the other hand, archaeological investigations have tended to lend primacy to ecological factors in the development and dynamics of the ancient Mayan civilization. These latter concepts consider religion epiphenomenal in Mayan culture change. Current views do not demand an “either-or” position on these ideas (see Demarest, 2004). Rather, these were societies where religion, economics, and politics were intricately intertwined, and much of the hieroglyphic and archaeological records reveal these complex interweavings: Kings were holy lords, legitimized by religious symbols and drawing on complex ecological adaptations to support their dynasties and cities.

The Classic Mayan Collapse

The collapse of the classic Mayan civilization by 900 CE is one of the great mysteries of antiquity. This cultural collapse extended over almost the entire southern Mayan lowlands, affecting hundreds of cities and smaller centers. It was, first and foremost, a demise of the elite. Commemorative monuments ceased to be sculpted and erected, large temples and palaces were no longer constructed or repaired, large cities fell into disuse, and the luxurious paraphernalia of kings and lords disappeared. The kings and their noble cadres clearly no longer ruled, or seemingly even lived in these once-magnificent cities.

It was also a demographic collapse, the elite debacle accompanied by a dramatic decline in overall population generally leaving scattered populations of farmers. Nonetheless, on the fringes of the southern Mayan lowlands, some centers (such as Lamanai in Belize) continued to thrive through the postclassic period. Indeed, cities to the north and south of this classic florescence grew and expanded throughout the postclassic.

What happened? A great many hypotheses have been forwarded to explain this region-wide collapse. Proposed explanations have included natural catastrophes such as earthquakes, hurricanes, and epidemics; environmental problems such as drought and ecological overkill; sociopolitical matters such as excessive elite demands on a stressed peasantry, revolts by a suppressed peasantry, and internecine warfare; and external factors such as invasions by foreigners. Investigations of these questions have led to some interesting insights. For instance, it is clear that there was considerable variation in the collapse among different classic Mayan centers. In some areas it was in effect as early as 750 CE; in others, it was 150 years later. In some areas it happened quickly; in others it involved a gradual decline. And perhaps

most important, in some cities certain factors took center stage while in others those same factors were minor players and still others appear as the primary causes of decline and collapse. For instance, warfare was devastating to the social order of the Petexbatun region; drought would have had a significant impact at Tikal and Calakmul; Yaxchilan and Piedras Negras may have been conquered; and overpopulation and ecological stress played a significant role generally throughout the region (Webster, 2002; Sharer & Traxler, 2006, pp. 505–520). At this point it is clear that there was no single cause of this widespread decline and demise; quite to the contrary, it involved a complex intertwining of many stress-generating factors, those factors expressed with differential force at individual Mayan centers.

Methodological Issues

Chronology

Chronologies of Mayan periods and events derive from two sources: hieroglyphic texts and archaeology. Histories of individual Mayan cities are becoming well-known through their hieroglyphic inscriptions. Alongside these histories, general periods in the overall cultural sequences in the Mayan area have been established archaeologically, although specifics (such as the early classic-late classic “hiatus”) continue to be debated. Disagreements over chronologies often stem from the variability of individual polities’ histories. On another chronological front, many characteristics typically associated with the classic Maya have been shown to have emerged earlier, in the late pre-classic, calling into question the time period designations for the current late preclassic-classic division.

Demography

Demographic studies in the Mayan area (especially the southern Mayan lowlands) confront particular challenges. The most immediate of these is the extremely dense vegetation of the environment itself, making survey archaeology, especially difficult. Population estimates are typically determined by counting house mounds and multiplying by a standard figure (usually 5.6, based on ethnographic analogy). But was a given mound actually residential? Was it occupied concurrently with other house mounds in the survey area? Was it occupied continuously, generation after generation? Is the average residential figure of 5.6 sound and stable, or did it vary over time and space, and with a family’s social and economic status? Were some household structures not raised on mounds, and hence not included in the surveys at all? With the highly dispersed, continuous settlements in the Mayan lowlands, where did one city or polity end and the next one begin? These and other questions continue to challenge archaeologists in determining the demographic characteristics of the Mayan population throughout its long history (see McKillop, 2004, pp. 162–170).

Hieroglyphic Writing

The decipherment of Mayan hieroglyphic writing has undergone several transformations over the past century. First seen as a documentation of calendric and cosmological matters, by the mid-20th century it became clear that large bodies of hieroglyphic texts dealt with kings and their extraordinary deeds. But actually translating the texts required more. Beginning with the realization by Yuri Knorozov that Diego de Landa’s “alphabet” (as cited in Tozzer, 1941) represented a syllabary, subsequent epigraphers have decoded the hieroglyphic writing to the extent that the majority of the 800 signs can now be read (Grube, 2006, p. 122). However, a full understanding of the hieroglyphic writing system, and especially its use by the ancient Maya, continues to offer challenges to epigraphers.

Future Directions

The theoretical and methodological issues discussed in this section continue to stimulate research endeavors. For the classic Maya, the manner in which sufficient surpluses were produced to sustain dense Mayan populations and urban centers continues to be studied and debated. There is a continuing emphasis on commoner populations, and a focus on middle-range persons such as artisans contributes to a well-rounded understanding of the ancient Mayan social order. Emphases on either ecology or religion as driving forces in Mayan life are giving way to more integrated views of Mayan culture and society: An important case in point is a recent volume meshing dimensions of ritual and economy (Wells & Davis-Salazar, 2007). The nature and extent of external influences and relations (especially from Teotihuacan) is a long-standing issue, and Teotihuacan’s impact on the Mayans continues to be debated. Similarly, arguments over the relations between postclassic Chichén Itzá and highland Tula have not been satisfactorily resolved. Variation in the development, composition, and collapse of individual cities and polities has emerged as a dominant theme in Mayan research for all periods. It serves as a necessary point of departure to increase scholarly knowledge of Mayan demography, urbanism, relations among kingdoms, and the classic Mayan collapse. Further advances in hieroglyphic translations and settlement survey projects will contribute immeasurably to ongoing debates and a more refined understanding of Mayan culture, history, and society.

Conclusion

Together, these three civilizations are of paramount theoretical and methodological interest and provide a valuable comparative backdrop for the study of ancient civilizations generally. The Aztec, Inca, and Mayan civilizations arose in contrasting environments, yet all three developed

complex state-level institutions, two of them becoming expansionist empires. Some persistent theoretical and methodological issues are shared by these civilizations, in different combinations. These entail issues of demography; urbanism; the nature of kingship; empire building; chronological control; and the nature, reliability, and translations of highly variable writing systems. Current trends in approaching these intriguing questions involve well-formulated interdisciplinary pursuits and the meshing of ethnohistorical and other written sources with a growing body of archaeological data.

TECHNOLOGY

ANDREAS SPAHN

Eindhoven University of Technology

The term *technology* is derived from the Greek word *techné*. The Greek word refers to all forms of skillful, rule-based mastery in any field of human praxis, originally encompassing both arts (like painting, sculpture, writing, and the like) and craftsmanship (like carpentry, shipbuilding, architecture, and the like). The Roman culture uses the Latin word *arts* for these domains. Accordingly the medieval terminology distinguishes between the seven free arts (grammar, rhetoric, logic, geometry, arithmetic, music, astronomy) and the mechanical arts (e.g., agriculture, architecture, tailoring), thus prefiguring the later distinction between arts (as linked to the study of humans and the humanities) and technology (as linked to engineering and the study and science of nature).

The modern word *technology* finally refers either to procedures and skillful application of sciences for the production of industrial or manual products or to the products of these processes themselves. In this sense, technology nowadays encompasses only a part of the original Greek definition. The place of technology as being on the one hand a product of humans (being thus rooted in human anthropology and human tool usage), and being on the other hand based on a solid scientific understanding of the laws of nature (modern technology), can be seen as the two key features of contemporary and recent approaches to analyze and understand technology. Technology is then in one respect as old as humankind: Many approaches in

anthropology thus refer to the general structure of technology in all of human history and relate it to the biological condition of humans. But recent anthropological thinking also reflects on the specific details of *modern* technology. It has often been argued that there is a structural difference between modern, science-based technology and older forms of craftsmanship of ancient or medieval types of technology. Therefore, a central question for modern anthropology is to analyze the consequences modern technology has for our picture of humankind: how to define man in the age of technology.

Reflection on Man's Relation to Technology: A Brief History

Reflection about the anthropological function of technology is probably as old as human self-reflection itself, since the ability to use tools and create cultural products has always been seen as a unique human feature, distinguishing humankind from most other animals (see also the next section on biological anthropology). But an analysis of technology was not at the center of political, social, anthropological, or philosophical thoughts before the development of the modern natural sciences and their counterpart, modern technology. Following Carl Mitcham (1994) one can roughly distinguish three approaches to technology before the 20th century, encompassing many

topics that later became essential parts of contemporary discussions about technology (p. 275). The three approaches are as follows:

1. In the ancient world, technology is looked at with certain skepticism. The use of tools is seen as necessary for survival, but also regarded as dangerous, since it might lead to human hubris and might raise the envy and anger of the gods. In this sense, mythological thinking envisions technology as, for example, stolen from the gods (the myth of Prometheus), and thus not properly belonging to humans. The extensive use of technology is often seen as leading to megalomaniac fantasies or unjustified overstepping of religious and ethical boundaries (e.g., myth of the Tower of Babel, myth of Icarus). Philosophical reflection, however, acknowledges the value of technology for an otherwise defenseless human being. Already Plato anticipates a central thought of modern anthropology: Human beings are poorly equipped for survival in nature. They need to compensate for this lack by developing skills of rational thinking and the usage of tools (this idea later becomes a central thesis of the famous anthropology of Arnold Gehlen [1988]). But the emphasis in ancient philosophical anthropology lies not so much on man's capacities to invent technology, but on man's moral character (exemplified by ancient wisdom or medieval religiosity). The usage of technical knowledge should thus be kept within strict ethical boundaries.

In the hierarchy of knowledge, ethical wisdom is regarded in principle as higher than and superior to technological skills. Socrates points to the question that we should not only seek knowledge about *how* to do certain things (technical knowledge), but rather about *whether* we should perform certain actions (ethical knowledge); this idea can also be found in the medieval distinction between the (superior form of a) life in contemplation (*vita contemplativa*) and the (lower) life in active involvement (*vita activa*). Ancient and medieval technology is thus embedded in an anthropological vision, in which human virtues play an important role. Different forms of virtues are combined in the original crafts, as opposed to the later, modern differentiation of these virtues: In craftsmanship one can find a union of economical virtues (e.g., efficient usage of limited resources), technical virtues (creating new entities that did not exist before), and often also aesthetic virtues (a sense of beauty that adds an aesthetic component to these newly created entities going beyond the modern idea that "form follows function"). In the Greek world, these three skills are combined in the realm of *poiesis*, while in modernity they are separated in the three domains of economy, technology, and art—each relatively independent of the others (Hösle, 2004, p. 366).

2. A profound change in the evaluation of technology emerges with modernity, a position that Mitcham (1994) summarizes as Enlightenment optimism. Already in the

writings of Francis Bacon (1620), the new science of nature and its application to experimental and technological research is highly welcomed. Progress in technology is seen as very beneficial to humankind, as it may lead to the cure of diseases, mastery over nature, and a constant progress toward a more human society. Many utopian writings mark the beginning of early modern thoughts in which technology is seen as essential in leading to a brighter future for humankind (e.g., Thomas More's *Utopia* [1516], J. V. Andreae's *Christianopolis* [1619], F. Bacon's *New Atlantis* [1627]). In a similar line of thought, Enlightenment thinkers defend science and modern technology against attacks from religious conservatism, pointing at the beneficial consequences of technological and scientific progress.

3. A countermovement to the Enlightenment is Romanticism, which accordingly has a different view on technology, referred to by Mitcham (1994) as Romantic uneasiness. Again, the central thought is an anthropological perspective in which man is seen as being good by nature, while it is civilization that poses the danger of alienating man from nature and from his fellow man, focusing only on his rational capacities and suppressing his emotional and social skills. Already Vico (1709) opposed Cartesian rationalism and feared that the new interest in science would lead to a neglect of traditional humanistic education. Rousseau's critique of modern societies then became influential, seeing an advancement of knowledge and science, but a decay of virtues and immediacy (*Discourse on the Arts and Sciences*; Rousseau, 1750). With the age of industrialism, the negative social consequences of modern labor work become the scope of interest of social theorists, leading up to Marx's famous analysis of modern societies (see subsequent section on cultural and sociological anthropology). In opposition to the positive utopias centered on technology in early modernity, the 20th century then sees the literary success of pessimistic dystopias, in which often technological means of suppression or control play an important role (e.g., already in M. W. Schelley's *Frankenstein or the Modern Prometheus* [1818] and later in H. G. Wells's *The Island of Doctor Moreau* [1896], A. Huxley's *Brave New World* [1932], George Orwell's *1984* [1948], and Ray Bradbury's *Fahrenheit 451* [1953]).

The tension between approaches praising the benefits of technology (in the spirit of the Enlightenment) and approaches focusing on negative consequences (in the spirit of Romanticism) still forms the background of most of the contemporary philosophical and anthropological debate; this debate circles around an understanding of modern technology, often rooted in the different "cultures" of the humanities and the sciences. It can be regarded as being a particularly vivid opposition at the beginning of the 20th century, that only later gave room for more detailed and balanced accounts of technology (some classics of the debate being Snow, 1959; McDermott, 1969).

Recent contributions toward a deeper understanding of the usage and development of technology stem from such different disciplines as biology, sociology, philosophical anthropology, metaphysics, ethics, theory of science, and religious worldviews. This chapter aims at a brief overview of important topics in the debate over technology during the 20th century to the present time. Three anthropological perspectives will be distinguished, depending on the main focus of anthropological interest. This will start with a brief summary of the biological anthropological perspective on technology, move on to those theories which focus more on social or cultural aspects, and conclude with more general philosophical anthropologies. This chapter is thus not chronologically organized, but tries to identify common themes of the debate, even though sometimes the topics might overlap (e.g., the case of Gehlen, a philosophical anthropologist who starts from a biological perspective and then moves on toward a more social view on technology).

Biological Anthropology

In contemporary anthropology, technology becomes a central issue for at least two different reasons:

1. From a biological perspective the usage of tools is regarded (next to the development of language and a cognitive rational apparatus) as one of the key features of humanization. Biological anthropology thus initially focuses on the differences and similarities of tool usage in humans and animals, trying to understand the role technology plays *in general* for an understanding of humans' biological and social nature. With the focus on human evolution, attention is often drawn to the question of which role technology played at the *beginning* of humankind.

2. While in this way always being a part of human culture, technology becomes arguably one of the single most influential key features of society only in modernity. According to Max Weber, science, technology, and economy form the "superstructure" of modernity, while they all share a common "rationality" (mainly of means-ends reasoning in economy and technology). The experience of the powers and dangers of modern technology (as in industrialized labor work, medical progress, nuclear energy and weapon technology, environmental problems due to pollution, and extensive usage of resources, etc.) has triggered many social, political, and philosophical reflections that—in opposition to biological anthropology—aim primarily at understanding the specifics of *modern* technology.

Let us look at these two tendencies in turn, starting with the biological perspective, before moving to the social or cultural anthropology of technology.

Biological anthropologists are interested in the role technology played during humanization, and they attempt to give evolutionary accounts of the development of tool usage and technology and compare tool usage in man with tool usage in other animals. The development of technology has often been regarded as an evolutionarily necessary form of adaption or compensation. Since most of man's organs are less developed than those of other species, he needed to compensate for this disadvantage in the evolutionary struggle for life (see Gehlen, 1980). Initially the usage of tools was considered a unique human feature, distinguishing the genus *Homo* from other animals (Oakley, 1957), but research on tool usage in different animals, especially chimpanzees, led to a more or less complete revision of this thesis (Schaik, Deaner, & Merrill, 1999).

Nowadays, many examples of tool usage in the animal kingdom are known (Beck, 1980). For example, chimpanzees use sticks to fish for termites, and elephants have been described as having a remarkable capacity for tool usage. Even though tool usage must thus be regarded as more common among animals, attention still needs to be drawn to the specifics of man's tool usage, which arguably in scope and quality goes beyond what is known from the animal kingdom. It has been pointed out that our biological anatomy offers us several advantages for an extended usage of tools: walking erectly frees the two hands, which can then be used for other purposes. Furthermore, the position of the human thumb and short straight finger are of great benefit, especially in making and using stone tools (Ambrose, 2001). Still debated, however, is whether social and technological developments go hand in hand or whether one of the two factors is prior.

Even though many anthropologists tended to see social behaviors and cultural revolutions mostly as a *consequence* of a change in tool usage or a development of new technologies, it has also occasionally been argued that the development of social skills precedes the development of technical skills (e.g., in joint group hunting). It has additionally been acknowledged that chimpanzees also pass over some of their technical knowledge through the mechanism of learning and establishing cultural "traditions" that resemble, to some extent, human traditions (Wrangham, 1994; Laland, 2009). But there seems to be a specific difference in human and primate learning, namely in the fact that human children learn tool usage mainly via imitation and by simply copying a shown behavior, even if it is not the most efficient solution to a given problem. Opposed to this, chimpanzees seem to learn through a process called *emulation*, which implies that they diverge from the paradigmatic solution that has been "taught" to them. It has been argued that learning through imitation has been selected in humans, even though it is a less flexible strategy, because it is a more social strategy of learning (Tomasello, 1999, p. 28). In this way, biological anthropology mirrors a debate in social anthropology about the role of technology;

this can be seen either as a driving force born out of necessity that calls for social changes (technical determinism), or as highly mediated or even constructed by culture (social constructivism).

Social and Cultural Anthropology

As already mentioned, technology was identified early on as a key feature of modern society (Misa, Brey, & Feenberg, 2004). Many studies have been written about the impact of modern technology on society, focusing mainly on the industrial revolution (e.g., Haferkamp, 1992; Pressnell, 1960; Smelser, 1969) or on the more recent revolution of the information society (e.g., Castells, 1999; Nora, 1980), as well as on the impact of technological change on traditional societies.

Marx

The analyses of Karl Marx and the Frankfurt School are influential, not only in trying to grasp the role of modern technology in society, but also in hinting on potential anthropological roots of technology and their essential interrelation with social aspects of the human condition. Marx insisted that the study of technology holds the highest relevance for human sciences, since it reveals the way humans deal with nature and sustain life (Marx, 1938). An essential feature of man's nature is that he has to work in order to sustain his life, that he is the "toolmaking animal" or—as he has later been called—the *Homo faber*. Marx analyzes the role of technology in Chapter 13 of his first volume of *Das Kapital*. He argues that the division of labor becomes fostered through machines, which at the same time replace more and more traditional manpower and can furthermore be operated by less skilled employees, thus leading to very bad labor conditions for the working class. Technology in general is, however, still greeted as an option to make humans' lives easier; it is mainly the social distribution of the possession of the means of production that Marx regards as problematic. (Also later thinkers, inspired by Marxian thought, tend to see technology as an important means toward establishing a better future.) On the other hand, at the same time, technology is seen as rooted in man's will to dominate nature.

Adorno

Following this later insight in particular, Theodor Adorno argues that Western civilization has developed powerful tools to ensure its self-preservation against nature. Technical rationality is regarded as the exercise of strategic power to dominate (external) nature, but it is at the same time also leading to a suppression of the inner nature of man (Adorno, 1979). The main strategy of this rationality is quantification, which lies at the heart of the

mathematical-scientific interpretation of nature and the development of modern technology. At the same time it brings forth a type of rationality, which leads to a self-mutilation. The will to exercise power becomes the main feature of modern rationality, thus leading to a dialectic that turns the noble aims of the Age of Enlightenment into a morality of humankind that is its very opposite: A new barbaric system of oppression and dictatorship arises, using technology for totalitarian purposes.

Habermas

While Adorno seeks redemption mainly in the arts (Adorno, 1999), seeming to promise the possibility of a completely different kind of subjectivity, Jürgen Habermas (1971) tries to propose an antidote; this does not lie outside of modern-Enlightenment rationality, but rather returns to its original intention. Habermas argues with Marx and Adorno, asserting that technological knowledge has its anthropological roots in the will to dominate nature and therefore serves a strategic interest of man. With this, man is not only *Homo faber* but also a social animal. Besides the strategic means-end rationality he also possesses a communicative rationality, aimed at defining common moral values and engaging in discourse over ethically acceptable principles of actions. In thus distinguishing two types of rationality, Habermas tries to incorporate much of the German tradition of cognitivist ethics into his approach. It is important for Habermas that technology be brought under the control of democratic decision-making processes; his discourse ethics has thus helped to inspire ideas of participatory technology assessment.

Winner

Outside the Frankfurt School, technology has not been at the center of social and cultural anthropology, as has been often complained (Pfaffenberger, 1988, 1992). Langdon Winner (1986) coined the term *technological somnambulism* to refer to those theories that neglect the social dimension of technology. According to this dominant tradition, the human-technology relation is "too obvious" to merit serious reflection. Technology is seen as an independent factor of the material and social world, one that forms a relatively autonomous realm of ethically neutral tools to acquire human ends. But already Winner argues that technology is essentially social and is shaped by cultural conditions and underlying value decisions. He claims in a famous article (Winner, 1980) that Long Island's low bridges were intentionally built in a way that would keep buses away, making it more difficult for the poor, and mainly the black population, to reach the island. Even though this particular claim has been challenged, Winner seems to be correct in pointing out that value decisions play a role in creating technology, and that the social value system leaves its trace in technological artifacts.

The STS Approach

In line with this renewed interest in social issues, a new field of studies related to technology emerged in the 1980s, focusing explicitly on this neglected relation between society and technology: the so-called STS approach. Having been labeled the “turn to technology” (Woolgar, 1991), *science and technology studies* (STS) analyzes society’s impact on science and technology, and science and technology’s impact on society. Several writers draw attention to the social shaping of technology. An influential author is Bruno Latour, who contributed to both the initial appeal to social constructivism (that he later gave up) and the development of the actor-network theory; both are at the center of the debate about the theoretical underpinnings of STS.

Social Constructivism

Woolgar and Latour employ a social-constructivist perspective in their early case study on the production of scientific results, in which they analyze scientists’ attempt to establish and accumulate recognition and credibility of their research through the “cycle of credibility” (Latour, 1979). The main idea of social constructivism is the attempt to interpret alleged objective “facts” in the social world as being socially constructed, so that knowledge of the world and its interpretation depends on social mechanisms and cannot be traced back to objective facts (Berger & Luckmann, 1966). In this sense technology is also not an objective, independent given, but shaped by social ideas and societal interpretations.

Actor-Network Theory

In the 1980s and 1990s, Latour became one of the main proponents of the actor-network theory (Latour, 2005); this is also attractive to scholars who reject social constructivism, since it can be combined with the idea that not all of technology is socially constructed. The social-constructive interpretation of this theory aims to develop a framework in which society and nature, or society and technology, are not separated. The idea of technology as a sociotechnical system implies that *agent* and *tool* form a unity, which cannot be explained completely by referring to one of the two elements in isolation. According to this idea, technological artifacts dispose over some form of agency and can be—to some extent—regarded as *actants*. This ascription of *intentionality* and *agency* to technical systems is, however, highly debated. The debate between realism and social constructivism has thus not been settled.

Philosophical Anthropology and the Philosophy of Technology

Research in philosophical anthropology peaked in early 20th-century Germany, discussed in the next section. But

outside of anthropological discussions, the topic of technology became an important issue for philosophy, so in this brief overview, important contributions and themes of the *continental* and *analytic tradition* will be discussed next. Finally, more recent developments and topics in the philosophy of technology will be sketched that do not try to revitalize a philosophical anthropology, but that nevertheless do touch in one way or another on anthropological perspectives on technology.

Classical Philosophical Anthropology

Classical philosophical anthropology was mainly interested in understanding the essence of human nature and often draws specific attention to the role of technology. Important contributions came from Gehlen, Plessner, and Scheler during the first half of the 20th century. The attempt to link technology to a biological interpretation of man in Gehlen’s early works especially deserves attention. Given his biological constitution, man must be seen as deficient by nature (*Mängelwesen*), since he is not endowed with instinctive routines and is not adapted well to a specific natural environment, but rather is open to the world (*welttoffen*). He compensates for this deficiency with the help of his mental capacities and tool usage. Gehlen interprets human language and human institutions as relief mechanisms (*Entlastungen*) that help him to interpret and organize the plentitude of impressions (the sensory overload, *Reizüberflutung*) that he is exposed to. Most technologies can thus be regarded to be either organ-amplification (*Organverstärkung*) or organ-replacement (*Organersatz*) (Gehlen, 1988). In *Man in the Age of Technology* (1980), Gehlen focuses more on sociological perspectives of technology. He identifies two essential cultural breaks marking principle changes in humans’ world interpretation and social organization, both of which are linked to technological developments: (1) the neolithic revolution of sedentism, marking the passage from a hunter’s culture to a society of agriculture and cattle breeding, and (2) the industrial revolution in modernity (Gehlen, 1980).

Scheler also analyzes man’s rational capacities from a biological perspective, but he concludes that a purely naturalistic approach does not render justice to our self-understanding. The human ways of sustaining life are from an often inefficient biological perspective. Therefore, it must be pointed out that the main function of human knowledge is not only to strategically ensure humans’ own survival, but also to be directed toward the discovery of moral values and toward the process of self-education (*Bildung*). Humans not only live in an environment, but also reflect on their place in the world—a capacity that marks a fundamental difference between humans and animals (Scheler, 1961).

This type of philosophical anthropology came to a certain end when the main interest of philosophers shifted from understanding “man” to understanding “society” during the 1960s. With the recent developments of sociobiology,

philosophers have taken a renewed interest in the linkage between biological and cultural interpretations of man. Let us look at some tendencies of later research in the philosophy of technology.

Philosophy of Technology

If we look at a philosophical interpretation of technology, we find the first origins of a discipline of the philosophy of technology by the end of the 19th and the beginning of the 20th century (see Kapp, 1877, and Dessauer, 1933). During the first half of the 20th century, the philosophical analysis of technology can, roughly speaking, be divided into two main schools of thought: the *continental*, often skeptical approach, and the *analytical*, often optimistic approach. As with all such very generic typologies, this distinction likewise does not claim to be more than an approximation, while the general tendency of recent research seems precisely to be to overcome this gap and to aim for a convergence or cross-fertilization of these two approaches. Therefore, what follows is an ideal-type distinction that tries to make some of the basic ideas of these two approaches more visible and aims at understanding their more general features.

The continental approach originally focused on a humanities-centered perspective on technology, its (mainly negative) consequences for society, and its rootedness in a problematic feature of human anthropology (the will to power), and finally tried to understand technology as such (its “essence”). The analytic approach, on the other hand, originally focused on a more science-based understanding of technology, its (mostly beneficial) potential for the progress of societies, and its rootedness in a rational (scientific) way to approach nature, and it finally tried to look not at technology as such but at specific problems or specific types of technologies.

The Continental Approach to the Philosophy of Technology

In the continental philosophy of technology, technology is often interpreted as closely linked to a certain form of consciousness, a form of approaching nature (and also human interaction) from a perspective that is rooted in a scientific understanding of the world, which itself is rooted in the will to dominate nature. This approach is seen to replace or at least to endanger a value-based approach to reality. In this sense, Edmund Husserl’s phenomenology regards science and technology as a mere abstraction from the full-fledged real experience of the world we live in. In this way, the sphere of technical knowledge is limited and needs to be guided by value decisions, which do not have their basis in scientific or technical knowledge, but stem from our ethical knowledge of our life-world.

While technology is not at the center of Husserl’s interest, José Ortega y Gasset (1914/1961) was one of the first

philosophers who aimed at a deeper understanding of the relation between human nature and technology. Rejecting Husserl’s later emphasis on the transcendental subject, he insists that human nature can only be understood by the formula “I am I plus my circumstances.” Philosophy can thus neither start from the isolated subject (as in idealism), nor can it interpret everything from the perspective of the material conditions (as in materialism). Rather, it must find a middle ground. The essence of humans is for Ortega not determined by nature; this distinguishes humans from plants or animals or from physical objects—all having a defined, specific given nature. Man must determine his own nature by himself by way of the creative imagination. Technology is interpreted as the material realization of this self-image; it is a projection of an inner invention into nature. According to Ortega, technology evolved in three phases: It started as a collection of accidental findings of means toward ends by pure chance. In a later state, these findings became traditions and skills that were passed on to the next generation. Modern technology marks a radical difference, since it is based on a systematic scientific approach, which forms the third phase. This approach, however, tends to become the dominant mode of thinking, so that man’s creative capacity for imagination (which is at the heart of man’s very essence) is in danger of being replaced or losing its importance (Ortega y Gasset, 1914/1961).

Martin Heidegger’s (1977) analysis of technology in his essay “The Question Concerning Technology” is also very influential. His philosophy aims at understanding the notion of *being*, which—so claims Heidegger—has been misinterpreted or neglected by traditional European philosophy. Since man is the only known being that can ask for the meaning of being, Heidegger’s analysis in *Sein und Zeit* starts from an interpretation of the existence of such a being (*Da-sein*). Even though his book is meant to be an exercise in philosophical (fundamental) ontology, it offers many anthropological insights about the specific human form of existence, in which the knowledge and the denial of one’s own mortality form essential human features.

In his later work, Heidegger (1977) understands technology as a specific form of disclosing reality. Asked for the essence of technology, people usually refer to it as a means to achieve an end (instrumental definition), or they define technology as an essential human activity (anthropological definition). Even though Heidegger admits that these definitions are “correct,” they do not disclose the essential truth about technology for two reasons. Essentially, (1) technology is not a tool for achieving an end, but rather the perspective under which everything that exists is seen only as a potential resource to achieve an (external) end. Furthermore, (2) this disclosure of reality is not a human-directed practice: Humans are driven objects rather than being themselves the active subjects. According to these conclusions, the instrumental and the anthropological definitions of technology do not capture the whole

truth of technology. Let us look at these two points in turn, as follows:

1. The essence of technology lies, according to Heidegger, in its capacity to disclose reality (*entbergen*) under a very specific, limited perspective. This perspective reduces everything to a potential object for manipulation, a resource (*Bestand*) for further activity. Technology is thus a way to disclose something hidden. Following his analysis of the Greek word for truth (*aletheia*) as referring to something undisclosed, he sees thus a “truth” at work, under which reality presents itself as a mere collection of resources for external purposes, rid of all inner logic and teleology that was so prominent in traditional understandings of nature. Heidegger points at the different ways in which a river is seen by a poet in an artwork (*Kunstwerk*), on the one hand, and, on the other hand, in which the same river is seen by an engineer as a potential resource for energy generation in a power plant (*Kraftwerk*).

2. Heidegger then goes on to claim that opposed to the image of man being in control of technology and using it for his purposes, he should rather be seen as being provoked (*herausgefordert*) by this coming to pass. Heidegger clearly wants to reject the optimistic idea of “man being in control” through the help of modern technology and, rather, revert it to its opposite: man being driven by a force greater than himself. He calls this driving force the essence of technology, the *en-framing* (*Ge-stell*) that prompts humans to look at nature under the idea of its usability. In doing so, man is in highest danger, but not because of potential hazards or specific negative consequence of modern technology. The danger is, rather, that he loses sight of understanding nature in a different way and that he might finally end up understanding also himself and other humans only as potential “resources” or potential material for manipulation and instrumentalization. Heidegger suspects that art might be a potential antidote to this development: In Greek, *techne* originally encompassed also the production of beautiful objects in art. Thus, a deeper understanding of technology might reveal its relation to art and might point to the fact that art offers a potential answer to the challenge that modern technology poses to human self-understanding.

Certainly, Heidegger’s contribution to the modern philosophy of technology lies more in highlighting this essential dimension of technology as a threat, rather than in elaborating strategies to counter these inherent dangers. Heidegger’s article is arguably the single most influential essay written in the philosophy of technology, although his mannered, often dark language allows for different interpretations and often lacks the clarity of philosophical contributions from the analytical school. But the idea that “technology” and technological rationality is a limited form of looking at reality—one that is in strong need of a

countervision, and that might further lead to a deformation of intersubjective human relations and that finally affects human self-understanding—has ever since been a prominent topic in different thinkers from Adorno and Marcuse to Jürgen Habermas, as illustrated earlier. This idea has often been linked with an ethical concern: Modern technology calls for new ethical guidelines, and despite some beneficial consequence, poses a potential threat to human existence. Much of this ethical debate about modern technology was triggered by its potential to radically destroy human life, be it through nuclear, biological, or chemical weapons or by consequences of environmental pollution and climate change.

Heidegger’s pupil Hans Jonas (1984) was one of the first philosophers to emphasize the need for a specific “ethics for the age of technology,” feeling that modern technology urges us to radically reconsider our ethical intuitions in order to meet the new challenges. Nevertheless, based on humans’ anthropological need to seek protection against nature, classical technology never fully reached this aim. Nature remained always more powerful than men, and the consequences of human actions were mostly not far-reaching. Traditional ethics could therefore focus on the “near and dear.” Modern technology, however, radically changes the picture: Its scope is unknown in premodern times; its consequences and potential dangers could be fatal, far-reaching, and irreversible. Focusing on the environmental problems of modern societies with, as the darkest perspective, the possible extinction of humankind, Jonas suggests broadening the scope of our ethical obligations: If our actions are more far-reaching than ever before in the history of humankind, we need to acquire a new ethical countervision. Jonas finds this remedy in the anthropological feature of our feelings of responsibility. Responsibility often expresses an asymmetrical relation, as in parents who feel responsible to care for their children. The old ethical intuition to derive obligations from the rights of free and conscious individuals, able to participate in argumentation and democratic decisions, seems to be too narrow to account for most environmental problems: Future generations are not yet born, animals and nature cannot in the same sense be regarded as having rights, as has been established in previous ethical approaches to the idea of universal human rights. But obligations may also stem from the idea of responsibility, from the idea that something has been given into our care.

The Analytic Approach to the Philosophy of Technology

Analytic philosophy is rooted in the quest for clear conceptualization, sound argumentation, and scientific precision. For early analytical philosophy in the Vienna Circle, the mathematical nature of scientific knowledge could serve as a role model for knowledge as such: hence, the need for and

the extended usage of logical formalization within analytic philosophy. Skeptical of the quest to address the essence of things like “the technology” in general, analytic philosophers very often focus on concrete problems linked to very specific technologies. Even though many thinkers in the line of logical positivism thus greeted scientific knowledge as the highest form of knowledge, this did not always lead to an unbalanced embrace of technology. In Bertrand Russell (1951), we find a skeptical attitude toward the social benefits of technology, especially if it is linked with totalitarian ideology. Thus, he stresses the importance of democratic education; if placed in a democratic context and applied in well-defined careful steps, technology is, however, beneficial for progress in a way in which Karl Popper (1957) typically advertises as piecemeal social engineering. Important early contributions to an analytic philosophy of technology stem further from Mario Bunge (1979), whose ideas closely link to the program of logical empiricism and oppose the “romantic wailings about the alleged evils of technology” (p. 68).

Recent Developments: Bridging the Gap

Even though this distinction between humanities’ philosophy of technology and engineering’s philosophy of technology (Mitcham, 1994) marks the background of the philosophical discussion on technology in the early 20th century, the debate soon moved beyond this opposition. Three tendencies seem to be of importance.

First, continental philosophy was moving away from the attempt to come up with metaphysical, religious, or anthropological answers to the big questions. With the emergence of postmodernism, the alleged end of the “big stories” was proclaimed, thus making a metaphysical approach less fashionable. Appealing to ontology (as in Heidegger), to metaphysics, or to religious ideals (as in Jonas) seemed less promising. Even though early continental philosophy was very critical with regard to strategic rationality and technology, it has been criticized by postmodernism as not moving radically beyond the central modernistic Western ideal of a rational philosophical synthesis or universal world interpretation.

Second, the focus within the philosophy of technology moved toward a renewed interest in looking at concrete technologies and the challenges they pose for analytical and ethical reflection, a movement that has been called the empirical turn in the philosophy of technology (Kroes, 2001).

Third, different attempts were soon made to bridge the gap between the two camps. In post-world-war Germany, the Society of German Engineers (VDI) established a dialogue about the responsibilities of scientists and engineers, addressing topics and worries of the humanities. The experience of the massive and systematic use of technology for organized mass murder during the holocaust and the development of technology for modern warfare, including the

development of the nuclear bomb, raised issues about the responsibilities of engineers. The debate of the VDI meetings resulted in a series of important publications on the philosophy of technology (Rapp, 1981); these must be recognized as an important attempt to synthesize different strands of philosophical thinking, even though it can be asked how far the VDI school was really successful in transcending its engineering-philosophical origins (Mitcham, 1994, p. 71).

Along a similar line, authors have tried to combine the phenomenological approach with American pragmatism, thus bridging insights of a more continental and a more analytical tradition. Common to phenomenology and pragmatism is the idea of the priority of praxis over theory and thus the tendency not to see technology as applied science but, rather, science as a purified or abstract form of (technological) praxis. Following the works of John Dewey, thinkers like Paul T. Durbin (1992), Larry Hickman (1990), and Don Ihde (1979) have tried to establish a pragmatist phenomenological approach to technology. The insights of Don Ihde that each technology either extends human bodily experience (e.g., the microscope) or calls for human interpretations (e.g., the thermometer) are of particular anthropological interest. If technology amplifies our experience, then it always does so at the cost of a reduction: In highlighting or amplifying certain aspects of reality, it makes invisible other aspects of this very same reality (as in an ultrasonic picture) (Ihde, 1979). The way technology thus “mediates” our interpretation of the world, and our actions within it, has been a further object of extended research (e.g., Verbeek, 2005).

A further attempt to bridge humanist and engineering tradition has been made by Carl Mitcham (1994), who nevertheless tries to defend the priority of the humanist perspective, but at the same time develops an analytic framework that should serve for further investigation within the philosophy of technology. He distinguishes among technology as object (tools), as type of knowledge, as activity, and as volition (expression of man’s intention or will). The 1980s and 1990s saw an increased interest, especially in the analyses of the first three aspects of this distinction.

With regard to the fourth aspect, ethical issues have been a central topic for many philosophers of technology, ranging from debates about the responsibility of scientists and engineers, medical and bioethics, business ethics, technology assessment, risk assessment and decision under uncertainty, to environmental ethics. Two of these fields are of particular interest from an anthropological perspective: In environmental ethics, those theories might shed light on anthropological questions seeking to interpret the environmental crisis as essentially rooted in human nature. It has been argued that it is a human tendency to value short-term (individual) interests more highly than long-term (collective) interests, thus putting a pessimistic neo-Hobbesian anthropology in the middle of the debate. According to Garrett Hardin (1968), it is this very human tendency

(together with a mismatch in the growth of the human population that exceeds the growth of the supply of the food or other resources) that leads to the “tragedy of the commons.” Research in game theory and environmental sociobiology indicates the possibility of holding a more optimistic view of the development of cooperative strategies in humans (Axelrod, 1984), though the issue is still debated and there is room for a more pessimistic perspective, as has been defended early on by some sociobiologists (Dawkins, 1978) or recently by some philosophers (Gardiner, 2001).

In the ethical debate on transhumanism, finally, many links can be found to classical anthropological questions about the essence of man (e.g., Baillie, 2005; Fukuyama, 2004). The central debated question is whether it is morally allowed, forbidden, or even demanded from us to enhance our human capacities through new technologies, ranging from short-term nonevasive ways (like taking performance-enhancing drugs) to fundamental irreversible changes (like genetic engineering). While bioconservativists argue against an extended usage of enhancement technologies, transhumanists point to the potential benefits of these new options. It is reasonable to assume that these issues will be with us as technology advances and opens new possibilities to alter the human condition. This opens a radical new challenge to anthropology, which until recently dedicated itself to understanding the *given* human nature, while it now has to face the normative question of which we should choose as our future nature, once technology offers radical new options of changing human nature (e.g., as by slowing down or even stopping the process of aging). It seems that the anthropology of the future must take into consideration, more and more, normative claims and it must reach out to incorporate ethics to prepare itself for the challenges modern technology poses.

Future Directions

Looking at recent tendencies in research, it can be argued that the initial focus on linking technology with a universal, philosophical anthropological vision, also rooted in biological knowledge, was one of the key achievements of early philosophical anthropology in the works of Gehlen and others. What made these anthropologies remarkable was their attempt to bring together the different traditions of anthropological thought, ranging from philosophy to sociology and biology. A turn toward a more social perspective was established first by Gehlen himself, the Frankfurt school, and later STS studies, sometimes leading away from or even lacking both an underlying philosophical vision and an interest in our biological nature. Very recently, however, sociologists and philosophers have shown an increased interest in biology (as is visible in the ever-growing numbers of publications in sociobiology and the philosophy of biology). This increased attention has not yet led to a revival of an interest in the links between anthropology and technology. But in order to understand man—both in his

evolutionary origins and (maybe even more) in his current historical situation—it seems to demand attention to man’s amazing capacity to develop technology.

It can reasonably be argued that what is thus needed is a new vision of how to synthesize the different fields of biological, social, and cultural anthropology. It seems that after the empirical turn to gather extended details over the biological and social aspects of technology, there is now a call for a new philosophical turn, seeking a new discourse synthesis. Many classical questions of anthropology will tend to remain unanswered, if academic research remains focused only on disciplinary perspectives, which always look at only a part of the whole picture. It is certainly true that man is a social animal, that he has biological roots and that he can ask ethical and philosophical questions about the good and about his place in this universe. The disciplinary separations in biology, sociology, and philosophy (to name just a few) tend, however, to distract from the fact that man in reality is a unity, meaning that a true answer to the most fundamental question of anthropology (What is man?) calls for a plausible combination of these approaches. To synthesize the different aspects of our knowledge about our own human nature is certainly far from being an easy task, but it seems more needed than ever.

But if this is not yet a big enough challenge, there is even a second aspect that makes the quest for a synthesis even more challenging. It seems that a new anthropological vision of humankind must answer a question that classical anthropology has not been dealing with: If technology soon allows us to alter our very nature, then we must know not only what the human condition is, but also what the human condition should be.

Ethics might again enter anthropological reflection, as has been hinted at already by early thinkers such as Scheler and Jonas. Recent attempts to place man in the middle of both a normative vision of ideals, on the one side, and against a profound overview of our descriptive knowledge about our essence, on the other side (as in the voluminous attempt at a synthesis in Höhle, 2004), deserve attention, as they might be the first steps toward a renewed synthetic anthropology that tries to bridge the gaps among the different disciplines. A deepened understanding of technology must be a central part of these efforts, since the way we use tools and produce artifacts is one of the remarkable features of humankind—a feature in much need of guidance by descriptive knowledge *and* ethical wisdom, especially in our age in which technology (of which humans have been the subject) is about to discover the *condition humana* as its potential object in a way more radical than ever before.

PART III

SOCIOCULTURAL ANTHROPOLOGY

CONCEPT OF CULTURE

LES BELDO

University of Chicago

Culture, as a concept, is one of the most complex ideas in academic use today. It is defined and applied in various and often incompatible ways and is the site of significant disagreement between academic disciplines regarding the fundamental character of human social life and the manner in which it is to be studied. For anthropologists, culture tends to refer to symbolic systems of beliefs, values, and shared understandings that render the world meaningful and intelligible for a particular group of people. While these systems—which provide the basis for such elementary concepts as food and kinship and even influence how individuals experience time, space, and other aspects of reality—often appear to their adherents as natural and objective, they in fact represent variable, socially agreed-upon models. In turn, humans must themselves construct these models in order to find order and meaning in a world lacking an inherent sense of either.

Ironically, just as the anthropological concept of culture has gained extraordinary momentum in popular use, as well as in areas such as law and political science, the concept has come under criticism from within the discipline of anthropology itself. Some anthropologists allege that the culture concept oversimplifies and stereotypes whole societies, erroneously treating them as isolated and uniform while underplaying individuality and diversity of opinion. Others maintain, however, that the concept has never entailed such assumptions, and that culture is simply a useful way to

think about the beliefs and shared understandings that make it possible for humans to understand their world.

While debates surrounding the concept of culture reflect legitimate ideological differences, they are often clouded by misunderstanding—not only is the word used to denote widely different ideas, but it is frequently defined in vague and ambiguous terms (if explicitly defined at all). This chapter seeks to provide a clearer picture of the concept by tracing the details of its use from its earliest applications through its role in contemporary anthropological thought. First, the origins and evolution of the concept are explored, with particular attention to key aspects of its development in American anthropology. Next, the contemporary concept of culture as meanings and symbols is examined in detail. Finally, major critiques of the concept and notable responses to those critiques are presented.

The Evolution of the Concept of Culture

Etymology

The original meaning of the English word *culture* was derived from the Latin *cultura*, in both the literal sense of cultivation (as in “of a crop”) and the metaphorical sense of self-improvement (the “cultivation of the mind”). The latter was commonly invoked in 18th-century England referring

to personal betterment through the refinement of judgment, taste, and intellect; and, by extension, to those activities believed to express and sustain that sophistication (Williams, 1983). This basic sense underlies the most common popular application of the term today, which identifies a specific segment of society as *cultural* (including, for example, theater and art) to the exclusion of all others.

The anthropological concept of culture took a less direct path in entering the English language, first passing through German in the form of the philosophical concept of *kultur*. *Kultur* had emerged from the idea of cultivation as well, but soon thereafter began to develop in opposition to the French word *civilisation* as the two concepts became the site of tension between the philosophical traditions of the respective countries. *Civilisation* was linked to the French enlightenment and the idea that society naturally progressed from a primitive state marked by ignorance and barbarism toward universal ideals in science, secularism, and rational thought. *Kultur*, meanwhile, came to represent local and personal concepts like religion and tradition—the “national character” of a people. In 1871, British anthropologist Edward Tylor combined elements of both concepts in defining culture as “that complex whole which includes knowledge, belief, art, law, morals, custom, and any other capabilities and habits acquired by man as a member of society” (as cited in Kroeber & Kluckhohn, 1952, p. 81). This is generally considered to be the first formal anthropological definition of the term, as it introduced the idea of culture as a learned, shared, and broadly inclusive framework encompassing nearly every aspect of human social life.

Cultural Relativism

While Edward Tylor’s definition was groundbreaking, it lacked an essential element of the original German concept that would later become a key feature of the anthropological concept of culture. Tylor was a cultural evolutionist—he believed that over time and with the right conditions, societies developed toward higher and better forms. Thus, he regarded 19th-century England as the absolute pinnacle of human civilization, and considered all other societies (especially those outside of Western Europe and North America) to be less developed and inherently inferior. Franz Boas, a German American scientist widely regarded as the founder of cultural anthropology, was among the first to dispute the evolutionist view. Boas regarded the principles of cultural evolutionism as unscientific and challenged the crucial assumption that the presence of similar practices across societies necessarily indicated their common evolutionary origin. He cited counterexamples where nearly identical cultural institutions had arisen in different settings for markedly different reasons. Applying an approach that was both historical and comparative, Boas (1940/1995) argued that society did not follow a linear progression toward one

ideal form, but instead moved in various directions based on fluid historical circumstances.

Most important, Boas asserted that individuals actually experience reality differently based on the cultural context in which they are raised—that “the seeing eye is the organ of tradition” (1940/1995). This in turn meant that the ideas and practices of a people could only be understood *relative* to the particular ways in which the members of that community perceived and envisioned their world (1889). Boas reasoned that if cultural patterns for perception and judgment were a product of socialization, their adherence must be grounded in emotions and unconscious attachment rather than in any rational or practical appraisals of their virtue or effectiveness. Thus he concluded that any attempt to rank or comparatively evaluate the practices of diverse societies would be nonsensical.

The mistake that cultural evolutionists made, then, was to view their own culturally derived ideas and perceptions as broadly applicable and uniquely valid. Boas pointed to the analysis of speech sounds as an illustration of why this is a hazardous thing to do. Someone who is unfamiliar with the sounds used in a particular language will often hear those sounds differently than a native speaker, by, for instance, failing to recognize the difference between two sounds treated as functionally identical in his or her own language. The Japanese language, for example, does not distinguish between the English /r/ and /l/ sounds, and unless exposed to English at an early age, speakers of Japanese tend to mistakenly perceive those sounds as the same. This propensity led to an unfortunate (if humorous) episode in which early cultural evolutionists misheard the speech sounds of an indigenous American language and declared it inferior for what they mistakenly perceived to be the lack of a fixed phonemic system.

According to the “linguistic relativity hypothesis” advanced by Edward Sapir and Benjamin Lee Whorf, the principle of relativism extends to systems of linguistic meaning as well. Sapir and Whorf argued that the language individuals speak has an impact not only on how they are able to talk about things, but also on how they actually perceive what would otherwise appear to be fundamental aspects of reality. This prompted Sapir to state that in learning a language, one effectively learns a “world.” Whorf drew upon his experience as a fire instructor to show how the connotation of a word like *empty* could lead people to behave carelessly around spent gasoline drums filled with dangerous vapor. Subsequent research in this field has uncovered linguistic influences on dimensions such as the perception of color and spatial orientation, as well as on moral reasoning and other forms of decision making. Whorf noted that the majority of linguistic categories are “covert,” or existing below conscious awareness, an observation that anthropologists Alfred Kroeber and Clyde Kluckhohn (1952) extended by concluding that all cultural knowledge incorporates both conscious and unconscious categories that “screen and distort” one’s conception of reality.

While linguistic analysis may offer the clearest illustration of relativism at work, the principle appears to hold for a wide range of cultural phenomena. Not only do beliefs, attitudes, and values differ markedly from one society to the next, but also comparative research has shown that members of different cultural groups can vary even with respect to their emotional and physiological responses to stimuli. Many Americans, for example, would experience disgust and perhaps even nausea at the very thought of eating live grubs. Yet for the members of many other societies, grubs are considered delicious, and the consumption of onions and mushrooms is seen as disgusting.

As a consequence of this relativistic dimension, the concept of culture has been criticized for its perceived role in undermining attempts to formulate objective and universally binding rules for moral human conduct. And indeed, if it is illegitimate to compare diverse beliefs and practices, and if everything from nausea to the nature of reality is experienced through the screen of culture, then it would seem quite difficult to argue in favor of objective, universal moral truth. As a number of theorists have maintained, however, this does not necessarily mean that moral beliefs are impossible. It simply implies that if normative statements are to make sense, then they must be made with reference to common understandings of what the world is like. As with varying ideas on the nature and meaningfulness of reality, the fact that conceptions of moral truth are inevitably local and particular does not necessarily mean that they are irrational, illegitimate, or untenable.

Culture and the Individual

A key question in anthropology has been whether culture represents its own level of analysis, or whether it can be reduced to (i.e., explained in terms of) the ideas and actions of individuals. According to Alfred Kroeber (1917), an influential anthropologist and the first of Franz Boas's many doctoral students, as soon as culture had been recognized as a "distinctive product of men living in societies," it was only a matter of time until culture constituted a "second level." Kroeber called that level the *superorganic*. Under this view, the behavior of individuals combines to form a system that follows its own set of rules. Cultural phenomena are emergent properties of that system, and thus require their own level of explanation. Thus, Kroeber argued, anthropologists need not concern themselves with individuals in dealing with culture; in fact, they might actually produce richer analyses by ignoring them.

Edward Sapir (1917), also a student of Boas and one of the founders of linguistic anthropology, was intensely critical of the superorganic, accusing it of representing "a social determinism amounting to a religion." Sapir felt the theory treated culture too much like a thing or a concrete object rather than an abstract concept, and left no room for individuals to act in accordance with their own volition. Sapir was similarly critical of the influential theories of

Ruth Benedict (1934), another student of Boas who advanced the idea of cultures as highly integrated wholes characterized by an overarching "personality." In a profile of three indigenous groups in Melanesia and North America, Benedict famously declared that each could be described by a specific personality type (the Dobu of Papua New Guinea, for example, she described as "paranoid schizophrenic"). Sapir was especially scornful of this attempt to use psychological terms to describe whole societies, famously remarking to his students that a culture cannot "be paranoid."

Sapir's own theory, presented in a 1924 essay titled "Culture, Genuine and Spurious," regarded culture as consisting of the peculiar attitudes and ways of life that gave a people its distinctive place in the world. A "genuine" culture, for Sapir, was a harmonious, balanced, and healthy "spiritual organism." But while this did imply a significant amount of integration, a genuine culture was not merely "efficient"; that is, individuals could not simply exist as cogs in a machine. For Sapir, culture and individual could not exist without each other, since culture could not perpetuate itself without individuals as "nuclei," and individuals could not simply create culture out of nothing. Sapir's solution, and his attempt to reconcile the contradiction he saw in Benedict and others, was essentially humanistic: The individual finds a "mastery"—a vocation expressing his or her unique individual skill but that is harmonious with the will and desires of the other individuals in the community. Sapir was careful to emphasize, however, that the very categories of "culture" and "individual" could only be recognized from the anthropologist's view, since the individual himself could perceive no such distinction, psychologically speaking. The more humanistic elements of Sapir's theory never achieved wide acceptance, but his ideas on the relationship between culture and the individual anticipated many lines of critique present in "postmodern" anthropological theory (see the section on "Critiques of the Culture Concept").

The Contemporary Concept: Culture as Meanings and Symbols

Later, some referred to Edward Tylor's pioneering definition of culture in 1871 as the "everything-is-culture" definition, as it included not only things like knowledge, belief, and values, but also customs and behavior, and even a miscellaneous category called "other capabilities." Franz Boas and his students gave the concept a more scientific cast in the early part of the 20th century, and added to it the crucial dimension of cultural relativism. But up to and through the 1940s, cultural anthropologists continued to draw little distinction between ideas and behavior—belief in the power of sorcery, for instance, was culture, but so too was the ritual dance performed by the sorcerer, and perhaps even the artifacts created and used to perform

the ritual. Margaret Mead, a student of Boas and one of the most well-known cultural anthropologists in history, employed a concept of culture that actually centered on the idea of a “complex of behavior.”

As part of a seminal treatise on the culture concept, Kroeber and Kluckhohn (1952) were among the first to suggest that the concept of culture should exclude behavior. Their conclusion was based on the recognition that other factors besides culture influence how humans think and act. The problem with treating a particular behavior as a part of culture was that it essentially proposed that the behavior belonged to or was a unique product of culture, ignoring the powerful psychological, social, biological, and material factors that also motivate action. Like the rest of those factors, culture could not include behavior, since, as Kroeber and Kluckhohn noted, culture was itself a “pattern or design” abstracted from observable behavior—something that made behavior meaningful.

This view does not entail, however, that culture is just like politics or economics or any other domain of human social life. Precisely because culture is not behavior itself, but the beliefs and ideas that render behavior meaningful, culture is an essential aspect of nearly every dimension of social-scientific analysis. Even those actions perhaps appearing on the surface to be purely economic or political in character, for instance, are impossible to decipher without an understanding of the particular cultural forms that make the situations in which they occur sensible and meaningful in the first place (see Sewell, 2005).

The contemporary concept of culture, then, focuses not only on behavior and artifacts as such, but also on what that behavior *means* and what those artifacts *symbolize*. For David Schneider (1868), an American anthropologist who helped found the approach known as “symbolic anthropology,” this meant that even behavioral norms should be excluded from cultural analysis. Schneider defined culture as a set of “definitions, premises, postulates, presumptions, propositions, and perceptions about the nature of the universe and man’s place in it” (p. 202), explaining that while “norms tell the actor how to play the scene, culture tells the actor how the scene is set and what it all means” (p. 203).

Culture as Meaning

The importance placed on *meaning* in the modern concept of culture—not only for the anthropologist attempting to understand social life, but for the individual who lives it—is perhaps best accounted for in the writings of Clifford Geertz, whose influential ideas helped to redefine the discipline of anthropology in the late 20th century. Geertz (1973a) observed that humans are “unfinished animals,” set apart not just by our ability to learn, but by the astounding amount that we *must* learn in order to be able to function at the most basic level. Geertz attributed this to the fact that cultural evolution and biological evolution

overlapped by millions of years in the phylogenetic development of the species, such that the human brain became utterly dependent on inherited systems of meaning. While our biological “hardware” might furnish us with basic capabilities, we must be socialized into specific social systems in order to use them. We cannot, for instance, simply *speak*; we must learn to speak English or Japanese or some other highly particular linguistic form. This accounts for the high degree of variability seen across human societies. As Geertz put it, “We all begin with the natural equipment to live a thousand kinds of life but end having lived only one” (p. 45), since the gap between what biology dictates and what we need to know in order to survive can only be filled with highly particular cultural forms. Without culture, then, humans would not revert to some basic and primary hunter-gatherer form, but would instead be “monstrosities” unable to accomplish even the simplest tasks (1973a, p. 49).

Culture as Symbolic Systems

A central feature of the contemporary concept of culture is the emphasis placed on symbols. More than just providing the means to express and transmit cultural knowledge from person to person and generation to generation, symbols are seen as essential to the *building* of that knowledge in the first place. Anthropologists now tend to regard culture itself as a collection of symbolic systems, where the construction of cultural models and concepts relies on the unique properties of symbolic representation.

The Nature of Symbols

According to David Schneider (1968), a symbol is “anything that stands for something else.” The idea is that this “something else,” called the symbol’s *referent*, is not logically deducible from any characteristic of the symbol itself, but is associated with it purely on the basis of an agreement made by a social group. The word *dog*, for instance, really has nothing to do with the actual thing that speakers of English call a dog, but the connection is made because a group (the speakers of English) has agreed that a particular symbol (the word *dog*) will stand for a particular referent (the domesticated descendants of the Asian red wolf). At first glance, this might seem unremarkable. But as Clifford Geertz (1973a) pointed out, while there are many instances in nature of “patterns for processes”—such as when a duckling learns a set of behaviors by imprinting on his mother, or when DNA issues “instructions” on how to build certain tissues—the capacity to represent objects and occurrences *as they are* is exceedingly rare, and probably unique to humans. Symbolic representation allows the users of symbolic systems to make reference to and reflect on things that are not actually present at the time, converting them into ideas that can be analyzed, manipulated, and combined with other such concepts in the medium of abstract thought.

Furthermore, symbolic reference involves much more than merely matching a word or other symbol to its counterpart in the “real world” of objects. In a famous example, Edward Sapir illustrated that when someone uses the word *house* in the general sense, they do not think of any one house, but of any and all houses that have ever existed or could possibly exist, as well as the set of collective beliefs, attitudes, and judgments associated with that class of objects. This is what is called a *concept*. Conceptual thought opens the door to the imaginative and productive capacities of the mind, allowing humans to do such extraordinary things as wonder about our place in the world, reflect on things that *could* have happened, but didn’t, and then lie about all of it. Closely related to the ability to lie is the ability to form conceptions of things pregnant with collective attitudes and value judgments that far exceed the natural or objective characteristics of the referents themselves. As French sociologist Émile Durkheim (1912/1995) emphasized in his landmark treatise on religion, symbols allow groups to focus their collective mental energy on concretized representations of social phenomena and give tangible expression to bundles of emotions and attitudes that might otherwise remain ineffable. As anthropologist Marshall Sahlins (1976) phrased it: “Men begin *as men* . . . precisely when they experience the world as a concept (symbolically)” (p. 142). It is for this reason that symbols are seen as the building blocks of culture.

The Pervasiveness of Symbols

Language is the most highly developed symbolic system, and the most common form in which cultural meanings are expressed. As the foremost means of “cutting up” the world into sensible and meaningful categories, language is virtually impossible to distinguish from culture, and it’s not surprising that the idiosyncrasies of its particular forms can have a powerful impact on how its speakers perceive reality (see earlier section, “Cultural Relativism”). But words are far from the only type of symbols used by humans. Clifford Geertz (1973b) regarded any “object, act, event, quality, or relation” as a potential symbol, and as it turns out, human social life is replete with organized systems of them. Geertz held up religion as a prototypical example, where acts, artifacts, relationships, and even people serve to symbolize the abstract concept of the supernatural and the beliefs and values associated with it (1973b). Religion also offers examples of what Roy D’Andrade (1984) would later call the *directive* and *evocative* functions of symbolic systems, as it serves to guide and motivate action by, as Geertz (1973b) put it, forming an idea of what the world is like and “clothing” that idea in such an “aura of factuality” as to make it seem self-evident.

Symbolic systems can become so engrained in a community’s understanding of the world that they become difficult to spot. Kinship systems, for instance, appeared for

a very long time (even to anthropologists) to be deeply rooted in biology. But David Schneider (1968) argued that there is nothing about shared ancestry or genetic relatedness that necessarily leads to a recognition of the rights, duties, and responsibilities associated with cultural systems of kinship. Numerous kin classifications, in fact, ignore that criterion completely. Schneider concluded that biological relatedness is a symbol just like any other, arbitrarily designated to denote shared identity and mutual responsibility among social groups.

The Constitutive Power of Culture

The very act of perceiving an object or event in the world as being a *type* of something (e.g., perceiving a certain creature as a *dog*, the clasping of hands as a *prayer*, or the meeting of lips as a *kiss*) entails the symbolic interpretation and generalization of a specific, concrete event. Because symbols represent concepts rather than just things as they exist in the world, almost everything humans perceive is at least partially constituted by collective representations and interpretation. But the power of culture is such that, in many cases, symbols do not attach to any referent at all, and instead actually *create* the objects or events to which they refer. Philosopher John Searle (1969) referred to this as the capacity to enact *constitutive rules*. In statements like “when a player crosses the goal line, he scores a touchdown” or “the candidate who receives the plurality of votes in the general election becomes president,” constitutive rules actually create the categories of *touchdown* and *president*. Societies are built upon intricate systems of these constitutive rules, which generally take the form “*x* counts as *y* in context *c*.” While usually thought of by the members of the community as natural or even commonsensical, these rules are entirely a matter of social agreement. The idea that one *owns* a house or car or any other piece of property, for instance, is based on the collective belief that transferring something called “money” to an institution called a “bank” entitles one to special rights over some material thing. Most often, others will not even question those rights. But when someone does seek to violate the agreement through force, such as by stealing a car or invading a home, it is understood that people in uniforms with guns will (hopefully) show up to stop them. Those uniformed enforcers of social consensus will only do so, however, insofar as they agree to obey the orders of an imaginary chain of authority that runs all the way to the president of the United States, whose power comes not from any physical or mental capacity of his, but from the collective agreement that he is to have such authority. Thus, personal property—like civil government or American football—relies on a complex, ordered hierarchy of constitutive rules and social facts that have no basis in material reality.

These institutions reflect a more basic property of symbolic representation: The meaning of cultural units tends to

be layered upon many other orders of meaning. Something as simple as reading this sentence, for instance, plays upon such varied levels of conventional meaning as the denotation of speech sounds by individual letters, the definitions of words and groups of words, the grammatical rules that operate at the sentence level, and matters of tone and style conveyed by the structure of the chapter as a whole.

Methodological Implications

The centrality of meanings and symbols in contemporary concepts of culture poses challenges for the study of social life. To begin with, there really is no such thing as a symbol per se, although almost anything can function as one. Symbolism is not an inherent quality of any word or sign, but rather a product of interpretation and consensus. Nor is the meaning of a symbol rigidly determined even by the force of collective agreement. As a number of theorists have argued, the interpretation of symbols relies on complex and often emotionally charged processes in the mind of the interpreter, which it must call upon a broad range of preexisting schemas, scripts, and tacit understandings in order to make any sense at all. Consider the following short description of a sequence of events: “Roger went to the restaurant/The waiter was unfriendly/Roger left a small tip.” In their work on artificial intelligence, Schank and Abelson (1977) showed how little sense such a sequence makes without detailed prior knowledge of what normally happens at a restaurant, what is expected of a waiter, and what is communicated in the complex practice of tipping.

For Clifford Geertz (1973c), the ambiguity and polysemy of the subject matter of anthropology meant that cultures could not be *explained*, but instead could only be *interpreted* through a process he called “thick description.” To truly grasp the meaning and significance of a belief or action, Geertz argued, one must first acquire a comprehensive understanding of the social and cultural context in which it occurs. Drawing on literary theory, Geertz suggested that culture must be “read” like a text—a text that, from the anthropologist’s point of view, is “foreign and faded,” full of abbreviations, omissions, and contradictions, and written not by anyone’s pen but by sporadic instances of socially meaningful behavior.

Critiques of the Culture Concept

Social Anthropology

While culture has long been the central object of inquiry in American anthropology (hence the term *cultural anthropology*), scholars in the British social-anthropological tradition have historically been skeptical of culture, and have instead framed their investigations around the concept of *society*. In social anthropology, society refers to a complex web of social relationships and systematized

patterns of behaviors and ideologies known as *institutions* (e.g., the military, primitive magic, the nuclear family, or the National Football League). Social anthropologists compare institutions across different societies in order to ascertain their “function.” They are particularly interested in “latent” functions: those consequences of institutionalized behavior of which the actors are unaware, but which nevertheless work to motivate the very existence of the institution. The functionalist approach rests on the assumption that particular types of institutions, such as kinship or government, are motivated by the same basic factors and oriented toward the same basic ends in all human societies in which they are present. Underneath their superficial differences, the various cultural manifestations of these institutions are seen as essentially similar, like species belonging to the same genus.

As concepts, culture and society are not necessarily incompatible, and have been viewed by some as closely related and even complementary. But for several generations of social anthropologists, culture was something of a taboo term. A. R. Radcliffe-Browne, one of the discipline’s founders, insisted that the concept of culture erroneously treated abstract ideas as real and concrete, and was too broad a concept to be useful in the study of social life. He claimed that society, on the other hand, was the proper object of anthropology, since societies were bounded and concrete, and social structure was embodied in directly observable social behavior. Eventually, however, social anthropologists recognized that no attempt to study social relationships could be successful without consideration of the cultural beliefs and values associated with them. Oxford anthropologist John Beattie (1964) identified this as the primary reason that Radcliffe-Browne’s limited conception of social anthropology as “comparative sociology” never fully caught on: The behavior of people in society cannot be understood without reference to what social relationships *mean* to those who participate in them.

Still, a number of social anthropologists remain reluctant to refer to the semiotic dimension of social life as culture. Adam Kuper (1999) argued that it is more legitimate to analyze religious beliefs, arts, and other institutions as separate domains than as “bound together in a single bundle labeled culture” (p. 245). But as William Sewell (2005) observed, and as Ruth Benedict (1934) noted before him, basic beliefs and symbolic representations of the world tend to cut across the lines that sociologists would use to carve up the social sphere, reaching across institutions, linguistic communities, age-groups, and even religions to span entire societies. This suggests that any attempt to approach such beliefs as though they were miscellaneous qualities of separate institutions risks completely missing the presence of a single, pervasive cultural theme. The more or less unquestioned belief in the sanctity of human life in modern society, for instance, affects almost every conceivable institution, from industrial development and urban planning to the cultivation of food

and medicinal testing. To effectively treat such an idea as a product of any one institution would thus be a significant analytical mistake.

Postmodern Anthropology

In recent years, some of the strongest criticisms of the culture concept have come from within the discipline of cultural anthropology itself. Adherents of a loosely defined movement known as “postmodern anthropology” (also variably referred to as postcultural, poststructural, and reflexive anthropology) have questioned the very usefulness and validity of culture as an abstract concept. Often associated with a 1986 collection of essays edited by James Clifford and George Marcus called *Writing Culture*, the movement can be viewed an extension of the theories of Clifford Geertz—particularly his use of literary theory and his emphasis on the importance of context. Michael Silverstein (2005) identified the “symbols and meaning-ism” that Geertz helped usher in as the point at which anthropology became a hermeneutic and interpretive project rather than an observational science. But for those affiliated with the *Writing Culture* movement, Geertz stopped short of the inevitable conclusion of his argument—that the description or “interpretation” of a culture is as much a reflection of the point of view of the anthropologist as it is of the culture itself. From this perspective, the anthropologist does not simply record facts about others’ ways of life; instead, she actually creates (or at least coconstructs) the culture as she describes it. This is obviously very troubling for the credibility of anthropological knowledge, and it becomes especially problematic when, as was traditionally the case, the anthropologist is a member of a dominant society granted unilateral authority to depict the beliefs and practices of a subjugated population. Critics point to this unequal power dynamic as at least partially to blame for misguided attempts to capture complex realities using false dichotomies like “savage vs. civilized,” “rational vs. irrational,” or “individualist vs. collectivist.”

This “reflexive” critique is linked to an older, more basic criticism in anthropology, suggesting that culture is a tool for the preservation of existing systems of power and oppression. Proponents of this view argue that by ascribing too much importance to tradition, the concept of culture legitimates the domination and mistreatment of traditionally powerless segments of societies. A frequently cited example is the disadvantaged place that women are perceived as occupying in traditionally patriarchal societies. Others have argued, however, that the perception of inequality and discrimination in other cultures is prone to error, since it often fails to take into account the subtle cultural mechanisms that redistribute power and shape social relationships. And while there certainly are cases where the idea of culture is misused to justify atrocities, this does not explain why the concept should be rejected as an analytical tool.

Another dimension of the postmodern critique takes specific aim at the practice of referring to *a* culture or to cultures in the plural. Some feel that this use—which is often traced, somewhat controversially, to the theories of Ruth Benedict and Margaret Mead—oversimplifies and stereotypes other societies, erroneously treating entire communities as uniform, isolated, and unchanging while downplaying diversity and internal disagreement. This implication is ever more frequently seen in popular usage, where terms like *Japanese culture* imply a universally shared, unquestioned, and totaling “way of life.” And while integration is not necessarily synonymous with cultural determinism, Benedict (1934), for her part, did little to dispel that interpretation in asserting that the individual “is the little creature of his culture. . . . Its habits are his habits, its beliefs his beliefs” (pp. 2–3). In response, critics like Clifford and Marcus (1986) stressed the importance of individual agency and “resistance” to cultural norms, pointing out that cultures are not bounded, homogeneous, or “pure.” Instead, culture is contested, contradictory, and only loosely integrated, constantly subject to change both from within and without. Postmodernists note that cultures have always been hybridized and permeable, but that this has become increasingly so in recent decades in the face of globalization and capitalist expansion. As Clifford and Marcus (1986) observed, difference is now routinely found next door and familiarity at the end of the earth, suggesting that received notions of culture are not only mistaken, but also irrelevant.

Others maintain, however, that the concept of culture has never implied uniformity, and that no serious anthropologist ever viewed individuals as mindless automatons totally controlled by a self-contained and unchanging cultural system. They argue that culture has always been an abstraction; that is, culture does not represent a “thing” that exists in the world as such, but is instead separated by way of observation and logical inference from the context of real-world actions and utterances in which it is embedded. Alfred Kroeber (1952) defended the practice of speaking of cultures in the plural on this basis, anticipating contemporary critiques in pointing out that one could speak at the same time of a Tokyo or a Japanese or an East Asian culture without implying that any of them represented a homogeneous or totalizing way of life. More recently, Marshall Sahlins (1999) has asserted that the concept of culture critiqued by postmodern anthropologists is a myth. Sahlins does argue that cultural communities can have boundaries, but that these boundaries, rather than being barriers to the flow of people, goods, or ideas, represent conscious designations of identity and inclusion made by the members of the community themselves.

Regarding the uniformity and homogeneity of cultural knowledge, anthropologist Richard Shweder (2003) has argued that culture never implied the passive acceptance of received beliefs and practices or the absence of dispute or

debate. Shweder points out that every culture has experts and novices, but that such unequal distribution of knowledge does not mean that anyone is more or less a member of that culture. As one of the chief proponents of the resurgent interdisciplinary field of “cultural psychology,” Shweder has helped demonstrate that basic psychological processes such as selfhood and emotion, rather than being products of deep structural similarity, are rooted in culturally specific modes of understanding (Shweder & Bourne, 1984). Such findings have provided some of the driving force behind the growing influence of the concept of culture in the field of social psychology (e.g., Markus & Kitayama, 1991; et al).

Conclusion

Whether prior theories or particular uses of the term carried misguided implications or not, anthropologists continue to recognize culture as an indispensable consideration in the analysis of human social life. As theorists from nearly every area of study surveyed in this chapter have agreed, shared cultural knowledge is absolutely essential for individuals to function in a way that is recognizably human (see Geertz, 1973a, 1973b, 1973c; Whorf, 1956; Beattie, 1964; Clifford & Marcus, 1986; Sewell, 2005; Sahlins, 1976). Clifford Geertz referred to a gap that exists between our species’ innate biological predispositions and what humans must know in order to survive and function—a gap that could only be filled with highly particular systems of beliefs, values, and representations expressed and transmitted through symbols.

Even those most critical of the concept tend to recognize the centrality and pervasiveness of culture. Culture represents the shared ideas that define and give meaning to objects, events, and relationships in our world and the collective representations that create and maintain social institutions. This is true even of those domains of human activity appearing to follow their own logic and obeying their set of rules and principles. Renato Rosaldo (1989), whose work was also included among the 1986 collection of essays that kindled the postmodern anthropological movement, wrote as follows:

Culture . . . refers broadly to the forms through which people make sense of their lives. . . . It does not inhabit a set-aside domain as does politics or economics. From the pirouettes of classical ballet to the most brute of brute facts, all human conduct is culturally mediated. Culture encompasses the everyday and the esoteric, the mundane and the elevated, the ridiculous and the sublime. Neither high nor low, culture is all-pervasive. (p. 26)

Thus, the concept of culture, in one way or another, is likely to remain of central concern to the discipline of anthropology for the foreseeable future.

ETHNOGRAPHY AND ETHNOLOGY

ISABELLE M. FLEMMING

Ela Area Public Library, Lake Zurich, Illinois

Ethnography and ethnology are related disciplines within the field of cultural anthropology. Cultural anthropology deals with all aspects of human culture from social to religious, to political, and beyond. Ethnography focuses on single cultures or specific structures within one culture, while ethnology is a study of the members and structures of cultures and of the relationship of members to their cultures. Ethnology is highly theory driven, using a comparative approach with the writings of ethnographers to search for commonalities that may underlie all cultures or human behaviors. In addition, ethnology takes a broad view, comparing cultures or looking at the deep history of a culture in order to explain why and how it functions as it does. In recent years ethnologists have moved into many subfields of anthropology, such as gender studies and folklore.

Fieldwork with participant observation is the defining method of the ethnographer. Ethnography applies in two ways. It is both an in-depth study of people within their own culture and based on their own words, and it is the detailed written record of that study. Often the ethnographer focuses either on the development of the culture and its operation over time or on how individual behavior and the culture relate to each other. Ethnographies differ from ethnologies in that the former are descriptive and are based on direct participant observation and interview transcription, while the latter are comparative and generally based on studies of material already written about aspects of cultures.

Learning the culture from the inside is termed the *emic* point of view. The emic view acknowledges that group members themselves are the true knowledge holders within their society. Hence the ethnographer attempts to reach as close to the insider's understanding as possible. Ethnographers cannot bring ready-made assumptions into a study, although they will have formulated a theory to investigate with respect to the culture. The point of view of the ethnologist, who looks at reports already completed, is *etic*. It is a view from the outside. There are a number of classic ethnographies, including the following: *The Nuer: A Description of the Modes of Livelihood and Political Institutions of a Nilotic People* (1940/1969) was written by Edward Evans-Pritchard, who studied African societies and focused especially on witchcraft and magic. Bronislaw Malinowski wrote *The Sexual Life of Savages in North-Western Melanesia: An Ethnographic Account of Courtship, Marriage, and Family Life Among the Natives of the Trobriand Islands, British New Guinea* (1929/1962), among other works, and Margaret Mead is well known for her study, *Coming of Age in Samoa* (1928/1961). Another classic writing in the field of ethnology is *Patterns of Culture* (1934) by Ruth Benedict.

Culture itself is defined variously as the shared knowledge passed on by learning that unites a group, or, in a broader sense, all of the institutions, material culture, beliefs, traditions, and knowledge within the human world. For cultural anthropologists culture is that which is both shared and transmitted within a particular group. Culture

includes the underlying beliefs and ideologies that motivate the actions and behaviors of people within a particular society—of interest to the anthropologist is what underlies this overt behavior. As illustrated in the previous chapter, the term *culture* involves the meanings a group attaches to occurrences and objects, and it encompasses the way societies create those meanings. Cultural values are learned from infancy and become a part of the person through observation, learning, and imitation of the actions of family and community. Along with this, the values and beliefs of the society are reinforced by ritual practices and use of symbols.

The potent influence that all aspects of a culture have over individual members was first recognized and investigated by the sociologist Émile Durkheim at the end of the 19th century. Later, 20th-century anthropologists came to see that the influence did not move in only one direction. They now study humans as they relate to and interrelate with their material culture, the rituals and practices of their society, and the surrounding environment. Humans are extremely adaptable—a product of the fact that they learn much of their behavior. They do not respond by instinct alone.

Historically, anthropology focused only on studying primitive cultures, yet this focus has shifted as the world has undergone a period of rapid change since the first recorders of such primitive societies did their work. The globalization of Western civilization has influenced, and often changed, societies, no matter how remote. Consequently the fields of study have diversified considerably. Today, the discipline of anthropology encompasses the study of humankind from prehistory to the present, and includes, but is not limited to, biological, social, cultural, and psychological elements. Major divisions are archaeology; biological anthropology; linguistics; cultural/social anthropology, which incorporates ethnology and ethnography; and applied anthropology, in which research is conducted to solve real-world problems. Subdisciplines fall into these major categories.

In the mid-20th century, anthropology passed through a period of criticism from within and from other disciplines, particularly criticism of its major form of communication, the written results of tribal and cultural studies. Cultural anthropology, sometimes termed sociocultural anthropology, already changing with the lack of untouched primitive cultures to study, was under attack for its seemingly literary, rather than scientific, approach. Critics questioned the authority and accuracy of the ethnographic records, generally monographs, produced by anthropologists after months to years of focused study. They claimed that the written record was stylistic, demonstrating the author's voice in too subjective a manner, and suggested that the writing often was meant to entertain more than to present objective, quantitative evidence.

Theory

In the 19th century, ethnologists believed that cultures evolved from primitive to advanced civilizations over

long periods of time. Therefore the study of primitive societies defined the role of anthropology, as it was believed that the roots from which modern man sprang could be understood by studying primitive cultures currently in existence. Edward Tylor was a major proponent of this evolutionary view and contributed significant writings to the field. Early ethnographies, including Tylor's, focused particularly on religion and on magical practices. Influenced by Darwin's *On the Origin of Species* and other speculation about evolution at the time, ethnographers considered the primitive societies, as well as fundamental aspects of those societies, such as religion, to be evolutionary in their development. In this way, Tylor believed he saw evidence of predictable advances in religion from the simple belief that all things are animated with some form of spirit to the more complex belief in multiple gods and on to the belief in a single god. Lewis Henry Morgan, another early ethnologist, operating within the evolutionary theory of cultures, focused on a study of kinship systems.

These early theories grew within the historical period of colonialism and imperialism. Tribal societies, so different from Western culture, were seen as primitive, and their own inherent developments and complexities often not recognized as such when compared with modern Western societies. The structures within such societies were perceived as static, operating within a system of natural law just as the rest of the natural world. This theory arose from the 18th century, which had witnessed great advances in the understanding of physical processes, for example, in geology and physics. Early anthropologists reasoned that such natural laws must permeate the world, including the way in which societies were organized and functioned. Franz Boas, an early significant figure in the shaping of anthropology as a discipline, believed that some underlying laws could be recognized after cultures were thoroughly studied and compared. This remained the goal of ethnologists for many years, until the true complexity even of so-called primitive societies was recognized.

Many earlier 20th-century anthropological studies revealed the Marxist materialist view that focused on methods of and control over production. Class conflicts and economic forces were among the factors believed to bring about change within society. This is a form of materialist theory, which is based on how people behave, not what they might be thinking. Customs, how people live on a daily basis, and other observable behavioral patterns are seen to drive the culture. Somewhat remodeled, materialist theory is one of two major approaches applied today. Interpretation and understanding is based on customs, how group members live on a daily basis, and other observable behavioral patterns. Modern theories of production and control are more sophisticated and complex, particularly as the world has become more industrialized and developed a global economy. Production and economic factors remain a significant focus in ethnographic research, often in applied research.

Linguistics

At about the mid-20th century, a theory referred to by some as “The New Ethnography” was introduced. Since a key aspect of human society is language, anthropologists began to see language as a model for cultural studies. Researchers attempted to improve the rigor of the ethnographical method, making it more of a science. They believed that since linguists had already found structure and order in human language, this order would assist in understanding human behaviors revealed through speech. A learned process, language is orderly, obeying certain underlying rules, and humans are born with the capacity for language. Individuals need not understand all of those rules in order to speak. Early learning and correction gradually render spoken language grammatically correct without thought given to the process. It is automatic, unconscious. This seemed to confirm a theory of structure in human behavior—a behavior bounded by learned habits and unconscious choice built into the function of the brain. Such linguistic determinism, as discussed first by Edward Sapir in the early 1920s and later by Benjamin Whorf, left no room for conscious human intervention in the structure of culture. Whorf suggested that ideas were a result of the format of a particular language, again leaving little conscious choice to humans.

Structuralism

Claude Lévi-Strauss advocated a view of society as built on particular structures that needed to be understood in relation to each other in order to make sense of the society as a whole. To begin a system of classification required collecting a great deal of data, where meanings varied according to the culture. Lévi-Strauss believed the human mind operated under constraints, while the culture was in part determined by the conditions of its economic situation and its technology. Influenced by linguistics, his theory of structuralism brought the human and the world together as one: The human is able to understand his world because he is literally a part of it. Lévi-Strauss considered much of the structure of human society to be a result of patterns built into the human brain. The structures were not conscious choices but inevitable. Therefore the combined limitations of human thought and of cultural developments produced a structural order that could be observed.

Gradually, developments in other fields led to a reexamination of the language process. Studying the manner in which sounds are made and by which meanings are created revealed a set of grammatical structures that did not rely on unconscious processes. This and other discoveries demonstrated that humans are not rigidly wired. They become active agents in their behavior and interact with their environment. Theories of structuralism as applied to primitive societies thus came to be seen as limiting, accounting neither for the historical background of each society nor for the flexibility and adaptive nature of individuals within the

culture. Culture is now recognized as dynamic, not static. Individuals learn, react, and change. Collectively, this in turn brings change to the culture.

Cognitive Theory

The redirected focus, from culture to individual, led to the growth of cognitive theory. Cognitive theory sees change arising primarily out of mental constructs—ideas and thoughts. Cognitive theorists focus on what people actually say to get a grasp on their thoughts, beliefs, and viewpoints, with clues from linguistic information and the use of symbols. Semiotics, the study of signs and symbols, is one form of ethnographic or ethnological study, depending on whether the study focuses on one culture or compares uses across cultures. Each society has its own meanings and symbols to denote those meanings, although the same symbol may be used in different ways by different societies. Cognitive theory, based on thoughts and ideas, is the opposite of materialist theory.

By the early 1980s, ethnographic theory incorporated aspects from fields as diverse as hermeneutic philosophy (the question of how humans are able to communicate at all), semiotics, linguistics, and psychology. Hermeneutic studies consider how people can understand a culture that is not their own. This allows more insight into the observational methods and results reported by the ethnographer. It also highlights the interpretive abilities of the ethnographer who must be careful not to read more into what he sees than is really there.

Contemporary Theory

Linguistics provided evidence of the complex, interactive relationship of humans and their societies. The changes wrought among societies after the Great Depression and World War II proved beyond doubt that cultures can change, often dramatically, as the people within the cultures respond to new stressors placed upon them. Anthropologists could no longer maintain the theory of static structures within societies.

Contemporary fieldworkers may study the culture of an institution, an industry, or a profession, with the group dynamic a key feature of such a study. Symbolic, social, economic, or other aspects of any given culture may be the major focus of fieldwork, driven by current theory.

As theories have shifted and globalism brings interconnectedness to all cultures of the world, primitive, untouched societies no longer exist. The era of colonialism and conquest introduced change to conquered societies through material exchange and introduction of new ideas. Such societies must be studied in their historical context to appreciate what has changed and how it has changed. The modern theory having perhaps the greatest impact is that of humans as true actors in the drama of the cultures. The rigid structure of societies, as conceived by early anthropologists, has given way to the notion of flexible, dynamic

societies that change as their members change. Humans respond and evolve in emotion and cognition. Humans adapt to their cultures, and the cultures in turn adapt to them. This forces ethnographers to position the culture under study in a historical context and affects their understanding of it. In this framework, members of a society may be studied in terms of current cognitive theory with ideas and thoughts being of central interest.

The materialist approach is also important today, with ethnologists classifying societies by political organization or methods of production. Although theories have changed, the essential methods and desired goal—understanding humans in every aspect of their lives and cultures—remain the same.

Throughout the later 20th century, outside critics as well as anthropologists themselves recognized a need to redefine, even re-create, the methodology of cultural anthropology. Underlying these concerns has been the question of whether anthropology falls into the major discipline of science or of the humanities. Questions about the rigor of research methods and possible subjectivity of ethnographies led many to reject anthropology as a science. But current methods incorporating statistical data and surveys bring anthropological studies into the sphere of science.

Two very important concepts embraced by contemporary cultural anthropologists also serve to reduce the level of subjectivity. The first is *holism*, meaning all-encompassing. Holism posits that events and behaviors must be viewed in the larger context of the culture in which they occur. Actions and events are never isolated, but are informed by the conditions and society within which they take place. Holism recognizes all societies of the world and views them in relation to each other. This comparative approach helps anthropologists recognize underlying patterns in the human experience. The second concept is *cultural relativism*, which means that a given culture can only be understood on its own terms. Value judgments cannot be made, for these judgments would entail assessing one society on the basis of the beliefs and understandings of another.

Methods

Fieldwork

The fieldworker may spend from several months to a year or more learning the language of the society under study, observing the rituals and interactions of its members, and when possible, finding informers or interpreters who will explain the reasons behind specific conduct and practices. Fieldworkers must find a way to fit in, without becoming one with their subjects of study. Integration and objectivity must both be achieved. It is therefore necessary to find people who are willing to explain the meaning of their actions and behaviors. Sometimes informers choose to mislead, but generally, observation and discussion

combined with note taking, sound recording, and other techniques help the fieldworker to put together a picture of the worldview of the society. Observation is neither casual nor sporadic, and anthropologists walk a fine line between observing and actively engaging in the culture under study. They must be careful not to influence or attempt to change the behavior of those observed yet must get close enough to learn the intricacies not evident to a casual observer. There is an element of chance and even luck in fieldwork. The cooperation of chosen informers plays a part in the results, as does the timing. Ultimately, the goal is to understand the people and their culture in their own terms, to come to the insider's point of view. Actions that seem irrational to outsiders make sense within the context of the world in which members of the society live. This is cultural relativism.

Methods are dictated by choice of study area and topic; this in turn may be prompted by the agency from whom the field researcher is able to receive funding. Current fashions in theory, academic budgets, and departmental decisions all contribute to the final choice of fieldwork location and the tone of the ethnography that follows. Before actually entering the field, the ethnographer has already designed a study based on a particular theory or problem and selected the techniques and tools that will be used to elicit the information sought. The methodology may call for a qualitative, description-driven approach, or it may require quantitative data, including statistics. The style of writing will depend on the ultimate purpose and reader audience. Multi-sited research is a method where the choice of topic dictates that the anthropologist will travel to several sites during the fieldwork term in order to make comparisons and build a larger picture. The researcher will not focus on one culture in depth but follow some aspect or object of culture as it spreads geographically or through time.

Participant Observation

The role for fieldworkers is especially difficult because ethnographers need to be participants in the culture they study as well as objective observers. This forces the researcher to be aware of his own biases, to acknowledge personal viewpoints, and to consider how these influence the final report. This is known as reflexivity and has become a major part of the process in recent years. The researcher's expectations or hopes about what she will discover are additional impediments to a completely objective account. This too requires the fieldworker to constantly reassess and reanalyze during the processes of observation and writing. In addition, subject awareness of the researcher's presence can inhibit open and honest discussion or behavior, and some local practices are apt to shock and disturb the observer who is committed to remaining neutral. In some societies, views about gender may also limit what information the ethnographer obtains, depending on whether

the ethnographer is a man or woman. In the early years anthropologists were careful not to allow any criticism of the imperial regime into their colonial studies. Even today political power is a sensitive matter. Researchers must tread very carefully in regimes where their presence and constant observation might be misconstrued.

The observer's field notes can include interviews, observations, quotations, descriptions, surveys, and any other pertinent data. Other tools used may include recordings, pictures, and videos or other newer technologies. Out of all of this, a meaningful ethnography must be created, keeping in mind the purpose of the study within current anthropological theory. When these are combined, a distilled product, the ethnography, is the result. It cannot be the whole story, and it is a story that would be different for another observer. Culture is complex, not countable nor easily classified. These realities underlie the debate about whether anthropology is a science or a humanities study.

Among the objects and behaviors the observer will likely focus on are symbolic items and symbolic gestures, as well as rituals performed. Symbols represent particular meanings and evoke strong feelings or emotions for members of the group. The same symbol can have a different meaning in another culture, so the ethnographer makes careful note of how and when it is used. Clifford Geertz has written much about the importance of studying the symbols and gestures of a society in order to make sense of what its members believe. He suggests that the researcher needs to refer back and forth between larger cultural practices and symbolic actions by individual members of the society to gain a better understanding of how members conceive of themselves and their world. Rituals are modes of behavior that are repeated patterns and represent something significant in the society's religion, politics, or daily life.

The relationships of systems and structures are other facets of the culture that the ethnographer attempts to understand. Some ethnographers will focus on the structures themselves, while others will look at the individuals and note how they respond and adapt. Gestures, motions—nodding the head, for example—and other forms of communication provide important pointers to the thought system of the society. Fieldwork and observation, then, are the hallmarks of the ethnographic method.

Ethnography (Writing)

The ethnographer begins by observing, striving to gain the view of the insider in order to understand the reality of a particular culture. As noted earlier, this is known as the emic perspective. The emic, or insider's, approach requires the ethnographer to take into account his own biases and cultural background in order to avoid ethnocentrism, a belief that one's own culture is the best. The native point of view may be very different from the ethnographer's worldview and cannot be understood in terms

of the ethnographer's background. This can be true even of studies done in one's own society.

Once fieldwork is completed, the ethnographer organizes notes, surveys, interviews, and other data collected into a written report—the ethnography. The writing process may reveal insights and lead to a better understanding of the culture or group than the ethnographer was able to grasp in the field. In the ethnography the researcher may make certain predictions based on, but beyond, her own observations. If independent observers agree upon what is likely to occur in given circumstances, such predictions fall into the category of etic (outsider) statements.

The most important task for the ethnographer is to describe what has been observed, considering both individual elements and the function of those elements or structures within the culture. Without good description or ethnography, comparisons cannot be made by others, nor is anyone else privileged to learn about such cultures. Writing it all down thus becomes essential.

The writing, however, has come under considerable scrutiny since the third quarter of the 20th century, and much has been written about it. Early ethnographers distanced their own voices from the cultures they described and observed certain stylistic conventions. In the 1960s, however, stylistic changes appeared, altering the balance between subjectivity and objectivity. Following these, the rise of feminism caused cultural anthropologists to reevaluate viewpoints and recognize that previous ethnographies were generally biased toward forwarding the males of the society. This not only caused subtle changes in the approach to the writing but also provided new grounds for fieldwork—gender studies.

In practice, perhaps the first decision made by the ethnographer is to what audience the description will be directed. The choice at once determines a style and a point of view. A second choice is how much detail to provide. The goal is to convince others that the ethnographer has truly come to understand the culture under study. Too much detail can cause readers to become bored and lose interest or even to lose the basic sense of what the author means to convey. Too little description may lack the power to convince others that this ethnography is authoritative. Outside criticisms of the lack of a scientific approach in anthropological studies have convinced many that a very granular description and inclusion of other data is necessary. As a result, modern ethnographies seek a balance between description and data-driven reporting.

Ethnography is the writer's interpretation of the field experience, a summation that takes place long after the actual event. Specific theories applied to field research, along with point of view and the expectations carried into the study, will influence what the ethnographer sees and hears. Original conversations explaining activities and meanings within the culture will be condensed, no longer the direct words of individual group members but rather a re-presentation offering a general explanation. Out of

respect for the people and values of the culture, an anthropologist may withhold some information, thereby coloring the interpretations others apply to the reading. The ethnographer must then decide whether omitting sensitive material will give the reader too incomplete a picture. Ethnographers also must adapt the style to the expected audience, considering their backgrounds and expectations as well.

Van Maanen (1988) identified certain narrative conventions associated with ethnographic writing. First, he discerned those presenting a direct discussion format that offered the facts without embellishing on the ways the information was obtained. The second and nearly opposite format placed the fieldworker at center stage above the culture under study. A third and more dramatic form presented both the cultural aspects and fieldworker's experiences in a personalized voice. In *Works and Lives*, Geertz (1988) studied the ethnographic production of many anthropologists, along with the reception given those works, and concluded that the key to a positive acceptance was the ability to convince. An authoritative voice that could not convey the reality of first-hand experience with the culture was not as highly regarded as one that drew the reader in, convincing him of the ethnographer's presence in the midst of that culture. Yet one of the most difficult things to do is to transform real experience and real voices into a condensed written account.

Ethnology

The ethnologist looks at ethnographic studies already completed and views them from the outside, using the etic approach. Ethnologists, dealing in comparative studies, may use the valuable resources of the Human Relations Area Files (HRAF; www.yale.edu/hraf/) for substantive information, rather than conducting intensive fieldwork—generally the preserve of the ethnographer. These files, created in 1949 at Yale University, constitute a database composed of text from manuscripts, articles, books, and other sources that bring together several hundred ethnographies. Works on ethnic groups, religious groups, and other cultures provide a rich source for material. The HRAF are still being developed, particularly as indexed electronic collections available online. Today there are a large number of online resources created for the many areas of anthropological study, and academic and special libraries provide additional print resources as well as digital collections from which material can be obtained. Ethnologists may now more easily make comparisons across time focusing on a particular group or culture. They may also engage in multi-sited field research as they make comparisons of cultural elements and structures or aspects of human behavior.

Historical Changes

Initially, in the late 19th and early 20th century, ethnographies were derived by “armchair” scholars from the

reports of missionaries, colonial administrators, or travelers. Each of these sources had its own particular view to report and none were interested in the primitive society's own reasons for its rituals and patterns of behavior. The theories held by early anthropologists, in combination with the already biased reports they received, had a significant effect on their writings, which were not impartial, although they might contain a great deal of description. Those who happened to travel to other locales to study the society did not employ the method of participant observation or fieldwork. They might have conducted a few interviews and made some observations, likely based on preconceived notions of the culture. In fact, there was little interest in how those within the culture actually behaved or thought.

Early in the 20th century, Franz Boas in America and Bronislaw Malinowski, working for the British, encouraged anthropologists to begin doing their own fieldwork and making their own observations. Thus, late in the first quarter of the 20th century, the central practice of the cultural anthropologist became fieldwork. The anthropologist spent months to years living within the society she was studying. The Chicago School is credited as a key factor behind the impetus for conducting serious fieldwork within sociology. This evolved when, just prior to the Great Depression, a group of social scientists at the University of Chicago began to promote empirical research, using both qualitative and quantitative methods in the urban environment. Cultural anthropologists, influenced by Boas and Malinowski, adopted the new fieldwork methods.

Early ethnographies were based on descriptions, as detailed as the writer was able to make them. In part this was intended to distinguish them from the less “scientific” travelers' reports. The detail was also meant to enable classification of societies from primitive to the most advanced, fitting in with the evolutionary theories of the time. Today ethnographers design a specific research topic, bringing the study into greater focus. In part, this change is due to the direction taken by American college students in the 1970s in which they demanded more relevance in what they studied and in its practical use. Today, field research may be in the ethnographer's own society, and the research may cut across more than one site. Yet another change in ethnographical forms arose out of a movement toward a more literary writing style. Margaret Mead's book *Coming of Age in Samoa* (1928) enjoyed popularity among nonacademics and exemplifies a literary style. More recently, Clifford Geertz and Claude Lévi-Strauss demonstrated interest in the literary style.

Globalism is another major issue in modern cultural studies. Understanding ourselves and others is critical. W. Penn Handwerker (2002) stated that we may now come face-to-face with people whom we previously considered to be “other”—that is, from distant, unfamiliar cultures—yet who might now very well share many of our patterns of thought and behavior. This opens up new fields of research and a need for better understanding in order to

interact at all levels. People of cultures formerly viewed as “primitive” or different are not willing to be studied as exotic subjects. They ask for a return of something that can benefit their own societies, or at the least they prefer to be considered a part of the larger, more modern world. Earlier cultural studies placed given societies within the larger world in terms of how that world might surround them and occasionally have some impact. Today, anthropologists recognize that all cultures exist as part of the larger world, and no society can be described or understood in complete isolation.

Finally, the field of anthropology has been affected by modern changes in the way universities are managed and funded. Scientific research is emphasized, often de-emphasizing the importance of anthropological studies that are seen as humanities-based, using qualitative rather than quantitative research. This compromises the amount of funding available, the ways in which ethnographical research is presented, and even the choices of topics made. The immediate relevancy of application becomes more important in order to attract support.

Applications and Criticisms

Major events in the 20th century, including World War II and the passing of colonialism, brought about a greater communication and interconnectedness among all world cultures. The untouched primitive society no longer existed. The discipline of anthropology, developed for the specific purpose of studying just such societies, foundered. Social scientists already studied other aspects of society, so it seemed there was no need for the cultural anthropologist in an increasingly complex and technological world. As society changed, new theories arose in other academic disciplines. One of these was postmodernism.

Postmodernism strongly influenced anthropology’s reevaluation of its methods. Essentially postmodernism does not acknowledge a single view or explanation but considers that each mind brings in its own interpretation, creating its own reality. There is no single, ultimate explanation, and hence any ethnography is only in the mind of that particular writer. Indeed, early ethnological comparative work soon revealed that ethnographic reports addressing the same topic often appeared quite different, depending on the particular academic training of the ethnographer. Some, for instance, would be more likely to explain or describe using a psychological approach, while others were more influenced by learning theory. Other differences arose out of the specific audience the ethnography was written for or the time when it was written. Earlier and later ethnographies of the same society might vary due to changes in the culture or because of the relationship established between the particular ethnographers and the groups they studied.

In spite of attempts to maintain a nonjudgmental evaluation, based on the theory of cultural relativism, ethnographies

of the same society have even been shown to differ based on the culture from which the ethnographer came. It is not possible to remain completely objective. Instead there is interpretation and mediation in the ethnographic report, and description filtered through the trained eyes of the beholder. These reconsiderations of the written material meant that fieldwork itself needed changes in planning and design. This opened up new directions for practice.

During the same period, academic realignment also contributed to greater diversification in anthropological fields of study. Often anthropology departments were subsumed into other departments in the humanities, no longer maintaining a separate identity within their institutions. Anthropologists began to explore areas of specialty within their own culture, some doing fieldwork among urban gangs, others researching such subcultures as education or science. Today there are biological anthropologists, psychological anthropologists, linguistic anthropologists, and many more subdisciplines with anthropologists exploring every facet of the human experience from birth to death and in between.

Applied Anthropology

These changes and diversification contributed to the growing field of applied anthropology in the United States. Since many anthropologists had also begun to look closer to home for areas in which to do fieldwork, the ethnographies they produced could be tailored to assist in answering questions critical to setting policy and making decisions. A better understanding of how humans and cultures function at every level sheds light on the many problems faced by urban planners, military personnel, international businesses, educators, epidemiologists, public health officials, and others. With boundaries breaking down and the variety of ethnic groups within a given city multiplying, it is ever more essential to understand the human experience in all of its facets. Cognitive or psychological anthropologists can point to the commonalities of human thought and to the likely responses of humans under stress or threat, thereby assisting urban planners or educators.

Anthropologists work within industry and other institutions, with Native American organizations, or in the government. They work in hospitals, mental health centers, and utility companies, with public interest groups, with education facilities, and in countless other areas. Practical applications of ethnographic research involve close observation of some particular group within a society, such as experts in a given field, the middle or upper class, or the linkages and relationships among certain institutions, such as industries and the media. Such ethnographies reveal a great deal to the political or social scientist charged with helping to shape policy. These fields of research place applied anthropologists more in the public eye and increase accountability. The work they produce may additionally be

of value in determining how funds will be apportioned, what is the best way to move forward with a project, or who or what will be most affected and how. Such studies can be applied to areas of public assistance, for example, where the way in which assistance is designed, such as in job training, has a significant impact on the success of that program. Whatever the study and tools used, fieldwork and participant observation remain the foundation upon which the studies are conducted.

Future Directions

Some of the new directions anthropology has taken are now well under way. The process of reflexivity or self-reflection is a method by which anthropologists look into their own attitudes and biases to understand why and what they are writing, and to attempt to bring about a more objective view. Following criticisms invoked during the literary postmodernism movement, writers of ethnographies are more aware of the problem of what truly is reality versus what a person experiences and interprets through the lens of his own life. This has led to relying upon archival research, statistics, and other cross-checks along with the writer's own experience before writing. Where ethnographies were once monographs they may now be written in a scientific format or as articles for various publications. The style of writing varies considerably. Fieldwork itself no longer always involves trips to remote areas of the earth but may take place in one's own hometown or some other familiar area where the focus is on feminist issues, studies of professions, or other fine-grained topics once more familiar to social scientists.

Cognitive anthropology is an important direction for new studies. Recognizing the role of the individual as an active rather than passive participant is a significant contribution to contemporary theory, reshaping fieldwork design. The question addresses whether individuals are in control of or products of their culture. Over time it has been shown that individuals learn to cope with changing circumstances in their environment and may make changes in the culture to adapt. While the culture changes somewhat as a result, a balance between individual and culture will eventually be achieved again. Recent history demonstrates this. Major 20th-century events such as war, depression, and greater communication bringing globalization have all produced the circumstances that wrought changes in cultures, forcing anthropologists to abandon previously held, more rigid theories.

Applied anthropology appears to be the new face of the field. Studies are expected to provide useful information that can be applied to improving situations, making changes, recognizing problem areas, and making policy and other decisions. This has influenced the method, calling for more rigorous—often quantitative—data, along with the qualitative ethnography. Surveys and statistical studies are just two

of the tools that may be used to provide hard evidence for particular conclusions. These methods may be used in studies of subcultures within society, such as gangs, the drug culture, or the commune. As this illustrates, the areas into which applied anthropologists are moving are constantly expanding. The long view for anthropologists is changing as they consider their individual studies within the context of a more global picture. Rather than focusing on a culture alone, they look at a group as it interacts regionally or even internationally.

A very important direction of future studies is in the fields of science and technology, perhaps especially biotechnology. As John Bennett (1998) stated, "Race is out; genes are in" (p. 2). The latter areas are of critical importance in decision and policy making. Ethnologists and ethnographers have moved into the present, finding the interconnections, interrelationships, and emerging trends among peoples, institutions, specific groups, and professions that define our highly technological societies today.

Political and economic structures are a target of research, viewed in a global context. Popular culture and media studies will also continue to be a focus. With the world in a period of rapid change due to greater industrialization and advances in technology, the need to revisit other geographically situated cultures to study how such changes have affected them will continue. Such studies require revisions in the earlier thinking and methodology of cultural anthropology. Whereas previous fieldwork called for long-term observation, many of the types of studies conducted today, both at home and in other societies, will be multisited with descriptions of association and linkages among the sites. Single sites that have already been visited may be visited again, but with new questions asked and perhaps new ways of observing and interviewing subjects. Fieldwork will require a more collaborative approach as cultures formerly considered "other" are now a part of the global community.

MARRIAGE AND THE FAMILY

LISA M. VAUGHN

Cincinnati Children's Hospital Medical Center/University of Cincinnati College of Medicine

Marriage and families are found in all societies; however, marriage and family customs vary significantly across cultures. Cultures differ with regard to what is considered appropriate premarital behavior, whom one marries, how one marries, a proper marriage ceremony, and length and purpose of the marriage. From an anthropological perspective, there are various marriage systems or “marriagelike” relationships that fulfill both biological and social functions. Regarding families, all societies have parent-child social groups but the size and form of the family varies. Although marriage remains customary across societies, it does not necessarily constitute the basis for family life.

Marriage

Marriage is found in virtually all societies, and the majority (some 90%) of people in every society get married at least once in their lifetime (Carroll & Wolpe, 1996; Ember, Ember, & Peregrine, 2006). Cultures vary with regard to what is considered appropriate premarital behavior, whom one marries, how one marries, a proper marriage ceremony, and length and purpose of the marriage. Each culture also defines marriage differently although there are some common criteria across many societies. Marriage is typically defined simply as a “socially approved sexual and economic union, usually between a woman and a man”

(Ember et al., 2006, p. 343), which is generally denoted symbolically in some way (e.g., ceremony, certificate, symbols—rings). Normally, there are reciprocal rights and obligations between the two spouses and their future children. Viewing marriage as a social process where new relationships are set up between the kin of both the husband and the wife essentially describes all forms of marriage. With this, marriage maintains social patterns through the production of offspring.

Traditionally, marriage was defined as a union between a man and a woman with children born to the woman being recognized as legitimate offspring to both parents (Royal Anthropological Institute, 1951). Marriage was thought to change the status of a man and a woman, stipulate the degree of sexual access for the married partners, establish the legitimacy of the children born to the wife, and create relationships between the kin of both the wife and husband. Anthropologists have since noted the exceptions to this standard definition and have expanded it to reflect broader practices. As such, Miller (2008) offers a working definition of marriage given the complexity of practices that fall under the umbrella of marriage—“a more or less stable union, usually between two people, who may be, but are not necessarily, co-residential, sexually involved with each other, and procreative with each other” (p. 140).

British anthropologist Edmund Leach (1955) observed that marriage may accomplish the following depending on

the society. Leach described these rights of marriage as possibilities for either or both spouses:

- Establish legal father and mother of children
- Provide control over sexuality of spouse
- Give rights to labor of spouse
- Give rights over spouse's property
- Create a joint fund of property (for children)
- Begin a socially significant affinal relationship between spouses and their relatives

In some cultures, there are other reasons for marriage. For instance, the Hindu religion considers marriage sacred and representative of the marriage between the sun god-deity Surya and the moon god Soma. Without a wife, a man is considered spiritually incomplete (Kumari, 1988). Representing the two interacting principles of *Yin* (female, passive, weak) and *Yang* (male, active, strong), long-term relationships in China are thought to be a spiritual necessity that ensures survival. Still others may marry to gain higher status (Sonko, 1994).

From the ethnographic literature, we know that one group of people did not have marriage as it has been typically defined. During the 19th century, a caste group in southern India called the Nayar appear to have treated sexual and economic relations between men and women as separate from marriage. At puberty, Nayar girls took ritual husbands but after the ceremony, the husband had no responsibility for his wife and typically never saw her again. The girl lived in a large household with extended family and was visited by other men through the years. If she became pregnant by any of them, the man was not responsible for supporting her or the child except for paying for a midwife. The female's relatives remained responsible for supporting her. Thought to be a response to extended male absence during military service, Nayar unions seemed to fulfill the needs of this particular caste group within a historical and cultural period. Today, the Nayar men are not involved in soldiering to the extent they once were, and stable marital relationships have become the norm (Ember et al., 2006).

Across societies, many people live in long-term, common-law domestic partnerships that are not legally sanctioned. Some people have civil marriages which are licensed and legalized by a justice of the peace while others go through religious marriage ceremonies so they are united from a religious perspective but not a legal one (Kottak, 2008).

Choice of Marriage Partner

Every society has directives and ideological notions about whom one should marry ranging from arranged marriages to exogamous individual choice of partner. Sometimes these directives are informal and implicit, and other times they are formal and explicit. Marriage is one of the primary ways to establish relationships of

affinity in contrast to consanguine relationships, which are from bloodlines.

Exogamy and Endogamy

Exogamy, the practice of seeking a husband or wife outside of one's own defined social group, has adaptive value because it links people into a wider social network that can nurture, provide for, and protect during times of need (Kottak, 2008). For example, the Hindus of northern India practice village exogamy in order to ensure that spouses live in a far-away village or town. In addition, exogamy ensures genetic diversity between groups and maintains a successful human species.

In contrast, endogamy is the practice of marriage within a particular group so that the spouse comes from a specific social category. Sometimes endogamy is based on geographic location. For instance, village endogamy is favored in the eastern Mediterranean among both Christians and Muslims, and among Muslims throughout India and among Hindus in southern India. In other cultures, endogamy occurs to maintain a strong kinship network. Some religious and ethnic groups prefer endogamy in order that groups remain intact. An extreme example of endogamy is India's caste system, which, although abolished in 1949, still remains in terms of structure and ideology. Royal endogamy, usually royal brother-sister marriage in a few societies, is similar to caste endogamy whereby certain sacred, political, and economic functions can be maintained. Inca Peru, ancient Egypt, and traditional Hawaii allowed royal brother-sister marriages. Other kingdoms, including European royalty, have practiced endogamy through cousin marriage rather than brother-sister marriage (Kottak, 2008).

Hypergyny, Hypogyny, and Isogamy

Status also plays an important role in the selection of a spouse across cultures. Hypergyny, or "marrying up," indicates a marriage where the bride has a lower status than the groom. Hypergyny is commonplace in northern India especially among upper-status groups and in middle- and upper-class individuals in the United States. The opposite of hypergyny is hypogyny, or "marrying down," in which a bride has a higher status than the groom. Hypogyny is relatively rare cross-culturally. Isogamy is marriage between partners who are status equals and occurs in cultures where gender roles are viewed as holding equal value (Miller, 2008).

Arranged Marriages

Arranged marriages are marriages that are "arranged" by parents of the bride and groom based on whether they believe the families are good matches. Arranged marriages are well-known in many Middle Eastern, African, and Asian countries. The most important criteria that parents consider are the family's reputation, social status, education,

occupation and income of the spouse, and the absence of undesirable family traits like mental illness or divorce (Miller, 2008).

Cousin Marriages

An example of kin endogamy is cousin marriages, which has two forms: parallel cousins and cross-cousins. The marriage between parallel cousins is comprised of the children of either one's father's brother or one's mother's sister (linking siblings are the same gender). The marriage between cross-cousins includes children of either one's father's sister or one's mother's brother (linking siblings are of different genders). Parallel-cousin marriage is practiced by many Muslim groups in the Middle East and northern Africa, especially patrilineal parallel-cousin marriage, which is cousin marriage into the father's line (Miller, 2008). Matrilineal cross-cousin marriage (cousin marriage into the mother's line) is favored by Hindus of southern India but only includes about a fourth of the population (Ramesh, Srikumari, & Sukumar, 1989).

Levirate and Sororate

Still common as a form of second marriage, cultural norms in many societies require individuals to marry the spouse of deceased relatives so that alliances between descent groups can be maintained. Levirate is the custom of a man marrying his brother's widow. Sororate describes when a woman marries her deceased sister's husband. In some societies, this practice is permitted but not required and widows make other arrangements (Potash, 1986).

Courtship Patterns and Mate Selection

There is a plethora of research about what attracts people to potential mates. Proximity has long been linked to attraction, and physical attractiveness seems to be a key ingredient in romantic relationships especially for males. Several hypotheses have been proposed about what attracts someone to a partner for a romantic relationship. The matching hypothesis proposes that people with equal physical characteristics select each other as partners (Brehm, 1985). The similarity hypothesis proposes that people with similar demographics of age, race, religion, social class, education, intelligence, attitudes, and physical attractiveness tend to form intimate relationships (Brehm, 1985). Another approach is the reciprocity hypothesis, suggesting that people like others who are unlike them (Byrne & Murnen, 1988).

How and why individuals are attracted to each other varies significantly across cultures. Despite some of the differences, there are cross-cultural similarities with regard to mate selection. In a well-known study conducted by evolutionary psychologist David Buss (1989, 1994), more than 10,000 respondents across 37 different cultures

responded to questions about factors in choosing mates. In 36 out of 37 cultures, females, as compared with males, rated financial prospects as more important, and in 29 of the 36 cultures, they rated ambition and industriousness as more important. In all 37 cultures, females preferred older mates and males preferred younger mates. In 34 of the cultures, males rated good looks as more important than did females, and in 23 of the cultures, males rated chastity as more important than females. Buss concluded that his findings represented and supported an evolutionary framework of universal mate selection across cultures whereby females look for cues in potential male mates that signal resource acquisition and males place more value on reproductive capacity.

Others have emphasized the cultural differences in Buss's study. As compared with more advanced or modern cultures, traditional, less advanced cultures place greater value on chastity, domestic skills (e.g., housekeeping), desire for home and children, and abilities to support the home (Zebrowitz-McArthur, 1988). In China, India, Taiwan, and Iran, chastity was viewed as highly desirable in a prospective mate while in the Netherlands, Sweden, and Norway, it was considered irrelevant (Gardiner & Kosmitzki, 2002). Being a good housekeeper was highly valued in Estonia and China and of little value in Western Europe and North America. Refinement/neatness was highly valued in Nigeria and Iran and less so in Great Britain, Ireland, and Australia. Being religious was highly valued in Iran, moderately valued in India, and little valued in Western Europe and North America (Buss, 1994, p. 199).

Gender differences were also revealed in Buss's study. Women across cultures place high value on characteristics of men that relate to providing resources—good earning capacity, financial prospects, ambition, industriousness, and social status. Men across the 37 cultures place a high premium on the physical appearance of a potential mate; according to Buss (1994), this supports an evolutionary argument because men use physical attractiveness as an indicator that the woman is fertile and has good reproductive capacity.

Other similar studies have shown that men across cultures rate physical attractiveness higher than women do in terms of preferences in a marital partner (Hatfield & Sprecher, 1995). However, there seem to be more consistencies than differences in descriptions of physical attractiveness. For instance, female attractiveness cross-culturally is connoted by characteristics of kindness, understanding, intelligence, good health, emotional stability, dependability, and a pleasing disposition (Shiraev & Levy, 2007). Attractiveness is usually described in terms of cleanliness, health, and feminine plumpness. Although the degree of plumpness varies across cultures, extreme thinness seems to be considered unattractive and unhealthy (Zebrowitz-McArthur, 1988).

Other theories, such as the social construction perspective, suggest that interpersonal attraction is due to individual and cultural factors instead of evolutionary factors.

One study conducted in the United States highlights gender similarities in mate selection with both men and women rating kindness, consideration, honesty, and a sense of humor as important traits in mate selection (Goodwin, 1990). A more recent study (Pines, 2001) of American and Israeli students and their perceptions of romantic relationships combines both the evolutionary and social construction theories. Pines (2001) found that more men than women, regardless of culture, reported physical attractiveness as a major part of attraction (evolutionary theory). However, culture was important in other factors of attraction (e.g., compared with Israelis, Americans indicated status, closeness, and similarity as key determinants of attraction—social construction theory). In one study demonstrating different standards of beauty, Daibo, Murasawa, and Chou (1994) compared judgments of physical attractiveness made by Japanese and Koreans. In Japan, attractiveness ratings were positively correlated with large eyes, small mouths, and small chins. In Korea, however, attractiveness ratings were positively correlated with large eyes, small and high noses, and thin and small faces. Koreans were more likely than the Japanese to attach other judgments such as maturity and likeability to judgments of attractiveness (Daibo et al., 1994).

Patterns of courting and flirtation have similarities across many cultures (Aune & Aune, 1994), but there are many exceptions to the rules. Kissing, for example, is a widely acceptable cross-cultural phenomenon but is unknown to people in some cultures in Africa and South America, who would not consider kissing as an aspect of mate selection and reproduction (Shiraev & Levy, 2007). In Mediterranean cultures, physical affection is displayed by touching as a form of communication and is considered acceptable and appropriate, whereas in the United States it may be considered inappropriate with some groups. The expectation of marital fidelity appears to be almost universal, although among some Arctic peoples, it is customary to offer a host's wife to a guest (Shiraev & Levy, 2007). Men everywhere react more negatively, as compared with women, when their partners share sexual fantasies about having sex with others. Women everywhere are more distressed than men when their partner is kissing someone else (Rathus, Nevid, & Fischer-Rathus, 1993).

A relatively new phenomenon is Internet dating and the development of computer-mediated relationships (CMR). Since the 1990s, the Internet has become a primary venue for social encounters across the globe—offering an expanded world of mate possibilities in a shorter period at less expense (Lawson & Leck, 2006). Although some theorists have lamented the technological isolation and reduction of face-to-face interaction leading to emotional disconnection or superficial attraction that can occur with the Internet (Lawson & Leck, 2006), others have suggested that the Internet can be helpful in promoting romantic relationships because physical attributes and traditional/constraining gender and relationship roles are downplayed

while other factors related to emotional intimacy (e.g., rapport, similarity, mutual self-disclosure) are emphasized (Lawson & Leck, 2006). Whitty and Carr (2006) describe how online relating is different than romantic and sexual relationships offline. Advantages include opportunity to “grow” a relationship, safe space to flirt and experiment with relationship development, and greater freedom for people who are anxious or introverted (Whitty & Carr, 2006). The biggest benefits of Internet dating are the sheer number of potential partners and the freedom of choice among partners (Lawson & Leck, 2006). In fact, in one study examining the dynamics of Internet dating, Internet daters reported being lonely and many said they were seeking comfort after a crisis situation. The majority of the respondents liked the control over the presentation of self on the Internet and the feeling of a safe environment for getting to know someone. Finally, respondents reported that Internet dating provided freedom from commitment and stereotypic roles (Lawson & Leck, 2006).

Some of the typical dating problems still remain with Internet dating—people still tell lies, trust has to be negotiated, presentation of self must be managed, compatibility continues to be important, and appearance and shyness issues do not completely disappear when dating online. Rejection and emotional pain still can be part of Internet dating, as they are with face-to-face dating. There is also a dark side of online relationships, including Internet infidelity, Internet addiction, pedophilia, cyberharassment, cyberstalking, and misrepresentation of self (Whitty & Carr, 2006). However, many Internet daters say they are willing to take the risks associated because of the advantages offered by this technology (Lawson & Leck, 2006). Overall, successful relationships online start with people being honest and upfront in their profiles (Whitty & Carr, 2006).

Restrictions on Marriage: The Incest Taboo

One of the most basic and universal rules of exclusion to marriage is the incest taboo, or a rule prohibiting marriage or sexual intercourse between certain kinship relations. The most common form of incest taboo across societies is against marriage or sexual intercourse between fathers and their children and mothers and their children. In the majority of cultures, brother-sister marriage is prohibited, although there are exceptions. Historically, brother-sister marriage in royal families was considered the norm and even existed to some extent in the general population (Kottak, 2008). A prime example of this was brother-sister marriages of royalty in Egypt at the time of the Roman Empire (Miller, 2008). In some cultures, incest taboos include cousin marriage, although in other cultures, cousin marriage is considered a viable option in order to build localized kinship networks. In other groups, such as the Nuer of southern Sudan, the incest taboo includes all members of the patrilineage in order to create widely dispersed kin networks (Kottak, 2008; Miller, 2008).

One of the most practical explanations for the incest taboo is that it arose to ensure exogamy, which was evolutionarily advantageous in terms of increasing survival via the creation and maintenance of alliances outside the social network. Despite prevalence of the taboo, in one study across 87 societies, some occurrences of incest were identified (Meigs & Barlow, 2002). Reportedly incest was “widely practiced” among the Yanomami of Venezuela and Brazil. Among the Ashanti people, punishment for incest shifted from death to merely being fined. Among 24 Ojibwa individuals, 8 cases of parent-child incest and 10 cases of brother-sister incest were found (Kottak, 2008). In Western societies, father-daughter incest is considered a risk under certain conditions (Meigs & Barlow, 2002). Father-daughter incest is most common with stepfathers and nonbiological male household members but also occurs with biological fathers, especially those who were absent or did little caretaking of their daughters in childhood (Kottak, 2008).

The Act of Marriage

Societies have some way of marking the onset of marriage. Many societies have formal ceremonies and rituals that denote the beginning of marriage while others use symbolic or informal practices to indicate that a marriage has occurred. In the societies where a ceremony occurs, several elements emphasizing important aspects of the particular culture commonly occur as part of the ceremony. For instance, feasting and celebrations typically accompany marriage ceremonies, often with the underlying purpose of bringing the two families and friends together in unification. Shinto customs are still followed by many in Japanese wedding ceremonies with the drinking of rice wine (sake) after the ceremony to confirm the marriage (Gardiner & Kosmitzki, 2002). In some cultures, marriage ceremony customs include ritualized expressions of hostility between kin groups such as the trading of insults, which occurs on the Polynesian atoll of Pukapuka (Kottak, 2008). In Kenya, the rebuilding of a house in the bride’s village represents an important part of the marriage ceremony (Gardiner & Kosmitzki, 2002).

Love and Marriage

The role of romantic love has been debated historically and cross-culturally. Many argue that romantic love did not become part of marriage until Western Europe and America accepted the idea given the strong influence of the Enlightenment and the individualistic emphasis during the French and American Revolutions (Coontz, 2007). Romantic love is more common in cultures where women are dependent on men economically, but increasingly, marriage based on romantic love is becoming widespread in many cultures (Levine, Sato, Hashimoto, & Verma, 1995).

There is cultural variation in the extent to which love plays a role in marriage. Marriage for love is a fairly recent development in the Western world and may be related to the individualistic orientation (Coontz, 2005). In many Western cultures, marriage is viewed as the culmination of romantic love represented by the idealistic and somewhat “fairy-tale” notion that people meet their soul mates, fall in love, marry, and live “happily ever after,” proving that “love conquers all” (Gardiner & Kosmitzki, 2002). People in collectivistic cultures place less emphasis on romantic love and love commitment in marriage. Historically, people married to acquire status through influential in-laws, for political reasons, to forge family alliances, to increase labor forces, and to effect business mergers. Romantic love was not unknown but it was not considered an essential part of marriage and thus was discouraged on the basis of being a selfish and weak reason to marry. For instance, in ancient India, love before marriage was perceived as irresponsible and anti-social. During the Middle Ages, the French viewed love as a type of insanity only curable through sexual intercourse either with the beloved or with someone else (Coontz, 2007).

In contrast, many of the arranged marriages common in Asia, Africa, and other parts of the world do not have romantic love as a basis (Gardiner & Kosmitzki, 2002). This “Eastern ideal” is based on the notion that individuals have several possible mates with whom they could have a successful and enduring marriage. Arranged marriage is still practiced in some places, such as India, where arrangements may be made between families during a child’s infancy. Such arrangements are typically based on the parents’ status and knowledge of other families and possible matches; the marriage is considered the blending of two families (Ember et al., 2006; Gardiner & Kosmitzki, 2002). Arranged marriages are viewed as more than just a union between two individuals and more as an alliance between families and even communities (Gardiner & Kosmitzki, 2002). However, trends are changing even in countries where arranged marriage has been popular. For example, in Japan, love marriages are replacing the earlier practice of arranged marriages, yet traditional customs often remain as part of the ceremony.

For thousands of years, the institution of marriage served many economic, political, and social functions at the cost of minimizing the needs and wishes of individuals (Coontz, 2005). Especially in the last 200 years, marriage, particularly in Europe and America, has become more personal and private with a greater emphasis on the emotional and sexual needs of the couple. With this historical transition came free choice in mate selection as the societal norm and love as the primary reason for marriage. As Coontz (2005) notes, “Marriage has become more joyful, more loving, and more satisfying for many couples than ever before in history. At the same time it has become

optional and more brittle. These two strands of change cannot be disentangled” (p. 306). For some, this transformation of marriage and love has been appreciated as a liberating option from restrictive social and cultural expectations. For others, the shift has meant a significant loss of rules and protocol for relationships with nothing offered in its place. With such factors, the need to marry or remain unhappily married decreases.

Coontz (2005) suggests historical factors that have supported single living and personal autonomy. Factors include the belief that women have just as much sexual desire as men; less societal/governmental regulation of personal behavior and conformity; reliable birth control, which became readily available in the 1960s, relieving women from fears of unwanted pregnancy; increasing economic independence of women; and more time- and labor-saving devices, which have lessened the demand on women to do housekeeping. Examining the role of love in marriage provides a unique lens that reveals many aspects of culture, economic, interpersonal, and emotional (Padilla, Hirsch, Muñoz-Laboy, Sember, & Parker, 2007).

Economic Aspects of Marriage

Most marriages (approximately 75%) are accompanied by some type of economic transaction, and exchanges between partners of goods or services and their families and friends (Ember et al., 2006).

Bride Price

Bride price or bridewealth, common in horticultural and pastoralist cultures, is the transfer of goods or money from the groom’s family to the bride’s family. This is the most common economic transaction across cultures. Payment of the bride price can be in the form of money, livestock, or even food. Bride price still occurs globally but is most popular in Africa and Oceania. For example, the Nandi typically offer five to seven cattle, one or two sheep and goats, cowrie shells, and money equivalent to one cow as the bride price.

Brideservice is a type of bride price where labor is transferred from the groom to his parents-in-law over a designated time period. This still occurs in about 19% of societies that have an economic transaction as part of marriage. One particular example is the brideservice still practiced in the Amazon (Ember et al., 2006).

Exchange of Families

In a few societies (about 6% who have economic transactions at marriage), a sister or female relative of the groom is exchanged for the bride. This occurs, for example, among horticultural and egalitarian societies such as the Tiv of West Africa and the Yanomamö of Venezuela and Brazil (Ember et al., 2006).

Gift Exchange

Gift exchange between the two kin groups linked by marriage occurs in some 11% of societies that have economic transactions at marriage. In the United States, it is customary that the groom’s family is responsible for paying for the rehearsal dinner the night before the wedding whereas the bride’s family is expected to pay the costs for everything else (Miller, 2008). Among the Andaman Islanders, kin groups become united through the parents exchanging gifts via a third party once a boy and girl have voiced their intention to marry (Ember et al., 2006).

Dowry

A dowry is the transfer of goods (sometimes money) from the bride’s side to the new married couple for their use. Occurring in about 8% of societies with economic transactions at marriage, the dowry normally includes household goods such as furniture, cooking utensils, and perhaps even a house. Dowries are still practiced in parts of Eastern Europe, southern Italy, France, and India (Ember et al., 2006).

In parts of India, the dowry passes to the groom’s family making the more accurate term groom price (Miller, 2008). Sometimes, an indirect dowry is provided from the groom’s family by giving goods to the bride’s father who then passes them along to her. Among the Basseri of southern Iran, the groom’s father gives cash to the bride’s father in order to set up the couple’s new household (Ember et al., 2006).

Sexuality and Marriage

In many cultures, marriage sanctions sexual relations between partners. In others, sexuality is confined to procreative purposes. Depending on the society, there are different views about procreation. In some societies, it is believed that spirits place babies in women’s wombs. Some cultural groups believe that a fetus must be nourished by continual insemination during pregnancy. The Barí of Venezuela believe that multiple men can create the same fetus (multiple paternity). When the baby is born, the mother names the men she recognizes as fathers and they assist her in raising the child (Kottak, 2008).

Sexual practices differ as well depending on the society. Some societies are more restrictive concerning sexuality. The regulation of premarital sex and extramarital sex differs depending on the society. For example, Inis Beag, off the coast of Northern Ireland, is a sexually conservative and prohibiting culture. Nudity is prohibited, sexual ignorance is widespread, female orgasm is unknown, marital sex occurs infrequently, and the idea of sexual pleasure is nonexistent (Messenger, 1993). In other societies, such as the Melanesian Islands in the South Sea, marital sex is

perceived as a normal and natural form of pleasure; however, premarital and extramarital sex are almost equal to the crime of murder (Davenport, 1965). Reportedly, in the Melanesian Islands, marital intercourse including orgasm is expected to occur two to three times per day in the early years of marriage, and later to subside to once a day or less. Premarital masturbation is encouraged for both males and females. The Trobriand Islanders approve of and even encourage premarital sex and provide thorough instruction in various forms of sexual expression for adolescents, believing that it is important preparation for later marital activities. The Ila-speaking population of central Africa encourage trial marriage between adolescents so that girls can “play wife” with boys of interest before marriage. Reportedly, virginity in this group does not occur after age 10 (Ember et al., 2006). Other cultural groups, such as many Muslim societies, “test” the female’s virginity by displaying blood-stained sheets from the wedding night as proof of her premarital chastity.

Extramarital sex is fairly common across societies, with about 69% of men and 57% of women engaging in extramarital sex more than occasionally. Most societies have a double standard with regard to women’s sexual behavior and expect that women will have more restrictions against extramarital sex.

One commonality of sex occurring during marriage is privacy in almost all societies. North Americans typically find privacy in their bedrooms while others have to locate other private areas or sometimes perform coitus with others present. Nighttime is generally the preferred time for coitus in most cultures although there are examples of preferences for daytime sex (e.g., the Rucuyen of Brazil). There are other prohibitions in some cultures restricting sexual activity, for example, before certain activities like hunting or planting or because of certain events like death, pregnancy, or menstruation (Ember et al., 2006).

The acceptance of homosexual relations differs widely across societies. Some more restrictive societies deny homosexuality and thus forbid homosexual practices. Historically in other groups, like the Siwans of North Africa, there are examples of much greater permissiveness regarding homosexuality, and all males were expected to engage in homosexual relations. The Etoro of New Guinea are reported to have preferred homosexuality to heterosexuality with specific prohibitions against heterosexuality most of the days during a year. Furthermore, male homosexuality was thought to make crops flourish and strengthen males (Ember et al., 2006).

Forms of Marriage

Typically, marriage has been between a male and a female, but some societies have recognized marriage between people of the same biological sex. In the anthropological literature, alternative forms of marriage have also been noted.

Monogamy

Monogamy is the marriage between two people (opposite gender if heterosexual and same gender if homosexual). Heterosexual monogamy is the most frequent form of marriage across cultures and constitutes the only legal form of marriage in many countries (Miller, 2008). Serial monogamy appears to be a common form of monogamy in North America, where people may have more than one spouse in their lifetimes but never legally at the same time (Kottak, 2008).

Same-Sex Marriages

Some societies recognize various kinds of same-sex marriages (Kottak, 2008). Same-sex marriages are legal in Denmark; Norway; Holland; South Africa; Ontario, Canada; and Massachusetts, in the United States. There is much debate politically and socially regarding the legal status of same-sex marriages (Miller, 2008).

Depending on the historical and cultural setting, same-sex marriages have been accepted. In some African cultures, for instance, women may marry other women in order to strengthen their social and economic status among society (Kottak, 2008). Among the Nandi of Kenya, approximately 3% of marriages are female-female marriages. The Nuer of southern Sudan are also reported to have woman-woman marriage. In this type of marriage, a woman with economic means gives gifts to obtain a “wife” and brings her into the residential compound just as a man would do if he married a woman. The wife in a Nuer woman-woman marriage performs productive labor by having sexual relations with a man, as the two women do not have a sexual relationship with each other. Her children, however, will belong to the two women who are married (Miller, 2008). In former times, the Cheyenne Indians allowed married men to take *berdaches* (two-spirits/male transvestites) as second wives (Ember et al., 2006).

Plural Marriages/Polygamy

Polygamy is marriage that involves multiple spouses, which is still permitted in many cultures (Miller, 2008). The most common form of plural marriage is polygyny, which is the marriage of one man with more than one woman. Polygyny in many societies serves as an indicator of a man’s wealth and prestige—in other words, the more wives he has, the greater status he accrues. In other societies, polygyny is practiced because a man has inherited a widow from his brother (levirate). In still others, polygyny is a way to advance politically and economically. For polygyny to work, there has to be some agreement among the wives about their status and household chores. Generally, there is a first wife or a senior wife who is in charge of the household and has some say-so regarding who is taken as another wife. For instance, among the Betsileo of Madagascar, each

wife lived in a different village, but the senior, first wife, called “Big Wife”, lived in the primary village of her husband where he spent most of his time (Kottak, 2008). Other customs like having separate living quarters for cowives who are not sisters helps lessen jealousy among the cowives. The Tanala of Madagascar require the husband to spend one day with each cowife in succession and assist with cultivation of that wife’s land. If this rule is not followed, a wife can sue for divorce and alimony up to a third of the husband’s property. Such a practice gives cowives greater equality in matters of sex, possessions, and economics (Ember et al., 2006).

Marriage between one woman and more than one man (polyandry) is extremely rare, although it is still practiced in Tibet and parts of the surrounding Himalayan region. In Tibet, fraternal polyandry (brothers jointly marrying a wife) is still practiced. Fraternal polyandry is one of the least common forms of marriage globally, but in Tibet, it remains a viable and ideal form of marriage and family. Practically, the eldest brother is normally the dominant authority. The wife is expected to treat all brothers equally, and the sexual aspect of sharing spouses is not viewed as repulsive by males or females. Any offspring are treated similarly, and the children consider all the brothers their fathers. The typical explanation given for this type of marriage in Tibet is that it is a materialistic and economically advantageous one. The brothers do not have to divide their property and can therefore have a higher standard of living. Due to changes in social and economic conditions, polyandry may vanish within the next generation (Kottak, 2008).

Other Forms of Marriage

In the Brazilian community of Arembepe, people can choose among various forms of sexual union including common-law partnerships (not legally sanctioned), civil marriages, and “holy matrimony” (religious ceremony but not legally sanctioned). This means that some can have multiple spouses at the same time from the different types of unions (Kottak, 2008).

Also common among the Nuer was what Evans-Pritchard (1951) called the ghost marriage. The Nuer believed that a man who died without male heirs in his family was likely to trouble his living kin through an unhappy and angry spirit left behind. To appease the angry spirit, a relative of the dead man would often marry a woman “to his name” so that the woman was married to the ghost but lived with one of his surviving kinsmen.

Universality of Marriage

The custom of female-male marriage practiced across societies appears to have adaptive functions that solve problems in societies. For instance, marriage has been proposed as an answer to gender division of labor that

exists in every society. If societies designate different economic activities for men and women, there needs to be a mechanism by which the products of labor can be shared between men and women, and marriage is one possible solution.

Another interpretation of why marriage is universal is based on the extended care required for human infants. It has been suggested that infants have a prolonged dependency on the mother (typically the main caregiver in most cultures); this limits the kind of work she can do (hunting, for example). Therefore one solution is that the man must be available to help the woman with certain tasks, thus the mechanism of marriage (Ember et al., 2006).

A third interpretation of why marriage is universal is sexual competition between males for females. Marriage offers one possibility for reducing male rivalry and destructive conflict so that societies can survive (Ember, et al., 2006).

Divorce

Many believe that divorce occurs more frequently in the modern United States as compared with other societies. However, anthropologists have reported comparable rates of separation and remarriage among hunting and gathering societies and other groups to those in modern-day industrial societies. For example, the highest rates of divorce ever recorded in the first half of the 20th century were in Malaysia and Indonesia, which surpassed the U.S. record rates of 1981 (Coontz, 2007). Depending on the society, ease of divorce varies. Marriage is much easier to dissolve in societies where marriage is more of an individual affair. In other societies where marriage represents a political and social union between families and communities, divorce is more difficult (Kottak, 2008). Considerable bridewealth and replacement marriages (levirate and sororate) work to preserve group alliances and thus decrease divorce rates. A wife among the Shoshone Indians could divorce her husband by merely placing her husband’s possessions outside the dwelling, which was considered her property. Divorce is official among the Cewa of East Africa when the husband leaves his wife’s village taking along his hoe, axe, and sleeping mat (Coontz, 2007). In the traditional society of Japan, a woman wanting a divorce had to complete two years of service at a special temple while the man could simply write a letter containing three and half lines in order to divorce his wife.

Coontz (2007) posits that the reasons for divorce in any given time period relate to the reasons for marriage. For example, a common reason for divorce in contemporary society is the loss of love, lack of individual fulfillment, or absence of mutual benefit. This has to do with the primary reason for marriage being love and romance.

In Western societies, there is more flexibility with the notion of a failed marriage. Generally, if romance, love, sex, or companionship dies out in a marriage, then couples

in contemporary Western society may opt for divorce. However, sometimes for economic reasons, obligations to children, negative public opinion, or simply inertia, couples may maintain “failed” marriages. Among countries across the globe, the United States has one of the highest rates of divorce, although rates have dropped as compared with the 1970s. From historical records of divorce in the United States, there is an increase after wars and a decrease after tough economic times. The high rates of U.S. divorce are thought to be related to the economic independence enjoyed by many women and the cultural ideas of independence and self-actualization which give greater permission for people to abandon marriage if it is not working for them (Kottak, 2008).

The Family

A family is a group of people who consider themselves related through kinship, while a household is defined as people who share a living space and may or may not be related (Miller, 2008). Most households consist of members who are related through kinship, although an increasing number do not. For instance, a group of friends sharing living quarters or a single person living alone constitute a household. Young adults in the United States usually live away from home when they go to college. In more complex societies, family members tend to live apart from one another, while in more simple societies, the family and the household are impossible to differentiate (Ember et al., 2006). Across most societies, a primary function of families is the socialization and protection of children so that the children can obtain the cultural behavior, beliefs, and values necessary for survival. The nature of the family inevitably shifts and reflects the social and cultural changes in economics, education, and political systems (Georgas, Berry, van de Vijver, Kagitçibasi, & Poortinga, 2006).

Family Structure and Types of Households

All societies have families, although family form and households vary from society to society. The nuclear household, still commonly referred to as the nuclear family, comprises one adult couple, either married or “partners,” with or without children. Most people belong to at least two different nuclear families during their lifetime. Anthropologists distinguish between the family of orientation, the family in which one is born and grows up, and the family of procreation, the family formed when one marries and has children of his or her own. Nuclear-family organization is widespread cross-culturally and varies in significance from culture to culture, but it is not universal. For instance, in the classic Nayar group, the nuclear family is rare or nonexistent (Kottak, 2008). In contrast, in North America, the nuclear family is the only well-defined kin

group and remains somewhat of a cultural ideal (Ember et al., 2006). Such a family structure is thought to arise from industrialism and contributes to geographic mobility and isolation from extended family members. Many North American married couples live far away from their parents in locations generally determined by their jobs in communities (neolocality) and establish households and nuclear families of their own (Ember et al., 2006).

An extended household is a domestic group containing more than one adult married couple related either through the father-son (patrilineal extended household) or mother-daughter line (matrilineal extended household) or through sisters and brothers (collateral extended household). Extended families are the prevailing form in more than half of the world’s societies (Ember et al., 2006). For example, in former Yugoslavia, extended-family households, called *zadruga*, consisted of several nuclear families living together. The *zadruga* was headed by a male household head and his wife, considered to be the senior woman. Also included were married sons and their wives and children, and unmarried sons and daughters. Each nuclear family had their own sleeping quarters; however, many items were freely shared among members in the *zadruga* (e.g., clothes, items from the bride’s trousseau, and other possessions). The Nayar, a caste of southern India, provide another example of extended households. The Nayar lived in matrilineal extended-family compounds called *tarawads* (residential complexes with several buildings headed by a senior woman and her brother). The *tarawads* were home to the woman’s siblings, her sisters’ children, and other relatives of matrilineal descent. These compounds were responsible for child care and provided the home for retired Nayar men who were military warriors (Ember et al., 2006).

Expanded-family households (those that include non-nuclear relatives) also exist in some cultures. For example, in lower-class families of North America, expanded-family households are more common than in middle-class families. If an expanded-family household consists of three or more generations, then it is considered an extended-family household. Collateral households, another type of expanded family, include siblings and their spouses and children (Ember et al., 2006). Polygamous married people are considered to constitute complex households in which one spouse lives with or near multiple partners and their children. Descent groups including lineages and clans of people claiming common ancestry may reside in several villages, but rarely come together for social activities. These descent groups are common in nonindustrial food-producing societies (Kottak, 2008).

Changes in Marriage and the Family

Globalization, including technological advances and international migration, has increased the opportunity for

interactions among different types of people and contributed to rapid changes in the structure and function of marriage and the family. The institution of marriage continues to retain popularity although many of the details of marriage are undergoing transformation. For instance, the Internet has provided new forms of finding a potential partner and courtship. Also, the age of first marriage is rising in most places due in part to increased emphasis on completing education and higher marital aspirations (e.g., owning a house). Marriages between people of different nations and ethnicities are another example, now increasingly commonplace and leading to pluralistic practices and customs of marriage and family. Coontz (2007) claims that marriage “has been displaced from its pivotal position in personal and social life” (p. 15) with many children being raised in alternative settings. The definition of marriage has also changed, given that most people today live in a global climate of choice with many options. This makes divorce and other relationship forms like cohabitation viable options for many people across the world.

In many societies, people choose to have children without being married, or being a single parent becomes a necessity, and thus one-parent families are becoming more common globally. Traditionally, single-parent families have been more common in Western societies, but there continues to be a large increase in one-parent families with the majority headed by women (approximately 90%). In the 1970s, of the Western countries, Sweden had the highest rates of single-parent families, but now the United States has the largest percentage. One-parent families occur for several reasons, including divorce/separation of two-parent families, births outside of marriage, deaths of spouses, and single people who decide to have children. Some parents may choose to remain single because of lack of suitable partners. For example, in the former Soviet Union, the ratio of women to men is much higher because males are more likely to have died from war, alcoholism, and accidents. In other countries, a common explanation is that one-parent families are able to manage because of support from the state; for example, in Sweden, unmarried and divorced mothers receive significant social supports, maternity leave, and educational leave (Ember et al., 2006).

Another family form that is making a comeback, at least in the United States, is the multigenerational family (three or more generations living together). According to the 2000 Census, there are almost 4 million U.S. multigenerational households; this represents about 4% of all households, and this number continues to rise. The majority of these households include grandparents living with their children and their grandchildren in the house of the grandparent. In about one third of these households, the grandparents live in the home of their children (or son- or daughter-in-law) and their grandchildren. A very small percentage of these households are comprised of grandparents and great-grandparents as well as children and grandchildren of the grandparents (Generations United, 2006).

Some of the reasons for the rise in multigenerational households include financial factors such as high housing costs, high cost of living, child care/elder care expenses, unemployment, parents returning to school, and parents working to save money to become independent. Cultural reasons such as immigration, value systems, importance of ritual and celebration of holidays and events, and desire to stay connected with one’s cultural group all are reported reasons for multigenerational households. Other reasons include individual beliefs that child care and elder care are family responsibilities or that age-integration within communities is important, and a desire to be involved and connected with offspring and elders. Situational factors such as the inability to live alone after being widowed, a divorce that requires moving to a parent’s home with children, an illness requiring regular care and assistance, single parenting, housing shortages, and extended life span also promote multigenerational households (Generations United, 2006). In the future, multigenerational families are expected to become more commonplace and continue to increase. By 2010 in the United States, it is expected that more children will know their great-grandparents, people in their 60s will be caring for 80- to 90-year-old parents, more children will grow up with the support of older relatives, and there will be an increase in four-generational households (Generations United, 2006).

Grandparenting in general is a relatively new phenomenon as of the last 100 years, due to increased life expectancy and good health. The number of grandparents parenting grandchildren has increased generally due to crisis situations involving drugs, divorce, desertion, and death (Glass & Huneycutt, 2002). Other factors contributing to the increase of grandparents raising their grandchildren include high teenage-pregnancy rates, more parents in prison (with some 80% having dependent children), more women using drugs, and parents dying from AIDS. All of these scenarios that lead to the number of grandparents raising their grandchildren are thought to be on the rise.

Increasing numbers of lesbian women and gay males are exploring parenting options (McCann & Delmonte, 2005) and taking on parenthood through donor insemination, surrogacy, fostering, and adoption. Although there appears to be no definitive research pointing one way or another, gay parenting has been a contentious issue for many because of the presumed damaging effects that gay parents can have on their children. Concerns have been raised regarding whether the child will become homosexual, whether the child will be bullied, whether the child will have appropriate opposite-sex role models, and more (McCann & Delmonte, 2005).

Another complexity for family structure is the challenge presented by international migration. Parents may still identify with their ancestral culture and children often become immersed in the new culture, quickly adapting to the language and customs. This can cause rifts in the relationship between parents and children and can contribute to

disagreements about social issues like dating, clothing, and careers. Sometimes children also serve as cultural brokers for their parents, navigating complex and unfamiliar bureaucratic systems since their parents may not speak the language or be acculturated to the new country and customs. Immigrant children typically adapt to the dominant culture faster than their parents, which also contributes to conflict between parent and child—parents trying to hold on to previous traditions, while children are adapting to the new, dominant culture as their new way of life. Immigrant children frequently become masters of both cultures, easily adapting between both worlds (Suárez-Orozco & Suárez-Orozco, 2001). Immigrant parents are often conflicted between encouraging their children to develop the cultural competencies of the dominant culture and trying to maintain their own traditions (Suárez-Orozco & Suárez-Orozco, 2001). In addition, resettlement issues such as obtaining housing, food, and employment, and dealing with the bureaucracy of immigration and documentation, can overwhelm parents' ability to attend to their children. Immigrant families may also experience stress due to adaptation to the United States, including such tasks as learning and/or enhancing English skills and finding employment, housing, and schools; these are difficult tasks for anyone, but especially for immigrants as they also deal with new and different social/cultural expectations and attitudes.

International adoption (sometimes referred to as transnational adoption) is becoming more common in the United States and European countries. Although still on a relatively small scale, international adoption represents a significant shift from historical adoption practices and constitutes an entirely different family structure (Conn, 2009). More than 20,000 internationally adopted children enter the United States each year (U.S. Department of State, 2005) from China, Russia, and Guatemala.

Conclusion

Marriage and family are universal forms of mating and relating; however, the forms of marriage and family are variable depending on social, cultural, and historical influences (Ferguson, 2007). Family arrangements are more diverse now than ever before, and relationships have shifted from having a biological emphasis to a social emphasis. In the future, there is likely to be increased diversity and transformation in the institution of marriage, along with family forms and households, across the globe (Miller, 2008).

KINSHIP SYSTEMS

RICHARD R. JONES

Lee University

Humans in every culture structure a set of social relations that classify its members within the framework of a family. The notion of what constitutes a family can be fairly extensive in some groups, and more narrowly defined in other groups. For example, the concept of family is restricted to a smaller number of people in American culture than in Egyptian culture. When asked, students in the United States typically write down the names of 80 to 120 relatives when asked to name all the members of their family, while Egyptian students can usually write down over twice that number. Likewise, categories of classification—kinship terms, such as *father* or *mother*—can be extensive and incorporate a number of different social relationships, as for example, when the term *father* in some kinship systems, refers simultaneously to one's biological father, one's father's brothers, and one's mother's brothers. Or kinship terms can be more narrowly defined, as in our own system where *father* refers only to one particular social relationship.

Kinship terms are also relative categories that classify according to one's position in the overall system of relations. Consequently, while a certain female might be classified as daughter by her mother, she may also be differently classified as mother by her son. These variant classifications are simultaneous, so that every person can potentially be every possible category at the same time, the only limitation being that some categories are specific to one's sex. Additionally, kinship classification is reciprocal. For example, a person

who classifies another as sister will be referred to by that person as "sister" or as "brother" depending on their sex. A person who classifies another as son will be referred to as either "mother" or as "father."

Kinship systems are structured by a variety of marriage practices but can also make allowances for the dissolution of structures through divorce. Kinship relations continue to persist even after the death of members of a society. Additionally, systems of bridewealth, brideservice, and dowry are an integral part of kinship systems, as are post-marital residence patterns. Most kinship systems are also malleable enough to allow the creations of "fictive" relations, that is, to allow for the incorporation of nonfamily members into the family.

Anthropologists are interested in studying kinship systems because such systems are found in every culture, and because a society's kinship system articulates in some way all other aspects of the culture, such as politics, religion, worldview, marriage practices, economic behaviors, and so on. Due to the pervasiveness and surprisingly small range of variability in kinship systems across cultures, and because kinship systems are easily accessible for study in most cultures, such studies seem to offer, perhaps more so than some other areas of study in anthropology, an opportunity to say something universal about humanity. Consequently, many studies in anthropology have devoted a lot of effort to understanding kinship systems.

This chapter offers an overview of the history and different approaches to the study of kinship; a discussion of the application of kinship studies in ethnography; a discussion and overview of what is known in anthropology about kinship systems, family, marriage, and related topics; and some speculation on the future of kinship studies in anthropology.

Development of Theory in Kinship Studies

In the mid-19th and early 20th centuries, scientific inquiry in a number of disciplines became focused on the natural history of humanity. In order to understand how kinship studies emerged in an intellectual context in anthropology, it is necessary to briefly review a few works from that time. During this time, biology, history, and the then emerging disciplines of psychology, sociology, and anthropology all attempted to address various “origin” questions related to humans. Charles Darwin’s *The Descent of Man*, first published in 1871, provided breaking ground for answering questions about human biological origins. Around the same time, the historian Fustel De Coulanges, in *The Ancient City* (1873), explored the origin of Greek and Roman cities and civilization. Sigmund Freud then, in 1913, attempted to explain the psychological origin of incest taboos in *Totem and Taboo*. In *The Elementary Forms of the Religious Life* (1915), the sociologist Émile Durkheim sought to explain how humans came to classify the world, prefaced by his work with Marcel Mauss in *Primitive Classification* (1903/1963). In anthropology, Lewis Henry Morgan wrote two books, *Ancient Society* (1877/1912) and *Systems of Consanguinity and Affinity of the Human Family* (1870/1997), in an effort to explain the origin and development of culture. Throughout all of these works, concepts such as family, race, descent, incest, lineage, clan, tribe, marriage, agnation, and others frequently occur, all of which are in the domain of kinship studies.

Biology, history, psychology, sociology, and anthropology all recognized that human kin relations were connected in significant ways to other social phenomena. Darwin (1871/1952) found it necessary to discuss polygamy as one manifestation of human sexual selection (p. 369); Fustel de Coulanges (1873) had to elaborate on the family system of the ancient Romans and Greeks in order to explain the organization of ancient cities (pp. 40–116); Freud (1946) could only understand incest taboos within the framework of kin relations (pp. 3–25); Durkheim (1915) believed the elaborate kinship structures of “primitive” people gave rise to the earliest religions; and Morgan (1870/1997) saw the study of kinship as a way to illuminate the evolution of culture from the primitive to the civilized (p. xxii).

Morgan and Durkheim

A few particular works of Morgan and Durkheim have had a significant impact on the study of kinship systems in anthropology and will be briefly reviewed here.

In *Ancient Society*, Morgan (1877/1912) described the complexity of the kinship system of an Australian group called the Kamilaroi. The Kamilaroi have a totemic kinship system. The society is organized into two clans that are in turn subdivided into three lineages each. Each lineage has its own totem, an animal that symbolically represents the group. The purpose of describing the complex kinship system of the Kamilaroi was to establish a description and overview of the evolution of culture.

In *Systems of Consanguinity and Affinity of the Human Family*, which, more than any other single work, established the foundation for kinship studies in anthropology, Morgan (1870/1997) systematically collected and organized a large volume of data from many different culture/language groups. These data were arranged in tables that display the names given to one’s various kin relations in all the different groups. In Table I of *Systems*, Morgan compared 196 different kin relations among 39 different languages/cultures—an impressive display of scholarship for the time. For example, the following is a portion of the list in Table I for Arabic, slightly rearranged and shortened and using a different system of transliteration for Arabic than that used by Morgan (pp. 77–127):

My great grandfather: *jidd abii*
 My great grandmother: *sitt abii*
 My grandfather: *jiddii*
 My grandmother: *sittii*
 My father: *abii*
 My father’s brother: *‘ammii*
 My father’s brother’s son: *ibn ‘ammii*
 My father’s brother’s daughter: *bint ‘ammii*
 My father’s sister: *‘ammtii*
 My father’s sister’s son: *ibn ‘ammtii*
 My father’s sister’s daughter: *bint ‘ammtii*
 My mother: *ummii*
 My mother’s sister: *khaltii*
 My mother’s sister’s daughter: *bint khaltii*
 My mother’s sister’s son: *ibn khaltii*
 My mother’s brother: *khalii*
 My mother’s brother’s daughter: *bint khalii*
 My mother’s brother’s son: *ibn khalii*
 My son: *ibnii*
 My daughter: *bintii*
 My grandson: *ibn ibnii/ibn bintii*

In the above data, there are immediately discernible patterns. For example, *ibnii* means “my son,” and *khalii* means “my mother’s brother,” and *ibn khalii* means “son of my mother’s brother.” (The suffix, -ii, is the first person possessive pronoun and means “my:”) Likewise, *bint khalii* means “daughter of my mother’s brother.” Morgan called kinship-terminology systems that narrowly describe kin relations, like this one, “descriptive” (p. 50). He believed that descriptive systems contrasted with another group of systems that he labeled “classificatory” (p. 143).

Classificatory kinship terminology, for Morgan, comprises a system that does not repeat core terms, such as

daughter or *son*, for the categorization of more distant kin, and because of this, classifies multiple relationships under one category. For example, the kinship terminology used by most North American English speakers has the categories aunt, uncle, and cousins to indicate the collateral relationships on both the father's and mother's side of the nuclear family.

As it turns out, Morgan's distinction between descriptive and classificatory does not stand close scrutiny. All kinship systems are classificatory. The term *aunt* classifies under one category, four relationships, two of which are consanguineal (i.e., blood relationships), and two of which are affinal (i.e., created by marriage): father's sister, mother's sister, father's brother's wife, and mother's brother's wife, respectively. Likewise in Arabic, the term *bint 'ammii*, my father's brother's daughter, can refer to all the daughters of all of my father's brothers, and in so doing classifies more than just one relationship.

Systems generated a vigorous intellectual reaction, raising an important question for anthropologists. Was kinship terminology a psychological or a social phenomenon? This is an important question. A. L. Kroeber, in a 1909 article titled "Classificatory Systems of Relationship," argued that kinship terminology is a linguistic phenomenon, hence psychological in nature, and not useful for the study of other social concerns. On the other hand, W. H. R. Rivers, in *Kinship and Social Organization*, published in 1914, argued that the study of kinship contributed significantly to understanding other social relations. Determining whether or not kinship terminology is merely linguistic classification, or whether it is causally linked to other social behaviors—such as marriage, descent, residence patterns, and so on—became, and remains, an important issue for anthropologists. It is clear that all these aspects of kinship are connected somehow, but to what degree one affects the other, and exactly how they influence each other, is not totally resolved.

Émile Durkheim and Marcel Mauss, in an essay first published in 1903, called *Primitive Classification*, argued that social classification is the basis for all primitive classification. Because humans form groups, the social structure of the group becomes the template for other classification by the group. Durkheim and Mauss argued this from the ethnographic literature of the time about how primitive people classify the world. The primitive people they analyzed in *Primitive Classification* were native Australians, Zuni, Sioux, and Chinese. Durkheim and Mauss claimed that primitive classification was quite different than most modern and scientific forms of classification in that the categories of primitive classification are inclusive, not exclusive. By this, Durkheim and Mauss meant that primitive people classified according to categories that lumped things together, rather than according to categories that distinguished things. Specifically, they referred to totemic systems in which, for the primitive person, "There is a total lack of distinction between him

and his exterior soul or totem" (1903/1963, p. 6). Myth and much of the religious thought that still existed in modern societies was seen by Durkheim and Mauss as survival of an earlier way of thinking, and modern scientific thought was an evolution away from it. In essence, according to Durkheim and Mauss, primitive people had a different way of knowing and thinking about the world that originated in the structure of kin relations in human groups. Of course, later scholars, such as Claude Lévi-Strauss (1963, 1949/1969), would challenge the notion that primitive thought was significantly different than modern thought, but the basic observation is significant: Kinship systems provide the model on which the world can be classified for some human groups.

In *Elementary Forms of the Religious Life*, published in 1940, Durkheim extended the ideas put forth in *Primitive Classification* by arguing that primitive religion is the ultimate product of primitive classification. He argues that totemic clans abstract symbols of their totems and place those symbols on objects, which become the focus of various rites; these rites in turn make those objects sacred. Beliefs, which are explanations of the rites directed at sacred objects, make the system understandable. Consequently, religion is society worshipping an abstraction of its own social order.

Lévi-Strauss

In the mid-20th century, the work of Claude Lévi-Strauss brought a new perspective to the understanding of kinship systems. Applying structural theory to kinship studies, he examined the nature of the relationships between different kinship categories in an effort to explain, for example, why many societies had different kinship classification systems, and why different descent systems had the same avunculocal postmarital residence pattern. In the avunculocal postmarital residence pattern, a man and his wife go to live with his mother's brother. His analysis of the avunculate focused on the relationship between the individuals directly involved in the practice: a man, his mother, his father, and his mother's brother. He referred to such a group as the "atom of kinship" and suggested it as the starting point for analyzing kinship structures (1963, p. 72). In structural analysis, focus is shifted away from the categories and is placed on the relationship among the categories. This approach is borrowed from modern structural linguistics.

Lévi-Strauss, in *The Elementary Structures of Kinship* (1949/1969), assumed that kinship classification, at least in some societies, is connected to marriage practices, and by doing some comparative analysis, he offered an answer to the question about the relationship between kinship systems and other social behaviors. He began by discussing incest and its origins. To him, incest prohibitions are manifestations of the transition from blood-relatedness (nature) to social alliances (culture) (p. 30). As a consequence, he suggested that the incest prohibition itself, by virtue of

limiting what is possible in marriage relations, brings about the organization of social relations. He further argued that this organization takes the form of exogamous marriage practices that are, in reality, reciprocal systems of marriage exchange (p. 51). He concluded that “the rules of kinship and marriage are not made necessary by the social state. They are the social state itself” (p. 490).

So, for Lévi-Strauss, kinship and marriage are the fabric of human society, consisting of social relations woven together by the warp and woof of marriage possibilities and marriage prohibitions.

The Elementary Structures of Kinship, as the title suggests, was only concerned with societies where there were preferred marriage patterns, such as preferences for matrilineal or patrilineal cross-cousin marriage. The work explicitly did not deal with complex structures of kinship, where the determination of eligible marriage partners is a result of other social processes, and not a result of the kinship classification itself.

Of course, Lévi-Strauss was careful to point out later, in *Structural Anthropology* (1963), that correspondences between behaviors, such as marriage patterns, and linguistic categories, such as kinship classification systems, will always be difficult to determine, especially in complex societies, unless another approach is adopted. That is because the relationship between language and culture is mediated by the human mind, which structures both language and culture (p. 71). He saw the study of language, on the one hand, and behavior, or culture, on the other hand, as two separate levels of analysis. Hence these were not directly comparable, but the fact that the human mind, and the way in which it works, underlies both language and culture suggests that by understanding the processes of the human mind, the relationships between language and culture can be better understood.

Recent Thought

There are currently many challenges to developing a more comprehensive approach to the understanding of human kinship systems. One recent book, *Relative Values: Reconfiguring Kinship Studies* (2001), edited by Sarah Franklin and Susan McKinnon, surveys many of those challenges. *Relative Values* “attempts to shift the terms of anthropological debate about kinship onto more contingent and productive terrain” (Franklin & McKinnon, 2001, p. 7). With this, the editors meant that it is necessary to remove kinship studies from the framework imposed by biology, that is, to focus more on gender, as opposed to sex. It is clear that the assumptions underlying much traditional work in kinship studies have implicitly unified sex and gender identity and have treated the two as one, when it is clear that the two are distinct. That being the case, traditional theories and approaches have failed to account for the emergence of new family forms, new conceptions of

certain social relations, and the new dimensions that reproductive technologies have brought into being.

Feminist anthropologists and gay and lesbian anthropologists have brought a new perspective to kinship studies that appreciates the malleable nature of kinship systems and the contexts within which they are articulated. Same-sex unions/marriages, single-parent families, cross-cultural/cross-ethnic adoptions, and surrogate parenting have all brought about reformulations of what it means to be “family.” Certainly, kinship systems have always been malleable, and have always been undergoing some degree of change in all times and places, but anthropologists have tended to use the ethnographic present when describing the kinship systems of the groups they study; until relatively recently, this has framed almost all kinship studies in the eternal present, making it appear as if they never change.

More contemporary studies in anthropology must also take into account the systems within which kinship systems and related behaviors are articulated. Conceptions of family, ethnicity, descent, marriage, and so on, exist within contexts of political power and technological ability. “Family values” are a familiar topic in American political discourse, and political power is brought to bear on determining the definition of exactly what constitutes a family. For example, consider current attempts to legally define marriage as being only between one man and one woman. Likewise, the technological ability to physically alter one’s body from male to female, or from female to male, has created social and legal conundrums in traditional thought and law. Power and technology have significantly impacted the nature of kinship systems and how they are now playing out in societies. In a truly holistic approach to the study of kinship systems, cultural context and power cannot be ignored.

Application of Kinship Theory

Kinship theory has found successful application in the ethnographic literature of anthropology. One characteristic of every well-written ethnography is a detailed description of a group’s kinship system and how that kinship system articulates into other aspects of that group’s culture. Kinship classification, descent system, and marriage practices have provided a focus for most of the classic ethnographic works in anthropology. In fact, most ethnographies reveal that kinship is intimately connected to all other aspects of a culture.

C. W. M. Hart and Arnold Pilling did ethnographic fieldwork among the Tiwi in Australia, 1928 to 1929, and 1953 to 1954, respectively (1979, p. vii). In their book *The Tiwi of North Australia*, the entire first chapter is devoted to discussing household organization, marriage, naming rules, levirate, sororate, and cross-cousin marriage—all of which provide the framework for discussing everything else in

Tiwi society in the remainder of the book. So important was kinship to the Tiwi that they had great difficulty interacting with people not related to them. To illustrate, Hart relates how he came to be accepted as a relative of the tribe. An old Tiwi woman kept harassing him for tobacco. He frequently told her to “Go to hell,” but she persisted in her efforts and, on one particular occasion, said, “Oh, my son . . . please give me tobacco,” to which Hart replied, “Oh, my mother, go jump in the ocean” (Hart & Pilling, 1979, p. 124). This exchange resulted in Hart being known as this woman’s son. The downside of being “adopted” into the Tiwi kinship system was that sometime later, Hart and all the woman’s other sons were asked to give their consent to “cover up” the woman who was getting too ill to take care of herself. This meant taking her out and burying her with only her head left above ground and thus causing her to die in the course of a few days. Hart gave his permission, and the woman was covered up, but he did not participate in the actual burying (pp. 125–126). The pervasiveness, social significance, responsibilities, and consequences of being a member of a kinship system are illustrated well in this ethnographic example.

Richard B. Lee had an experience similar in many respects to Hart’s on a different continent, Africa, and some three decades later, in the 1960s. Lee was “named” by the wife of a headman’s son. She referred to him as /Tontah (the / is a dental click), which was the name of her deceased uncle. The naming stuck and defined Lee’s relationship to the group (1993, p. 61). In *The Dobe Ju’hoansi*, Lee devotes two chapters to kinship, social organization, marriage, and sexuality. Those chapters are essential to understanding Ju’hoansi conflict, politics, exchange, religion, worldview, and relations with their neighbors.

It was also during the 1960s that Napoleon Chagnon first studied the Yanomamö, a forest people living along the border between Venezuela and Brazil. In *Yanomamö: The Fierce People* (1983), Chagnon found that simply asking genealogical questions can be problematic because of taboos against speaking the names of the dead, the mischievousness of some villagers, and the fact that some wives are obtained by raiding neighboring villages. Chagnon was routinely lied to during the first five months of his field research and said, “I had to throw away almost all the information I had collected on this the most basic set of data I had come there to get” (p. 20). Chagnon eventually figured out how to work around those obstacles to get the data he sought, but those obstacles also opened up many other productive avenues of ethnographic inquiry.

The examples chosen from these three ethnographies, which were selected from among many other possible examples, demonstrate clearly the importance of kinship as an organizing principle in culture. The description and analysis of kinship systems is the starting point for most ethnographic work. Describing and understanding kinship systems is still a primary activity in anthropological inquiry,

and the development of a comprehensive theoretical framework is still an important epistemological goal.

What Anthropologists Know About Kinship Systems

What do anthropologists know about kinship systems? What are some of the generally accepted concepts in kinship studies? What follows is a brief summary of thought in the discipline. This knowledge is a product of the seminal contributions of the anthropological works just discussed and the intellectual stimulus that those works, and others, have provided to many other scholars who have refined and extended the understanding of kinship systems.

Kinship Systems

All humans are classified, at birth, within a system of kin relations. This system of relations organizes a society in a systematic way, such that it provides for the continuity of those relationships, and for the continuation of the society, through time. Ideally, the kinship system is perpetual and classifies all children at birth and maintains those classifications even after death; people continue to be sons, daughters, fathers, and mothers, and so on. The depth of the genealogical memory of groups varies tremendously, however. In some groups, the knowledge of the genealogy of one’s ancestors can go back many generations, as in the lists of ancestors found in biblical genealogies. On the other hand, such knowledge in other groups may only go as far back as grandparents or great-grandparents, as is common in North America. The depth of genealogical knowledge is, however, not as significant as the idea that kin relations persist through time.

There are all sorts of rituals found in human societies that occur to bring about the incorporation of a baby into the social structure of the society into which it is born. Baby showers, infant baptisms, and the naming of the infant herself are some of the ways that the social position and classification of the new member of society are recognized and reified.

Kinship systems are also flexible regarding the formal incorporation of nonkin into kinship systems. For example, adoption, in various forms, exists in most human societies. Though the establishments of such relations are “fictions,” they are very powerful fictions. Other fictive kin relations include such practices as choosing godparents, calling religious affiliates brothers or sisters, using the title of “Father” for priests, and the practice of female husbands among the Nandi of Kenya—where a “woman pays bridewealth for, and thus marries (but does not have sexual intercourse with) another woman. By so doing, she becomes the social and legal father of her wife’s children” (Oboler, 1980, p. 69).

Kin relations consist of two fundamental types: *consanguineal* and *affinal*. Consanguineal kin relations are blood relations. When a person is born, he is genetically closely related to his mother, to his mother’s siblings and their

offspring, to his mother's parents, to his father, and to his father's siblings and their offspring, and to his father's parents. Consanguineal relations are the primary structuring categories of the entire kinship system.

Affinal kin relations are those created by marriage. When a man marries one's mother's sister, he becomes one's uncle by virtue of marriage, not because of blood-relatedness. Keep in mind, however, that in some social groups, marriage may occur between consanguineal kin, such as when the preferred marriage pattern for a male is to marry his father's brother's daughter, as is the case in some areas of the Middle East. In cases like this, the bride and groom would hold simultaneous kin classifications, one consanguineal (parallel cousins) and the other affinal (wife and husband). By extension, all other members of the society would have a dual classification for the two. For example, the bride's father would simultaneously classify his daughter's husband as his son-in-law and as his brother's son.

There are basically five different ways or patterns by which consanguineal kinship relations are classified. Three of those patterns distinguish between parallel cousins (the offspring of one's father's brother and mother's sister) and cross-cousins (the offspring of one's father's sister and mother's brother). The other two systems either classify parallel and cross-cousins as a distinct category (i.e., cousins), or classify parallel and cross-cousins as brother and sister. The five types are called Iroquois, Omaha, Crow, Eskimo, and Hawaiian.

In Iroquois, Omaha, and Crow one calls his father's brother "father," and his mother's sister "mother." Consequently, in these three terminologies, his parallel cousins are called "brother" and "sister." Also, in Iroquois, Omaha, and Crow, one's father's sister is called "father's sister" (i.e., roughly equivalent to aunt), and his mother's brother is called "mother's brother" (i.e., uncle). Beyond those kin relations just discussed, these three systems vary in important ways.

In the Iroquois kinship-terminology system, as just stated, a person's parallel cousins are referred to with the same kin terms used for brother and sister. However, cross-cousins are referred to collectively by some other unique term that could be translated as "cousins."

With Omaha kinship terminology, one calls her parallel cousins brother and sister, but refers to her cross-cousins differently than in Iroquois. In Omaha, her cross-cousins on her mother's side of the family are called "mother" and "mother's brother." One's father's sister's children are "nephew" and "niece," if one is a male, or "son" or "daughter," if one is a female. The reason for the different kin terms between males and females is due to the fact that if one is a male, the cross-cousins called nephew and niece refer to him as "mother's brother" (i.e., uncle), but if one is a female, those same cross-cousins, which she calls son or daughter, refer to her as "mother."

The Crow kinship-terminology system is a mirror image of the Omaha system. In Crow, one calls his parallel cousins "brother" and "sister." Cross-cousins on his

father's side of the family are his "father" and "father's sister." Cross-cousins on the mother's side of the family are called "son" and "daughter," if one is a male, or "nephew" and "niece," if one is a female. The cross-cousins referred to as son and daughter, or as nephew and niece, will use either "father" or "father's sister" (i.e., aunt) depending on gender.

The following two systems do not distinguish between parallel and cross-cousins. In the Eskimo system, one classifies all cross-cousins and parallel cousins into one category that can be called *cousins*. Similarly, one's father's brother and sister, and one's mother's brother and sister, are classified into two collective categories referred to as "aunts" and "uncles," depending on their sex. This classification system should be familiar to most North Americans.

Hawaiian kinship terminology classifies all cross-cousins and parallel cousins as "brother" and "sister." Consequently, one's father's brother, father's sister, mother's sister, and mother's brother are all called "father" or "mother," depending on their sex.

In the five general patterns covered here, only a very restricted set of kin relations—14 to be exact (father, mother, father's brother, father's sister, mother's sister, mother's brother, brother, sister, father's brother's children, father's sister's children, mother's sister's children, mother's brother's children, son, and daughter)—have been discussed. Remember that Morgan gathered data on 196 kin relationships. Kinship terminology beyond the 14 relations covered here includes a great amount of variability for more distant kin relations among different cultural groups. Nevertheless, these five basic patterns, allowing for some slight variations, underlie the categorization of all human kinship systems.

Note that depending on the kinship classification of a group, there are implications for what marriage patterns are possible. For example, the father's brother's daughter preferred marriage pattern is not found in cultures that classify kin in the Iroquois, Omaha, Crow, or Hawaiian systems. That is because marrying a brother or sister violates a universal incest taboo, and in Iroquois, Omaha, Crow, and Hawaiian, parallel cousins are classified as brother and sister. When anthropologists examine particular kin classification systems within the context of particular cultures, many other implications are frequently discovered.

Descent

In addition to classifying individual relationships, as we have just seen, kin groups also organize into descent groups, which create a collective identity by classifying a number of people into one group, according to a line of descent that is traced through either the father, the mother, or both.

When descent is traced through the father or through the mother, we refer to such groups as patrilineal or matrilineal, respectively. Collectively, the two are referred to as unilineal descent systems. A unilineal descent

system—patrilineal or matrilineal—can have, theoretically, any of the five kinship-terminology systems. Whether someone thinks of herself as a member of her father's or of her mother's family is a completely separate matter from the system by which one classifies one's kin relations.

A significant number of societies have both patrilineal and matrilineal, creating a more complex kind of descent system, in which identity with regard to both lines of descent is recognized and perpetuated. Such descent systems are called *cognatic*. Lévi-Strauss (1949/1969) suggests that a third of all descent systems are cognatic (p. 105).

Of course, lineal descent systems, whether unilineal or cognatic, always exist alongside systems of inheritance, status, marriage, and so on. Also, rather than thinking of patrilineal, matrilineal, and cognatic descent systems as three distinct systems that different societies map onto, it is better to think of patrilineal and matrilineal systems as two ends of a continuum along which varying degrees of emphasis on the mother's or father's line can be expressed, with full recognition of both lines being in the middle and called cognatic. As a special case of cognatic descent, a few societies allow a certain degree of freedom for individuals to emphasize or affiliate with one line or the other, and those systems are called *ambilineal*.

Many societies do not have lineal descent groups. Rather, they identify with both parents' families. Bilateral groups such as this can recognize a fairly large set of relations as family, or, in a special case, called the *bilateral kindred*, will recognize a smaller set of relations that are only the same for siblings. The bilateral kindred is typical for most North Americans, where a group of siblings recognize their mother, father, sister, brother, son, daughter, grandchildren, aunts, uncles, cousins, grandparents, and nephews and nieces as their family. The cousins of the siblings in the example just given will have a different set of people in those same relationships, and, consequently, they will have a different bilateral kindred.

What is clear is that how a society structures its understanding of descent has significant implications for how the group defines its identity. Consequently, there are significant effects on many other aspects of social organization.

Marriage

Marriage creates new social relationships between the family of the bride and the family of the groom. Marriage patterns vary significantly around the world but are reducible to a few general types, with some variation within each type. Those types are monogamy, polygyny, and polyandry.

Monogamous marriages are those between just two people. Traditionally, this has been defined as between one male and one female, and in many communities undoubtedly will continue to be defined this way, but a more contemporary definition incorporates the observation that many same-sex couples are marrying worldwide, and that

those marriages are being accepted within some groups. Also, in parts of the Western world and elsewhere, due to the prevalence of divorce—a formal legal and/or religious process for ending a marriage—the practice of serial monogamy has emerged, in which an individual may have several spouses throughout her or his lifetime.

As discussed in the previous chapter, marriage may also involve some form of economic exchange, such as brideservice, where a male renders economic service, such as gardening or herding, to the bride's family, in exchange for the opportunity to marry the bride. Bridewealth is found in other groups, where the economic exchange will take the form of money or other material wealth paid by the groom's family, either all at once or over a period of time, to the bride's family. Dowry is another form of exchange linked to marriage, in which wealth is given to the bride by the bride's family, and in many cases it functions as a sort of insurance policy against the loss of a husband because of death or divorce.

Polygynous marriages are between one male and more than one female. Polygyny has been common throughout human history. Various preferred marriage patterns have an effect on the social outcomes of polygyny. For example, there are social implications for a preference for exogamy (marrying outside one's group), or endogamy (marrying within one's group). There are further implications associated with a preference for either parallel cousin marriage, or cross-cousin marriage, and whether or not sororal polygyny (marrying a group of sisters) is allowed or prohibited.

Polyandry is very rare compared with monogamy and polygyny. In polyandry, a female is married to more than one male. As in polygyny, there are social implications for the particular preferred marriage patterns in a society.

Finally, many societies have mechanisms, such as polygyny, to ensure that most people, especially women, get married. To ensure that they remain married, many societies have additional practices. In some societies, if a woman's husband dies, the husband's brother or one of his other close male kinsmen must marry her. This practice is called the *levirate*. In some other societies, if a man's wife dies, her family must find another woman to marry the man. This practice is called the *sororate*. In both cases, not only is the structure of the marriage preserved, but also all kin relations created by the marriage are preserved.

Households and Residence Patterns

Once a person is married, the couple must live somewhere. There are several patterns found in the ethnographic literature. If the couple lives with the husband's family, the pattern is called *patrilocal* residence. If the couple lives with the wife's family, it is called *matrilocal* residence. If the couple forms a new household, it is called *neolocal* residence. Some societies allow for residential affiliation with either the bride's or the groom's family, and that practice is called *ambilocal* residence. Finally, there is the pattern in which a man and his new wife go to live with the man's

mother's brother. This pattern is called *avunculocal* residence (or *uxorilocal* residence in some older sources).

Households are a subset of a family that lives together and cooperates economically. Households can be *nuclear*, consisting of a husband, wife, and children; *patrilocally* extended, in which two or more patrilineally related nuclear families reside together; *matrilocally* extended, in which two or more matrilineally related nuclear families reside together; or *ambilineally* extended, in which both patrilineally and matrilineally related nuclear families reside together.

Future Directions

Much work remains to be done in kinship studies. Until recently, anthropologists have looked primarily at the larger, or macro, aspects of kinship studies with the goal of applying the comparative method to arrive at conclusions reaching across cultures and saying something universal. At the same time, anthropologists have left the smaller, or micro, aspects of kinship studies, such as family studies, largely to the sociologists. Anthropologists need to bring both the macro- and micro-aspects of kinship studies under scrutiny together. Currently, anthropology is headed in that direction.

Some of the original questions asked in kinship studies remain either unanswered or answered incompletely. Why do kinship classification systems vary? Why are there a small number of types? To what degree and how do kinship classification systems influence other social behaviors? And perhaps the most intriguing question: What is the relationship among the mind, language, and culture? This last question seems one of the most promising for furthering our understanding of kinship systems and the roles they play in human societies.

Just as important as the original questions are the emerging questions about power, cultural context, and group identity in relation to kinship studies. In what way do kinship systems articulate discourses of power? How does cultural context shape and reinterpret kinship systems? What aspects of kinship systems are most important to group identity?

All of those questions, and more that will emerge with additional research, need to be addressed in future kinship studies. New methodologies and new theories need to be developed and adopted in order to analyze kinship as process and to account for the variability that is observed from the micro- to the macrolevel of analysis. Kinship studies will stay a key focus of anthropological research, just as they always have. Most likely, kinship studies will become even more important as the place of kinship systems in culture becomes better understood over time.

Conclusion

From the very beginning of the discipline of anthropology, kinship studies have been at the center of the study

of culture. Kinship systems structure and influence many of our social behaviors and have a dynamic presence in the synergy among language culture, and the mind. The concepts and understanding gained from kinship studies are essential fundamentals of anthropological knowledge and continue to be applied in ethnographic research today. Future scholarship will undoubtedly generate new theoretical insights and lead to a more sophisticated and holistic knowledge of what it means to be human.

POLITICAL ORGANIZATIONS

ELAINE M. REEVES

University of Toledo

Political anthropology is a subset of social and cultural anthropology, with a special interest in the political process as a way for societies to institutionalize common values. Specifically, British anthropologists in the 1940s helped to establish political anthropology as a subdivision of anthropology.

Politics is the arena of power relations, serving as the social institution through which power is acquired by people and groups. Government is a formal organization responsible for regulating relationships among members of a society and between a society and other foreign societies from outside of established boundaries. When resources are allocated by a governmental authority structure, the political process is in place and active.

Political organizations express power and authority in both traditional and modern communities. Power can be egalitarian and decentralized or it can be centralized and elite. In either case, political organizations interact with other parts of the community such as family life, religious beliefs, economic resources, and even physical geography. With these interactions, political organizations draw on the cultural life of the community for ideas. This is the political process that allows intangible ideas, important to the life of the community, to become concrete. The community sanctions leaders who have the power to control important human and material resources on behalf of everyone else. In smaller, more traditional communities, it is easier for all members of the society to share power more equally. In larger, modern

societies, power is distributed, often unequally, among highly defined classes of people with very distinct roles.

The most common forms of these political organizations identified by political anthropologists are bands, tribes, chiefdoms, and states. Foraging is often associated with bands, pastoralism with tribes, and horticulture with chiefdoms. Modern states and the city life that they support are often referred to as civilization. However, the definition of civilization is not exclusive to modern states alone. It has been applied to ancient cultures that show evidence of a certain level of material culture, such as writing for record keeping and the use of money.

The categories of bands, tribes, chiefdoms, and states were first developed in the 1940s as a way for political anthropologists to describe and discuss political organizations. By the 1960s, questions were raised about the meaning and usefulness of these categories. For the sake of a common conversation, these categories continue to be used within an ongoing discussion about the best and most useful way to describe political organizations within the discipline of political anthropology.

Definition

The most important issue that a society will confront is related to the means for survival—food to eat, clothing to wear, shelter from natural elements, and protection from

outside foreign intrusions. When a society organizes all of its resources around basic survival issues, anthropologists refer to it as a *subsistence culture*. Bands and tribes are often referred to as nonstate, subsistence cultures.

In subsistence cultures, all of the members work together to gather and distribute the resources needed to survive. The power or labor is shared equally among members, so the political organization of bands and tribes can be described as egalitarian. Some other aspects of subsistence cultures can include seasonal migration, limited capacity for food storage, and a sense of common ownership toward available material goods.

By contrast, chiefdoms and states are often permanent settlements that have evolved over time to include a city or group of cities within a well-defined geographic territory. In states, the population is especially dense. Technology permits higher levels of food production and storage, and instead of migrating and foraging for food, members of chiefdoms and citizens of modern states can rely on crops produced by agriculture. With food supplies readily available, the population can grow. The large population is then divided into specialized classes with specific responsibilities. The division of labor required by these large populations thus creates complex and unequal relationships among classes.

Societies can also be defined as *noncentralized* or *centralized*. Bands and tribes often fit into the noncentralized category, while chiefdoms and states generally fit the centralized description. The main difference between a noncentralized society and a centralized society is the role played by kinship to provide connections between individuals and groups and for making decisions that affect everyone. Noncentralized societies rely primarily on marriage alliances and kinship ties to integrate members into the society. A key characteristic of these societies' governance is that there is no formalized code of law used to justify punishments or the use of force by a standing army. Instead power is spread among the various groups of families that may connect with other families to form temporary groups for the completion of a specific task, such as hunting or defending from an outside attack. A noncentralized society will become centralized when political mechanisms for forming connections between people or groups, and for making community-wide decisions, become impersonal and permanent through the use of a codified law with a standing body to enforce this law.

Bands/Foragers

Since the 1960s, the use of the term *band* has become less frequent. Anthropologists are not able to reach a complete consensus about the features that distinguish a band from other political organizations. However, there are general characteristics that apply.

Bands are very small communities formed around one family who usually depends on foraging for survival.

The number of members in a band might be as few as 25 or as great as 150, but bands are still small enough that there is no special division of labor. The resources available will also be a factor in determining the size of a band. Regardless of age or gender, the members of the band have the same access to all of the resources, which are usually very scarce and restricted. Leadership is temporary and based on the situation and need. If the band is hunting, the best and most experienced hunter might be in charge. For religious ceremonies and celebrations, a shaman will take the lead. These leadership roles are not permanent, and as a group, the band will not permit any single member to coerce other members or place restrictions on resources. A band's search for food and resources is often seasonal, and migration allows the band to forage for the best resources available at any given time.

Tribes/Pastoralists

Tribes are a village or collection of family groups. Tribes are somewhat more organized than bands because herds of animals and horticulture supplement foraging. Tribes are thus able to remain more settled and less migratory by practicing horticulture. With herding and common land use, tribes can also develop some sense of communal ownership. In addition, by practicing horticulture and communal herding, the tribe has a domesticated food supply that may permit longer settlement regardless of the season, but the overall economy of the tribe is still at the subsistence level.

Tribe power is decentralized and egalitarian, but a leadership lineage might exercise some force from time to time. A strong network of kinship contacts keeps power largely in the hands of the entire band, although families with more animals may benefit from some extra status. Because of the relatively small size of the band and the decentralization of power, there is little specialization of labor or division of roles to accomplish political, religious, or economic goals. However, a headman may emerge from time to time because of unusual skills or wealth. Village councils might also form for the purpose of making emergency decisions. Overall, the lower population level in a tribe promotes sharing of labor. Small subgroups within the larger tribe might form temporarily to complete a specific task, then dissolve when the task is completed. Although the organizational level in a tribe is somewhat more developed than in a band because of communal ownership, power is still decentralized and there is little specialization of political, religious, or economic functions. Examples of tribes are the Shoshone and Paiute Indians of North America.

Chiefdoms/Horticulturalists

A chiefdom is a settlement of several hundred of members. Because the group stays in one place over longer periods of time, it relies on both crops and animals for a fairly stable subsistence, although food storage is limited.

Chiefdoms differ from tribes in two important ways: by practicing horticulture on regular basis and generating food productivity with some surplus. The food surplus allows the population to grow. To meet the greater demands of the higher population, the overall level of organization is more complex with some form of permanent, centralized authority able to provide ongoing leadership without interruption. As a result, chiefdoms have more complicated and more permanent mechanisms for collecting and redistributing economic and labor surplus. Instead of headmen or ad hoc subgroups that emerge to meet a specific task or immediate emergency, authority is successive, allowing for the development of a power elite and the development of a ranked society.

In a chiefdom, the chief is the symbolic provider in charge of the redistribution of resources. He has some ability to coerce subordinates and can collect taxes on food or other kinds of goods. While actual class stratification might not be evident in a chiefdom, there is a clear inequality of persons and groups in the society. Some individuals and groups are closer to the chief than others and receive the deference of subordinates at a lower rank.

States/Industrialists

The state, or nation, is densely populated with high levels of food surplus and permanent settlement or residence in one geographic area. In these systems, all political power is monopolized by a centralized elite. Division of labor is sharply divided and access to resources is dependent on social rank. Government is based on territory and property, and states are traditionally defined by sharp divisions among social classes; clearly defined geographic boundaries; and centralized, elite authorities who hold a monopoly on political power. The monopoly extends to the legal system, courts, and the armed forces, with power over national borders, citizenship, and foreign policy.

Anthropologists have an ongoing debate about how and why traditional, nonstate political organizations become modern states. Political anthropologists connect the decision-making process and the conflict-resolution process with the emergence of the state. The high population levels increase conflict over resources internally and externally that might lead to the formation of a state. Political anthropologists are still discussing the use of new technology to move a society from a subsistence mode of living to food supplies that then allow a traditional society to stratify into specializations and classes. Other useful theories explain the formation of the state as a result of environmental limitations, the use of irrigation to produce food in hostile environments, and in some cases, the influence of a previously existing state.

Most early states seem to have developed out of a combination of these factors interacting with each other in no special sequence. However, anthropologists have identified six early states considered to be examples of societies that

evolved into states with no outside influence. The primary states are Mesopotamia, Egypt, the Indus River Valley of India, the Yellow River Valley of China, Mesoamerica, and Peru. These states appeared hundreds and even thousands of years apart from each other. Their appearance raised the question of finding a universal process to work as an equal model for all events of state formation.

More recent definitions of states try to take into account the effect of rapidly developing global-communications technologies that have the capacity to create online, virtual communities on a global level. This new ability to communicate rapidly, yet intimately, on a global level affects all areas of life—financial, cultural, and social.

Evolutionary Theories

Theories of Evolution

Anthropology has its roots in Enlightenment ideals (1700–1800) about human development universally unfolding in clear, identifiable stages and therefore considered a law of science. The human race was assumed to have a common point of origin. This common origin gave the human race a psychological unity that made development parallel for all cultures. A final outcome of human progress and development was expected and recognized by the appearance of certain kinds of material and cultural experiences. Philosophical and historical traditions assumed that government and politics were the products of civilization and that lower stages were characterized by anarchy. This viewpoint, with an emphasis on the importance of civilization as the highest level of development and evolution, lends itself to asking questions about how the lower stages of anarchy moved to the higher stage of civilization.

One of the foundational thinkers for anthropology was the British law scholar Henry Sumner Maine (1822–1888). In his *Ancient Law* (1861), Maine defined one of anthropology's earliest and most difficult questions: Where did the state come from? And what accounts for the differences between highly evolved societies, civilization, and less-evolved societies, or primitive ones? Maine described kinship-based societies that held land and goods in common as *primitive*. Societies organized around the individual and based on the ownership of private property protected by law were described by Maine as *civilized*. Somewhat contradictorily, Maine's description of the sequence of evolution as moving through a family-based society to a tribal organization and finally to an urbanized and economically sophisticated society links him to evolutionary determinism. At the same time, he rejected the belief that human society always moves through the same series of changes.

Colonialism provided the context for the development of a theory of social evolution that placed Christianity and Western culture at the pinnacle. In the 19th century, theories about social evolution made Western culture the most

civilized. Non-Western societies were viewed as primitive but able and expected to become civilized by developing in defined stages from band to tribe, to chiefdom, to state. Developing through these stages was seen as social progress. Social progress was in turn viewed by many theorists as a law of history and therefore scientific.

The ideas of British naturalist Charles Darwin (1809–1882) in combination with the work of German political theorist Karl Marx (1818–1883) were very significant in shaping the anthropological point of view in the 19th century. Darwin's work with the process of natural selection postulated that life evolved naturally from simple to complex. Simple forms of life were lower and inferior; complex forms of life were higher and superior. When anthropologists applied the idea of natural selection to groups of people, it became an opportunity for ethnocentric points of view to categorize some cultures as simple and inferior, while other cultures were complex and superior.

The ideas of Karl Marx influenced anthropology by emphasizing and giving importance to survival and adaptation in the material world. Societies would reorganize and change relationships among individuals and groups as a result of the need to adapt to physical conditions in order to survive. Natural or primitive societies, sometimes called nonstate societies, lived in a condition of relative equality with no private property. In primitive societies, material goods were held in common and authority was diffused throughout the community. With the emergence of civilization, central authority gained control of the land. An unequal class system allowed the elite authority to remain in control. All modern societies take this form of states with unequal class distinctions.

The German philosopher Friedrich Engels (1820–1895) combined the ideas of Karl Marx with the work of American anthropologist Lewis Henry Morgan (1818–1881) to form theories that looked at internal class conflict as the catalyst for evolution. The earliest form of social organization was noncentralized and communistic. All members shared equally in the resources of the community, and personal property did not exist. When new technologies made agricultural surplus possible, a class of nonproducers developed to protect the supply. The new nonproducing class erected a strong centralized governmental mechanism to ensure that the producers could not share in the wealth that they produced. In the internal theory, the evolution is caused by economic and material developments, an unequal concentration of wealth, and the effort of an elite class to maintain unequal access to power. The class system requires strong centralized government to give a few elites access to resources while exploiting the majority of producers. The American writer Morton Fried (1923–1986) added to the class-conflict model with his book *The Evolution of Political Society* (1967). Here, Fried observed that social stratification destabilizes a society, forcing power to become fully centralized to prevent disintegration to a lower level of organization.

The English economist and philosopher Herbert Spencer (1820–1903) articulated the theory of external conflict as the process leading to state formation. Using Charles Darwin's ideas about the survival of the fittest of individuals, Spencer applied the idea to whole societies. If a society feared invasion from an outside intruder, it would organize using a strong, centralized form of government to create a standing army able to force or threaten an intruder to leave or stay away. The American ethnologist Robert Carneiro (1927–) generally agreed with Spencer, but he believed that conflict can only lead to state formation in specific situations and clearly defined conditions. His book, *Evolution and Cultural Anthropology* (2003), provided details about what conditions and situations can lead to statehood. When combined with environmental limitations such as mountains, seas, or deserts, external conflict could lead to the centralization of government for the sake of raising an army because the geographic barriers prevented escape. Without barriers to prevent escape, Carneiro believed that it was more likely that a society would disperse, rather than fight, when confronted with an external threat. Carneiro also took into account the pressures created by population expansion in a land area that becomes too crowded. In this case, small separate groups will unite into one larger unit. Smaller units continue to create larger units until a true state is finally formed with complete control over all of the available land area. Carneiro predicted the complete political unification of the entire planet by the year 2300.

The social scientist and writer Karl Wittfogel (1896–1988) believed that the ability to develop land for agricultural use could be as important as the need for military power in motivating the organization of centralized government that leads to the creation of a state. Water is always necessary to crop development. When a society is organized to supply water for agriculture, the result is a food surplus that permits population growth. Organizing and coordinating for the construction of an irrigation system then set the stage for the emergence of a centralized, state bureaucracy. Wittfogel used Neolithic Egypt as an example of a society that was dependent on natural flooding from the Nile River to irrigate crop fields once every year. Irrigation by natural flooding can produce at most only one crop per year, giving farmers the best possible motivation for seeking and slowly finding alternative ways to control the flooding process with a primitive system of dikes and reservoirs. As the land became more productive, the food supplies were able to sustain a higher population level, in turn requiring irrigation systems of even greater complexity. The specialists who emerged to control the construction of complicated irrigation systems became an administrative elite capable of controlling a centralized state government.

The work of Henri Claessen and Peter Skalnik in *The Early State* (1978) brings together cross-cultural data from numerous early states. Multiple factors in state development can be identified—population growth, warfare, trade,

environmental limitations, the need for irrigation systems, the use of innovative technology, and the influence of pre-existing states. However, it is not easy to say that any one of these factors is decisively causal. It is not always possible to distinguish among factors that cause the state to emerge and factors that function as qualities of the state after the fact of its emergence. Classen and Skalnik identified only four causal factors with certainty: population growth, war, conquest, and the influence of states already in existence. It is best to allow that most states develop out of a unique combination of multiple factors that may or may not be found in any other state. One classic work that remains useful is Lawrence Krader's *Formation of the State* (1968) from the *Foundations of Modern Anthropology Series*.

Anthropology recognizes the power of the idea of nationhood. It also examines the reality of what actually is or is not present in concrete experience through ethnographic research.

British Colonialism in the 19th Century

British anthropologists in the Victorian era (1860–1890) formulated the ideas about cultural progress and civilization to show specifically how bands, tribes, and chiefdoms became states. The development of a society from a small, simple band to a larger, more complicated tribe that led to the final, heavily populated, civilized state corresponded with British expansion into colonial territories, reinforcing the sense of superiority over the British colonies. Britain represented the modern, civilized state. The colonies held by Britain were viewed by British anthropologists as primitive and unevolved, not having yet become fully civilized states. Some of the British anthropologists of the Victorian era were Herbert Spencer (1820–1903), Edward Tylor (1832–1917), Sir James Frazer (1854–1941), and A. R. Radcliffe-Brown (1881–1955). Radcliffe-Brown is noted especially for his leadership in defining the theoretical aspects of anthropology.

British colonial anthropologists also included significant ideas from non-British scholars. Important thinkers and writers from outside of Britain during that same time period were the American Lewis Henry Morgan (1818–1881), Bronislaw Malinowski (1884–1942) from Poland, and Frenchman Émile Durkheim (1858–1918).

The term given to development from lower to higher forms was *unilineal social evolution*, a theory that originated with European anthropologists in the Victorian era. Civilization was defined as material culture, technology, cities, good surplus, monumental buildings, money, and writing.

During the British colonial period, anthropologists often viewed civilization as the inevitable and ultimate goal of the “lesser” societies—the bands, tribes, and chiefdoms. The evolution began with simple societies (savages), moving to somewhat more complex societies (barbarians),

and finally evolving into very complex societies (civilization) with large populations using advanced technology to maintain a settled way of life. Morgan outlined the three-stage sequence from savage to barbarian to civilization in the book *Ancient Society* (1877). Working in the United States, Morgan believed that native indigenous societies provided evidence of the development from primitive to civilized. The movement from the lower, primitive stage to the higher, civilized stage was measured in terms of leadership, complexity, and scale.

To explain the consolidation of civilization at its highest levels, Victorian anthropologists used the theory of structural functionalism. Structural functionalism is largely a consensus theory that explains society in terms of stable, balanced, orderly relationships. Relationships between social subgroups permit the society as a whole to maintain smooth functionality. Shared values and a common sense of purpose make it possible to agree on a moral order that is beneficial to the community as a whole. Through agreement and stability, the society maintains internal integrity and survives over time.

British anthropologist Edward Evans-Pritchard (1902–1973) is usually referred to as the originator of structural-functionalism. This approach consolidated the view that the modern state was the ultimate goal of development for human societies. The modern state was perceived to be harmonious and stable. With the social structure securely in place, individual parts of society could function effectively to keep the whole society in equilibrium. In the 1930s, Evans-Pritchard lived among the African Nuer people in Sudan and studied the problem of how a society without a political system or government of any kind—no chiefs or kings—could hold together and work. *The Nuer* (1940b) became Evans-Pritchard's most widely read book along with *African Political Systems* (1940a). *African Political Systems* helped to establish the four categories of band-tribe-chiefdom-state that, while recently called into question, remain part of anthropology's contemporary vocabulary.

Evans-Pritchard believed that structural functionalism explained why the African Nuer, a primitive, stateless society, could remain orderly and stable over time. The Nuer society was organized around kinship groups. Responsibility for certain social functions was passed from kinship group to kinship group by descent. Along with inheriting responsibility for certain functions in the community, the kinship groups also inherited territory. The sense of common purpose in the kinship group motivated that group to cooperate for the completion of their group task. Individual groups might come into conflict with each other, but the conflict among individual groups kept the community as a whole strong and stable. The groups, and the inherited land and responsibility belonging to the groups, were more permanent than any single member of the group. Individual members of groups were defined by their roles in the group, and the group roles remained stable from generation

to generation, allowing the Nuer society to perpetuate itself over time with no chief or king.

Criticism of structural functionalism points out that it is focused primarily in one place, the African Sudan, at one limited period of time, the 1930s, and does not include historical antecedents to explain events. Even though structural functionalism does give some attention to competition among subgroups, critics point out that structural functionalism does not account adequately for conflict and the disorder that often comes with change. Finally, the critics asserted, there was not enough real scientific evidence to support structural functionalism, and overall the theory was serving the cause of British colonialism.

Although structural functionalism as a theory no longer holds the dominance that it once did, the writings of Evans-Pritchard, *The Nuer* and *African Political Systems*, are still held in high esteem by anthropologists, and today function as important points of reference for the conversation among anthropologists.

American Response in the 20th Century

American anthropologist Franz Boas (1858–1942) criticized cultural evolution, arguing mainly against its basis in ethnocentrism. Western society was seen as most valuable—the most highly developed, the most civilized. Cultural evolution assumed that all cultures would follow the same path and progression with the same final outcome of a modern state. By making it a scientific theory, cultural evolution often justified racist practices connected to British colonialism such as slavery and inequality in industrial European economies.

By the early 20th century, other anthropologists used different methods to interpret data and arrived at a different conclusion about the evolution of societies. Boas rejected definitions of societies as “civilized” or “modern” and wanted to use fieldwork data that examined exactly what already existed, without imposing an abstract and fixed expectation for development in a certain way through a certain progression. States did not always develop as a result of geographic boundaries, outside invaders, or war. Boas wanted to shift from speculating on abstract, universal stages of growth from historic societies, to the direct observation of societies that were current and living.

As British colonial rule dissolved after World War II, definitions of the state based on a European model were brought into question. Prior to World War II, the state was defined by geographical territory. Within that given territory, the state could require and enforce loyalty above and beyond that of family, ethnicity, subcultures, and classes. Within its own territorial boundaries, the state could replace family and kinship ties with Enlightenment values such as a secularized government, citizenship, and equality mediated by an impersonal legal system.

While acknowledging the existence of a variety of sectors, the Enlightenment model of the state would

nonetheless encourage the creation of a national culture and the dominance of a single language. This form of the state as an “imagined community,” where most of the citizens never meet each other face-to-face yet hold a sense of common ideals and values, first became possible in 18th-century Europe with the advent of print technology and the distribution of pamphlets and newspapers on a wide scale. Ordinary people were thus able to learn about and identify with people whom they otherwise would have known nothing about.

Pamphleteers and publishers were able to undermine kings and contribute to the creation of a national consciousness by encouraging feelings of unity, since publications focused on a national cultural myth instead of a sense of personal allegiance to the ruling king. Before this, kings in Europe were often viewed as father figures, reinforcing the sense of drama that could accompany the revolutionary actions taken for the creation of a national state that would replace kinship ties with citizenship and equality before the law.

When British colonies became independent after World War II, the overarching nationalism imposed by the British authority gave way to smaller independent groups based on ethnic, linguistic, and cultural loyalties instead of geographic unity. When subgroups reemerged as an important force in political negotiations, anthropologists responded with a new way to explain the dynamics that occurred within smaller, coexisting groups that were no longer held together from the outside by a unifying national myth. The structural functionalism of Evans-Pritchard, with its view of society as an idealized whole, was replaced by a new process-oriented approach. When political actions are studied using the process approach, the emphasis shifts to competition, conflict, history, and change and away from norms, values, and impersonal social structures. For the study of postcolonial states, the process approach provided a flexible model that promoted an understanding of how individuals were able to influence the larger system, making room for the idea of individual agency. In the 1950s and 1960s, the process approach was able to replace structural functionalism as the dominant orientation for political anthropologists in the United States and Europe.

The result was a change of interpretation of the data that acknowledges differences among communities without making value judgments about them. By the 1960s, anthropologists substituted Morgan’s savagery, barbarism, civilization sequence with the three-state sequence of hunting and gathering, horticulture, and developing agriculture. The new rhetoric avoided making a negative contrast between civilization, viewed as most evolved, and savagery and barbarism, viewed as less evolved.

The change in the method of interpreting the data continued to develop, and by the 1980s, the new approach was identified as postmodernism. Many if not most of the earlier ideas of anthropologists such as Radcliffe-Brown were criticized for containing a subjective Western bias that

included the justification for 19th- and 20th-century colonialism. Enlightenment assumptions about anthropology as a science utilizing universal models were challenged and sometimes entirely rejected.

During the 1990s, the effects of economic globalization and the information and communications revolutions raised even more questions for anthropologists to consider. Some of the specific aspects of globalism considered by anthropologists in conversations about the state include sustainability and ecological justice, cultural assimilation, nativistic movements, and forced migrations. The state was more and more required to accept the outside influence of international forces on domestic policies. Parallel challenges then emerged from internal ethnic and identity politics, and there was a greater demand for all domestic cultures to receive equal recognition from the state. Internal, fundamentalist religious movements presented a challenge to the secular identity of the modern state. With this, assumptions about the linear movement of history toward democracy and secularism began to be questioned. Advanced industrial societies showed signs of moving toward postmaterialistic concerns. Cultural issues about the environment, human rights, and sexual orientation were also becoming at least as important as issues related to material well-being.

As the 20th century came to a close, the postmodern interpretation observed that new emerging world conditions required new assumptions. Some of the new assumptions formulated by postmodern anthropologists involved breaking down the distinction between domestic and foreign affairs, the growing irrelevance of territorial borders, basing security on mutual interdependence, and a growing rejection of force for resolving territorial disputes. Traditional and postmodern anthropologists currently use a combination of traditional and postmodern ideas; these are a new synthesis of the best and most useful ideas from both schools of thought.

Political Organizations Today

Significant changes have occurred in the way political anthropologists gather, discuss, and interpret data about the cultures and societies being studied. At the same time, some ideas have lasting influence. Political anthropologists today accept that reliable indications of the emergence of a modern state include the recognition of territories, an increase in population and conflict, class stratification, and a monopoly of coercive power.

Anthropologists also rely on political scientists for an understanding of how states develop and emerge. Political scientists have identified a series of five crises that lead to the development of the modern state: (1) Identity is the process of forming a common national identity. (2) Legitimacy is the confirmed acceptance of the state policies and institutions throughout the population. (3) Penetration is the early spread of the state's authority, including the establishment of a center and the use of force to stop resistance. (4) Participation is possible in the peaceful phase following the confirmed

acceptance of the state's authority, as the population looks for ways to become involved in the governance of the nation by voting and forming political parties. (5) Distribution is an ongoing conversation and debate about how to divide the nation's resources and wealth, with established political parties making demands on the government for fair and equitable taxes and the provision of a safety net for the underprivileged sectors.

Some significant questions have been raised about the formation of the state through a crisis sequence. Is the sequencing of steps inevitable? Can the crises reoccur? Does it matter if several crises occur at the same time? How easy is it to recognize and identify the formation of crises in historical studies? Are the steps universal or based primarily on Western experience? In defense of the theory, it can be pointed out that the steps define categories that might not be universal but are useful when they do apply. And if the sequence of steps does not apply universally to all states, it is still possible to recognize that a nation is formed through a series of steps, allowing for variations from situation to situation.

In 1975, anthropologist Elman Rogers Service published *Origins of the State and Civilization*, a detailed summary description of what anthropologists had learned over time about the specific characteristics of political organizations, including the importance of communities based on geographical territory. By the late 1980s, the growth of a world market sparked a debate about the changing relationship between a globalized economic marketplace and the territorialized national state.

Today the term *deterritorialization* is used to express anthropology's awareness of the many activities—economic, social, and cultural—occurring in the new “space” created by communication-extension technologies. Extension technologies include the Internet, e-mail, broadcasting, computer networking, and telephoning. For example, the Internet and electronic mail can be used by anyone, from any place at any time, with no concern for geographical place.

When politics and identities become detached from local places as part of the globalization process, anthropologists also use the term *deterritorialization*, in this instance referring to the lessening of state authority and the trend for some ethnic groups within the state to identify less with the state and more with their ethnic identities. It can be argued that the deterritorialization of politics is a positive process, making the world as whole a more democratic experience for more people. For instance, some indigenous groups are able to find justice in the global community when the territorial nation-state denies it. The global recognition of the need for environmental awareness often views indigenous groups as making a positive contribution to the environment. When indigenous peoples create transnational alliances based on their contributions to the global ecosystem, they position themselves to advocate powerfully for their own state-based conflicts with international human rights movements. For these

reasons, deterritorialized social movements such as global environmentalism and international human rights are increasingly able to transcend territorial sovereignty. Some political scientists and anthropologists suggest that the appearance of deterritorialized social movements indicates the end of state territorial sovereignty.

Future Directions

In 1994, the American Anthropological Association (as cited by Givens & Tucker, 1994) published a survey describing issues and trends in anthropology for the following 25 years. The survey predicted a “greater emphasis on the contemporary world and processes of global change . . . such as sustainable development, world ecology, environmental studies, comparative global perspectives, global interdependence, and internationalization” (Givens & Tucker, 1994, p. 1). The survey clearly defines areas of research and study that have been and are being addressed in recent publications, conference sessions, papers, and introductory anthropology texts. What new understanding do these areas of recent research bring to the study of political anthropology and political organizations?

The words *global* and *globalization* occur frequently in the latest literature from anthropologists. As recently as 1990, Anthony Giddens in *The Consequences of Modernity* defined globalization as “the intensification of world-wide social relations which link distant localities in such a way that local happenings are shaped by events occurring many miles away and vice versa” (p. 64). Globalization usually refers to an impersonal process that occurs with no reference to any nation. Examples include technological developments in communication, mass popular culture, and global finances. Globalization affects anthropology’s understanding of human relations as interactions become disembodied, place no longer determines identity, territorial boundaries are no longer constraining, and communities are not defined by territory. Globalization also affects the social/cultural experience through a rapid spread of ideas. Economically, there is a rapid change of economic conditions from one region to another. Demographically, migration promotes cultural contact among populations. Government that rules by territorial boundaries must consider people who migrate into the territorial boundary but consider themselves as still belonging to the “homeland.”

To account for globalization by the new technologies, anthropologists talk about the contemporary state as transcending physical boundaries. Many traditional societies were formed to protect geographic boundaries from outside invaders, but in the new global communities, war is no longer inevitable because global communities transcend physical boundaries. The global communities are defined as *transnational* and the citizens belonging to them are global as well. A transnational state is described as

abstract, less institutionalized, and less intentional than the previous description of the modern state.

Transnational is a frequently used term that overlaps with globalization but has some specific limitations related to the territorial national state. The term *global* can be appropriately used to describe environmental concerns affecting the entire planet. No specific national territory is the center of the wide awareness of the need to protect the environment. By contrast, transnational events, such as the migration of refugees from one territory to another, involve several nations but originate in a homeland that can be identified as the anchoring point.

Corporations operating on a worldwide scale are transnational because they are centered in a national country of origin. Examples of corporations that are transnational include Wal-Mart, McDonald’s, Sony, and Honda. Truly globalized corporations such as the World Bank, the International Monetary Fund, and the World Trade Organization can be said to somewhat reduce the power of the state by taking on some of the functions that were once exclusively monopolized by the state alone. Technological changes, international communication, global mass culture, global finance, and the world environment all influence transnationalism. With this, anthropologists are watching the contemporary state reemerge in a new form with fewer boundaries and limitations. Some theorists speculate that globalism will replace nationalism in the same way that nationalism replaced tribalism.

At the same time that globalism gives the abstract impression of inclusivity, anthropologists are noticing the reemergence of an awareness of identity and place experienced concretely in face-to-face relationships with others. For those who are experiencing the relationship, this reemergence of an awareness of the need for face-to-face social integration is sometimes referred to as *tribalism*.

Anthropologists continue to find new problems and topics to study as societies continue to change throughout the world. Communication and transportation allow people of all cultures to interact and experience each other, exchanging material goods and cultural ideas. An event from a very distant place can shape local experiences because of the links created by mobility, including space- and time-altering technologies. Anthropologists can no longer understand power as happening exclusively at the local or state level. Anthropologists now look at the changing relationship between the local and the global and how the two experiences interact.

MAGIC AND SCIENCE

ISABELLE M. FLEMMING

Ela Area Public Library, Lake Zurich, Illinois

Religious and magical practices in primitive cultures were the focus of research among the first anthropologists in the 19th century. The attempt to distinguish religion from magic and define each sharply has continued to be a significant topic in anthropology. In more recent years, anthropologists have broadened their studies to include the practice of science along with the many other facets of human beliefs and endeavors. Cultural anthropology is one of the four fields of anthropological study, the others being archaeology, biological anthropology, and linguistic anthropology. All such research takes into consideration the context of the particular culture within which the study is focused, and accumulated records offer growing opportunities for the comparison and contrast of beliefs, rituals, and behaviors worldwide and across time.

Cultures are defined as human groups united by their social practices and beliefs, passed down in oral and ceremonial traditions. Cultural anthropologists consider every facet of cultures, both past and present. Art, industry, beliefs, rituals, kinship, and child rearing are among the topics studied. Methods of study involve fieldwork, direct observation, interviews conducted within the society, consideration of the manner in which various systems in the society relate to each other, and the comparison of observations recorded about other societies. This enables anthropologists to understand the culture's own value system and thought processes, and to discover the logic of its practices within the context of the culture.

Magic, science, and religion are related, each playing a part—to a greater or lesser degree—in societies across the world and throughout time. An ongoing area of anthropological study has been the attempt to define clearly the boundaries of each. Science is evident in the use of technology, agricultural techniques, materials and weapon production, and record keeping. Technology is the application of science and may develop by trial and error. Anthropological interpretation of the use of magic in primitive and nontraditional cultures has evolved over time. While some aspects appear fundamental to magic across cultures, such as the need to bring order and control to an unpredictable world, actual practices may differ among the cultures. Religion, often linked with magic, allows intercession with the gods and spirits and provides answers about the world and how it came to be.

Early anthropologists believed all human cultures developed within the same framework of stages, from savage to civilized. Information about non-Western groups came from explorers and missionaries who reported what they observed. Eventually, this theory proved too narrow to accommodate all facets of a given culture. In the 20th century, the discipline of anthropology moved away from those “armchair” scholars who based their theories primarily on anecdotal evidence. Researchers came to recognize the need for direct observation and even participation in the cultures they studied. What began as a study of religious practices among primitive, or nontraditional, societies broadened in scope as

anthropologists took to the field and experienced directly the richness of the many different cultures.

Today, studies may look at characteristics of human behavior common across boundaries, or they may view each culture within its own microcosm. It is impossible to understand another culture in terms of one's own, as the foundation will be different. At the root of the research is the necessity to learn the core beliefs upon which each individual society is based.

History of Anthropological Theory

Evolutionism

The 19th-century introduction of Darwin's theory of evolution and social Darwinism (a social theory that borrowed from it) led to the idea of the evolution of cultures. In the United States, Lewis Henry Morgan led the study of primitive cultures, based on the concept of evolutionism. He observed Native Americans in New York and found that direct observation made the internal logic of their cultures more apparent. In England, Edward B. Tylor, also an evolutionist, was the first anthropologist to advance a definition of culture, describing it as an inclusive unit where beliefs, customs, art, and other aspects of human behavior combined to form a cohesive whole. He believed that there were general principles of thought and action found in all cultures, but that different cultures were in varying stages of development. His influential book, *Primitive Culture* (1871/1958), was later published in two volumes. He proposed that magic was practiced by cultures at the lowest stages of civilization, by the "lower races," uneducated and superstitious. He suggested that a progression toward modern civilized cultures was based on an advanced education, which gave people the growing ability to use testing and experience as a means of forming opinions. Primitive "savages" erroneously assumed that associations in thought must necessarily occur in reality as well. Occult magic therefore was based on an association of ideas. Analogy and symbolism were the foundation of the magical arts, and Tylor likened them to superstitions still held by Europeans in his day.

The progression of cultures could be seen in the practice of religion, to which Tylor gave a basic definition of the "belief in spiritual beings," and to which he applied the term *animism*. Animism included the belief that souls of individuals could exist after death, as well as the belief in other spiritual beings that interacted with society and individuals on some level. He suggested that the notion of the existence of such spirits arose from dreams, hallucinations, and related experiences, and he saw no value or truth in the magical beliefs of primitive cultures. Tylor stated that the animistic spirits were what humans imagined their own souls to be. The spirits were meant to explain the workings of nature, based on the idea that all forces and things in nature were inhabited by various spirit forms—both good and evil.

The Englishman James George Frazer developed the idea of sympathetic magic in *The Golden Bough* (1890/1981), a book that grew into several volumes. He presented a complex picture of primitive magic, suggesting that the practice first arose from a need to control nature. Spells and rituals, by means of compulsion, were meant to have a direct effect on successful hunting and food gathering, and also on the weather. When coercion failed, pleas and propitiations to gods and spirits were introduced, and religion, as a separate practice, was born. When cultures grew more sophisticated, they would adopt the methods of science.

Frazer's book had a deep impact on many disciplines of study, discussing the myths and religions of a number of non-Christian cultures of the world, as well as sharing concerns such as birth and death. Like Tylor, Frazer saw a progression of intellectual development from the simple to the more complex. Cultures first used magic, advanced to religion, and finally to science. He described primitive magic as based on notions of sympathy, wherein an effect could be brought about by imitating it. In part, the evolutionary focus was the result of the biases built into the material Frazer collected from those who provided him with information, such as missionaries and colonialists.

Cultural Relativism

Franz Boas came to the United States in the late 19th century and contributed significantly to the growing field of anthropology during the early 20th century. Based on his experiences among other societies, he rejected the notion of evolutionism, with its cultural biases, and stated that every culture must be studied and understood in terms of its own system of values. Looking at cultures this way called for probing their individual histories. No longer placing them in a one-size-fits-all set of developmental steps, Boas valued each culture's historical development on its own merits. This is the theory of historical particularism. Boas defined culture as a set of learned behaviors. He emphasized research and promoted use of scientific methods by anthropologists, bringing the practice of anthropology into the modern era.

Functionalism

Functionalists moved away from a focus on historical context and studied the structures within a society. Each system or structure contributed to the integrity and stability of the whole society. This approach in the early 20th century also helped to shed the racist biases and evolutionist views of earlier theories. However, by ignoring history, functionalism did not account for change and did not provide for the changes that may take place in a society when it is transformed by exposure to the outside world.

There were two approaches to functionalism, as seen in the theories of Bronislaw Malinowski, who focused on

individuals, versus those of A. R. Radcliffe-Brown, who looked at the structure of the society. Malinowski attempted to disentangle religion from magic in *Magic, Science and Religion and Other Essays* (1948/1954). *Coral Gardens and Their Magic* (1935) addressed agricultural magical rites practiced by Trobriand Islanders of Melanesia. Malinowski considered magic to be nothing more than a specific set of acts, practical in their intent as a means to accomplish a goal. The emotions concurrent with the act were also critical to the success of the magic. He found that different types of magic acts were associated with different goals. Melanesians, for example, performed the most powerful magical rites when engaged in the most dangerous or uncertain operations. House building, although complex, presented little risk and therefore required no accompanying magic to ensure success. Fishing, when it involved such dangerous fish as the shark or others difficult to catch, called for a great deal of magical preparation. Magical forces played a part in certain human emotions and in forces of nature for the Melanesians, calling upon the need for associated magic rites and acts. Malinowski concluded that magic was not unlike science, since it called for acts toward practical ends and was governed by theory and principles that determined how the acts must be performed.

E. E. Evans-Pritchard expanded on the structural form of functionalism and specialized in the study of African cultures. Two of his books have had an especially strong impact in the field of anthropology. In *The Nuer* (1940), he examined the political organization of the Nuer society in detail. The book has become a classic ethnographic study. *Witchcraft, Oracles, and Magic Among the Azande* (1937) was a major study of the magical beliefs of a society based on non-Western thought. Evans-Pritchard demonstrated the internal coherence of the Azande culture and the logic of their magical beliefs within the context of Azande society. His rich, well-documented description of magic and witchcraft in Azande society can be contrasted with the practices of other groups elsewhere.

Other Notable Figures in Anthropology

Émile Durkheim, a French sociologist, strongly influenced the theory of structural functionalism. He wrote the book *Elementary Forms of the Religious Life* (1912/1965), which discussed the origin of religions in society. He separated magic (profane) from religion (sacred), stating that because magic was always performed in private, it could not be seen as part of religion, which was social. He viewed magic as a precursor to science, but preferred to focus on religion.

Ruth Fulton Benedict, an early 20th-century cultural anthropologist, did fieldwork among various Native American groups and wrote the classic *Patterns of Culture* (1934/1959). Like her colleague Franz Boas, she rejected theories of racism based on heredity and environment.

Margaret Mead, a major figure in American anthropology, used the ethnographic method to conduct field studies, focusing on child rearing and gender issues in Samoa, New Guinea, and Bali. She was a prolific writer, promoted women's rights, and was among the first to use photography as a way of adding to the record of a culture. Her best-known work is *Coming of Age in Samoa* (1928/1961).

The French anthropologist Claude Lévi-Strauss was strongly influenced by linguistics. He focused on those common characteristics of the human mind that produced an underlying structure among cultures. This theory is known as structuralism. He posited that the same set of general rules underpins all cultures. The thoughts of humans are patterned in binary oppositions arising out of the human need to classify. In *Myth and Meaning* (1978/1995), a collection of his lectures, he states: "To speak of rules and to speak of meaning is to speak of the same thing; and if we look at all the intellectual undertakings of mankind . . . the common denominator is always to introduce some kind of order" (pp. 12–13).

Clifford Geertz, a cultural anthropologist focusing on symbolism, was particularly concerned with symbolism evinced by a culture. He defined culture as an expression of the symbols used by a society. He posited that, in order to gain an inside view of a culture, the anthropologist must first learn how its individual members view selfhood. It is impossible to climb into the skin of another, Geertz said, but it is essential to understand what the individual really conceives that it means to be a human. The sense of self is not the same in every culture, and culture itself is transmitted through symbols that carry meanings. These symbols are what members of society use to communicate, and it is these symbols that shape the worldview.

Alice and Irvin Child coauthored the book *Religion and Magic in the Life of Traditional Peoples* (1993). It discussed and compared rituals and other religious practices conducted among the traditional societies of the world. They found trends and recurring elements of religion. Later, Irvin Child, a Yale psychologist, became interested in the paranormal and conducted research in the current practices of Western society.

Magic and Science: A Comparative Overview

Anthropologists, psychologists, and social scientists generally see the function of magic as a way of controlling and organizing the world. Magic, along with religion and myth, is a way of explaining the world and its natural history. This may serve to explain things, as in creation stories of how the world began. Magic, religion, and myth may also provide social control, help increase crop yields, and improve the hunt or predict the future. Science has its own creation myth, the big bang theory, developed on the evidence of astronomical and mathematical studies. The perception of

what is taking place when one practices science versus magic may be different, while the purpose remains the same. A culture's viewpoint and the instruments at hand will also determine which practice it is perceived to be by those *outside* of its culture.

Magic and science have elements in common. Mathematics is fundamental to science, but has also been considered a highly magical art. The Pythagoreans did much to develop mathematics, but they saw numbers as magical, possibly even the true foundation of reality. Other cultures viewed numbers as magical symbols. Magic involves ritual and symbol, and symbols are a cornerstone of magic, as they are in science. Magic relies on a belief in forces beyond the everyday world. Magic often requires a very orderly progression of routines and practices that, if done correctly, will lead to the desired result. It is generally practiced in secret and carried out by individuals or small groups.

Science, too, involves ritual in the proper implementation of experiment, and the scientific method calls for an orderly progression of routines. Symbols are used in all areas of science. Natural forces are a foundation of modern science, but these forces have been studied and described, and they are not viewed as spirits or gods. For the scientist, forces are a part of the natural world—as are spirits to those who believe in magic—but are explicable in concrete terms and are not whimsical in their behavior. Scientific forces are predictable in their operation, and they can be described mathematically and their effects demonstrated. Scientists share their knowledge, often building on the work of others.

Magic Practices

Magic may be recognized by ceremony and ritual practices, a demand for secrecy, and an attempt to control nature or other humans. Those performing rituals, whether in earlier societies or today, see these acts as transformative. There is not only a public act, but also an inner sacred experience. The magic arts can be part of a very complex structure or very basic and direct. The successful performance of magic is based on the belief in the underlying connection of all objects, peoples, and animals through a supernatural force—a perceived connection between similar things. Sympathetic magic, also referred to as imitative magic, is in practice when a voodoo doll is used to cause pain or illness in the person whose image is represented by the doll. Contagious or contact magic depends on the notion of a continuing tie between items or persons who have once been in contact. In some cultures, nail clippings or hair may be used to turn harm back on their original owner.

Mana was a Polynesian term that referred to a kind of power—a supernatural force—possessed by someone or something. Marcel Mauss studied the concept of mana extensively, believing it to have been a universal belief at an earlier time. This term came to be related to taboo,

which also refers to a power, generally of evil or pollution inherent in a person or object. The taboo power may only be temporary, and in some societies taboo also refers to the special power of a king, for example, where his position elevates him away from the common folk. Power was often construed as hierarchical.

Magic and religion are often difficult to separate when used to explain life itself. The mysteries of life and death hold great importance to humans. Archaeologists have found evidence of ritual burials from as long ago as 60,000 years. Deliberate burial suggests an awareness of or belief in something beyond the mortal body, and goods buried with a body could suggest ritual practices and the belief in an afterlife. This suggests the belief in souls that live on after human flesh decays. The notion of a soul could have contributed to the belief in supernatural forces, such as gods and spirits.

While pleas, prayers, and other propitiatory acts point to religious beliefs, the manipulation or coercion of forces to produce specific results may be defined as magic, according to Frazer (1890/1981). Magic can be divided broadly into good (white) and bad (demonic). Occult magic, used for either good or bad, is that which appeals to unseen forces, as *occult* means hidden. Attitudes and practices associated with magic vary widely from culture to culture, although the underlying theme remains that of control or manipulation of gods, demons, or other forces. Superstition, still apparent today in such acts as nailing a horseshoe above a door or carrying a rabbit's foot, expresses the remnants of ritual magical acts and beliefs.

Cave Drawings and Rock Art

The earliest evidence of magical practices is found in prehistoric cave drawings. Cave drawings and rock art are found throughout the world, some created over 30,000 years ago; the last of it perhaps died out in the 19th century with the passing of the San in southern Africa. Especially in Australia, oral tradition about the creation of rock art still exists. However, the religious and magical practices of societies do change over time, and what modern oral traditions describe may not capture the true meaning and purpose of much older work; care must therefore be taken when using that evidence to interpret the drawings of former centuries.

One of the most recently discovered sets of cave paintings is in Grotte Chauvet in France. The work is believed to be more than 32,000 years old and consists of paintings, geometric forms, images picked out of the rock by sharp implements, and hand prints. The many animals depicted represent animals actually hunted by those early people, as proven by the types of animal bones found in the area. Often the geometric forms are near the animals and perhaps suggest counts or rituals. The images of hands are more difficult to explain, but they could have been part of a ritual.

A recent comparative study of rock art in western North America led to the conclusion that Columbia Plateau rock art represented several different types of ritual, performed by different social groups at different times. The art was seen to represent rituals by shamans, such as vision quests, where the shaman entered a trancelike state to interact directly with spirit guides, and rituals associated with death. Some rock art was clearly sympathetic magic associated with the hunt. Interpretation of any such drawings or engravings may depend on time and place. It is doubtful that one interpretation fits all the cases.

Jean Clottes in *World Rock Art* (2002) points to certain themes and practices that are generally recurrent in cultures, such as birth, death, and initiation rites for some purpose, as well as coming of age and marriage. Any of these may be surrounded with ceremonies, some of which may be recorded or symbolized in rock art. Other themes could include the creation stories of a culture and those sacred stories or legends that are significant to it. Members of traditional cultures in both the recent and distant past saw themselves not as separate from, but as part of, the natural world. Seeing all of nature as related, they could believe that the images held the magic of spirits or natural forces. Depiction of the images therefore represented an attempt to influence, coerce, or seek help from the inherent power of the image.

One of the most puzzling recurrent depictions in cave drawings and rock art is that of hands. They also appear nearly worldwide. Sometimes the hand was pressed in pigment and then rolled onto a surface to leave the imprint. On other occasions, pigment was placed in the mouth and blown around the hand pressed against the wall in order to produce a stencil effect. It is still not possible to interpret the purpose, which could have been part of a ritual, or merely a means of leaving behind the identity of oneself. In some areas, the imprints include fingers that appear to be missing some bones. Clottes noted that, in Australia, these images were a form of sign language and could be the same elsewhere. He found that sign language was used for communication, especially in hunter-gatherer cultures, often during a hunt. But sign language could also have been used to communicate with the spirits.

Images of humans and animals are common motifs in cave drawings and rock art. Animal images might have been intended to enhance success in the hunt, although some argue that the evidence is open to other interpretations. Some images resemble humans in other guises, suggesting shamans interceding with the spiritual world. Such *therianthropes*, as they are called, may have shown persons in costumes, but for traditional cultures these probably held a greater significance, perhaps of a shaman passing into the animal or spirit world. The latter images appear most often in Africa and the Americas. Other universal designs include patterns referred to as geometrical designs, objects, and shapes engraved or gouged out of the rock. Despite similarities in appearance, any of these would need to be studied within the context of place, time, and culture.

Anthropologists interpret the drawings and engravings found in rock art by noting several variables. The methods by which the images are depicted, along with their locations geographically and within the cave, are considered. Comparisons are also made with the ethnological record. Caves were viewed as other worlds. Art created far in the depths of the cave could have been especially sacred, as the cave was seen to exist in another realm. Other sacred places included “boundary zones,” those areas where one physical geography came into contact with or connected to another. Such examples included where mountains touched both earth and sky, or where the depths of canyons connected deep earth and water. The accumulating records of anthropological study show that there are some basic similarities of thought and action found among cultures in like stages of development. Because humans are the same in terms of physical makeup and needs, the foregoing records permit some analogy to be made between more recent and more fully documented rock art with that of the ancient past.

Shamans

Shamans are specialized practitioners who can enter a state in which they have direct contact with spirits or animistic elements of matter and life. By asking or compelling, shamans obtain assistance from the spirits on behalf of their tribe or individual members. Healing often plays a key part in the shaman's role. Shamans exist now, just as they did millennia ago, and they are powerful members of their societies.

Traditionally, shamans seem to have appeared most often in hunter-gatherer cultures. Their practice often involved the trance state, reached through any one of several methods. Enduring excessive pain, fasting to the point of near starvation, dancing to the point of exhaustion, and taking some form of powerful drug were among the many routes to the altered state necessary for the shaman to journey into the world of the spirits. The “New Age” has seen the rise of neoshamanism, prompted by the belief that there is something valid in shamanism. Mircea Eliade contributed to this explosion of interest when he described shamanism as a form of ecstasy in his book *Shamanism: Archaic Techniques of Ecstasy* (1951/1964). Although some points in this classic work have been questioned by more recent anthropologists, it nevertheless remains an important study.

A key to shamanic practices has been the belief that multiple worlds exist in the cosmos, either alongside or within the world of everyday existence. Here, science and magic seem to meet, for the many worlds theory (parallel universes) is accepted by many physicists today. Shamans could interact directly with creatures of the other worlds in order to obtain help, practice healing, or wreak evil on other members of the society. Usually, those who dealt evil

were considered sorcerers rather than shamans, however. In many cultures, particular animals served as helpers or guides for the shaman. In such cases, the shaman was believed to transform literally into the animal itself. Often, shamans were associated with healing. Through ritual, dance, and a variety of other techniques, shamans have successfully cured members of their tribal group. A key to success was the belief that they truly had power to cure.

Other Magic Practitioners

Depending on the culture both present and past, witches, sorcerers, shamans, wise men or wise women, or some combination, were set apart as powerful figures to contend with the hidden spirits of nature, demons, and gods. For each culture, the training might be different, yet such figures had access to magic potions, prayers, amulets and talismans, or trances in order to manipulate the magic. Religions, too, had access to supernatural powers, and the line sometimes blurs, depending on the point of view. For example, the 16th-century Reformation saw Protestants accusing Catholics of practicing magic because liturgical books contained rituals for blessing wells and animals, for driving away thunder, for exorcising evil spirits, and for the miracles claimed to occur at holy shrines.

E. E. Evans-Pritchard (1937) lived among the Azande, an African tribe, making careful note of all systems and practices within their culture. He learned that, among the Azande, witchcraft was literally a physical characteristic, a specific material present in the bodies of certain individuals. Witchcraft was inherited and was performed psychically, without rites or spells. Sorcerers, however, did harm by using bad medicines in magic rites. Diviners were consulted to identify witches. Evans-Pritchard suggested that for the Azande, witchcraft explained why bad things happened and provided a way of dealing with those occurrences.

The curse of a witch doctor was no idle threat. The beliefs of the one cursed and of his fellow tribe members were shaped by the views of the culture. The cursed one was shunned, because he was polluted, a term related to taboo. Hopeless, ostracized, and convinced of the curse's power, the member would die, providing proof of the magical powers leveled against him. Success reinforced the belief and the magic was validated.

A number of Native American tribes incorporated fears of witches or sorcerers into their belief systems, and this may have offered a form of social control. Mental illness has also been attributed to witchcraft in societies that embrace magic. Witch doctors or wise women appear in some societies as healers, using spells, rituals, and special medicines to drive out the evil spirits that produce illness. There are countless examples of these beliefs and practices. Differences may be great or subtle, so care is taken in evaluating magic activity within a given culture.

Divination uses any of a variety of methods to predict the future, such as the outcome of a battle, or to locate an item or person. Oracle bones, animal livers, tea leaves, and the position and movement of stars and planets are among the varied sources used by diviners. Early astrology was a complex form of divining that required a familiarity with the motions of the stars and planets. *As above so below* developed out of the tenets of astrology. This practice, begun in ancient Babylonia, was based on constant observation of the stars and planets, which were regarded as gods or other supernatural beings. Their activities could be used to make certain predictions about occurrences in the world below. Astrology passed on from culture to culture, with embellishments and reinterpretations added over time. Careful observations made by astrologists and recorded over a long period of time gave real information upon which scientific hypotheses could eventually be made. This contributed to the growth of astronomy. Even in this era, there are people who rely on astrological readings to assist in decision making.

The belief in the link between the heavens and earth served as an underpinning for the practice of alchemy, a form of magic prevalent in medieval and Renaissance Europe. The preparation, the incantations, the secrecy involved, and the connection with astrological symbols bespoke magic. Yet, practitioners would argue that the labor, the time involved, and the withdrawal into an inner world were necessary to move up to a higher, purer level of existence as good Christians. References were made to heavenly bodies and their influence on the world below. At the end of the alchemist's journey, she should have both created gold and achieved a position among the elite. Alchemy continued to be practiced into the 17th century, and while it involved magical rituals, many of its early laboratory practices served as precursors to chemistry.

Magic Today

Western society has seen the reemergence of magic after the so-called rationalizing influences of the 17th and 18th centuries and the rise of science. Witchcraft, or secret societies with magic rituals, attempts to contact the departed through psychic mediums, and Ouija boards are just one of the forms this has taken. Wicca, or modern witchcraft, is often seen as an expression of feminism and as benign in its practices. Its chief ceremony is the Drawing Down of the Moon, where the goddess is drawn into the high priestess.

In 1888, Dr. Wynn Westcott established the Order of the Golden Dawn, a secretive society based on various historical magical traditions, such as the Kabbala. Members desired to achieve the goal of emerging into the light—a spiritual rebirth—by ascending the Kabbalistic tree of life in sacred ceremonies. Aleister Crowley was a well-known wicked magician, a controversial member of

the Order of the Golden Dawn. This group of practitioners helped to restore an interest in magical practice in modern times. A need for greater fulfillment, disappointment with what current religion has to offer, or a desire to turn away from an increasingly complex world and embrace a more rural, natural world may contribute to the desire to practice magic today.

For the first time in human history, a cyber world exists within our own. Access to computers and the Internet has led to increasing communication via new technologies, such as social-networking pages, blogs, online games, and interactive Web pages. As technology advances, it may become difficult to separate our world from the virtual world—the joining of magic and science in ways never dreamed of before.

The Scientific Method

Through research and experiment, scientists manipulate nature according to specific methods that could be interpreted as ritual, yet science differs from magic. The way science is practiced is what sets it apart and validates science's findings and creations, according to a scientific worldview. Accurate observation and careful, replicable experimentation is part of the scientific method, and what is proven must also be falsifiable—able to be proven false based on newer data or other findings. If a new experiment yields better interpretations, then the old theory is discarded. Fundamental to science is the ability for an experiment to be repeatable anywhere, anytime, in any culture.

Science consists of both theory and application. Technology is the application of scientific principles to create machines, medicines, or other aids to human progress. Technology has always been with humans. The principles of science behind the practice need not be understood. The discovery of making bronze to create stronger weapons is one example. It was not necessary to understand the chemistry of metals to produce the new substance—trial and error probably led the path to discovery.

According to sociologist Thomas Kuhn, the process by which consensus is reached in the scientific community is not a smooth accumulation of information over time. In his landmark book, *The Structure of Scientific Revolutions* (1962/1996), he explained the process. First, there is a stable belief system, based on a particular worldview. The world appears to function within the tenets of that system, and certain predictions can be made based on it. When consensus breaks down—as it may with the appearance of many inexplicable events, observations, or experimental results—attempts will be made to explain these oddities within the old system. Scientists will go to great lengths to save the system that is the entrenched worldview. As negative evidence builds up, the old system gradually breaks down. When every

effort has been exhausted to fit the oddities into the current science, a new science may erupt. According to Kuhn, it will be a revolutionary leap, a paradigm shift, and will be completely incommensurate with the system it replaces. Consensus is reestablished only gradually, but when it is reached, the new science becomes the “true” science. The shift from a belief in an earth-centered planetary system to the sun-centered heliocentric system is an example of such a shift.

Careful observation is the first step in the process of the scientific method. Cultures now and in the past were keen observers of nature. In this respect, most cultures may be said to practice the first step. The next step is to create a hypothesis, or test description, based on the results of the observations or experiments. The experiments must be reproducible by anyone and yield the same results. Anyone should be able to make the same observations. Consistency of measure, observation, and results is the key to a sound scientific method.

The third step calls for scientists to make predictions based on the developed hypotheses and then test the predictions through further experiment and observation. If additional testing does not support the hypothesis, it must be revised or perhaps changed completely. With consistency of results and predictability of further results, the hypothesis may become a theory.

Finally, a theory must be both repeatable and falsifiable. Falsifiability means that some further observation or experiment could prove the theory untrue. On the other hand, if one claimed to hear voices from Mars and further claimed that he alone was a special agent of that reception, it would not be a falsifiable theory. Science is not individual, nor is it secret. It is designed to accommodate change, while magic is generally a very traditional system.

Science and Technology in Magical Societies

Cultures based on the use of magic often used science and technology for practical purposes. Agricultural societies found it necessary to develop a method for determining, in advance, when planting or reaping should begin. By closely observing natural signs, such as the regular movement of the sun, moon, and stars through the seasons, cultures learned to recognize the signs. The development of calendars grew out of this. As with so much else, the calendars might also involve magic for prediction or as indicators of times appropriate for particular rituals and practices. Careful observation, record keeping, and mathematical skills were required to create accurate calendars. The creation of bronze and iron, of pottery and glass, all required much technical skill. Metal making, in particular, was associated with magic and secrecy, as the scientific reasons for success were not understood.

Conclusion

Magic served practical purposes, was based on a belief in the interconnectedness of all things in the world, and could be put to good or bad uses. Magic helped to introduce order to a complex world marked by unpredictable events and often served as a means to preserve social order. It could explain why things happened and how the world came to be. Creation myths are among the most powerful foundations of cultures and shape a worldview, sometimes even dictating how physical structures will be laid out in the landscape. As a means of explanation and as an application of acts toward a practical end, magic can be likened to science.

For some, magic was seen as the means to obtain ultimate power. For others, it served and continues to serve as a form of religion. In practice, magic tends to be individual, while science depends on the work of others. While magic and science both operate with natural forces, the understanding of what those natural forces are and how they may be harnessed is different. Each approach is logical within the realm of the culture that engenders it. Magic may be compared to science as a way of creating order and achieving success in human endeavors that promote health and well-being. Magical acts sometimes contributed to scientific ideas, yet the two can exist side-by-side, founded on entirely different views of the world.

Anthropological Studies

The Present

In the recent past, anthropological studies have expanded and enriched the study of other cultures, incorporating biological, psychological, or gender aspects. In addition, structuralism—associated with linguistic factors and symbolic anthropology—has added greatly to the understanding of both traditional and nontraditional societies.

Daniel O’Keefe’s *Stolen Lightning: The Social Theory of Magic* (1982) and Stanley J. Tambiah’s *Magic, Science, Religion, and the Scope of Rationality* (1990) have contributed to the recent understanding of magic. O’Keefe’s book discusses both how and why magic works in various societies and breaks it down into the many categories found in practice. It is a very comprehensive book about all aspects of the supernatural. Tambiah’s book explores the evolving worldview of the Western European tradition as it has shaped the understanding and interpretation of magic, science, and religion in other cultures. He emphasizes the “continuities in experience” and the “psychic unity of mankind.” Tambiah, who did his field studies in Asia, considers how anthropologists, rooted in the Western worldview, can analyze and describe the magic, science, and religion in comparative studies of other cultures.

The Future

Investigations into the nature of virtual reality are on the cutting edge of studies. *Technopagans* are those who are comfortable in the changing world of cyberspace, where reality can be modified, as well as in the world of computers and electronics. An article in the *Anthropology News* (Gusterson, 2004) pointed out how religion and science can overlap. Recent political decisions in the United States show evidence of this mixture where there has been a call for banishing the teaching of evolution in schools. This is an area that calls for investigation. The same article discusses “the way that magic and science, far from being opposites, are increasingly fused at the hip.” The return to magical practices and witchcraft in modern societies calls for study. Shamanism has reemerged as well, but shedding its trappings of superstition and sorcery. There is a need to understand how it fits into modern society, and why.

With the advances made in genetics and cognitive studies, earlier theories may need to be reconsidered. Questions will address which concepts and behaviors are passed on genetically rather than culturally. Further studies of the human brain have revealed a more formal and organized structure than was understood in the past. Studies in linguistics, and in the use and comprehension of symbols and signs, provide fertile ground for further exploration.

SHAMANISM

GWENDOLYN J. REECE

American University Library

Shamanism has commanded scholarly and intellectual attention in Western academia since the 18th century. Current anthropologists discredit much of the historic literature as methodologically unscientific, revealing more about the biases and fascinations of Western writers than about their subjects. Nevertheless, the ethnographic record on shamanism is rich and has informed scholars from numerous disciplines, including religious studies, history, and psychology.

Anthropologists use *shaman* in several different ways. Most narrowly, and arguably most appropriately, it denotes magico-religious specialists of the Siberian Tungus people. The word *saman* comes from the Tungus verb *sa*—"to know." Noting similarities and cultural diffusion, scholars expanded the term to indicate similar practitioners in other circumboreal cultures and central Asia. Most commonly, shaman refers to a theoretical category of magico-religious specialists in cultures all over the world and across time. Scholars debate vigorously about what constitutes shamanism in this broader sense. Indeed, they argue about whether such a global phenomenon really exists, or is just a construction of the modern Western imagination.

This chapter provides an overview of shamanism, first reviewing theories that advance core characteristics of shamanism, and then summarizing the critiques of the category of shamanism. Next is a discussion of several major topics: the shamanistic worldview; the call and training of the shaman; the shaman and altered states of consciousness;

the work of the shaman in the community; and neoshamanism, a recent form of shamanic practice developed in Western urban areas. The chapter concludes with suggestions for future lines of inquiry and a select list of core works on the topic for further reading. Discussion of specific cultures is beyond the scope of this chapter.

Definitions of Shamanism

By the 1930s, the term *shamanism* was applied indiscriminately to almost anything "supernatural" outside the "world religions" and became virtually meaningless. To discover their essential characteristics, Shirokogoroff (1935) returned to the Tungus shamans. Acknowledging that shamanic methods differ from culture to culture, he perceived a complex that extends beyond cultural boundaries that would be recognizable to the shamans themselves. He reported that the Tungus shamans and the Manchu shamans recognize each other's power without knowing each other's methods.

Shirokogoroff's Definition

Shirokogoroff proposed six formal characteristics of shamanism. First and putatively most important, shamans are masters of spirits. Shamans control the spirits and their interactions with them in sharp contrast to those controlled or possessed by the spirits.

Second, the shaman masters numerous spirits. The spirits in the shaman's arsenal have various qualities under the shaman's command. Typically, the shaman begins with one or a few spirits, and then learns to master others with their help. In many cultures, the assessment of a shaman's power is directly proportionate to the number of spirits mastered.

Third, there are culturally recognized methods for working with spirits. The techniques include means of contact and breaking contact, and ways of attracting and caring for spirits and maintaining right relations with them. These practices vary from culture to culture and continually develop and change, yet they exist in some form wherever there is shamanism.

Fourth, except perhaps where shamanism has been outlawed, shamans in every culture use paraphernalia, costumes, or special equipment to enhance their power.

Fifth, for shamanism to exist, there must be some accepted theoretical basis. A belief in spirits and an understanding of their characteristics and modes of operation is essential. Moreover, people must believe that humans can interact with spirits and "master" them. The level of theoretical sophistication varies from shaman to shaman, but shamanism is always rooted in a theoretical foundation.

Finally, shamans play a recognized and integral role in their culture. A shaman does not master spirits for the sake of mastering spirits, but to serve the community.

Eliade's Theory of Shamanism

Shirokogoroff's work strongly influenced the Romanian historian of religion Mircea Eliade (1951/1964). Eliade was not an anthropologist. He was the quintessential armchair scholar, fluent in several European languages (but not native languages) and well versed in the literature. Philosophically, Eliade believed in a core human nature and therefore common types of experiences. However, he acknowledged the variety of ways the core experiences can be expressed and interpreted in different cultures. One type of core experience is what he called a *hierophany*, a direct experience of the sacred. In the ethnographic record of shamanism, Eliade believed he had discovered archaic techniques that enable direct perception of the Divine. He called shamanism "techniques of ecstasy," from the Greek *ekstasis* of the Dionysiac mysteries, "to stand outside oneself."

Eliade built on Shirokogoroff's definition of shamanism, enunciating a more general pattern of shamanism that he claimed is universal, justifying his theory in a *tour de force* review of the literature. One emphasis added to the definition was a focus on the shamanic sickness as initiation. This sickness is ecstatic and often contains experiences in which the shaman-to-be is dismembered, descends to the underworld, and ascends to the celestial world. During these experiences, a spirit being—usually a tutelary spirit—informs the future shaman of his calling. The training from the tutelary spirit operates simultaneously with that provided by elder shamans.

In Eliade's conception, the soul journey, or magical flight, is the quintessential shamanic experience. The soul of the shaman can go into the spirit world, including down into the underworld, elsewhere in the middle world in an "out of body" state, or up into the celestial world. All of these are linked by the *Axis Mundi*, often understood as the cosmic or world tree. The ecstatic flight or journey is highly visual and strongly geographic. The shaman also experiences the other senses in trance. Like Shirokogoroff, Eliade excluded trance states in which the individual is possessed by spirits. Eliade's work emphasized the psychological and mystical state of the shaman, touching upon, but not deeply analyzing, the role of the shaman in the community.

Other Definitions

Shirokogoroff and Eliade remain powerful influences in the continuing debate about shamanism. This section will summarize some of the major directions of the debate.

One of the most significant points of contention is whether categorically excluding possession trances is correct. In numerous cultures, shamans call the spirits and are possessed by them rather than going on a soul journey to the spirit realm. In many of these rites, the shaman maintains full consciousness and control. The exclusion of possession trances, then, is related to the concept of mastery. At first glance, it seems as though those who are possessed by spirits are mastered by them rather than being the master. A closer look reveals that often both soul-journey trances and possession trances are practiced in a single culture, and sometimes by the same individual. The *medium* often deliberately invokes and concludes the trance, rather than being controlled by the spirits. There is not agreement among scholars about whether possession-type trances should be considered as a type of shamanism. Some researchers refer to such practices as "shamanism of the possession type," whereas others exclude it. Hultkrantz (1973) presents a phenomenological definition that accepts the emic view. In this definition, the shaman is a professional, inspired intermediary who has direct contact with the spiritual world through ecstatic experiences and uses this contact on behalf of the shaman's society. What, therefore, separates a shaman from a different type of professional intermediary is the use of ecstatic experiences.

Another key issue in shamanic studies is the tendency to emphasize ecstasy to the neglect of investigating the role of shamans in relation to their societies. Porterfield (1987) advanced a definition of shamanism that emphasized the role of the shaman's body as the locus of symbolic activity. Shamans embody symbols in performance on behalf of their community, and the meaning ultimately resides not with the shaman but with the audience's interpretation of the performance. Porterfield's attention to the interactive and social nature of shamanism is a corrective to theories that neglect this aspect. However, this and similar theories

are criticized by some scholars for being materialistic and reductionist, the spirits being defined as “disguised representations of human desire” (p. 736).

Problems With the Category of Shamanism

Generating a clear, agreed-upon definition for shamanism is a difficult undertaking. Anthropologists worry that classifications across cultures may overgeneralize from the particular cultural data. As a result, such universalized, conceptual categories may reveal more about the culture of the scholars than the cultures they study. Therefore the construction of the exotic “other” is not and has never been politically neutral. In addition, contemporary anthropologists are gravely concerned not to harm the subjects of their studies. Shamanism is a particularly worrisome category because of how closely it is bound to Western attitudes toward indigenous peoples.

The history of shamanic studies is problematic from the beginning. Cultural anthropology began with evolutionary notions that the so-called “primitive” societies were vestiges of earlier developmental stages and represented the “past” of modern, Western industrialized man. All societies deemed primitive were non-Western and nonindustrialized, and they were not state-based societies. Shamanism was, therefore, considered a more primitive form of religion and was often mentioned in the company of words like *superstition* and *delusion*. The category was applied fairly indiscriminately to specialists who had some dealing with the supernatural. Eventually, the field of anthropology changed and smaller-scale and nonindustrialized cultures were no longer interpreted as being vestigial.

The next significant phase in interpreting shamanism focused on the putative insanity of the shaman. Now a new Western norm, derived from the modern field of psychology, determined the understanding of shamanism. The shaman was typically diagnosed as neurotic or schizophrenic. In some studies, especially prominently in Soviet studies, the shaman was portrayed as a huckster, manipulating the naive and credulous populous for personal gain. Either way, these interpretations undermined indigenous epistemologies and served an agenda of acculturation. Shirokogoroff (1935) and others challenged the view that shamans were insane, demonstrating the integrity of the worldview of the Tungus and the shaman's place within it.

Eliade's tome, *Shamanism: Archaic Techniques of Ecstasy* (1951/1964), marked a significant shift. Suddenly, shamanism was idealized rather than pathologized. However, critics of Eliade's work have argued that he was careless in generalizing from particulars, overstating the case in support of his larger philosophical project. Eliade relied on numerous sources, but not all were of high quality, and he did not spend any time in field studies. Instead Eliade spent his life trying to uncover the nature of religious consciousness. In shamanism, he saw direct apprehension of the sacred. He believed

the pure and continual revelation of the sacred had been dissipated and removed from direct experience by the institutionalization of the historical world religions. In shamanism, it had not. For this reason, Eliade and some scholars who have used his theories in their own works are criticized for romantic primitivism, the projection of an idealized simpler and more sacred way of life onto a people deemed more pure and primitive.

Some scholars, like Kehoe (2000), question whether the concept of shamanism is anything but a Western construction of a stereotyped “other.” This school of thought limits the study of shamanism to the Siberian practitioners from whom the term was derived. More commonly, scholars replace a universalist concept with the idea of *shamanisms* or use the adjective *shamanistic*. But the category of shamanism is still widely used.

The Shamanic Worldview

Most contemporary scholars of shamanism acknowledge that while there is considerable variation in practices and beliefs among cultures that contain shamanism, there are several core theoretical elements in the shamanic complex that are shared. First and foremost is a belief in the spiritual, or noncorporeal, worlds. Not only are the spiritual worlds real—they are populated. Human beings can communicate and interact with these spirit beings.

There is also a particular understanding of the composition of a human being. All people have at least one *free* or *separable* soul; that is, a person is not contained within her body but has an aspect that can travel in the noncorporeal worlds. This ability to travel in the spiritual worlds enables shamans to be mediators between the spirits and their communities. This understanding of the body as a host for a separable soul or souls is also behind the theories of the illnesses that shamans cure.

Other beings, including animals, plants, and natural phenomena, also have separable souls. Therefore, all beings are conscious or are linked to a spirit in the spirit world; it is important for communities to maintain harmonious relations with these other beings so that the spirits are not motivated to harm them.

Societies with shamanism often observe an annual rite of renewal. Frequently, a pole or tree symbol unites the upper, middle, and lower worlds. Sometimes rivers flow into the spirit worlds, or special holes with ladders make the connection. Regardless of these differences, there is some symbolism linking the physical world and the spiritual worlds, and this “geography” is used by shamans to move between the worlds. For the shaman, this geography is not metaphoric but experiential.

The relationship of the shaman to his spirits is central to this worldview. The shaman demonstrates mastery in relation to the spirit helpers. Typically, one spirit plays a special role with the shaman. Often it is the first spirit the shaman

works with and is sometimes called a tutelary, guardian, or familiar spirit. This spirit teaches the shaman-to-be about the spiritual worlds and helps her master other spirits. Spirits often have areas of expertise or particular personality traits, and the shaman's powers are related to the number and qualities of the spirits mastered. These spirits may take on multiple forms, including animal forms.

The shaman's relationship with the tutelary or familiar spirit is different from the relationship with other spirits, sometimes a type of marriage. This main spirit may be an ancestor who was a shaman or the spirit of a recently deceased shaman. In some traditions, the shaman may merge with this spirit, enabling the shaman to shape-shift in the spiritual worlds and enabling the spirit to act through a corporeal body.

Spirits perform numerous roles for the shaman. They teach. They deliver messages and inspire. They travel and gather information. They assist the shaman in journeys in the spiritual worlds. They may possess the shaman in order to act in the physical world. They assist with healing.

The Shamanic Vocation

The shamanic call, or vocation, is one of the most analyzed aspects of shamanism. The literature usually discusses the spontaneous call, but in various cultures people choose the vocation.

In Siberian shamanism and elsewhere, the calling is involuntary and spontaneous. The shaman-to-be experiences uncontrolled altered states of consciousness in which he is possessed or tormented by spirits demanding that the candidate learn to shamanize. This state, sometimes called the *shamanic sickness*, was widely analyzed in terms of a type of hysterical psychopathology that, through the process of learning to shamanize, does not lead to mental illness. Common symptoms include lethargy, erratic behavior, shaking, uncontrollable weeping, or significant physical illness. Seeking solitude in culturally abnormal ways (e.g., running away to live in the wild with animals for a period of time) may be a symptom. The spontaneous calling frequently occurs at the transition to sexual maturity, although for women it may be as they are passing out of their child-bearing years.

The psychological state of the candidate includes unsolicited and often unpleasant or frightening contact with spirits. The shaman-to-be may have visions and dreams, but these are fragmented and not controlled. Although not universal, experiences of being killed and resurrected by spirits while in an altered state of consciousness are common. At some point, the candidate accepts the call to become a shaman and starts learning to shamanize. Often this acceptance is accompanied by a belief that it would be fatal to resist.

From the emic perspective, the candidate receives training from two sources. First, the shaman is trained in an

altered state of consciousness by the spirits who called the candidate. Second, the candidate begins training with an elder shaman, learning techniques and culturally specific aspects of the worldview. Through this process, the new shaman gains control over the altered states of consciousness, entering and leaving them at will. The new shaman also masters the knowledge and techniques essential for the societal role. Through this training and communal service, the shaman is recognized by the community as being a shaman. The assessment of whether an individual is a real shaman and the strength of the shaman's reputation is in the hands of those served, based on whether the work is deemed effective. The community, including other shamans, also judges whether the shaman's work is benevolent or malevolent. The initiatory levels or structures vary, but the ability of shamans to continue to gain supernatural power and corresponding prestige continues throughout their career.

The classic model of shamanic vocation is involuntary and spontaneous. This does not necessarily conflict with the fact that it is quasihereditary in many cultures. Often families are known to produce shamans. In those families, specific individuals are not predetermined to be shamans, but it is likely that someone will have the shamanic illness. More unusually, there are cultures in which candidates wishing to be shamans seek apprenticeship with experienced shamans without a spontaneous vocation.

The Shaman and Altered States of Consciousness

The aspect of shamanism that has generated the most discussion concerns the shaman's ability to enter a normal state of consciousness. This section explores the characteristics of these altered states, the techniques used to induce them, and the significant explanatory theories. The terms in the literature vary. Early studies often used words that pathologized these states of consciousness—*hallucination* or *fantasy*. Eliade used the term *ecstasy*, which many others adopted. Unfortunately, ecstasy has a connotation of emotional excess in contemporary English. Later, to be more objective, scholars used *trance* or *altered state of consciousness* (ASC). Michael Harner (1980) postulated a specific shamanic state of consciousness, yet for the purposes of this chapter, ASC and trance refer to the state of consciousness experienced by shamans during their work.

Characteristics of Shamanic Altered States of Consciousness

There are two types of ASC in shamanism. The first, sometimes called the soul journey, is most often referred to as *magical flight*. The second is spirit possession.

Magical Flight

From the emic perspective, the magical flight is the travel of the shaman to the world of the spirits. The magical flight is a controlled visionary state and is strongly lucid and powerfully multisensory. The shaman in this state of consciousness believes these experiences to be as real as those experienced in the physical world during ordinary consciousness. The shaman is in control throughout. The magical flight has three phases: the journey to the spirit world, the experiences within the spirit world, and the return to the physical world. The shaman believes the experiences to be objectively real. However, shamans can distinguish between the spirit world and the physical world.

The shamanic spirit flights, from the perspective of the audience, appear very active. Shamans may speak as or embody the spirits, or make reference to them in dance or through the use of culturally shared symbols. They may describe what is happening on the journey or enact it. There is communicative interplay between the shaman and the audience during the séance. At the end, the shaman may give a fuller account of her adventures in the spirit world.

Spirit Possession

Although some scholars believe that spirit possession is not shamanic, many do identify a possession type of shamanism. In reality, shamans in most cultures perform both types of ASC. A shamanic-possession ASC may be distinguished from a mediumistic ASC by the fact that the shaman controls his possession. In this type of ASC, the shaman initiates the possession, allowing a spirit to use his body, and determines the duration of the possession. Sometimes a spirit may speak through the shaman, although in some cases the spirits enlighten the shaman who then conveys the information to the audience.

One area of inconsistency is whether the shaman remembers the possession trance. This seems to be largely a function of cultural expectations concerning the nature of possession. If the cultural theory is that the soul of a possessed shaman is no longer in the body, then the legitimacy of the possession is partly established by the fact that the shaman does not remember the trance. Numerous studies attest that in such societies, if pushed, the shamans usually remember. Possession type trances are more common among shamans who occupy oppressed positions within a society, particularly among women shamans in male-dominated societies. The putative amnesia functions to protect the female mediums from retribution. This calls into question whether or not the memory loss is feigned. In cases of spirit possession, as with magical flight, there is interactive communication between the shaman and the audience during the séance.

Depth of the Altered State of Consciousness

In both types of ASC, the shaman may be in a deep or a light trance. In the deeper state, she may appear to be

comatose, even if full memory is retained afterward. In a lighter state of trance, the shaman may appear to be in an ordinary state of consciousness, but believes she is communicating with spirits. In the course of a séance, there is often a rhythm in which the shaman moves into deeper and lighter states of the ASC. It is usually not a steady state.

Techniques for Inducing Altered States of Consciousness

Although the methods for inducing the shamanic ASC are culturally specific, there are some common means by which these states are achieved. A particular culture may use multiple methods in combination, even within the context of a single séance.

Music

Many cultures employ types of music, and sometimes dancing, to induce trance. The instruments are often believed to be independent beings. Siberian shamans speak of riding the spirit of their drum to the other worlds. Rouget (1980/1990), a musicologist, studied the types of music in various cultures that lead to an ASC. Musically, there were no common elements that could explain the trance-inducing properties. He concluded that in each culture the specific type of music that induces trance is identified as such and used within those contexts, and there is an expectation that it will produce an ASC. He proposed that the expectation creates the ASC.

Psychopharmacological Methods of Trance Induction

Some cultures use hallucinogenic substances to induce the ASC. The use of hallucinogens is most prominent among shamans in Central and South America but is found in other traditions. For example, Siberian shamans sometimes use the *fly agaric* mushroom to induce an ASC.

In many traditions using hallucinogenic plants, the plant ingested is understood as the body of a being that exists in the spirit world. This being is frequently met in the ASC and may act as a spirit helper. For example, the serpents encountered in ASC induced by *ayahuasca* are believed to be the spirit of the vine itself. These plants may be interpreted as “teachers.”

Meditative Techniques

Not all techniques for entering an ASC are as externally obvious or performative as those that use music or hallucinogens. Some shamans enter an ASC by quietly using internal imagery and contemplation. These methods may utilize sensory deprivation. As with all forms of shamanic trance, the shaman remains in control of the state of consciousness. These techniques are common in many North American tribes and, because of the quiet internal nature of

the induction and the degree of lucidity, have sometimes been overlooked by researchers who did not realize the shaman was in an ASC. The significant difference between a shamanic trance induced by meditative techniques and one induced by meditation is that shamanic ASC is intended to enable shamanic work, which requires interaction with others. The goal of meditation is usually to achieve a state of absorption in which awareness of the outer world ceases.

Explanatory Theories

Scholars have advanced numerous theories about the shamanic ASC. There is no consensus about any of the theories.

Acceptance of the Emic Theories

Anthropology uses participant observation. In the course of research, some scholars have both undergone shamanic initiations and arrived at the conclusion that the emic theories about the shamanic ASC are correct. The most influential is Michael Harner (1980). From the emic perspective, there are legitimate, nonrational epistemologies that reveal the real, although noncorporeal, spirits and spirit worlds. Scholars convinced of the reality of the emic perspective believe that the other scholarly explanations are reductionistic and are modern Western overlays that reinforce the hegemony of Western materialism. Critics of those who accept the emic perspective call attention to the requirement in the scientific method that anyone be able to replicate the experiment. They are unwilling to accept the testimony of the anthropologists who had shamanic experiences in the course of their fieldwork. The rejoinder is that anyone who is willing to take the time and go through the arduous training to become a shaman can have such experiences. If, upon doing so, their testimony is automatically discounted by those who have not done the training, then the argument is circular and biased. If, on the other hand, a candidate who goes through the training and does not have shamanic experiences is always interpreted as being insufficiently prepared, then the argument becomes circular on the other side.

Insanity

Although not currently accepted, the theory that the shamanic ASC is the result of insanity has a long history. Most commonly, the shaman's claim to see and talk to spirits that others could not see was interpreted as a type of schizophrenia.

Drug-Induced Visions

The use of hallucinogenic substances yields a variety of explanatory theories. For some, the use of hallucinogens is interpreted through a purely materialist lens involving

delusions that arise from manipulations in brain chemistry. On the other side of the spectrum, some of the strongest advocates of the emic perspective come out of traditions that used psychoactive substances to induce the ASC and see the physical changes as only one part of the experience.

Cultivation of the Imaginative Faculties

Noll (1985) analyzed shamanic training in terms of cultivating both the vividness and controlledness of visions. In the training process, the master shaman helps the apprentice develop high-imaginative vividness by systematically reinforcing those aspects of the apprentice's experiential reports that are highly sensory. In this theory, the contact with spirits is understood as an increase in the vividness of the imaginative faculties, and mastery of the spirits is an increase in how well the visions are controlled. This theory is ontologically neutral. It does explain the shamanic ASC through the active use of imagination, but it makes no claim about whether or not imaginative experiences are also real.

Role-Taking Techniques

This theory emphasizes the shaman's understanding of his or her role, the expectations that go with it, and the community's understanding and expectations of the shaman's role. The ASC is interpreted symbolically and is determined by the cultural construction of the nature of the spirits and appropriate relationships with them. The shaman embodies this cultural script. This theory does not deny that there are psychological effects on the performer, but the emphasis is on the social role. What is particularly significant is the importance of the shaman's body as a symbol. The shaman embodies, through his performance, the interaction with the spirits or the struggle of a sick person toward healing. Shamanic experiences are a type of performance art. It is not to be inferred that the shaman is performing without belief. In this way, it is different than theater. Much as with self-hypnosis, the expectation of what should happen allows the expectations to be met. This theory can be combined with other theories.

The Work of the Shaman in the Community

The shaman's ASC is not an end in itself. The purpose is to work on behalf of the community. Shamans may have specialties and may not perform every function, but generally shamans work as healers, perform divination, serve as psychopomps, and facilitate hunting. The shaman maintains harmonious relations between the community and the spirit world and may fulfill other duties to this end, such as serving as a sacrificial priest.

The Shaman as Healer

Arguably the most central and universal role of the shaman is as a healer. Within the shamanic worldview, disease has two origins, both related to the separable soul. The first is when the soul or a part of the soul is separated from the body, creating *soul loss*. The second occurs when some foreign element from the spirit world is introduced into the body. This object is typically conceived as having a consciousness of its own and an independent existence in the spirit world. This type of sickness is called *intrusion*. Sometimes the two combine in a form of possession in which an entity from the spirit world occupies the body to the extent that the separable soul of the patient is forced out.

During the course of the cure, the shaman may use either magical flight or lucid possession. In many instances, the shaman may move back and forth between modalities in the course of a *séance*.

Soul Loss

The possibility of soul loss is implied in the separable soul theory. Causes are often attributed to psychological reasons, such as fright, grief, social stress, difficulties in adjusting to life transitions such as puberty, and so forth. In these cases, the psychological tension of the patient is strong enough that a part of the soul becomes severed from the body. In other cases, the putative cause of soul loss is supernatural. The patient's soul was stolen and often imprisoned by a spirit. The soul might be taken by a lonely ghost, or it might be in retribution for either some ill the patient has caused in the spirit world, such as violating an ancestral taboo or trespassing into forbidden territory, or in response to something the whole community did that disrupted right relations with the spirit world.

The shaman's work in healing a patient of soul loss is twofold. First, the shaman diagnoses the cause of illness and locates the missing part of the soul. The shaman may journey into the spirit world or send spirit allies to investigate. Once the soul is located, the shaman and spirit allies travel to retrieve the patient's soul, often engaging in supernatural battles to win it back. The healing *séance* is typically a highly dramatic affair, attended by the shaman, the patient, family, friends, and other members of the community. It is extremely interactive, with the shaman acting out what is happening in the spirit world and showing, through her body, the struggle for the soul of the patient. The shaman employs many of the methods of theater, including special costumes, lighting, sound effects, and what could be considered "special effects." Sometimes there are physical interactions with the patient's body, including blowing part of the soul back in, or touching the body with special objects to call the soul back. The audience—including the patient—participates, supporting the shaman and actively demonstrating their concern for the patient's well-being. These theatrical healing sessions powerfully dramatize the community support for the patient's healing and are emotionally stirring events.

Intrusion

In sicknesses caused by intrusion, the explanation is that something has become lodged in the patient's body that does not belong there. This foreign entity also exists in the spirit world and must be removed from there as well. There are similarities between this type of healing *séance* and the type used for soul loss. Both are theatrical and involve not only the healer and patient, but also an audience. Both call on the spirits and use dramatic effects. In curing intrusion, the shaman identifies what is in the patient that should not be, where it is located, and how it got there. The latter is particularly important if the intrusion was sent by a magical practitioner using baneful magic, or from a spirit in retribution for some slight.

Once the intrusion is identified, it is removed. Methods vary, but some frequent motifs include sucking the intrusion out, blowing it away, sweeping it away, cutting it out in the spirit world, or convincing it to leave the patient's body. The *séance* is interactive. In some cultures, it is common for the shaman to produce some physical object at the end of the *séance* that is claimed to come from the patient's body. Early scholars used these sleight-of-hand performances in which the shaman produces an object as evidence of their charlatanry. Later scholars who asked shamans about this use of special effects discovered that, from an emic perspective, the shaman understands the real object to have been removed in the spirit world and does not see a conflict between that and theatrically producing an object to reassure the patient.

Support for the Cure

Once the *séance* is over, there is usually a dramatic change in the state of the patient, who soon recovers or dies. During the *séance*, the shaman may receive guidance about activities to perform afterward. These may include prescriptions for native medications. These remedies, especially if they are from particular plants, are often understood as spirit allies who assist the healing. The patient, the family, or the whole community may perform propitiation or protection rites, especially if the illness was diagnosed as spirit-inflicted. Increasingly, there may be a referral to Western medicine for a particular treatment.

Explanations for Efficacy

The efficacy of shamanic healing has been demonstrated repeatedly. Medical anthropologists and ethnobotanists have evaluated some native remedies. Most explanatory theories focus on similarities between shamanistic cures and psychotherapy, prompting some scholars to call shamans psychologists. In the course of the cure, the patient's state is externalized through the drama of the *séance* within a context of overt social support and care, and catharsis is achieved. The patient, by virtue of his belief in the cure, has an expectation of full recovery.

Scholars have suggested that this creates a placebo effect. The difficulty is that, far from being truly explanatory, this takes us into domains that remain inexplicable. The placebo effect is one of the greatest mysteries of medicine. Why should a powerful conviction that one is cured produce a cure? Why is catharsis healing? How do mental states cause disease and why can changing a mental state eliminate disease? Why does the demonstration of communal support affect an individual's physical health? These are all questions that deserve further research, and the dynamics of shamanistic healing is one arena in which they can be approached.

The Shaman as Divine Solicitor

Shamans may use their skills to gather information, for example, to find lost or stolen objects, find lost people, locate game, investigate conditions in a distant location, or uncover the causes of some ill that an individual or the community faces. Again, shamans may go into the spirit world to find answers, send spirit helpers to find answers, or allow a spirit to use their body to communicate the answer in a possession-style séance. The etic explanations for the shaman's success in divination typically posit that shamans are skilled observers of both individuals and nature, that the séances are interactive with the shamans soliciting answers to questions, and that the shamans make wise guesses based on their deep knowledge. Depending on the nature of what is discovered, the shamans may prescribe certain activities to restore right relations with the spirit world.

The Shaman as Psychopomp

A *psychopomp* is a guide for the souls of the dead. This role arises from the separable soul theory. If a soul can exist and travel outside the body, then at death it enters the spirit world. However, since a soul can get lost, the soul of the dead may not know where to go. In many cultures with the separable soul theory, there is fear that the soul of the dead will remain around what is familiar to it, causing problems for the soul of the dead person and danger for the living.

Shamans play a unique role because they can move in and out of the spirit world at will and know its terrain. Therefore, shamans have the responsibility of ensuring the right relationship between the spirits and the community. The shaman must lead the soul of the newly dead person to where it is supposed to be. Through the dramatic enactment of the psychopomp journey, the shaman reassures the community of its safety from the dead and provides comfort to the grieving who witness, through the performance, that their loved one, although dead, is fine.

The Shaman as Facilitator for Hunting

Some scholars restrict the use of the term *shaman* to hunting societies. Facilitating hunting is an important role. Shamans often divine the location of herds. The animals are

conceptualized as being under the protection of spirit beings who must be consulted and propitiated. Part of the shaman's work is to contact the game-giving spirits and convince them to agree to sacrifice the animals without threat of retribution.

The Shaman as Keeper of Harmonious Relations With the Spirit World

Virtually all the shaman's work involves maintaining or restoring harmonious relations with the spirit world. In the course of uncovering the cause of illness or some other blight upon the community, the shaman may recommend rites to restore harmonious relations. If this is the case, then the shaman may preside as a sacrificial priest. The shaman may also proactively ensure right relations through regular rites of care, feeding, and direct contact with the spirits on behalf of the community.

Neoshamanism

Neoshamanism has a unique, and sometimes uncomfortable, relationship with anthropology. Neoshamanism is a spiritual movement in the contemporary West in which practitioners—typically belonging to a network of like-minded people—believe they are practicing shamanism. Neoshamanism can be considered a subset of neopaganism, both of which are flourishing in the cultures where they are found.

A significant inspiration for neoshamanism is the ethnographic record. Some anthropologists, such as Michael Harner, actively contribute to the development of neoshamanism. Harner's *Way of the Shaman* (1980) posits the theory of "core shamanism," derived from his research. The idea is that the culturally specific content in shamanic practices can be stripped away to reveal a culturally neutral "core" that can be learned by any person in any culture from any religious background. His book, his workshops, and the method that is taught by his Foundation for Shamanic Studies are intended to help modern Westerners become shamans. The proponents of core shamanism emphasize presumably safe methods and eschew the use of hallucinogens.

Additionally, some groups teach neoshamanic traditions borrowed from existing cultures. Cultural insensitivity and gross commercialization of the sacred traditions of oppressed peoples is a decided risk. Many anthropologists are concerned that their ethnographic work may be used in ways that violate their professional ethics. Other groups attempt to reconstruct cultural traditions of the past, such as Celtic shamanism. Although these groups are not ethically problematic like some that borrow from existing cultures, the popular authors and teachers often make historical claims that are insufficiently rigorous to satisfy most academics.

Among the few ethnographic studies of neoshamanism, Jakobsen's (1999) work is a stellar exception. This study explores the similarities and differences between traditional shamans of Greenland and contemporary neoshamans

from Denmark and England. A significant difference is that neoshamanism is primarily individualistic. The neoshaman's relationship with the spirits typically concerns the spiritual path of the individual, rather than functioning within a particular role for the sake of the community. Another distinction is that the spirits are not mastered in neoshamanism and they are not threatening. They are transformed into benevolent spiritual guides. Neoshamanism democratizes shamanism, in that every person can become a shaman by putting forth effort; this is quite different from traditional shamanism, where the shaman-to-be is chosen, often unwillingly, by the spirits. Jakobsen concludes that neoshamanism responds to stress caused by having spiritual experiences in an increasingly materialistic and desecralized society that provides no basis for understanding these experiences.

Future Directions

This chapter discussed shamanism in broad strokes. While most material on shamanism is part of the ethnographic record, the ethnographies that cover shamanic practices often are old and the communities have changed dramatically. It would then be worthwhile to repeat the studies from the past, track any changes, and investigate reasons for them. More thorough explorations of shamanism's interactions with gender, social hierarchy, and other categories of difference would be useful.

Another future possibility is to explore syncretism between shamanic and other traditions. An intriguing syncretism exists between shamanic healing techniques and modern Western medicine, both in the West, where shamanic-style healing has become a form of complementary medicine, and in traditional societies that now have access to Western medicine.

Ethnographic studies of neoshamans should yield interesting insights into the construction of meaning in Western societies. It might be particularly enlightening to investigate how practitioners reconcile the epistemologies of shamanism with the epistemologies of the dominant society in which they live.

The placebo effect and the mind-body connection in health and healing are among the greatest unsolved medical mysteries. Shamanic healing séances provide a context where these topics can be investigated. Continued research in medical anthropology and ethnobotany is also needed, especially in endangered ecosystems.

Finally, an exploration of shamanic epistemologies from a philosophical perspective would be fascinating. The shamanic worldview claims that there are nonrational ways of knowing that yield true information, yet there has not been a systematic attempt to uncover the rules of shamanic epistemologies. Shamanic traditions provide potentially powerful case studies for exploring nonrational epistemologies.

WITCHCRAFT AND SORCERY

JACKY VALLÉE

Vanier College, Montreal

The belief that some individuals have supernatural powers allowing them to harm others is present in many societies around the world. Regardless of whether these individuals are said to use psychic power or magic to do their work, whether they do harm intentionally or not, or whether they are born with these powers or have to learn them, they are often feared or reviled by members of their societies—embodying traits that are defined as immoral or evil according to local cultural norms. Based on ethnographic fieldwork over the past century, social and cultural anthropologists have described witchcraft and sorcery beliefs, and the practices associated with them, in various societies around the world. With this, they have examined cross-cultural patterns in what are seen as the causes of witchcraft, the characteristics and actions of witches, actions that can be taken against witches, and patterns of accusation. This has allowed anthropologists to elaborate various theoretical models explaining the existence of witchcraft and sorcery beliefs, as well as the mechanisms by which people deal with the results of these practices.

Anthropologists are interested in witchcraft and sorcery beliefs because they constitute an important part of the worldviews of many peoples. As such, these beliefs and practices are an essential component in understanding the total cultural contexts within which they are located, as well as in understanding the means by which humans create explanatory schemes for the world around them.

Terminology

Anthropologists apply the terms *witchcraft* and *sorcery* to concepts in various cultural groups, referring to practices that involve the manipulation of supernatural forces or energy to malicious or evil ends, such as physical harm or misfortune. Although the two terms are often used interchangeably in Western popular culture and in lay conversation, anthropologists have tended to distinguish between the two practices. The term *witchcraft* usually applies when the ability to do harm is innate and when the manipulation of supernatural energy is done primarily through the power of one's mind. Sorcery, on the other hand, is often used for practices that are learned and require the magical use of special equipment such as tools, herbs, and potions. However, this distinction is not always applicable. Indeed, Victor Turner (1967), an anthropologist of note, pointed out that this distinction was elaborated by E. E. Evans-Pritchard (1937) with specific reference to the Azande of Sudan with no intention to apply it across cultures. Nevertheless, the terms have retained this particular usage in much of the anthropological literature on the topic, although they are sometimes used interchangeably. In this entry, the terms used by the authors of the works consulted are maintained, regardless of the degree to which they correspond to their respective usage in the model described above. In general discussions that do not refer to specific examples, witchcraft inclusively refers to both witchcraft and sorcery.

Another important distinction is the one between the anthropological use of the terms *witchcraft* and *sorcery* and the way the terms are used in Western popular culture. The general understanding of the term in the West stems largely from films and literature that draw from Christian conceptions of witchcraft. Anthropologists apply the terms in reference to culturally specific practices that often have little to do with the European and Euro-North American understanding of what witches and sorcerers actually do. It is also important to clarify that societies with belief systems that include the practice of witchcraft or sorcery have their own terms for these practices and the people who are said to employ them.

Finally, it is important to clarify that the traditional anthropological definition of witchcraft as described here does not take account of the neopagan practice of witchcraft, or Wicca. Wiccan witches perceive witchcraft as a spiritual practice with beneficial outcomes, rather than as a practice driven by malicious intent.

Ethnographic Case Studies

The following case studies, based on ethnographies and historical studies, provide an overview of beliefs and practices related to witchcraft in various societies. It is important to note, however, that there can be as many differences as there are similarities between neighboring groups. Therefore, these case studies should not be taken as representative of witchcraft beliefs and practices in their entire region. Rather, they should be read as examples among many others.

These case studies provide a brief description of cultural behaviors and are therefore useful in seeing how witchcraft belief systems operate in various societies. The sources of this information, listed in the bibliography at the end of this entry, contain more complete descriptions of these systems, as well as their wider social, cultural, and historical contexts.

The Azande (Africa)

The most widely cited anthropological work on witchcraft is Evans-Pritchard's (1937) *Witchcraft, Oracles and Magic Among the Azande*. Evans-Pritchard conducted ethnographic fieldwork among the Azande (singular: Zande), an indigenous African society, in the 1920s. The Azande occupied a territory referred to as Zandeland, on the Nile-Congo divide. Evans-Pritchard conducted his work in the portion of Zandeland that extended into Sudan.

According to the Azande, witchcraft, or *mangu*, had a physical cause. Some individuals were born with "witchcraft-substance," also named *mangu*. This substance caused the individuals that carried it to have powers that could be used to cause harm to others. *Mangu* was transmitted from mother to daughter and from father to son,

grew with the rest of an individual's body during his lifetime, and could be found during autopsies. Indeed, definitive proof that someone was a witch could only be obtained after death. Moreover, accused individuals could claim their innocence by pointing to the fact that none of their close deceased relatives of the same sex were found to carry *mangu*.

More immediately visible indicators that would lead people to suspect someone of being a witch were found in personalities and behaviors. Bitterness, spitefulness, greed, and an ill temper were all mentioned as signs that someone was a witch. Furthermore, habits perceived by the Azande as dirty or disturbing, such as urinating in public, eating without washing one's hands, or insulting and cursing others, were read as signs that an individual was likely to perform witchcraft. Women and men were equally likely to be witches.

Although *mangu* was said to have a physical cause, its manifestation was through psychic means. Zande witches could cause harm without resorting to spells or charms. Through the power of their will, they would send forth *mbisimo mangu*, or the soul of witchcraft, from their bodies to their victim in order for it to eat the soul of their physical organs. In this way, after many psychic visits, witches would eventually kill their victims. These visits tended to occur at night, and the Azande claimed that a light could be seen in the sky along the path of the flying *mbisimo mangu*. However, witches could project this psychic power at any time. Interestingly, the Zande knowledge system posited that these powers could be active without the witch knowing. Moreover, an individual possessing *mangu* might not have used her powers at all.

Witches, according to the Azande, could cause various sorts of harm to other individuals. Physical harm, and even death, resulting from illness or accidents were major forms of harm that were considered to be results of witchcraft. Other common misfortunes included harm to their crops. As farming was their main livelihood, it stands to reason that crop failure could have dire consequences for a family.

A classic example of the way the Azande induced that witchcraft had occurred is the case of the fallen granary. Granaries were elevated structures, built on wooden posts, in which the Azande stored their grains. People would often sit underneath granaries to get some shade in the middle of the day. Because of the gradual work of termites, the granaries would occasionally fall. If this should happen while people were resting underneath, the obvious cause was witchcraft.

As with other misfortunes, the Azande knew that there were physical causes for this misfortune. For instance, they were aware of how termites operate, which is why they would inspect the posts on a regular basis and repair the structures as needed. Nevertheless, they also knew that witchcraft was the cause for the granary falling at that particular moment when there were people underneath. Witchcraft on one or more of those individuals was the obvious cause. The falling granary, or any other physical cause

of misfortune, was merely a tool used by the witch to exercise harm on others. The actual result that needed explanation was the harm on a particular individual or group.

Although the effects of witchcraft constituted a prominent threat to safety and livelihood for the Azande, they were not helpless before its effects. Indeed, there were a series of actions that could be taken to determine whether witchcraft was the real cause of an event, and then to determine the identity of the witch. The Azande had recourse to various modes of divination to answer these questions, some of which were available to all individuals and some which required the intervention of a specialist. Evans-Pritchard described Azande oracles in detail in his ethnography.

Once a specialist determined the identity of a witch, a relative of a victim of witchcraft could ask a person in authority, such as a prince or deputy, to confront the witch. They would provide the prince or deputy with the wing of a fowl that they had killed in the witch's name. That person would then bring the wing to the accused. Generally, since the Zande system included a belief that these powers could be active without knowledge or intent, the accused would claim that they were unaware of the actions of the *mangu*. The accused would also state their good intentions toward the victim, take water in their mouths, and blow it on the wing as a sign of good will. However, a witch found guilty of causing death could be expected to give some form of compensation. If one had caused multiple deaths, this individual could be subject either to formal persecution or vengeance magic.

The Diné (North America)

Another well-documented example of a witchcraft belief was found among the Diné, or Navajo, of the southwestern United States. Clyde Kluckhohn (1967), in the course of ethnographic fieldwork among the Diné in the 1930s through the 1950s, was able to collect data on witchcraft beliefs in this area in spite of the reluctance of many Diné to discuss this topic with non-Diné. He described the results of his research on this topic in *Navaho Witchcraft*.

The Diné described different types of witchcraft, each with its own Diné name. Kluckhohn used the terms *witchcraft*, *wizardry*, *sorcery*, and *frenzy witchcraft* to differentiate between them. However, witchcraft is used in this chapter to include all these forms of what the Diné considered to be evil magic.

Among the Diné, witchcraft was something that was obtained or learned, usually from relatives. Diné accounts point to the murder of a sibling as part of the initiation that allowed the novice witch to learn and acquire powers. Both males and females could be witches, but more male than female witches were reported. The Diné attributed greed, as well as other traits considered as antisocial, such as vengeance or envy, as major characteristics of witches. They met together to practice immoral acts such as incest, cannibalism, and necrophilia. In short, witches displayed

traits and behaviors that went against the core values of the Diné, which were balance, harmony, and equal access to material resources.

Diné witches were said to take on various animal forms, such as wolves, coyotes, or sheep. Consequently, they could be seen fleeing homesteads at extreme speeds and frequently left tracks, allowing people to find them. Evidence of someone's identity as a witch could be found in a wound that matched one inflicted upon an animal thought to be a witch in disguise.

The actions of witches ranged from grave robbery to causing illness or death. In many cases, witches were said to act on their greed to accumulate wealth. Two witches could enter a partnership in which one witch would cause an illness and the other would offer the victim a cure for a fee. Greed as a common characteristic of witches reflects the social pressure against the accumulation of wealth among the Diné at the time of Kluckhohn's study. Indeed, sharing was an important social norm, and the acquisition of wealth constituted grounds for witchcraft accusations.

The Diné believed that witches harmed their victims through various means. One primary technique was the use of *corpse poison*, a powder made from the flesh of human corpses. Witches were said to introduce this powder into the mouths or noses of their sleeping victims, for example. Other techniques included burying of items belonging to the victim—such as nail clippings, feces, hair, or body dirt—with corpse poison and chanting spells over them; the insertion of small pieces of human bone into the victim through magic; and the use of narcotic plants. Effects of witchcraft included intense pain, seizures, emaciation, and illnesses leading to death.

The Diné had some means to prevent the work of witches. Since witches were thought to work at night, people would avoid walking around alone after sunset. Also, it was usual for people to hide personal material that could be used by witches, such as nail and hair clippings. There was also knowledge of some plants that could offer some protection. In addition, individuals with ceremonial knowledge were seen as strong enough to withstand the actions of witches against them. Curing ceremonies, which were typically held in cases of illness, would include additional elements that would turn witchcraft back against a witch in the case of witchcraft-induced illnesses. A witch who was targeted by a curing ceremony or made to confess was said to die by magical means. Alternately, individuals accused of witchcraft were sometimes put to death if they were captured but refused to confess. Finally, witches who remained uncaptured were assumed to eventually be killed by lightning.

Among the Diné, witchcraft was not automatically assumed in the case of illness. The primary causes of illness were seen as transgression of the norms that enabled individuals to live a harmonious life and to maintain order in the universe. Indeed, the central tenet of Diné life was the maintenance of order. This was accomplished by

observing a number of taboos concerning food, work, and social interactions. Failing to observe these norms could lead to punishment by the *Holy People*, the Diné deities, in the form of illness. Another common cause of illness was the action of ghosts. However, if an illness seemed mysterious or persisted despite the usual curing techniques, witchcraft was considered to be the most likely cause.

The Burmese (South Asia)

In the early 1960s, Melford E. Spiro (1967) conducted fieldwork in Burma. While he concentrated on small villages, he gathered data in cities such as Mandalay and Rangoon. Spiro noted that the spiritual system of the Burmese was colored by both Buddhism and the indigenous folk religions based on animism.

Spiro's research brought to light the existence of a gender division in terms of the types of witchcraft that were practiced. Female witches, or *souns*, were said to be much more numerous but less powerful than male witches. Souns usually acted within their own village. Their actions were known to be based on spite, malice, and sexual jealousy. Spiro's informants claimed that they could identify souns by the dimness of their eyeballs and the inverted reflection in their pupils when they looked directly at another. For this reason, they claimed, *souns* would avoid looking directly at other people.

Some souns were born with the ability to cause harm because of bad karma, while others learned their abilities from ghosts and other malevolent supernatural beings. Those who were born with powers were considered stronger. Thus the illnesses that they caused were fatal since they were immune to the actions of exorcists. Souns who were born that way could also perform other feats such as flying, transforming into animals, and animating inanimate objects. Both kinds of souns ate human feces.

The Burmese, according to Spiro, identified four primary techniques, all involving some form of food poisoning, that souns used to cause illness. A soun could offer a meal to a victim and then verbally curse the person; mix a foreign element such as a human hair or piece of leather into a person's food so that the element would multiply inside the person's stomach; transform feces into food and feed it to her victim; or poison a fish made from a palm frond by rubbing it against her vulva, which, like male genitals, was attributed with evil qualities. Souns also acted by cursing something associated with a person, such as hair, feces, or spittle, or by taking someone's soul when it left their body during a dream.

If souns acted out of personal spite, male witches, or *aulan hsayas*, usually acted on behalf of paying clients. However, they were still considered malicious. Unlike souns, *aulan hsayas* were found in other villages. The Burmese specified that it was impossible to identify one since they pretended to be moral and religious. The Burmese attributed greater power to the *aulan hsayas*, who

were not born with their powers but had to learn them. These practitioners caused harm by coercing ghosts and other evil beings into doing their bidding.

The Burmese employed some means of protection against witchcraft, such as leaving food outside the house at night to placate a witch who was thought to be lingering in the area, wearing amulets, or practicing Buddhism. Practicing Buddhism was said to render one immune to the effects of witchcraft, while exorcism was used to cure people who were ill as a result of witchcraft. In the case of death caused by witchcraft, the witch became a target of retaliation by magic or legal punishment.

Witchcraft Beliefs in the Western World

In mainstream Western culture today, witchcraft beliefs are largely perceived as superstition, and the media-driven image of the female witch with the green face, the black pointed hat, and the broomstick is predominantly found at Halloween, when children dress as various supernatural figures to collect candy from neighborhood households. Historically, Western witchcraft beliefs are commonly associated with intense periods of witch trials in Europe and New England. Furthermore, there is a growing movement of people who practice a neopagan religion called Wicca, mentioned earlier. Wicca practitioners have reclaimed the term *witchcraft* and associate it with the use of magic for beneficial purposes.

European and American Witch Trials

Although European beliefs in witches began far earlier than the time of the famous European witch craze starting in the 1400s, this period of time is renowned in the West for the intensity of witch hunting and persecution. Rebecca L. Stein and Philip L. Stein (2005) point out that, in medieval times preceding the witch craze, witches and other heretics were occasionally brought to trial due to accusations by individuals. However, in the 1200s, the Franciscan and Dominican orders began seeking out witches by holding inquisitions. Very few accusations led to executions in these early inquisitions—the goal was to allow the accused to confess and repent.

In the 1400s, Heinrich Kramer and James Sprenger, two inquisitors of the Dominican order, wrote an influential book called the *Malleus Maleficarum* (*Hammer Against Witches*) in which they described the characteristics and behaviors of witches. Witches were characterized as extreme heretics. Not only did they renounce Catholic ideology; they signed pacts with Satan, offering him their service in exchange for the power to work evil magic that would cause economic misfortunes such as crop failures as well as illness and death, often among infants. Witches could cause harm with the mere power of their gazes. They could also place evil charms in someone's property to cause harm.

Women, especially those without social support such as widows, were the most likely candidates for witchcraft, according to church authorities and reinforced by Kramer and Sprenger. Described as less intelligent and more likely to succumb to Satan's charms, they were said to have intercourse with him during their nighttime gatherings, to which they flew on broomsticks. They would also engage in orgies where they would kill infants as a sacrificial offering and practice cannibalism.

Throughout the two centuries that followed the end of the Middle Ages, the sanctioned inquisition of the Catholic church reached its peak. With this, witches were sought out in various regions of continental Europe. Innocence was nearly impossible to prove, and a mere accusation was enough to condemn a suspect. Extreme torture was used as a means of eliciting both confessions and further accusations. Whether or not suspected witches confessed, they were condemned to burning at the stake.

In the American colonies of the 1600s, the witch craze was a more localized phenomenon. The most well-known case is that of the Salem witch trials from 1692 to 1693, when girls and young women suffering from convulsions that the community's physician could not explain led to a series of dramatic witch trials. As a result of these trials, 19 people were executed by hanging. Stein and Stein point out that, as in England, tried witches were hung rather than burned. Burning was reserved for religious heretics and, in England and its American colonies, witchcraft was a civil offense even though witches were still said to engage in pacts with Satan.

John Putnam Demos (1983) demonstrates, however, that witchcraft beliefs and the resulting trials and accusations had been present in the decades leading up to the Salem witch craze. Witchcraft was an ongoing concern in New England communities such as Salem as part of a struggle between good and evil that was manifested in daily activities. Misfortunes ranging from capsized boats to beer going bad in the barrel were enough to lead people to ponder a potential case of witchcraft. Demos specifies, however, that these ponderings led to witchcraft accusations only if the victims could recall a recent conflict with specific individuals who were likely to engage in witchcraft. Therefore, there were no actual witch hunts, but witchcraft remained a plausible cause for misfortune.

Wicca

Practitioners of Wicca generally identify as witches. However, they describe witchcraft as a beneficial, rather than evil, practice. The word *witch* itself is often taken by Wiccans to derive from ancient English terms meaning "wise," and to be a witch signifies accessing wisdom relating to nature. Based on the works of Margaret Murray (1962) and Gerald Gardner (2004), many Wiccans see Wicca as a continuation of pagan beliefs and practices dating back to pre-Christian Europe. Persecuted by the church

during the period of inquisitions, pagan practitioners hid and continued to pass knowledge through the generations, resulting in their revival in the 20th century. Not all Wiccans adhere to this particular explanation for the origin of Wicca, however.

The Wiccan belief system is rather flexible and allows for the belief in many deities of the practitioner's choice. Some Wiccans believe in a single Goddess, others believe in a Goddess and a God, and others incorporate various deities taken from Roman, Greek, Norse, Egyptian, and other mythological systems. Many Wiccans also give special regard to the elements of earth, fire, water, air, and spirit, using the pentagram to represent these five elements. The cycle of birth, life, and death—often associated with an agricultural way of life such as that found among pagans in pre-Christian Europe—is important to the Wiccan ritual system, and eight yearly sabbats mark important times of the year.

Some Wiccans practice in solitude and base their belief and practice on their own blend of traditions whereas others practice in covens. Magic is an important element in the practice of most Wiccans. Magical rituals are performed to achieve good ends such as personal success in work or studies; the maintenance of good health; or simply a connection with deities, elements, and spirits. A common element of Wiccan belief is that one can do as one will, provided that it does not harm others. This, as well as variations on the threefold law, where both good and evil come back to the practitioner threefold, are incitements for Wiccans to practice good magic.

Theoretical Perspectives

As is the case with all cultural practices related to beliefs in the supernatural world, anthropologists are not concerned with proving or disproving the truth, validity, effectiveness, or morality of witchcraft and sorcery. Rather, anthropologists are interested in how various societies conceptualize these practices. Some of the goals of the anthropological study of witchcraft, sorcery, and other ritualistic activities are to examine how these practices tie in to a larger cultural framework and how beliefs related to these practices vary across societies and through time. This allows researchers to outline cross-cultural patterns and variation with respect to beliefs in the origins and causes of witchcraft and sorcery; ways people have to deal with effects of these practices; and connections to political, economic, and familial systems within a society. This also allows researchers to establish theories about why humans have these belief systems. Another goal of studying witchcraft and sorcery in a cross-cultural context is to increase our knowledge about how humans interpret their world and develop strategies for coping with the problems that occur as a part of human life. Anthropologists want to understand the benefits that human belief systems have for humans

and their societies. In brief, anthropologists are interested in *how* and *why* human societies have the types of belief systems and practices that they do.

Social and cultural anthropologists, as well as sociologists and psychologists, have utilized various theoretical models to explain the ubiquitous existence of beliefs in witchcraft and sorcery. As with theories regarding religious and spiritual beliefs and practices in general, these models are based on data gathered in ethnographic research. The models then attempt to make sense of these beliefs and related practices by locating them within wider social and cultural processes.

Many scholars working in the earlier part of the 20th century applied a functionalist approach in their analyses of witchcraft beliefs and other beliefs and practices pertaining to the supernatural. This enabled them to locate various ways in which these practices fulfill human needs such as understanding the world around them, alleviating anxiety in a world that is out of their control, forming community, and maintaining social norms.

One of the universal needs found among humans is the need to understand why bad things happen. Illness, threats to food sources, and other misfortunes may sometimes have apparent physical or environmental causes, but the existential question of “why this person or this group at this particular time” remains unanswerable. A functionalist analysis of witchcraft beliefs shows how these beliefs help fulfill this explanatory need. Evans-Pritchard’s (1937) case of the fallen granary among the Azande is a classic example. Rather than rely on the possibility of coincidence when a granary happened to fall when people were underneath, a belief in a specific cause such as witchcraft gave meaning to something that might otherwise have been meaningless.

Keith Thomas (1970), in his contribution to Mary Douglas’s (1970) volume titled *Witchcraft Confessions and Accusations*, argued that the explanatory function on its own is insufficient to support the existence of witchcraft beliefs. In the case of witchcraft beliefs in England from the 1500s to the 1700s, other supernatural causes for misfortune, such as punishment by God, were prevalent. If witchcraft was used as a frequent explanation, it was because a belief in witchcraft carries with it a course of action to which people can resort to prevent or reverse its effects. In societies where there are witchcraft and sorcery beliefs, there are usually corresponding practices devoted to protection from the effects of malevolent practitioners, divination to determine their identity, or practices to cure individuals who have been targets of their practice.

In societies such as the Diné, among many others, where witches or sorcerers could make use of things like human hair or nail clippings, the act of hiding these things was one such practice. Divination techniques such as those found among the Azande and rituals such as Burmese exorcism or Diné curing ceremonies are other examples. All of these practices enable people to assume control in

the face of the many misfortunes that can happen in all human societies and over which they would normally have no control.

Other functions of beliefs in witchcraft and sorcery that anthropologists have elucidated involve group cohesion and the maintenance of social norms. In terms of community and group cohesion, Douglas (1970), in the introduction to her edited volume, commented on the variability with respect to patterns of witchcraft accusations. In some instances, people tend to accuse people that are close to them, either in terms of kinship bonds or geographical location, whereas in others, people tend to accuse distant people who are sometimes not directly identifiable. In situations where the accused tend to be outsiders to the community, more attention is paid to curing the victim than identifying the witch. This can lead to greater group solidarity.

On the other hand, when the witches are insiders, they become emblems of social deviance. This provides a clarification of social norms and moral codes. In many societies where these beliefs are present, witches and sorcerers are said to embody many of the characteristics that are diametrically opposed to those that are encouraged among the population. Indeed, Kluckhohn’s (1967) work demonstrated that greed, which is considered one of the trademark characteristics of witches, stands in stark opposition to the value of sharing in Diné ideology. One who accumulates wealth therefore stands a chance of being accused of witchcraft. This portrayal of greed—and other traits and actions such as murder, cannibalism, and incest—as traits of witches thus enforces adherence to the social norms.

While this description reveals a possible social function of witchcraft beliefs where adherence to norms is implicitly promoted through the vilification of persons who go against these norms, Marvin Harris (1974) suggested that a belief in witchcraft, specifically in medieval Europe, was used more directly as a mechanism for the maintenance of power on behalf of the church and the state. The characterization of witches in this particular context posited them as people, mostly women, who would sign pacts with the devil, pledging to do his work. While antisocial behavior, or behavior that went against the church-established norms, was said to be typical of the actions of witches, Harris proposed that there was a conscious desire on behalf of those in power not only to encourage adherence to the norms but also to keep the population divided due to mutual fears of witchcraft or accusations. This division would prevent people from identifying the economic oppression perpetuated by those in power. According to Harris, then, a belief in witchcraft could serve as a tool for political power.

In relation to accusations within a community, Evans-Pritchard (1937) also pointed out that allegations helped to bring underlying social tensions to light. This was the case in accusations between Azande cowives, for example.

However, these tensions could also be alleviated by the ritual described earlier, where the accused blew water on a fowl wing and expressed good will toward the victim. This act served to acknowledge the potential that witchcraft occurred without the accused's knowledge and helped to diffuse the existing tension.

Witchcraft beliefs may serve functions at the societal level, but several authors have pointed to functions for individuals as well, both those who claim to be victims of witchcraft and those who are accused. Kluckhohn (1967) elaborated on some of these functions with reference to his work with the Diné. He argued that some individuals might actively seek to become witches to gain supernatural power, especially if they were unable to achieve such powers through socially approved channels such as becoming singers, who have important spiritual roles among the Diné. Thomas (1970) also discussed the possible point of view of the accused in his historical work. Since people tended to accuse individuals who were economically and politically marginal, such as elderly widows, and who were dependent on neighborly goodwill for support, these individuals could benefit from the way people's fears would keep them from withdrawing such support. Being seen as a witch, according to Thomas, could therefore serve as a mechanism of empowerment for those who were poor and marginal.

Kluckhohn (1967) also pointed out that Diné individuals who claimed to be targets of witchcraft were often people with low status who could get some kind of attention and support from other community members through their claims. Moreover, he argued that witchcraft beliefs and accusations served to channel people's feelings of aggression and hostility, and desires for drama and excitement, in a way that would be socially approved. Similarly, fantasies about incest or necrophilia could be mentally played out in guilt-free ways when these actions were ascribed to witches.

If the theoretical explanations described here seem appealing, there has been criticism of the functionalist approach on the grounds that it tends to reduce human activities to mechanical processes. Demos's (1983) work presents an outline of some of the major criticisms. For example, some scholars have argued that functionalism posits static models of culture, neglecting to examine the effects of social change, and that it presents a potentially disruptive social phenomenon, such as witchcraft accusations, strictly in positive terms. However, functionalist analyses of witchcraft and sorcery beliefs have remained useful in anthropology as a means of understanding how beliefs and practices surrounding witchcraft and sorcery are located within social and cultural structures.

More recent scholars who focus on witchcraft and sorcery have often confirmed the applicability of the traditional functionalist approaches. These approaches have emphasized the ways in which witchcraft beliefs worked to fulfill certain human needs, such as explaining misfortune or providing a course of action against it. For example, Alexander Rödlach (2006), like Evans-Pritchard and

Kluckhohn, has noted various functions served by witchcraft beliefs. In contemporary Zimbabwe, in the wake of much health-related misfortune and economic turmoil related to the HIV/AIDS epidemic, witchcraft accusations abound. In addition to serving the functions of explaining and dealing with misfortune, witchcraft beliefs, according to Rödlach, often reflect social relations that are strained by the stresses and uncertainties caused by such massive social crises. Moreover, the authors cited in the remainder of this entry all acknowledge that explanatory and social functions are, indeed, fulfilled by these beliefs.

However, there has been a tendency to explore other layers of analysis while acknowledging that these functions of witchcraft belief exist. Indeed, several anthropologists since the days of Evans-Pritchard and Kluckhohn have found the functionalist approach incomplete in explaining social phenomena, especially in an intellectual context where anthropological thought has moved away from the idea of culture as a bounded, internally coherent whole. Rather, internal heterogeneity with respect to access to prestige and power is increasingly recognized, as are external influences and the ways in which people adapt to them or contest them.

As early as the 1960s, anthropologists such as Victor Turner and Melford E. Spiro were expanding on earlier functionalist paradigms by considering witchcraft beliefs, among other supernatural beliefs and practices, in social and psychological contexts. Turner (1967), in his work among the Ndembu of central Africa, espoused a processual approach where rituals and their associated beliefs were intertwined with processes in the community in which "social dramas" took form. These dramas, based on existing social tensions, unfolded through various mechanisms. These then led to the redefinition of social boundaries by casting people as outsiders because of their witchcraft practices.

Spiro (1967) was more concerned with psychological factors that motivated individuals to believe in witchcraft. He argued that a strictly functionalist explanation limits itself to explaining the belief system in terms of its latent results. He stated that it is essential to also examine the perceptual, cognitive, and motivational explanations for human belief in witchcraft, sorcery, and other ways in which people suffer at the hands of supernatural power.

Based on fieldwork in Burma, where beliefs pertaining to the supernatural were influenced by both Buddhism and animism, Spiro claimed that fear of aggression from witches or sorcerers was a projection, or displacement, of the inner turmoil that resulted in an individual after the brutal rejection that all children faced from their parents at a certain age after an initial period of tenderness. Believing in witchcraft allowed individuals to externalize the anxiety and to project it onto something that they could deal with directly. It also avoided exacerbating feelings of antagonism toward one's parents. Moreover, possession through witchcraft, which was one of the ways Burmese witches

were said to attack people, allowed the possessed person to engage in acts of aggressiveness that would otherwise have been unacceptable since it was, in principle, the witch who was acting through this person. It is interesting to note that this is similar to one of Kluckhohn's (1967) theoretical points about socially sanctioned feelings of aggression. However, whereas Kluckhohn included this as a latent function of witchcraft beliefs, Spiro located it as a motivational psychological factor of these beliefs.

Spiro also explained the role of cognition in the continued belief in witchcraft among the Burmese. Learned knowledge about witches and witchcraft informed an individual's interpretation of events; events that were interpreted as involving witchcraft, in turn, substantiated their knowledge. To Spiro, this approach took greater account of human interpretation than the majority of functionalist explanations.

As with their predecessors from the 1960s, anthropologists dealing with witchcraft beliefs since the 1980s have not denied the validity of functionalist explanations for the existence of witchcraft beliefs. However, they have increasingly considered the impact of changing political and economic contexts as well. The consideration of interactions between traditional local systems and the remaining ideological systems of colonizers is now considered essential to an understanding of indigenous beliefs and practices in any location. Furthermore, power dynamics within and across national boundaries are an unavoidable factor given the relationship between witchcraft ideology and social power.

In this vein, Pamela Stewart and Andrew Strathern (2004) have employed a theoretical perspective, largely based on Victor Turner's processual approach that considers local social dynamics as a basis for the study of witchcraft beliefs. In a cross-cultural study that examines witchcraft beliefs in Africa, Europe, India, Indonesia, Papua New Guinea, and Sri Lanka, they argued that these beliefs are intertwined with the social processes of rumors and gossip. Accusations of witchcraft, they asserted, are based on pre-existing rumors and gossip that circulate within communities and that reflect ongoing tensions and conflicts. These tensions escalate in moments of social crisis, leading to accusations that will result in some sort of outcome—in the form of resolution by trial or further conflicts.

Similarly, Isak Niehaus, Eliazaar Mohlala, and Kally Shokaneo (2001) focused on the relationship between witchcraft and power in the South Africa Lowveld in the 1990s. Their analysis of this postcolonial context, where people of various ethnic backgrounds coexist in a society that has been impacted by colonialism, apartheid, and Christianization, attempts to balance the explanatory function of witchcraft with the role of power dynamics in witchcraft beliefs and accusations. They described how the oppression of people by dominant powers and attempts to repress local ideological systems, including witchcraft beliefs, contributed to the marginalization and poverty that

actually helped to maintain these beliefs as an explanation for the misfortunes that people had to deal with. Witchcraft beliefs, then, can be perceived as a tool of empowerment.

Alternately, as Peter Geschiere (1997) as well as other contributors to Henrietta L. Moore and Todd Sanders's (2001) volume addressed, witchcraft beliefs can operate as power mechanisms for both those with official power and those without. In the case of the former, perceived access to supernatural powers related to witchcraft or sorcery can legitimize or solidify their social power. In the case of those without social power, it can operate to level out social inequalities since those in power will fear the effects of witchcraft.

Neil L. Whitehead and Robin Wright (2004) argued that this leveling mechanism operates on a larger social scale among various peoples of Amazonia. In many of these societies, shamans are as capable of harming as they are of curing. Sorcery, then, is seen as a necessary counterpart to healing practices. Although this duality leads to some ambiguity toward shamans within their communities, their potential power over outsiders can work to give people a sense of integrity with respect to outside threats.

As can be seen from this recapitulation of theoretical approaches to the analysis of witchcraft beliefs, anthropologists over time have sought to explain the existence of these beliefs and associated practices in various social and cultural contexts. It is generally acknowledged that these beliefs, along with other beliefs related to the supernatural world, help fulfill some basic functions in human societies such as the desire to understand misfortune and the maintenance of social norms. However, recent scholarly works on the topic have been careful to relate their analyses in social and political processes that operate both within societies and between societies, and how these processes influence the social dynamics within which witchcraft accusations take place. Witchcraft beliefs are therefore one example of the ways in which humans both make sense of their worlds and find ways in which to influence the course of their lives.

Ongoing and future work in the field will undoubtedly continue to explore the ways in which indigenous beliefs and practices related to witchcraft and sorcery intersect with various religious, political, and economic forces that circulate in an increasingly globalized world. It will also be interesting to consider how members of the societies where anthropologists have documented witchcraft beliefs react to these ethnographic documents. Undoubtedly, anthropologists will continue to debate the accuracy of the terminology that is used within the discipline to refer to the variety of local beliefs and practices that exist in the world.

Conclusion

A belief in witchcraft or sorcery is found in many societies around the world. Certain individuals are believed to be

able to cause misfortune to others either through the power of their own will or by the magical use of substances. These individuals are sometimes said to be born with these capacities, inherited from one of their parents, but they usually are said to learn witchcraft or sorcery. Certain types of people are more likely to be the target of accusations. Very often, people who are marginal in some way and have little social status are easy targets. People who are perceived as embodying antisocial traits are routinely subject to accusations and symbolize the traits that a society's members should avoid displaying. In some cases, individuals such as healers who are responsible for the well-being of others are potential objects of scrutiny since their powers to do good are counterbalanced by their powers to do harm.

Where there are witchcraft beliefs, there are also means of protection against witchcraft or of reversing the misfortunes brought about by it. People resort to charms, the hiding of substances that witches or sorcerers can use against them, or, in case of witchcraft-induced illness, curing ceremonies. In some cases, the process of accusation and confession can solidify community bonds, and in others, they can lead to greater conflict.

Rather than attempt to validate or invalidate witchcraft beliefs and associated practices, anthropologists have attempted to understand why they exist and how they manifest in various cultural contexts. Anthropologists generally agree that these beliefs serve certain functions in human societies such as explaining misfortune, giving people recourse in the face of misfortune, maintaining social norms or power, and providing psychological outlets for both individuals who are accused of witchcraft and those who claim to be victims. Recent work has focused on power dynamics within and across groups in the face of economic, political, and religious changes and how people use witchcraft beliefs to maintain or improve their lot in life.

While the general attitude toward witchcraft beliefs in mainstream Western culture is one of amusement at best and ethnocentric scorn at worst, anthropologists maintain that witchcraft and sorcery beliefs make sense as an element of the systems of thought and of the social contexts in which they exist.

RELIGIONS AND BELIEFS

HANS OTTO SEITSCHEK

Ludwig Maximilian University in Munich

Religions and beliefs are of great importance for anthropological research on the development of humankind and its history, as they represent the human reaction to an extrahuman, holy, transcendent, or divine object. Almost no other terms of the mental and intellectual human life seem to have such a big and colorful variety as “belief” or “religion.”

At first, a look into the past: The term *religion* has its etymologic and historical roots in the ancient Roman world. A different context can be found for the terms personal *belief* or universal *faith*; they have their semantic origin in the Greek word *pistis*, which Saint Paul used in his letters, or in the Latin *fides*. Whereas religion gives the framework, belief fills this framework with individual religious activities. Faith means the universal religious activity of a group of people of the same religion. The Latin noun *religio* stems from the verb *re-legere*, which has the meaning “to do something diligently, to do something again, to re-read something,” according to Marcus T. Cicero (106–43 BCE). The prefix *re-* could even be translated as “to do something diligently again and again.” The careful execution of rituals was prescribed by rules, which were only valid through their exact observance. Therefore in the ancient Roman culture, the Latin noun *religio* expresses the right observance of cults and, as a consequence, the respect for the gods. The verb *re-legere* is the opposite of the verb *neg-legere* (to neglect).

The derivation of the noun *religio* from *religare* (to connect, to reconnect) is in general problematic, because

this reconnection can be seen in a feeling of an inner attachment to something transcendent, which was not common to classical beliefs. In its character, *religio* is in Roman antiquity rather a virtue than a kind of feeling. Central in the diligent performance of rituals was a kind of “pious awe,” which was not so intensive that the acting person in religious affairs was moved inside. This is one of the reasons why ancient Roman *religio* is basically incomprehensible to us. Nowadays, the adjective *religiosus* means “pious.” In a later development, *homo religiosus* means “member of an order,” a person who lives according to the three evangelical counsels: poverty, chastity, and obedience. This person wants to be, in his religious life, a good example to others. It was this meaning of the word *pious* (*religiosus*) that brought the noun *religion* into the Christian-shaped, Western culture, and less the Latin noun *religio*, in the ancient Roman sense.

To exhaust the full meaning of religion or belief, it is not sufficient to speak only of *devoutness* or “expression of devoutness.” Religion and belief also cover the sentence *fides quaerens intellectum* (faith or belief that searches for insight). Therefore, it has also to do with rationality and the search for reasonable causes. Saint Augustine (354–430 CE), as an exponent of Christian antiquity, and Saint Thomas Aquinas (ca. 1224/5–1274 CE), as a philosopher of high scholasticism, shaped the concept of *religio* as identical with Christianity. Other, non-Christian religions or beliefs could only be classified as *lex*, *secta*, or *fides*.

The meaning of the term *lex* is universal, according to our expression “denomination” or “total structure of life.” There is also a *lex Christianorum*, which means “doctrine and law of the Christian faith.” By no means is the forming of the concepts “religion” and “belief” steady or logical. Within the historical development, beginning with classical antiquity up to the advent of Protestantism in the 16th century, it is not possible to find a strictly continuous development to the modern term *religion*. So, *religio* cannot be translated by or equated with religion or belief in today’s meaning.

If the Christian context of the word *religion* is left aside, then religion and also belief can be defined as the relationship of a human to a personal or impersonal transcendent, in whatever shape of “the Real”: a divine *persona* or *impersona*. The meaning of the Western terms *religion* or *belief*, influenced by Christian thoughts, changes in other European and non-European languages from “something that is owed to the transcendence” to “law/doctrine” and “eternal, never-ending structure.”

As a result, the term *religion* is more objective than the rather subjective term *belief*. Also, the concepts of belief—characterized as individual, personal belief, or conviction—and faith—characterized as universal belief—can be differentiated. Religion is in general the system of faith that people of the same conviction have in common. Belief is the personal activity, the “personal” faith, within the framework of religion. *Belief system* is very near to religion, but it emphasizes the personal religious activity more than universal faith.

Further Development of Religions and Beliefs: Historical Perspectives

After this etymological study, the paradigmatic development of the modern terms *religion* and *belief* will now be described in order to give a contemporary view on them. A religion that prescribes a belief in a deity of imaginable terms is marked as rational, according to the Lutheran theologian and historian of comparative religion Rudolf Otto. In his classic work, *The Idea of the Holy* (1917/1925), Otto also asked for the objectivity of religion or belief, and emphasized the “contrast between Rationalism and profounder religion.” One cannot do justice to religion or belief only by rational terms. The two opposite characterizations of religion are, as Otto pointed out, the *tremendum*, or the “awefulness,” and simultaneously the *fascinans*, or the “fascinating.” The *tremendum* shakes people in awe in sight of the mysterious, completely different being, God. This form of fear is by far different than the “natural,” or ordinary fear of a human, and applies more to the general “world-fear.” The *tremendum* derives from a “numinous dread” that terrifies and fascinates people at the same time.

The Romanian historian of religion Mircea Eliade, who worked at the University of Chicago, addressed Rudolf

Otto’s reflections at the beginning of his book *The Sacred and the Profane* (1957/1959). Eliade focused on the nature of religion or belief, describing the manifestations of religion and the religious in a world that dissociates itself more and more from religious dimensions. But even in a secular world, there is something sacred that is characterized by humans as the opposite of the profane. The process is always the same: the “completely different” is a reality that is not of our world and manifests itself on things that are components of our natural, profane world.

Eliade repeatedly spoke of *homo religiosus*, and he wanted to make clear that religion and belief belong to the human nature. Therefore, people live as long as possible in the sacred universe. By the word *sacred*, the dimension of the religious is described. This dimension surrounds, carries, and holds the human as a religious being. On the other side, a secular person, who is able to live without any religious feeling, has a completely different, secular experience of the universe. She lives in a desacralized world. The religious feeling has to find its way by another, maybe hidden means. The secular person lives totally differently from the *homo religiosus*.

Almost 150 years earlier than Eliade, Friedrich D. E. Schleiermacher, a German Lutheran theologian and philosopher, classified religion and belief as a “feeling,” as the French philosopher Jean-Jacques Rousseau did before him. Schleiermacher called religion a “feeling of infinity” in his second speech, “On the Nature of Religion,” of his five speeches appearing in *On Religion* (1799/1996).

The German philosopher of the Age of Enlightenment, Immanuel Kant, stood in strong contrast to the definition of religion or belief as “feeling.” In his work *Religion Within the Boundaries of Mere Reason* (1793/1998), Kant proved that there was no way to conclude the certain feature of direct divine influence by a feeling. Hence, according to Kant, religion must be based on reason alone in order to be universal. For Kant, religion had to be a “pure religion of reason.” Although these two characterizations of religion as a “feeling” (Schleiermacher) or as a “pure religion of reason” (Kant) are opposing, these two definitions of religion may be coincident in the fact that religion or belief is something agreed according to human nature. Therefore, around the year 1800, a concept of internal religion developed, which remains effective today.

Statements on religion or belief by the Protestant theologians Ernst Troeltsch (1912/1981) and Paul Tillich (1955, 1961/1988) underlined this fact. In another way, Tillich’s works can be regarded as examples of the effective power of the concept of religion or belief. In a different approach to Immanuel Kant, he distanced himself to consider “feeling” as the basic determination of religion. If religion could be connected to the pure subjectivity of emotion, then it would decline, because religion would lose its seriousness, its truth, and its highest sense. Without a highest content, religion would stay empty. In his essay “Religion as a Function of the Human

Mind?” (1955/1988), Tillich defined religion as “something that concerns us immediately,” in the deepest sense of the universe. That which “concerns us immediately” referred to all creative functions of the human mind. However, this did not mean that religion and belief are fictions of the mind, created by human beings.

According to Tillich, the human mind is able to be creative in relation to both itself and to the world. But this creativeness is limited by the relationship to God. Religions and beliefs contain all areas of the human life and of the mind, as they build the substance, the basis, and the depth of the human intellectual life. Therefore religion or belief is not based on a function of the mind at all. Religion is universal; belief is individual. They are consequently the unconditioned components in every situation of human life. Being moved by religion is always related to a religious object. In this context, Tillich emphasized two points: (1) Religion and belief are always related to a content, which cannot be explained in the end; and (2) religion has always a social dimension, too. Nobody is alone in being religiously moved or in feeling any kind of religious emotion. Therefore, the objectivity of religion is founded by its social dimension, according to Tillich. As a consequence, religion and belief are situated in the human being, who is touched by a “revealed unconditioned being,” by a religious object. This can generally be applied to everyone. “Religious reality,” however, goes along with a secret consciousness: *tua res agitur*, “your situation is concerned.”

Two definitions of the concept of religion can be found in Tillich’s work. Both differ crucially from the traditional one—religion or belief as the human answers to the transcendent. (1) Tillich spoke of an “autonomous religion” that does not know a representational God, nor, consequently, any form of prayer. But in contradiction to that, religion is not impious or lacking a God. It just does not know any kind of ecclesiastical objectification of God. With mysticism, it is different again, because mysticism elevates itself beyond the objectification of God. (2) In his later essay, “Christianity and the Encounter of the World Religions” (1961/1988), Tillich mentioned *quasireligions*, which are similar to religions and have some features in common with religions. But quasireligions are only related to secular objects and consequently to secular institutions. Tillich differentiates between quasireligions and *pseudoreligions*. Both pretend intentionally to be similar to religions. The expansion of the concepts of religion or of belief as inward phenomena, which have been developed since the beginning of the 19th century, became clear in Tillich’s considerations.

The two concepts of quasireligions and pseudoreligions must be strictly distinguished from traditional, historical religions. Similar to quasireligions is what Eric Voegelin (1938/1999) and Raymond Aron (1965/1968) spoke of as *political religion*. An explosive nature is exhibited in the relationship between religion and politics, as it is demonstrated in the concept of political religion, and later on in the concepts

of state religion or civil religion. The term *political religion* has its roots in *religio politica*, going back to the early 17th century. Since the 1930s, it served to classify the political-totalitarian mass movements of this time in a critical attitude toward ideology. This modern “political religion,” however, must be clearly distinguished from the “political religion” of classical antiquity and the later concepts of state religion and civil religion, which tried to institutionalize the relationship between religion and politics, not always in a fruitful way.

Generally speaking, it is possible to identify religion or belief as being situated in a person. Religion or belief must be further defined as a relationship and interchange between a human being and transcendent reality, which is relevant for humans. But the relationship to transcendence is not the only decisive criterion for a religion or a belief. Religions and beliefs are rather connected by a kind of “family resemblance,” as defined by Ludwig Wittgenstein (1953/2001). They are determined by overlapping qualities, including holiness, prayers, and services. Religions and beliefs also show similarities that connect them. These similarities, however, must not necessarily be alike in every religion or belief. Regarding those similarities, the reference to transcendence plays, of course, an important role. John Hick (2005) pointed out that another fundamental “family resemblance” of religions and beliefs, in addition to their reference to the transcendence, is their soteriological content, which describes the ability of a religion or belief to redeem human souls and allow salvation. However different their contents and traditions may be, this soteriological quality is a feature that all religions and beliefs have in common in various manners. Also, the validity of religious traditions was of great importance for Hick.

Religion and belief in the modern ideology can carefully be defined as generic terms, or concepts, which slowly have grown in importance in our modern age. These concepts are very different from the ancient meaning of the word *religio*, which first described all imaginations, attitudes, and actions of a person concerning the ultimate reality. Humans accept the ultimate reality as powers or a power, spirits or demons, gods or God, the “Sacred” or the “Absolute,” or just “Transcendence.” In ancient times, religion was not used as a collective name for each belief or as a universal term, in which various beliefs were summed up. The term *religio*, representing the past view on religion or belief, was used in a very narrow sense from antiquity up to the 16th century. At first, religion referred to the exercising of the rituals prescribed by law, but only later with regard to the Christian denomination. In general, it took a long time before *religio* and later “religion” had achieved their meaning, which led to the modern understanding of “religion.” Religion is more than the mere name of a personal belief. It expresses that humans are concerned about something beyond them. Also, death obtains a different meaning within a religious worldview. Romano Guardini (1940/1998), the Catholic priest, theologian, and philosopher of religion, considered death as

the gate to the other side of human life, which remains secret to those who still live in this world. For religious people, death is no longer the end of life but, instead, is the turning point to a different reality.

Summing up, the terms *religion* and *belief* can be characterized by the following three points:

1. There are no universal terms for all religions or belief systems of humankind in each epoch.
2. There is no term that includes all aspects of what is meant by religion or belief today. Even all these terms together cannot cover every aspect now meant by religion or belief.
3. Earlier terms of *religio* or religion stand in contrast to the modern meaning of religion. They emphasize the external practice of religion, the observance of ritual instructions and regulations, and the obedience to religious laws.

These three points, however, cannot unambiguously classify religions or beliefs and they do not ultimately define them. But they do outline the broad frame of the modern concept of religion and belief.

Early Explanations for Religions and Beliefs

Since ancient times, as many sources teach, people have had various religious or pseudoreligious systems. In the past, religions and beliefs were the result of natural phenomena, which led people to fear and to require that these natural phenomena be explained. Also, social facts and mechanisms had to be explained through religious patterns. Ancient Egyptian, Greek, and Roman religions show this function of early religions or belief systems. These religions and beliefs were polytheistic (i.e., there were many different gods, who had different things to take care of). In many cases, one god is honored as supreme among the others (e.g., Zeus in ancient Greek religion or Jupiter/Jove in ancient Roman religion). The holy or the deity was often linked with nature. Humans found in nature the powerful influence of God: Therefore trees or fountains or mountains (esp. the peak, like Mount Fuji in Japan) were adored as holy, or as the place where the deity lives. Also in *totems*, things of everyday life or symbols or even animals, the spirit of a deity is believed to be effective. Therefore, it is forbidden, it is a *taboo*, to kill an animal in which a deity is believed to be present. These original religious aspects can be found within African religions and beliefs, or within the religions of the Pacific islands.

In the Egyptian and Roman traditions, the emperor was adored as a god and found his place in the Pantheon after his death. Archaeological proofs of these ancient religions and belief systems can be found in the pyramids in Egypt, as well as in the ancient Roman temples around the Mediterranean Sea. From the onset of European

culture, politics, religion, and society were interconnected within the ancient state, the Greek *pólis* or the Roman *civitas*. So religions and politics were interlinked in ancient European societies. Later on, these three aspects differentiated more and more. Today, politics, religions, and societies are almost separated, but one should be aware that humans are oriented toward religious belief, as civilians within a political state and a civil society. So it is useful to respect religion and belief even within a political point of view.

At the beginning of ancient Greek culture, the explanations for the reasons why the universe came to exist, and why it exists the way it does, were given in the myths of the writers Homer (ca. 8th century BCE) and Hesiod (ca. 8th century BCE). Next, there was a shift from *mythos* (myths) to *lógos* (reason). This shift can be found in the quotations and fragments of the pre-Socratic philosophers, who turned their interests toward nature and the reasons for natural phenomena. Thales of Miletus (ca. 624–546 BCE), for example, a philosopher of nature living on the Ionic coast (today's Turkey), gave a precise forecast for a total eclipse by calculation, but people took him almost for a prophet, and, what is more, he could forecast a rich bearing of olives, so that he lent all the olive presses in his country for a small amount of money, and consequently he was able to borrow them for a very good price. The next step from myths to reason can be found in the philosophy of Plato (ca. 428/427–348/347 BCE), a disciple of Socrates (ca. 469–399 BCE). Plato underlined his arguments in his dialogues with myths, in order to explain them better to his disciples. Among them, there was another important philosopher, the educator of Alexander the Great, Aristotle (384–322 BCE). Aristotle was also very interested in investigating natural phenomena and in explaining the world by reason, not by myths.

The general aim of this early Greek philosophy was to explain the universe by using human reason rather than mythical explanations. As a result, the soul of a human should not be in a disturbed situation, but in a quiet state, which is characterized as *eudaimonía* (felicity). The early philosophical schools in ancient Greece always had the intention of caring for the soul by giving reasonable explanations for the universe and its existence. Consequently, these early philosophical schools played the role that religions or beliefs play in our own time.

Major Religions and Belief Systems

There are many religious systems, including ancient systems or natural religions, or smaller derivatives from the major religions or belief systems. All religions and belief systems aim to provide answers to human questions on the transcendent and to major questions on life and death. People thus find orientation for their lives within these major religions and belief systems.

Eastern and Western Traditions

In general, Eastern traditions differ from Western traditions. Among Eastern traditions, which have more the character of belief systems than religions, there is Hinduism and Buddhism, but also Confucianism in China, which concentrates on the ethical life, and the animistic and polytheistic Shinto in Japan, which honors and prays to the ancestors. These are known as very old religious traditions in the Eastern part of the world.

The Western traditions are better described as religions than as belief systems. The most important are Judaism, Christianity, and Islam. All three of these religions refer in quite different ways to Abraham (ca. 2000 BCE) as an ideal of a pious and religious person.

Also, Zoroastrianism is counted among the major religious traditions or belief systems. It is considered to be the first monotheistic belief system, with Ahura Mazda as the universal God. But it is also a dualistic system; *asha/arta* is the principle of “truth” and “order” whereas *druj*, “lie,” is the opposite. Both principles “fight” against each other in the world. Zoroastrianism was founded by the prophet Zoroaster, or Zarathushtra, in the farmland area of today’s Western Iran. The main teachings of Zoroastrianism can be found in the scripture Zend-Avesta.

Hinduism

In Asia, the Hindu traditions are well known; the religion of the Vedas and the Upanishads is grounded in very old scriptures (e.g., the Bhagavad Gita or “Song of God”). The beginning of these traditions is about 4,000 years BCE in India. The Hindu traditions have a polytheistic basis, with Shiva and Vishnu as the central deities, but only one eternal aim: the unification of the individual soul, *atman*, with the highest spirit, Brahman. After several lives, the soul can enter the Brahman, leaving the system of reincarnation (*samsara*), if the *karma*, the balance of all individual actions, is good enough. Five elements are considered to be central for Hindu beliefs: (1) *dharma* (ethics and duties), (2) *samsara* (cycle of reincarnation), (3) *karma* (action and resulting reaction), (4) *moksha* (liberation from the cycle of rebirth), and (5) *yogas* (paths and practices). Though it is controversially debated among scholars whether the caste system is an important part of Hindu teaching, this social system remains strong even today. There are four castes, called *varnas*, beginning with the highest cast: (1) Brahmins (teachers and priests); (2) Kshatriyas (warriors, nobles, and kings); (3) Vaishyas (farmers, merchants, and businessmen); and (4) Shudras (servants and laborers). The caste system is very rigid. Marriage is only possible within one caste. People outside the caste system, Parjanya or Antyaja (or now Dalits), the “untouchables,” have almost no chance to progress in social life. Therefore, this system has often been criticized as discriminatory (e.g., by Mahatma Gandhi [1869–1948], whose ideal was absolute peacefulness).

Buddhism

Also in Asia, the Buddhist tradition is founded on the philosophy of Siddhartha Gautama Buddha (ca. 563–483 BCE), who was a teacher of spiritual wisdom. There are two main traditions in Buddhism: the Mahayana (great vehicle) Buddhism and the Theravada (ancient teaching) Buddhism. A smaller tradition is the Hinayana (low vehicle) Buddhism. Central Buddhist teachings contain the Four Noble Truths: (1) the nature of suffering (*dukkha*), (2) suffering’s origin (*samudaya*), (3) suffering’s cessation (*nirodha*), and (4) the way (*marga*) leading to the cessation of suffering. This “way” (*marga*) is characterized by the Noble Eightfold Path: (1) right view, (2) right intention (wisdom), (3) right speech, (4) right action, (5) right livelihood (ethical conduct), (6) right effort, (7) right mindfulness, and (8) right concentration (concentration). The Noble Eightfold Path contains the ethical “program” of Buddhism.

One aim of Buddhism is to bring cessation from suffering to the human soul. There are several traditions within Buddhism. Among them, there is Zen Buddhism in Japan and Tibetan Buddhism, whose head is the Dalai Lama. The monastic tradition is also very common in Buddhism, because its discipline helps the adherent to succeed in achieving the aim, the *nirvana*, as a unity of the individual soul with the universal in the absolute nothingness (*nirvana*).

Judaism

The Mosaic tradition, later Judaism, is historically the first major tradition in Western culture. Christianity and Islam followed. In Judaism, humankind has been given the advice to follow God’s law, which was revealed on Mount Sinai, or Horeb to Moses. This revelation took place during the Exodus, the Jews’ escape out of Egyptian slavery. Moses was the leader of the people of Israel during that time. A life in accordance to the law will end up in felicity and prosperity, even after death. The prophets played a major role, because they renewed the concentration on God’s revelation within his law. During the reign of the Babylonian emperor Nebuchadnezzar II (ca. 630–562 BCE), the Jewish people were kidnapped and taken to Babylon. The Babylonian Talmud was written during this time, a commentary on the Torah, with respect to other commentaries and the oral tradition, in order to give a set of rules for everyday life. Literature interpreting the Torah is known as *midrash*.

When the people of Israel returned to the Holy Land, they built the first temple. In the year 70 CE, the temple was destroyed by the Romans, and the rabbinic phase began in Judaism. Rabbis are teachers of the Holy Scripture and they interpret for believers. They also give advice to pious Jews on how to manage life and how to decide in problematic situations. The *halakha* means to follow properly the way of the Jewish tradition.

Judaism today is quite various. There are liberal branches, as well as orthodox branches, whose believers

observe the traditional religious law very strictly. As predicted in the prophecies of the Hebrew Bible, Jewish people still wait for the Messiah, who will come in the future in order to complete the divine law in his person.

Christianity

In Christianity, Jesus Christ is believed to be the son of God, who came to redeem people. After the original sin of Adam and Eve, humankind survived for the redemption. The redeemer is Jesus Christ, who was crucified by the Romans after being accused, by the Jews in Jerusalem, of heresy for pretending to be the Messiah, and whose resurrection after 3 days astonished people, especially his own disciples. After another 40 days, Jesus Christ went up into heaven. After another 9 days, the Holy Spirit was sent down to earth in order to lead the faithful and to give consolation to them. God is the Holy Trinity in Christian tradition: God-Father, God-Son, God-Holy-Spirit.

Later, the Christian church developed into a more and more powerful institution, which secures the tradition of belief and teaching. Although crusades have occurred, the Christian doctrine is against force and tends toward peace on earth. In the year 1054 CE, the Eastern Greek Church turned away from the Latin Roman Church with the pope, the bishop of Rome, as Vicar of Christ and head of the church. Formally, there were two reasons for the East-West Schism: First, the Western and the Eastern traditions could not find a proper date for Easter, and second, the Eastern tradition could not agree to the *filioque* (“and by the Son”) within the credo, the big confession of the faith. The *filioque* means that the Holy Spirit was sent by the Father and Son together.

In the 16th century, the Protestant Reformation movements began with the Augustinian monk Martin Luther (1483–1546) in Germany, Huldrych Zwingli (1484–1531), and John Calvin (1509–1564) in Switzerland. The theologians Erasmus of Rotterdam (1466 or 1469–1536) and Philipp Melancthon (1497–1560) both followed the Lutheran teaching and supported the Protestant teaching in the academic sector (e.g., by writing important letters). The Protestant Reformation movements wanted to renew the Western Church (e.g., by providing new translations of the Bible, and a new structure by changing the hierarchy). But in the end, these movements divided the church again as a result of a second big schism. Protestant Christianity then divided again into the many small movements and churches, or denominations, of today.

In 1534, the English Church separated from the Roman Church, and as a result the Church of England or Anglican Church was founded. The king or the queen of England is the head of the Anglican Church, and meanwhile the Archbishop of Canterbury exercises this office worldwide in the Anglican Church (e.g., the Episcopal Church in the USA). Whereas the High Church is near to the Catholic Church, the Low Church is nearer to the Protestant Church. So the Anglican Church regards itself as a “middle way” between Protestantism and Roman Catholicism.

In contrast to Protestantism, the Catholic Church keeps up its 2,000-year-old tradition and discipline, although the Second Ecumenical Council of the Vatican (1962–1965) has changed some elements in this tradition.

Islam

Islam was founded by the prophet Muhammad (ca. 570–632 CE), who had a direct revelation from God (*Allah*). This revelation is written down in the Koran, the holy book of Islam. In 622 CE, the first year of the Islamic calendar, Muhammad went from Mecca to Medina; this event is called the *Hijra*, or “walk,” which was the founding act of Islam. Sometime later, Muhammad returned to Mecca with his soldiers and gained a lot of followers and power. Islam regards itself as the final religion, which is based on the ultimate revelation given by God to Muhammad. This revelation gave perfection to the Mosaic and Christian revelation. Muhammad, the prophet of God, is the last and the highest of the prophets.

In the Islamic tradition, on each Friday there is a ritual prayer in the mosque. Ritual prayers are among the most important elements of Islam, the so-called Five Pillars of Islam: (1) fasting in the month of Ramadan, (2) the pilgrimage to Mecca (hajj), (3) ritual prayers (*salát*) several times a day, (4) charity (e.g., giving money to the poor), and (5) the profession of faith. Also, the observance of religious law (*sharia*), which contains rules for all areas of human life, is central to Islamic teaching. Islam is a religion or belief system of strict discipline, and it has gained a lot of influence in the states of both the Near East and the Middle East, as well as in Indonesia and Africa.

Religious Objects, Symbols, and Rituals

Each major religion or belief system knows certain objects and symbols, as well as rites. The rite is often connected with specific objects or symbols. In Buddhism, for instance, the wheel is a symbol of the recurrence of life and, more important, the Noble Eightfold Path. In the Mosaic tradition, the Star of David is the central symbol of identification. In Christianity, the cross, on which Christ was sacrificed, is the core symbol. And in the Islamic tradition, the half moon, as well as the sword, is central.

Symbols serve to give meaning to rites. In Jewish service, for example, the scrolls of the Torah must not be touched by humans, because they are absolutely sacred and represent God’s presence. Therefore signs exist, sometimes formed like a human hand, with which the scrolls of the Torah can be touched in order to follow the lines, which have to be cited. Another symbol in Jewish service is the *shofar*, a horn (e.g., from a ram, which is blown in preparation for and during Yom Kippur, the Day of Atonement, when humans reconcile with God). Yom Kippur is celebrated 10 days after Rosh Hashanah, the Jewish New Year.

In the Catholic Holy Mass, wine and bread are leavened and then transubstantiated into the blood and body of Christ as an unbloody renewal of the Crucifixion of Christ. The Host is then essentially Christ, and it is carefully venerated and adored. Also, the Virgin Mary is venerated in the Catholic faith as the Mother of Jesus Christ (i.e., the Mother of God). In the Protestant traditions, the transubstantiation is interpreted in a different way. The essential real presence of Christ is limited to the moment of the transubstantiation. Also, the veneration of the Virgin Mary and the saints is not common in the Protestant tradition. In order to venerate the *Corpus Christi* (body of Christ), the Virgin Mary, or the saints, there are often processions of Christians, especially in the Catholic tradition.

The pilgrimage (*hajj*) to Mecca, one of the holy cities of Islam, has its aim in circling around the *Kaaba*, or “cube.” The Kaaba is a thousand-year-old small building and the most sacred place in Islam. In the Eastern corner of the Kaaba, there is the Black Stone, the most important feature of the “cube.” All Muslims pray in the direction of Mecca, as it is the center of Islam.

Also, ritual dances or specific music or songs help to bring people into a state of mind that leads them toward a deeper understanding of the transcendent. The location for rites is, in most cases, a sacred place or a temple (in Christianity, a church), which can be seen as the house of God. These “houses of God or gods” attach a specific place to religions or beliefs, thereby providing an identity for them; also, they provide a meeting point for the believers as a kind of “home.”

Religious Manuscripts and Teachings

Religions and belief systems express themselves in teachings, on the one hand manifested by oral traditions and on the other by sacred manuscripts. The basis for most of the teachings is a divine revelation.

The most common religious manuscript in our times is the Holy Bible, the “book of books.” But in the Far East, we have a lively tradition of Holy Scriptures: In the Vedas and Upanishads, Indian religious wisdom is written down, as in the Bhagavad Gita, or Song of God, as mentioned earlier. In the Bhagavad Gita, Sanjaya, who has a supernatural eye, tells the blind-born king Dhritarashtra about the big battle (between the near-related royal families of the Pandavas and Kauravas) that took place in the region where now the city of Delhi is located.

Judaism and Christianity refer in different ways to the Holy Bible. The Mosaic tradition is based on the five books of Moses, the Mosaic law or the Torah, the books of the prophets, and the psalms. Another important writing of Jewish tradition is *The Guide of the Perplexed* by Moses Maimonides (ca. 1135–1204), which considers religious and philosophical aspects, and helps to interpret the Jewish law properly. Maimonides’s influence on Jewish thinking

still remains intense. Christianity is also based on the Old Testament, partly equivalent to the Hebrew Bible (*Tanakh*), but also on the New Testament: the Four Gospels, the Acts of the Apostles, the Epistles of Saint Paul, and the General or Catholic Epistles, as well as the Apocalypse of Saint John.

In the Koran, or “the recitation,” the holy book of Islam, the revelation to Muhammad resulted in the central teachings of Islam, which are the core of the religious law, the *sharia*. Furthermore, the *sunna*, the history of the life of Muhammad, is the model of a good life for a Muslim. In Islam, the religious law, the *sharia*, has a great meaning, so the most important religious leaders are judges.

Teachings of all religions provide explanations for the beginning of the universe, as in Genesis, the first book of the bible, moral teachings, and orders for a good life, which must match the will of God. These moral teachings belong to the realm of natural rights, which are similar in all religions and belief systems and their teachings. Natural rights follow human nature and therefore human rationality. Religious teachings give answers to crucial human questions concerning the universe, ethical problems, and life and death.

Future Directions

In the field of religions and beliefs, many fruitful future research areas can be found. The humanities, especially the studies of religion, which are linked to anthropological and sociocultural research, create new research areas: using the structuralistic method of the French ethnologist Claude Lévi-Strauss, rituals are analyzed in order to discover the common structures of rituals in different religions or beliefs. Furthermore, the discourse of religions and beliefs are examined as well. Therefore, the dynamics and controversies within this discursive process are analyzed and described in order to obtain more results concerning the relationship between different religions and belief systems.

Also, the aesthetics of religions or beliefs are currently under scrutiny. Religions and beliefs can be described as aesthetical systems or systems of symbols, which influence the human realization of reality. The aesthetics of religion build up a systematic coherence for religions and belief systems. Another field of interest is the influence of religions and beliefs on different human societies and politics, because religions and belief systems provide ethical rules and values. Psychological studies examine the inner processes caused by the personal beliefs of a human being, for example during religious examinations, such as prayers or meditations. Very important for future research on religion is the investigation of human nature. All religions or belief systems provide concepts of human nature. This question of human nature is important for answering many questions and solving many problems in terms of the sciences in the future (e.g., in human-genetics research).

Also, in philosophy and theology, there are new areas of research, especially the examination of the relationship

between rationality and religion or belief. For example, the context of metaphysical considerations of late antiquity and the appearance of Christian revelation in the first centuries, beginning with early Fathers of the Church like Origen (185–254 CE) and ending with Saint Augustine (354–430 CE). During that time, theology has its origins in the confrontation of philosophy and religion. A major rational concentration on religious thoughts can be found in the Middle Ages (e.g., in the *Summa Theologica*, written from 1264–1274, of Saint Thomas Aquinas). The rationalism of the European Enlightenment emphasized critical views grounded in logic and nature. After rationalism, German idealism included religion systematically within philosophy as a philosophical perfection of the spirit. The German philosopher Friedrich Nietzsche (1844–1900) understood his philosophical work as a negative profile of religion in contrast to Christian thinking, which, he posited, is not suitable to human nature. But in the 20th and 21st centuries, religions and beliefs soon came back to the intellectual agenda. Therefore, religions and beliefs are truly fruitful objects for future research, as well as for anthropological research.

Conclusion

Summing up, the following three points are important for an anthropological perspective of religions and beliefs:

1. Religions and belief systems want to give humans a special place in the universe and within reality itself, which is of course a different orientation from the scientific worldview, but nevertheless one way to consider the universe and humans within it.
2. People may not want to refer to religion or beliefs as something entirely made by humans. For many people, religions and beliefs should include a serious transcendental relationship (e.g., based on a revelation). Otherwise, religion is in danger of becoming an ideology, which may lead people to the use of force and cruelty, as in totalitarian political systems. Such systems are often characterized as political religions, like fascism, national socialism, or communism.
3. Moreover, religions and belief systems need not be rigid systems of moral teachings in order to suppress others. Religions offer guidelines for life respecting the truth, with the aim being a future life (of the soul) in truth and peace. In religions and belief systems, people want to live their lives in accordance with God, as fruitful and successful individuals. And, what is more, people want to gain the hope for eternal life or redemption after death, which thereby gives a meaningful sense to human existence, like a gate to paradise, near to God or the transcendent.

Religions and beliefs belong to many fields in the humanities: theology, philosophy, sociology, history, religious studies, and psychology (among others). It is very

important that, in many perspectives on human life, religion and belief play a role as an answer to the question of the sense of human life and death. In religions and belief systems, humans seek answers to many other questions as well, especially in terms of ethical questions and the question of a good life. As a result, religions and belief systems play a major role within anthropological considerations of any kind.

COSMOLOGY AND MYTHOLOGY

ANNA MARIA DESTRO

Eastern Piedmont University

The term *cosmology* comes from the Greek word *kosmos*, meaning “the world or universe as an ordered and harmonious system.” A cosmology is any composition or cultural construct relating to the structure and process of systems of creation: the origins of physical elements of earthly or astronomical spheres, the genesis of the material world, the order and function of the observable universe. In philosophy, it is taken to mean that part of metaphysics dealing with the idea of the world as a totality of all phenomena in space and time.

According to Greek thought, *cosmos* came out of chaos—the formless void, or a state of utter confusion and disorder—by separating the different elements. The concept is often associated with *cosmogony*, referring to a theory or system of the generation of the universe.

In social anthropology, the definition of cosmology is closely connected to the empirical study of religious myths. Edmund Leach (1982) defined it as “the system of beliefs and practices which social anthropologists commonly refer to as ‘primitive religion’” (p. 229).

If, however, one tries to abide by the more rigorous definitions, then cosmology in anthropological usage encompasses both more and less than religion. In some way or another the study of cosmology means taking account of the relationship between the whole and the parts: the macrocosm and the microcosm.

Because the word *kosmos* can mean “order” as well as “the world of order,” in Greek thought, microcosm can

signify not only humans in relation to the universe, but also any part of a thing, especially a living thing that reflects or represents the whole it belongs to (Guthrie, 1962).

In anthropology, Hocart (2004) was an early theorist who tried to elaborate this point. His aim was to establish that the root idea in human existence is the procurement of life. This, he claimed, is done through ritual that derives its meaning from the “life-giving myth.”

The Importance of Dreams in Ancient Japanese Mythology

Dreaming is a subconscious activity that occurs while a person is sleeping. Images occurring in dreams have been interpreted in various ways by different cultures. In our modern, materialistic and scientific culture, we tend to treat dreams as irrational and personal. However, in many cultures of the world, dreams are still considered very important, not only on a personal level but also in a public way. In these contexts, dreams are believed to foretell actual events that will occur in the future, represent the dreamer’s physical and mental condition, communicate with supernatural forces, and so forth. Thus, these cultures use dreams as devices to predict the future, to communicate with others, to make day-to-day decisions, to educate the youths, to heal the sick, and to enforce rules and laws. Japan is one culture that particularly emphasizes this type

of significance for dreams, connecting its own rich mythology very closely with the concept of dream.

Definition of Historical Phases

Six phases in Japanese history have been defined by anthropologists to describe the evolution of dreams in Japan and the connection with cosmology:

- *Phase 1 (Jomon period, 10,000 BCE onward):* Archaeological evidence reveals that the societies were small, with a simple social structure, of which the dominant economy was hunting and gathering.
- *Phase 2 (500 BCE onward):* Paddy-field rice cultivation was introduced to Japan from China, through Korea. According to Chinese documents, a queen in Japan regularly brought tributes to the emperor and reported that a civil war continued in her land. This means that the society grew large and complex enough to have the formation of tribal territories. Such a process is reflected in the mythologies compiled in *Kojiki* (Record of Ancient Matters) (see Philippi, 1968) and *Nihongi* (Chronicles of Japan) in the 8th century (see Singer, 2002).
- *Phase 3 (5th century CE onward):* Japan was established as a state and became a member of the East Asian political system, adopting Chinese law. The highly developed philosophies of Confucianism, Buddhism, and Taoism were introduced and well-accepted.
- *Phase 4 (9th century onward):* As the political and economic system matured, the aristocratic culture of literature and religion developed in the court, amalgamating alien and indigenous elements.
- *Phase 5 (13th century onward):* The Samurai class came into power. They were realistic and practical entrepreneurs who demolished the old aristocratic sociopolitical system.
- *Phase 6 (19th century onward):* Japan started to accept the influence of Western culture. It began in the 16th century, but the process was slow until Japan's ports opened in the latter half of the 19th century.

In the period following Phase 6, Japan aggressively learned the techniques and philosophy of Euro-American culture.

Iconography During Phase 1

For this prehistoric stage, few data are available to help to understand the socioanthropological dimension of the culture, and no written records remain. The only possible clue is iconography, or the study of art. The realistic figures found from this phase are limited to humans and animals and are probably the most conspicuous feature of the Jomon period. Human figures were most popular throughout the period, figurines made of clay or stone. Almost all of the figurines were female, of whom the bosoms, bellies, and buttocks were exaggerated. Masks usually hid their faces. Figurines have been found in various situations at the sites; placed alone in a stone structure or in a dwelling. Many pieces were discarded in holes. They were sometimes

goddesses of fertility and at other times used as substitute human beings for curing sickness as votive gifts.

Snakes are another noticeable motif in the art. Realistic figures have been found from middle Jomon sites in central Japan. Snakes often decorated vessels of peculiar shapes, but later, these were replaced by abstract designs such as spirals or waves. Such designs were characteristic decorative motifs of this culture throughout the period. During the late Jomon period, figurines of bears and wild boars were produced in the eastern and northern regions. Some scholars claim that monkeys, dogs, fish, reptiles, and insects were used as motifs, but others believe that the expressions are too vague to determine exactly what they are.

Symbols and Cultural Changes

Two eminent icons, humans and snakes, offer us an interesting suggestion. In Japanese mythology, one of the popular themes is that the snake was the spirit (god) of the land but was subdued by a hero of royal blood in the course of forming Japan. This theme may reflect a transition period with a change of culture and population. Another theme in mythology is that a snake transforms itself into a man and visits a woman at night to fertilize her. There has also been another anecdote saying that a man visits a woman only to find out that her natural shape is that of a snake. He runs away as a fierce snake chases him. This kind of story is referred to in many localities, where particular groups believe that their ancestors were snakes. The fact that the Jomon figurines always wore masks may indicate that they could transform to any shape at will.

The philosophy of merging humans and animals can be observed in many cultures. This is based upon animism, the belief that living beings are composed of two elements, spirit and body. Spirits are eternal and intangible, while visible and tangible bodies are temporal. If this is so, there is no limit on where a spirit may rest in humans, animals, or plants, or even in natural objects. Such a mythic world, where waking life and the life in dreams exist in the same horizon, has been experienced in Arnhemland, Australia. In Australian Aboriginal society, dreams are considered sacred and important. They have named their mythological era *Dreamtime*, which in fact rules their actual life. They use dreams to discover pregnancy and the birth of children, bad accidents, the visit of friends, and so forth. Dreams can also allow discovery of causes and the ways of curing sickness or preventing accidents. Artists in this society claim that they create designs and write poems revealed in dreams.

What happens in dreams was considered real and true, and waking life was temporal or just one of the possibilities of what could happen in the world. Aborigines believe that the world of dreams is operated by spirits: ancestral, powerful, good, and bad. We might consider that a similar atmosphere could have existed in the Jomon period.

Cosmology and Dreams During the Second and Third Phases

It has been estimated that more than one million people moved in and occupied central Japan from about 500 BCE, pushing the Jomon stock out to the southern and northern margins of the Japanese archipelago, Hokinawa and Hokkaido. It is not difficult to assume that they brought in a vast number of new cultural elements. As for the archaeological remains, iconographic characters have been found both in drawn and figurine form. The line-drawn figures were simplified signs that which decorated the surface of pottery vessels or bronze bells. Motifs were expressed either as a single figure or in scenes of daily activities such as hunting, harvesting, or seafaring. Human, deer, and boar motifs were most popular. Dogs, waterbirds, turtles, fish, dragonflies, spiders, and dragons have been observed occasionally.

Figures of humans and birds were made of wood, stone, or clay. It is noticeable that these two characters fly. This coincides with the fact that newcomers believed that they were descendants of celestial gods of the land in mythology. The newcomers also used mirrors as a symbol of the sun. A quantity of Chinese bronze mirrors have been excavated from large-scale tombs—apparently very important artifacts, with decorations on the backs of some of the mirrors depicting Taoist cosmology.

Dreaming took on an important role in governance as well. In written records, Chinese history reveals that the queen governed her nation by shamanism. They used oracle bones to foretell the future and make decisions. Pieces of deer bones and boar bones, with incised lines or small perforations, have been excavated from many sites. *Kojiki* (as cited in Philippi, 1968) describes how dreaming was used to decide national policy. Emperor Sujin had a sacred bed made so that he could dream in order to make a decision in a crisis, for example, to stamp out epidemics or to nominate the heir to the throne. He often listened to the dreams of his subjects in order to make national policy. It is clear that during this period people still believed in the supernatural world, and dreaming was considered a domain where qualified persons communicated with powerful spirits.

As Japan started to actively participate as a member of the East Asian political order, it had to adopt the contemporary Chinese system and philosophy that was a combination of Confucianism, Buddhism, and Taoism. Confucianism denied admission of irrational supernatural phenomena into its own scheme. Taoism is the science of deciding calendar and time, but it also involves supernatural features such as fortune-telling by astronomy and omens. An octagonal building in Horyuuj Temple is said to have been built by Prince Shotoku so that he could shut himself up in isolation for days to get inspiration. It is called the Dream Hall, which reminds us of the sacred bed of Emperor Sujin. A continuation of old ideas and customs can be observed in various archaeological remains: figurines of humans, animals, and various tools for cursing and votive gifts. The

characteristic of the third phase may be described as the confinement of dreaming to the private realm.

New Cultural Contaminations

As the sociopolitical system matured, a strong recurrence of the old psychology could be seen, including fear of supernatural beings such as ghosts, demons, furies, wraiths, and incarnations. The practice of reading omens, fortune-telling, cursing, and pointing was also more widespread. Buddhism adopted a lot of Shinto elements and Shinto shrines were reactivated. Novels and diaries written by aristocratic female artists described vividly such a social climate. Dreaming continued to play an important role as a device to see the future. Dreams could be discoursed by actions and interpretations—they could buy, give, or steal. Some temples or shrines had special compounds for dreaming. People rushed to such places all at once and stayed until they had a good dream. By now, there were professional dream interpreters and dreamers by profession. Nightmares and sleep disorders were commonplace during this period.

The signs of rational individuals can be observed from Phase 4. The author (known as Mother of Michitsuna) of *Kagero-Nikki (The Gossamer Years)* commented that an interpretation of her dream given by a priest was a “stupid lie.” Myoe’s description of his dream was as subjective as modern psychological analysis (see Tanabe, 1992). The Samurai, the realistic warrior class who emerged from entrepreneurial farmers, also brought in rational thinking. According to the *Taiheiki (Chronicle of Great Peace)*, Aoto refused to receive an award after being told that his lord wanted to give it to him because he dreamed of Aoto’s distinguished service. He said he couldn’t receive such an irrational award. What would have happened if he dreamed another way? For such people, the difference between dream and reality was clearly distinct. So, after the Samurai class came to power to rule Japan for centuries, such a rational and pragmatic way of thinking prevailed and provided a suitable precondition for the smooth assimilation of Western culture and philosophy.

The Role of Dreams in the Last Stage

How to evaluate dreams, real and important or fantastic and absurd, depends on the cosmology of the culture. Japanese people today believe that they are a rational and scientific nation. However, millions visit Shinto shrines on New Year’s days, put portable shrines in computer rooms, and have charms in their cars. Most young adults believe in the existence of the soul, and a majority of them practice more than two religions.

Although it has been deformed in the course of history, it is believed that people have retained animism since the Jomon period. In such a psychological climate, they can smoothly shift to soft, personal, irrational, and transient reality in order to avoid the difficulty of hard reality. There, they can enjoy pleasant sleep and dream. For anthropologists, this

is a very interesting characteristic of the Japanese, whose image varies from one of purely economic human types to one of quiet peaceful people in the eyes of Westerners.

Significance of the Struggle in Ancient Norse Mythology

Anthropologists frequently emphasize the newfound interest in cosmology as, to a large extent, attributable to the influence of the work of Lévi-Strauss. Although in his early writings he does not use the word *cosmology*, and hardly does so subsequently, his work inspired a new and different interest in cosmology. Data derived from many different cosmologies, together with mythologies, were being used to put forward general theories about the workings of the human mind. Whether the focus of anthropological studies is on kinship, ritual, house construction, or even social change, most find it impossible to discuss cultural and social practices without relating them in some way to indigenous, often ancient, cosmologies.

Vafpruðnismál is the *Codex regius* manuscript dated to around 1280, often known simply as the Poetic Edda, but it is one of the few Eddic poems also found elsewhere. All texts commonly date from the 13th century in their present form, but the Poetic Edda is usually regarded as old, even originating from before the Christianization of Iceland in 1000. It is one of several gnomic mythological poems composed in the meter of wisdom poetry: All verses but one are spoken by the protagonists, making it dramatic in form, regardless of whether it was ever performed. The Eddic poem depicts a contest of wisdom between Odin and a wise giant. It reenacts the conflict between gods and giants, which seems to lie at the heart of the heathen worldview, as reflected in 13th-century sources. Paternity is a major theme, and Odin's quest for knowledge of the origins and the end of the world outline the poem's core.

The relationship of gods and giants in these classic works is complex. The giants are the ancestors of the gods (including Odin himself) and of the world. Their Otherness is entwined with proximity. The giant's foremost attribute is his extreme old age and wisdom, whereas his size may be secondary to his paternal role. When Odin has plied the giant for information about the past, he turns to the future, the impending last battle of gods and giants and how he himself will meet his end. He then wins the contest by asking a fraudulent last question about what he whispered into his own son's ear. The death of the giant is closely associated with the proclamation of Odin as the new father and his growing awareness of his own mortality.

The Mission

Most studies of this Nordic text concentrate on two aspects: (1) the wisdom contained in the poem, which concerns important parts of heathen cosmology, and

(2) the duel itself and its significance. J. Cohen (1999) has claimed that in the Poetic Edda "constructing an identity for the subject and composing a history for the world are two versions of the same process" (p. 94). Without this poem, the importance of giants in the Nordic cosmos would be far less clearly represented. The battle is a duel of words, which concerns knowledge and the cosmos. The first five verses are a prelude to the contest and yet contribute much to the poem's overall meaning, since they establish the contest as a symbolic journey.

Odin, the wandering high god of Old Norse heathenism, informs his wife Frigg that he wishes to engage in a battle of wits against a giant called Vafpruðnir. He wants to seek out the giant and claims he is curious about the ancient knowledge that this all-knowing giant may possess. Frigg warns that he is the mightiest of giants. She is, nevertheless, persuaded that this mission is fundamental for Odin. From his point of view, the journey is a test—a challenge and a rite of passage. Odin needs to face the giant, to conquer him and to acquire knowledge and power from him.

The rest of the poem takes place in Vafpruðnir's hall, where the giant first has to discover whether his dissembled guest is an honorable antagonist. Then god and giant engage in a contest of wisdom where the stake seems to be the loser's head. This tragedy with two main characters is relatively plain, as Eddic stories go, and there are no descriptions of scene. It is left to the audience to stage the duel in their own heads and, as is so often the case with the mythological narrations of the Poetic Edda, the scene seems to refer to a lost mythical world. The text is not obscure in itself, but perhaps it has been made so by a loss of context. It is not clear, for instance, why Odin needs to contend with the giant and wherein Vafpruðnir's significance to him lies, but the epic impresses upon us that Odin is interested in the contest: It is he who starts it and who needs it. Odin is the aggressor, whereas the giant merely accepts his guest as an adversary. However, the reason given for Odin's eagerness is the figure of the antagonist. To fathom the quest, it is important to understand who he is and what he means to Odin.

The answer is complex, and indeed the giant of the Eddic world is a complex figure. The word *giant* occurs many times, as if to establish that it is an important attribute as well as wisdom. This may seem unusual in light of later folktales, where trolls and other relatives of giants are presented as stupid, but stupidity is rarely a quality of Eddic giants. There is also an emphasis on the giant's strength, but it is not clear whether this is pure physical strength or the strength derived from magical wisdom; the word *powerful* is often conjoined with a sort of witchcraft in Old Norse texts. It remains to be seen what kind of wisdom the giant possesses and how it is important to our perception of him.

The Symbolic Role of the Father

When Odin comes to the giant's hall, it is said that Vafpruðnir is a father, but not, however, the only father in

the duel. In the prose of *Snorra-Edda*, Odin is frequently named the father of all the gods. In this Poetic Edda, Frigg also calls her husband “father of men.” The contest is established as a contest of fathers before it begins. This makes it an attractive possibility that paternity might be a major theme of this particular poem and perhaps lie at the heart of the giant’s significance in Old Norse mythology. The quest is for a showdown between the two fathers—a conflict that may be characterized as oedipal (not necessarily in the Freudian sense), with Odin acting out the role of the son, since in the *Snorra-Edda* Odin is, on his mother’s side, the grandson of a giant. Of the two fathers, one is depicted as a son as well, and the two represent two different worlds. But which two worlds? Considering the giant’s close relationship to nature, the first assumption might be that the god and the giant represent the opposing forces of nature and civilization. Odin’s first questions to his rival concern the elements of nature, and questions about giants and natural elements are interwoven in the poem. After Odin has asked Vafprudnir about the origin of the sun and the moon, day and night, and winter and summer, he turns suddenly to the origins of the oldest living being, Ymir. He asks about his origins and how he grew.

The answers sometimes involve giants as well, which is best exemplified when Odin asks about the origin of the wind and the giant reveals that its originator is a giant in the shape of an eagle, called *corpse-swallower*. In narratives such as romances and folktales, giants dwell on the periphery, in the wilderness. Whether Vafprudnir rules over a distant kingdom in a spectacular landscape is unclear, for it is merely established that the giant possesses knowledge about nature. He lives in a hall, which does not suggest the wilderness. While Odin has to travel to get there, it is not revealed how lengthy his journey is, or where the giant resides (the Norse tradition says East, in frozen lands). It may be precisely the status of the giant as a father that makes Vafprudnir knowledgeable about nature and the elements, as nature is often seen as preceding civilization.

The Struggle Between Gods and Giants

There is an ongoing conflict between the gods and the giants; however, the relationship is complicated by the fact that they are also ancestors. In Odin’s case, this ancestry is direct. Giants are also known as ancestors of royal families in other sources (for instance, Giant Dofri as a foster father of King Haraldr, the legendary founding father of Norway). The enemy of gods turns out to be their grandfather. Furthermore, the enemy of the cosmos (earth) is its own past self, the giant descending from Ymir, whose body now has been transformed into earth. The enormity of giants is easily explained as a secondary trait going with their ancestral role—in the eyes of small children, their parents are giants. This means that monstrous enormity may go hand in hand with proximity. It is important to emphasize that, in Norse ancient mythology, otherness

is entwined with proximity; the giant is not just an alien, he is a familiar character. The frequent use of the word *father* forces us to regard the contest as a generational conflict, a symbolic battle between the past and the present, the old and the new.

We might define this conflict as oedipal or refer to the myth of Kronos-Saturn, which was known in medieval Iceland. The choice of father-son conflict seems to be subject to the protagonist’s point of view: Odin is like Oedipus in seeking out and killing a paternal figure, and the giant is a Kronos-like figure who poses a threat to his descendant. In Greek mythology, Kronos was the father of Zeus, who swallowed his own children, only to be toppled, castrated, and exiled by Zeus. In Old Norse mythology, this deposed and exiled ancestor (represented by the descendants of Ymir) had not admitted defeat and is an exile only in that he seems mostly to live on the outskirts of the known world and persist in distressing the current rulers of the world. The relationship with the Kronos-Oedipus myths is further complicated by the fact that it does not at first seem right to regard Vafprudnir as the aggressor in the struggle; he is a father figure who is sought out and defeated.

It has often been argued that the giants represent chaos, which in the beginning was embodied in the progenitor Ymir whom the gods had to kill in order to make the present world (cosmos). However, since the giants were not all drowned, they have continued to be a destructive and chaotic force, opposing the natural order of the gods and waging war on them. The narration may be seen as a reenactment of this struggle between two wise fathers, order and chaos. At stake is the head of one of the competitors, but the death of both of them closes the circle. There is a symbiosis between the future and the past, perhaps inspired by the notion of fate, that the future of the world is predestinated and the decisions were made long ago, so that a very ancient being is more likely to know the future than ourselves.

The last few verses of the cosmogony indicate that Odin has succeeded in his quest for the father role. When he asks about his own death, the giant answers by using the term *father of men* (the wolf will swallow the father of men). In spite of all their cheating, the Old Norse gods, somewhat uniquely for gods, nevertheless face extinction in the end: as scholars have noted, the Old Norse end of the world differs from the Christian account in that evil triumphs over good. This is logical if the gods represent order and giants chaos. The perfect only needs one flaw or imperfection for the adversary to win; a tiny chink in the armor of order leads to chaos. While good must be whole, evil is allowed to be sundered, imperfect, and chaotic, and in the end that may prove to be advantageous. The world goes on but the individual’s end is final. Odin has learned that the world will survive his death. Like a giant, our death is a huge and horrific presence, intertwined with our creation and being, but negative in that it signifies its end. This may account for the paradoxical nature of the giant in Old Norse mythology: We observe a duel of two fathers to the death

but we also learn about death, where the giant father gets a rare chance to enunciate his own point of view. He also has the last word, triumphing over Odin while he admits his own defeat.

Nature and Culture in Amazonian Cosmology

An important aspect of Amerindian culture has been called *perspectival quality*: The conception, common to many peoples of the continent, is based upon the idea that the world is inhabited by different sorts of subjects or persons, human and nonhuman, which apprehend reality from different points of view. This idea cannot be reduced to our current concept of relativism, which it at first seems to call to mind. As many anthropologists have already concluded, the classic distinction between nature and culture cannot be used to describe domains internal to non-Western cosmologies without first undergoing a rigorous ethnographic critique. Such a critique, in the present case, implies the redistribution of the predicates subsumed within the two paradigmatic sets that traditionally oppose one another under the heading of nature and culture: universal and particular, objective and subjective, physical and social, fact and value, the given and the instituted, necessity and spontaneity, immanence and transcendence, body and mind, and animality and humanity, among many more.

Such an ethnographically based reshuffling of our conceptual schemes leads many scholars to suggest the expression *multinaturalism*, to designate one of the contrastive features of Amerindian thought in relation to Western *multiculturalist* cosmologies. Where the latter are founded on the mutual implication of the unity of nature and the plurality of cultures—the first guaranteed by the objective universality of the body and substance, the second generated by the subjective particularity of spirit and meaning—the Amerindian conception would suppose a spiritual unity and a corporeal diversity. Here, culture or the subject would be the form of the universal, while nature or the object would be the form of the particular. This inversion, perhaps too symmetrical to be more than speculative, must be developed by means of the plausible phenomenological interpretation of Amerindian cosmological categories, which determine the constitutive conditions of the relational contexts we can call *nature* and *culture*.

Humans and Animals: A Perspective View

There are numerous references in Amazonian ethnography to an indigenous theory showing how the way humans perceive animals and other subjectivities that inhabit the world—gods, spirits, the dead, inhabitants of other cosmic levels, meteorological phenomena, plants, and occasionally even objects—differs profoundly from the way in which these humans see themselves. Usually, in normal

conditions, humans see humans as humans, animals as animals, and spirits (if they see them) as spirits; however, spirits and animals see humans as animals, either as predators or prey. By the same token, animals and spirits see themselves as humans: They perceive themselves as (or become) anthropomorphic beings when they are in their own houses or villages, and they experience their own habits and characteristics in the form of the culture. They see their food as human food (e.g., jaguars see blood as manioc beer, vultures see the maggot in rotten meat as grilled fish); they see their bodily attributes (fur, feathers, claws, beaks) as body decorations or cultural instruments; they see their social system as organized in the same way as human institutions (with chiefs, shamans, ceremonies, and exogamous moieties).

The allocation *to see as* refers literally to percepts and not analogically to concepts, although in some cases the emphasis is placed more on the categorical than on a sensory aspect of the phenomenon. Generally, animals are people, or see themselves as persons. Such a notion is virtually always connected to the idea that the manifest form of each species is a mere envelope—a garment concealing an internal human form, usually only visible to the eyes of the particular species or to certain trans-specific beings such as shamans. This internal form is the soul or spirit of the animal: an intentionality or subjectivity formally identical to human consciousness, materializable, in a human, bodily schema concealed behind an animal mask.

The Essence and the Appearance: A Cosmological Transformation

At first sight then, there is a distinction between an anthropomorphic essence of a spiritual type, common to animate beings, and a variable bodily appearance, characteristic of each individual species but which, rather than being, is instead changeable and removable clothing. This notion of clothing is one of the privileged expressions of metamorphosis—spirits, the dead, and shamans, beasts that turn into other beasts, and humans that are inadvertently turned into animals. This is an omnipresent process in the highly transformational world proposed by Amazonian culture. This perspectivism and cosmological transformation can be seen in numerous South American ethnographies and it can also be found, and maybe with even greater generative value, in the far north of North America as well as in Asia and among hunter-gatherer populations of other parts of the world.

Perspectivism does not involve all animal species (besides covering other beings); the emphasis seems to be on those species that perform a key symbolic and practical role, such as the great predators and the principal species of prey for humans. In fact, one of the central dimensions, possibly the fundamental dimension, of perspectival inversions

refers to the relative and relational statuses of predator and prey. On the other hand, however, it is not always clear whether spirits or subjectivities are being attributed to each individual animal, and there are examples of cosmologies that deny any consciousness to postmythical animals. Nonetheless, as is well-known, the notion of animal-spirit masters (e.g., mothers of the game animals or masters of white-lipped peccaries) is widespread throughout the continent. These spirit masters, clearly endowed with intentionality analogous to that of humans, function as hypostases of the animal species with which they are associated, thereby creating an intersubjective field for human-animal relations even where empirical animals are not spiritualized.

We must remember, above all, that if there is a virtually universal Amerindian notion, it is that of an original state of undifferentiation between humans and animals, described in mythology. Myths are filled with beings whose form, name, and behavior inextricably mix human and animal attributes in a common context of intercommunicability, identical to that which defines the present-day intrahuman world. The differentiation between culture and nature, shown by Lévi-Strauss as the central theme of Amerindian mythology, is not a process of differentiating the human from the animal, as in our own evolutionist mythology. The original, common condition of both humans and animals is not animality, but rather humanity. The great mythical separation reveals not so much culture distinguishing itself from nature, but rather nature distancing itself from culture: The myth tells how animals lost the qualities inherited or retained by humans. Humans are those who continue as they have always been; animals are ex-humans, and humans are not ex-animals.

The common point of reference for all beings of nature, then, is not humans as a species but rather humanity as a condition. The distinction between the human species and the human condition has an evident connection with the idea of animal clothing hiding a common spiritual essence and the issue of the general meaning of perspectivism. It is important to note one of its many corollaries: The past humanity of animals is added to their present-day spirituality hidden by their visible form in order to produce that extended set of food restrictions or precautions. These restrictions or precautions either declare certain animals inedible that were mythically consubstantial with humans, or demand their desubjectivization by shamanistic means before they can be consumed (neutralizing the spirit, transubstantiating the meat into plant food, semantically reducing it to other animals less proximate to humans). This all comes under the threat of illness, conceived of as a cannibal counter-predation undertaken by the spirit of the prey turned predator, in a lethal inversion of perspectives that transform the human into an animal.

These views illustrate how Amerindian perspectivism has an essential relation with shamanism and the valorization of the hunt. The hunting ideology is also, and above all, an ideology of shamans, insofar as it is shamans who administer

the relations between humans and the spiritual component of the extra-humans, since they alone are capable of assuming the point of view of such beings and, in particular, are capable of returning to tell the tale. If Western multiculturalism is relativism as public policy, then Amerindian shamanism is multinaturalism as cosmic policy.

Nature and Relations With Humans: Animism in Amerindian Culture

In recent studies, Descola (1986) distinguishes three modes of objectifying nature: (1) totemism, where the differences between natural species are used as a model for social distinctions (i.e., where the relationship between nature and culture is metaphorical and marked by discontinuity); (2) animism, where the elementary categories structuring social life organize the relation between humans and natural species, thus defining a social continuity between nature and culture, and founded on the attribution of human dispositions and social characteristics to “natural beings”; and (3) naturalism, typical of Western cosmologies, which suppose an ontological duality between nature (the domain of necessity) and culture (the domain of spontaneity) as areas separated by metonymic discontinuity. Animism is characteristic of societies in which animals are the strategic focus of the objectification of nature and of its socialization, as is the case among the indigenous peoples of America, reigning supreme over social morphologies lacking in elaborate internal segmentations. But this mode can also be found coexisting or combined with totemism, wherein such segmentations exist.

The contrast between animism and naturalism is not only classificatory, but primarily cosmological. Animism could therefore be defined as an ontology postulating the social character of relations between humans and nonhumans: The space between nature and society is itself social. Naturalism is founded on the inverted axiom: Relations between society and nature are themselves natural. Indeed, if in the animistic mode the distinction nature/culture is internal to the social world, humans and animals being immersed in the same sociocosmic medium (and in this sense nature is a part of an encompassing sociality), then in naturalist ontology, the distinction nature/culture is internal to nature (and in this sense, human society is one natural phenomenon among others). In Western naturalist ontology, the nature/society interface is natural: Humans are organisms like the rest, body-objects in ecological interaction with other bodies and forces, all of them ruled by the necessary laws of biology and physics; productive forces harness, and thereby express, natural forces. Social relations, that is, contractual or instituted relations between subjects, can only exist internal to human society.

The problem with this view is that given the universality of nature, the status of the human and social world is unstable and, as the history of Western thought shows, it

perpetually oscillates between a naturalistic monism and an ontological dualism of nature/culture. Culture is the modern name of spirit, or at least it is the name of the compromise between nature and grace. Of animism we would be tempted to say that the instability is located in the opposite pole: There the problem is how to administer the mixture of humanity and animality constituting animals, and not, as is the case among ourselves, the combination of culture and nature which characterizes humans; the point is to differentiate a “nature” out of the universal sociality. Animism, interpreted as human sociality projected onto the nonhuman world, would be nothing but the metaphor of a metonymy. Among the questions remaining to be resolved, therefore, is that of knowing whether animism can be described as a figurative use of categories pertaining to the human-social domain to conceptualize the domain of nonhumans and their relations with the former.

Conclusion

Connecting spirit and body between myth and cosmic world remains a challenge. As we know, the status of humans in Western thought is essentially ambiguous: On one hand, humankind is an animal species among others, and animality is a domain that includes humans; on the other hand, humanity is a moral condition that excludes animals. These two statuses coexist in the problematic and disjunctive notion of “human nature.” Our cosmology postulates a physical continuity and a metaphysical discontinuity between humans and animals, the former making of man an object for the natural sciences, the latter an object for the “humanities.” Spirit or mind is our great differentiator: It raises us above animals and matter in general; it distinguishes cultures; it makes each person unique before his fellow beings. The body, in contrast, is the major integrator: It connects us to the rest of the living, united by a universal substrate (DNA) which, in turn, links up with the ultimate nature of all material bodies.

In contrast to this, Amerindians postulate a metaphysical continuity and a physical discontinuity between the beings of the cosmos, the former resulting in animism, and the latter in perspectivism: The spirit or soul (here not an immaterial substance but rather a reflexive form) integrates, while the body (not a material organism but a system of active affects) differentiates. The body appears to be the great differentiator in Amazonian cosmology. However, the Amerindian emphasis on the social construction of the body cannot be taken as the culturalization of a natural substrate, but rather as the production of a distinctly human body, meaning naturally human. Such a process seems to express not so much a wish to de-animalize the body through its cultural marking, but rather to particularize a body still too generic, differentiating it from the bodies of other human

collectivities as well as from those of other species. The body, as a site of differentiating perspective, must be differentiated to the highest degree in order completely to express it. As bundles of affects and sites of perspective, rather than material organisms, bodies “are” souls, just, incidentally, as souls and spirits “are” bodies. Indeed, body and soul, just like nature and culture, do not correspond to substantives, self-subsistent entities, but equally to types of bodies, endowed with properties—affects—*sui generis*.

PEASANT SOCIETIES

KATHLEEN NADEAU

California State University, San Bernardino

By the latter part of the 20th century, most scholars of the peasantry agreed that global capitalism had a disintegrating effect on traditional agricultural societies. What they were at odds over was the issue of how such economies were changed, and the consequences of these changes. *Formalists* were of the opinion that the capitalist market improved individual well-being by rewarding farmers who adopted new economic behaviors and farming techniques to maximize productive yields and profits (Popkin, 1979). *Substantivists* contended that the appearance of capitalism had an adverse effect on the traditional value structure and practices in these communities by instituting new classes and outside alliances that undermined the preexisting system at the expense of the common person (Scott, 1977). *Marxists* argued that capitalism led to the differentiation of formerly integrated peasant societies into fragmented societies composed of competing individual farmers who became either better-off entrepreneurs or poor-wage workers. Or, they argued, if this polarization between two predominant and opposing classes does not occur, then the peasantry as a class, in itself, becomes a stratified, divisive, and unstable class because peasant farmers shift between capitalist and precapitalist relations of production in a transitional economy (Kahn & Llobera, 1981; Stoler, 1985).

This chapter reviews the major debates on the nature and consequences of globalization and culture change in peasant societies, while speculating on the future of these

societies. It is arranged accordingly: First, the origins of this disagreement in the classical literature on Marxism are reviewed. This is followed by a discussion of the successive substantivist versus formalist controversy. Finally, the *modes of production* debates that overtook and went beyond this controversy are examined and some conclusions are drawn.

Classical Theory and Debates

In the classical literature, scholars investigated the question, first raised by Karl Marx, of whether or not the effects of capitalism would result in the proletarianization and fragmentation of formerly integrated and, largely, self-sufficient peasant societies. Followers of Lenin argued that capitalist penetration would end by destroying and expropriating the peasantry, while Chayanov and his followers contended that, although this may sometimes be the case, it is not necessarily so. Terry Cox (1986) explains that Lenin initially theorized that class differences occurred in peasant societies as a result of the penetration of capitalism. Lenin isolated the rise of capitalism as the root cause of inequality in the peasantries. According to his view, peasant involvement in commodity production led to the unequal distribution of the means of production between households. This began the process of class polarization and the proletarianization of those households with insufficient means of production.

Later, Lenin expounded a twofold explanation to account for varying forms of capitalist differentiations then occurring in the Russian countryside. He theorized that class differentiations occurred, first, through preexisting, internal divisions in the peasantry and, second, as a result of the process of changes already taking place on large-landed estates where peasants were acting collectively as a class on behalf of their own interests. Cox (1986) explains this as follows:

Agrarian Marxists' theoretical heritage was one which, despite hints to the contrary in Marx, tended to assume that inherent in the growth of commodity production in peasant agriculture was the necessary emergence of capitalist farming and, associated with it, the class differentiation of the peasants. (p. 19)

That is, unless farmers consciously resisted such tendencies, capitalism would develop as a result of the growth of commodity production in agriculture. Lenin drew on the existing statistical data on rural inequalities to argue that peasant societies represented a beginning stage in the development of the bourgeois and proletarian classes, but he did not yet mean that the peasantry was being divided into two separate and distinct classes.

Accordingly, differentiation in the peasantry, largely, came about as a result of differences in wealth between households who shared the same means of production or way of life, without regard to their position in the wider stratified social system. In contrast, Chayanov (1966) argued that differentiation seemed to occur among the peasantry in predictable cycles—that is, households were known to be relatively rich and relatively poor at different periods in their life history (pp. 249–250). Therefore, Chayanov minimized inequalities among peasants. He considered inequality to be intrinsic in peasant societies in a natural economy, and not necessarily a threat to the economy or a result of the introduction of capitalism. Yet, when Chayanov conducted his fieldwork, everywhere the peasantries were already involved in the capitalist market economy. Hence, Chayanov failed to recognize that if the peasantry becomes divided by capitalism, they face the danger of becoming a marginalized class of landless laborers or labor pool. With this, Lenin argued that peasants represented a preliminary stage in the development of agrarian bourgeois and proletarian classes. But Chayanov refused to accept this view. He proposed that it was important to distinguish demographic differentiation from capitalist divisions taking place in the countryside. He also thought that it was important to treat distinct types of differentiation with particular methods and theories, and not to confuse them, which, ironically, he did (see Chayanov, 1966, pp. 249–250, 255).

Hence, Chayanov's research came in for criticism and debate. Kritsman (as cited in Cox, 1986) found fault with Chayanovian theory for failing to place the peasants in the perspective of their wider economy. He argued that the general disintegration of the Russian countryside was a

result of the war and revolution that was forcing former proletarians into subsistence farming to survive. He suggests that Chayanov mistook these farmers for peasant households persisting in a natural economy. Kritsman argued that Chayanov did not recognize that the outcome of war was an intertwining of different social and ideological structures, and that the most important question to ask was about how these different structures interact and affect each other. Cox (1986) clarifies that the Russian peasantry represented the petty bourgeoisie mass and the point of research was to distinguish how far this mass retained its basic homogeneity, and how far it was differentiating into discrete classes with different class interests. Alavi and Shanin (1982) put it this way: "Peasantries are new creations and not simply survivals of a pre-capitalist past that are conserved as such, to subserve capitalism" (p. 188). Once peasants become involved in the capitalist market economy, they exist in relation to it because they have lost their precapitalist moorings. According to his adversaries, Chayanov failed to understand the nature of capitalist farming. Rather, he understood capitalist farming, largely, in the same way as he did peasant farming, involving individual family farms using the same social organization and technological machineries, except that capitalist farms employed wage labor. This basic misperception gave rise to other shortcomings in Chayanov's theory.

Chayanov, inadvertently, supported a view of peasant societies that ignored the forces and relations of production. He stressed the determinant role of natural factors on consumption and labor as opposed to the influence of technological changes that were tied to political, ideological, economic, and social forces of production. Chayanov developed a theory of how different farm machineries could be best used in different and particular sorts of farm communities or social organizations, without first analyzing the effect of the introduction of machinery on peasant farm organization itself (Godelier, 1986; Pfaffenberger, 1988). In other words, his theory was abstract and bore little reference to real social life. He assumed that the sources of change in peasant societies were derived from natural factors, rather than socially constructed factors. This assumption led him, and his followers, to view peasant farming as an independent type of social organization that could survive the onslaught of capitalism. However, Chayanov did not consider how the influence of petty commodity production could slowly transform the relations of peasant farming, giving rise to new forms of exploitation and class interests. Chayanov did not factor into consideration the historical contexts in which peasant societies were situated.

Cox (1986) explains that the development of capitalist class stratification occurs in peasant farm communities when the workers are separated from their means of production. On the one hand, it is the conversion of the peasant worker into the proletariat or the hired laborer. On the other hand, it is the conversion of the means of production into capital (p. 87). However, the democratization or liberalization of capitalism

has resulted in all kinds of nonconventional reactions in agrarian societies that do not immediately fit this model. According to Kritsman (as cited in Cox, 1986), for example, class stratification had already begun to develop in the Russian countryside where those carrying out capitalist exploitation were broadly not the strong, but also the smaller peasants possessing the means of production. Hence, the conventional categories of rich, middle, and poor were called into question. Clearly, the middle peasantry cannot be characterized as independent farmers who were neither exploiting nor being exploited in their daily work. Thus, the study of the peasantry is problematic as illustrated by the question of proletarian households with small vegetable gardens, or of determining the accuracy of class boundaries between households.

Cross-culturally, students of the peasantry still grapple with theoretical questions first raised by Karl Marx concerning the direction of social and economic change in precapitalist agricultural societies that have entered into relation with capitalism. The same arguments can be heard in new contexts. Dogmatic Marxists contend that under the capitalist system, the integrated natural economy of the peasantries becomes disrupted. Small-scale landowners either become capitalists or wagedworkers who lose their control over the means of production. This polarization process will eventually produce a revolutionary crisis. In contrast, nondogmatic and creative Marxists or Marxist-postmodernists (e.g., Godelier, 1986; Kahn, 1980; Stoler, 1985; Wolf, 1986) counter that there are already various peasant societies in contact with capitalism that do not necessarily fit such a dogmatic model. They declare that there is no singular and universal definition of the peasantry.

Peter Worsley (1984) explains that early Marxists interpreted mode of production theory mechanistically. They saw the economic base of society as giving rise to social relations or the superstructure of society in all of its political and cultural aspects. They did not realize that world capitalism becomes embedded and transformed through preexisting relations of power and dominance. In the third world, these relations were forged early on between the subdued peasantries and their colonial overlords. So, rather than replacing precapitalist modes of production, capitalism dominates and exists side-by-side with them. Early Marxists thought that the working classes, not peasants, were the chief agents of social and economic change in history. But the idea of some amorphous working class being a culture-free economic unit in social history is a myth. Which class will be the vanguard for socialism is a function of the history and resultant social structure of a particular society. What is needed for the study of peasant societies is a dialectical theory that encompasses all of the exploited classes in rural and urban areas, rather than one that rejects segments of them as being counter to the revolution. New revolutionary movements cut across boundaries of class,

gender, and culture by forming strategic alliances with other proactive groups who fight for greater equity and justice. They need to be examined and analyzed in the historical context of the actual societies in which they are situated.

According to Worsley (1984), "Exploited classes are not inherently revolutionary, nor reformist, or anything. What they become is a function of the values and institutions available to them" (p. 232). The concept of class becomes potentially meaningful through political and ideological processes that bring about the development of class consciousness and political mobilization. Marx theorized that peasants lacked revolutionary consciousness (were like a sack of potatoes) and, thus, had to be liberated by outside leaders. Lenin thought that class consciousness had to be brought into the peasantries by an outside revolutionary party. In contrast, Rosa Luxemburg (as cited in Bottomore, 1985) argued that "the experience of class struggle creates the conditions necessary for the development of class consciousness and that patronizing the [peasant] proletariat by intellectual elites leads only to weakening, and to passivity" (p. 81). Also, before capitalism entered, peasants already had the makings of class consciousness and were already organizing collectively on their own behalf as their bylaws and customary laws demonstrate.

Contrary to Marx's description of the poor as being a lumpen proletarian mass who hinder the revolution because they stand ready to take workers' jobs, the poor are part of the working classes, not marginal to them. Veblen (as cited in Mitchell, 1964) argues that the revolutionary consciousness needed for socialist revolution is often derailed by another working-class revolution of rising expectations and conspicuous consumption. Working classes are already stratified among themselves prior to their entrance into the labor forces, and their internal divisions are intensified in their relationship to capitalist production. The working upper class usually arrests the potential for political activism by luring some activists into its hierarchical ranks to help control the rest of the population by giving them job security and decent wages. From this perspective, the poor become vulnerable to a wide range of astute and powerful influences because they are responding to their poverty in an instrumental manner, not ideologically, because they want to escape their dire circumstances. They pursue their own best interests, as they see them, within the context of their society and culture.

Likewise, models that reduce peasantries to family farms worked by family members who provide for the needs and reproduction of the household, as a unit of production, are inadequate because they fail to account for the wider context in which these families are found. Bernstein (1979) explains that these models are without history. They cannot distinguish between medieval European peasants, whose surplus labor was extracted in the form of rent by feudal lords, and contemporary, third-world peasants who operate in a world that is dominated by global capitalism (p. 422). Models of the peasantry need to take into account

the relations between different units of production, between various classes, and of the process of social reproduction as a whole. One model equal to this task is found in articulation theory, which is the study of how different modes of production interact with each other. In Southeast Asia, some anthropologists have employed this theory to separate out the different modes of production and contingent aspects of class, ideology, and culture in modern-day peasant societies. These anthropologists, also, have used articulation theory to study migration patterns of individual family members, and the effects of migration on the local community. Such an approach is able to account for how family members and households use outside monetary and material goods to perpetuate, or transform, rural social relations. This approach will be discussed in greater detail in the next section.

Substantivist-Formalist Debate

By the latter part of the mid-20th century, most of the literature dealing with peasantries emerged out of the widely publicized dispute between the substantivists, represented by James Scott (1977), and formalists, exemplified by Samuel Popkin (1979). This moral economy versus rational peasant debate looked at the interpenetrating structures of capitalism, ideology, and peasants in terms of the relationship between subsistence strategies and peasant rebellions in Southeast Asia. Substantivists argued that peasants live in communitarian villages that work for the common good. Village bylaws and customary laws work against norms of individualism and personal achievement that are characteristic of “Western” capitalist societies. According to this view, landlords and peasants negotiate patron-client contracts that provide farmers with their basic needs for social security. These mutually interdependent relationships, though still unequal, are based on norms of reciprocity that guarantee peasants their subsistence needs. This safety-first maxim, explains Scott, is a logical consequence of peasant dependence on agriculture and embodies the relative preference for subsistence over high-earning wages. However, once this promise to provision the peasants’ basic needs is broken by landlords, the peasants will rebel.

Scott (1977) proposes that the penetration of capitalism into peasant villages will lead to family discord and breaks the traditional landlord-to-peasant bonds because earlier patterns of reciprocity no longer apply. For example, the Green Revolution, which promoted the use of artificial fertilizers, pesticides, and new hybrid varieties of rice and corn and mechanized farming in agriculture, disrupted traditional landlord-to-peasant exchanges and the associated subsistence ethic. Landlords and machine operators no longer needed the support of peasants to legitimate their authority because they could rely on the backing of powerful, outside-state authorities. They were able to take advantage of farmers who needed cash to live in the new economy. There was

no longer a need for local elites to establish a personal bond with those who worked their farms; rather, they could easily shift and choose between personal and impersonal ways of dealing with them. Mechanized farming effectively led to the loss of farmers’ traditional social security system as many became unemployed.

In Southeast Asia, many small farmers were hesitant to adopt the new farm technology and seed crops being promoted by the Green Revolution because they entailed high risk in the face of unreliable weather conditions and outside forces. In order to lessen these uncertainties, peasants help each other to maintain a given level of production, even if they may not be maximizing yields. Subsistence farmers prefer to produce crops for home consumption, rather than for sale on the market. They select traditional seeds that have proven successful, even if they produce less than the high-yield varieties. In like manner, they tend to diversify their risks by multi-cropping, rather than mono cropping (Scott, 1977, pp. 4, 23). However, Feeney (1983) points out that Scott employed Roumasset’s safety-first model for the study of the family farm. If the risks are too high, the family will take certain steps to ensure their income will not fall below a certain dangerous level. What Scott describes as risk aversion could be interpreted as maximizing behavior. Feeney suggests that a farmer might choose to diversify his crops and plots if there are different types of land on his farm, and such a strategy would end by maximizing his profits. Or the farmer may seek to optimize his profits by working considerations of available family labor into his calculation, in terms of time factors and seasonal variations. Furthermore, when peasants are faced with an unpredictable market where prices are variable and subject to sudden change, they may have more incentive to produce for home use, rather than for sale.

Another model that Scott (1977) uses is Chayanov’s (1966) model. Scott focuses on the provisioning of a secure existence as the stabilizing factor in peasant communities. He argues that so long as peasants’ basic-security needs are met, they will no longer strive for profit. Furthermore, states Scott, “Peasants are not interested in social mobility” (pp. 186–187). However, Chayanov developed his hypothesis that the degree of self-exploitation is determined by a peculiar equilibrium between family demand satisfaction and the drudgery of labor itself, in relation to family farms in a natural economy. He did not place them in their historical context. Chayanov viewed peasant households as a distinct type wherein social differentiation occurred demographically through the fusion and fissioning of families. Yet, he also considered social stratification occurring in peasant societies as a result of such factors as commodity production in relation to the development of capitalism. He stressed the distinction between demographic differentiation and the development of classes due to the penetration of capitalism and stipulated that it is important not to confuse the two kinds of social

classes because each type calls for a different theoretical framework (Chayanov, 1966, pp. 249–250).

However, Chayanov's model, for the study of family farms in a natural economy, begins from the perspective of use value, not exchange value. It is not applicable to the particular communities in Scott's study because these communities have long been dominated by capitalism. Southeast Asian peasants compete and desire to increase their economic well-being, but the system works against them. Chayanov's theory is inadequate to the task of explaining underlying motivations and behaviors of peasants living in relation to the wider capitalist economy. Southeast Asian peasant communities have a long history of involvement in production for export under the various earlier colonial regimes and, prior to colonialism, under earlier kingdoms in a wider, maritime-trade economy based on semifeudal, lineage, and tributary modes of production. Paternalistic features of landlord-to-peasant relations are intimately connected to patterns of dominance and exploitation evolved under such traditional settings. This brings Scott's hypothesis that peasant behavior and reproduction results from their having to meet basic needs into question.

In contrast to the substantivist viewpoint, the formalists, represented by Popkin (1979), hold that peasant society is made up of individuals who pursue their own personal interests. From this perspective, peasants are household-utility maximizers who are motivated by individual rationality in ways similar to individuals in highly developed capitalist societies. They will take risks, and even go against group norms, so long as it is profitable to do so. Traditional peasantries can be highly stratified, as were Confucian villages in Vietnam before the Vietnam-American war, and individual survival in such instances is not necessarily the concern of the whole community. Also, the articulation of capitalism with the peasantry does not always result from outside penetration; rather, in some cases, it is sought out by local elites who proactively cultivate powerful outside allies to strengthen their positions in power struggles already taking place at the village level. Thus, peasants may have been already disillusioned with their villages before the appearance of capital because traditional norms governing behavior may have been violated. Popkin argues that the Green Revolution or the introduction of capitalist farm inputs can improve the quality of life for many in these traditional villages.

Popkin (1979) examined villages in Vietnam before the fall of Saigon and the rise of communism, arguing that villagers act rationally as self-calculating individuals, not in communion, to avoid risks. If this were not the case, peasants would have worked the land together as a whole group to increase production, rather than as individual farm units. But, at the same time, he recognizes an ecological basis for individual holdings: "Land reallocation is adapted to the environment and decreases the chance of a family losing all of its land at once in event of inclement weather" (p. 105). Popkin finds that Scott's thesis of a village-wide social

security system does not apply in all cases. In traditional Vietnamese villages, land was divided by rank, and rarely was it awarded to orphans. Peasants actively competed as individuals to increase their personal popularity, which is tantamount to gaining more political sway and power in their villages so as to maintain and accumulate more property. *Fiestas* in the Philippines and *slamatans* in Java, Indonesia, are examples of this form of competitive individualism. Hence, traditional village rituals sponsored by local elites serve to protect wealth, not level it. Peasants seek out patrons to provide them with social security, not the reverse, just as patrons are clients, themselves, to more and more powerful patrons. That is, instrumental rationalism is the motive force behind patron-client ties. Another example is the tendency of farmers to have large families to help them tend the land and themselves in their old age. Popkin finds that it is the individuals who manipulate each other for selfish gains who are the instigators of social stratification at the village level. Traditional peasant societies are both open and plural, states Popkin: "More stratification within the village resulted in differential access to and control over the bureaucracy and other ancillary institutions of the market, rather than from the markets themselves" (p. 28).

Finally, Popkin (1979) argues that peasant uprisings do not flare up as a result of violations against a code of ethics that guarantees farmers their subsistence rights. Instead, farmers actively recruit political leaders who will lead them, successfully, in their rebellions. However, Feeney (1983) finds fault with Popkin's theory of peasant revolution because he fails to explain the underlying motivations of their leaders, who may or may not have ulterior motives (p. 781). Greenough (1983) suggests that both Popkin's and Scott's interpretations of peasant rebellion are based on European assumptions that do not apply cross-culturally. Conversely, Polachek (1983) combines both theories into a slightly different approach. He proposes that competitive frameworks are useful for the study of peasant political coalitions and maneuverings, but, at the same time, revolutionary mobilization plays on peasant cultural ideas of redistributive justice (p. 822). This approach is different than Scott's theory of unitary consciousness because it considers the notion of rival factions in peasant societies.

Both Scott and Popkin attempted to develop a framework for the study of the peasantry. Scott tried to construct a universal theory of peasant behavior based on a generalized peasant economy. Popkin sought to make institutional rationalism, developed for the study of economic behavior in industrial capitalist societies, fit peasant behavior. Neither theory provides a completely satisfying explanation for peasant behavior. Scott does not take into account that peasants live in different societies with unique cultures and moral economies. He separates out the peasantry as a category for study and falls back on functionalism to explain it. Popkin, in contrast, overemphasized individual rationalism to the exclusion of the moral world in which peasants live. His methodological individualism also

sidesteps the dialectical relationship humans have with their society. Nonetheless, both theories point to a more definitive approach because peasants do make rational choices in the context their cultures and moral economies.

By the 1980s, this point of convergence in their theories became well known in anthropological circles. Anthropologists involved in Southeast Asian studies began to take it for granted that peasant societies have their own unique worldviews and cultural traditions, which, in turn, are interconnected with the wider, world capitalist system (Keyes, 1983, p. 854). Views of peasants acting both communally and in terms of their own selfish interests apply, more broadly, to human behavior in general. There is no universal definition of peasant societies. Rather, as Bernstein (1979) explained, new theories were needed to account for the articulation between different units of production, the relationships between various classes, and the wider process of social reproduction.

Current Perspectives

By the 1990s, students of the peasantry had gone far beyond substantivist and formalist frameworks by placing their case studies in local, regional, and global contexts. They were concerned with issues of social and economic transformation in traditional, agrarian societies undergoing capitalization. Yet, even then, especially after the fall of the Soviet Union, which caused the demise of communism, some scholars began to question whether theories aimed at discerning the dominant type of production and class structure in peasant society were necessary. Aguilar (1989), for example, criticized writings involved in the articulation of mode of production debates for being guilty of holding a teleological assumption about the end result of capitalism (pp. 41, 47). According to his argument, poststructuralist and neo-Marxist scholars studying peasant societies in Southeast Asia were using a dogmatic and ethnocentric model. Similarly, Hart (1989) found fault with them for “having been far more concerned with what is, and is not capitalist (and/or functional to it) than with understanding the dynamic processes at work in particular settings” (p. 31). Both Hart and Aguilar call for more flexible theories that can be used to study peasants in specific nation-states that have their own unique histories and structures of economic and political power.

However, Aguilar (1989) and Hart (1989) failed to recognize that new structural and neo-Marxist studies were open to the possibility of different cultural economies and societies being based on premises other than capitalist ones. For example, Scott’s (1985) *Weapons of the Weak* and Ann Laura Stoler’s (1985) *Capitalism and Confrontation in Sumatra’s Plantation Belt, 1870–1979* demonstrate the significance of first determining the capitalist nature of the peasantry under consideration, because it is through the particular peasantry that traditional peasant

communities are reproduced and transformed. Scott, looking at the controversial issue of class in a Malaysian farm community, built upon his earlier thesis of a moral peasant economy. He investigated the question of how small farmers organize openly, or covertly, to express their class interests. Scott contends that the moral economy becomes eroded by the infiltration of capitalism. He describes the objective effects of mechanized farming, double cropping, changes in demography, land tenure, and rents by looking at how large-scale cultivators, small-scale cultivators, and landless and tenant farmers interpret them. Scott argues that the Green Revolution, or the post–World War II introduction of new hybrid varieties of rice and artificial inputs together with mechanized farming, had created a situation of increased inequalities between peasants (p. 147). That is, the introduction of capitalist farming destroyed traditional patron-client ties.

On the one hand, poor peasants no longer had a legitimate patron-protector through whom to voice their protests, so they expressed their complaints indirectly. On the other hand, wealthy farmers adopted behaviors derived from the logic of the global market economy, while their authority continued to be based on traditional leadership styles. In other words, the relationship between large-scale cultivators, small-scale cultivators, and landless laborers had become an impersonal one based on capital. While wealthy farmers could still revert to using their traditional power of authority to call upon peasants to do extra work for free, the peasants, being waged workers, could no longer depend on landlords to provide emergency assistance. Although Scott’s thesis was that the Green Revolution transformed peasant societies into capitalist societies, he was opposed to theories of hegemony that depicted them as being dominated by capitalism because they were mystified. Rather, peasants continue to believe in their earlier moral economy and they express this alternative worldview in subtle and covert ways.

Evans Grant (1986) argues that this aspect of Scott’s thesis is his most controversial contribution. Scott argues that the concept of hegemony is institutionalized and embodied in elite values and myths found in bureaucracies, schools, churches, and the media. It does not work its way down, uniformly, to the villages in the countryside. An exception to this is religion, but Scott (1977) explains that religion is selectively reinterpreted from the core to the periphery, and religious interpretations and meanings vary in accordance with the organization of the religious intermediaries (p. 281). Grant states, though, that “Scott has been searching all along for a social basis of a radical subject other than the proletariat who is fatally compromised because he is organically linked to the capitalist class” (p. 20).

Hence, Scott argues that peasants are not reformists sharing the same ideology as the working classes in urban areas, but rather they share the make-up of ideal-typical revolutionaries because they are fundamentally opposed to the values of capitalism.

However, to use Worsley's (1984) expression, "There are factories without roofs" (p. 14), and capitalism can cover the gap between rural and urban sectors. It could be equally argued that the specific forms of peasant resistance Scott depicts are further evidence of their having been mystified by their new capitalist relations of production. Scott argues that peasants perceive the local owners of capital to be the cause of their circumstances, and for this reason, they are not mystified. But, if they were truly demystified, would not they recognize the unequal and oppressive conditions of the capitalist mode of production? Also, Scott's peasants are not necessarily made up of two opposing classes; rather, instead, they may be stratified in competition among themselves, although they may simultaneously converge in a wider context as a class in relation to other classes within a national, or international, class system (Ossowski, 1973, p. 89). Scott seems to shuffle his concept of class around as needed. Sometimes he speaks of only two predominant and opposing classes, while at other times he talks of classes stratified into a hierarchy. This makes the question of who is struggling for whom unclear. He cites the destruction of property, tampering with machinery, acts of theft, and killing of livestock as examples of covert peasant resistance (1985, pp. 271, 289–290). Scott questions whether these actions can be considered a collective form of resistance. His conclusion is that they are collective movements because they pave the way for other struggles that can catapult peasants into rebellion (p. 273). However, when an individual peasant maces a cow, is he really doing it against well-to-do households as Scott claims? Or is he only trying to protect his own land from overgrazing by his neighbor? Are such secret acts of sabotage done by hired thugs, working for local warlords or patron bosses to control peasants in their domain? Also, are peasants themselves, in relation to capitalism, perhaps already involved in manipulative and stratified subclasses at the local levels? If peasants are driven to such extreme acts of violence, not resorted to in the past, is this not indicative that peasants are being mystified by capitalism? The clandestine acts of peasant resistance Scott cites in making his case that they are demystified may also be shown to be similar to passive forms of resistance committed by urban workers.

Scott's (1977) work raises an old yet relevant question derived from the classical literature on the peasantry: Do peasants form a class "for themselves" as he claims, or are they merely a class "in themselves" as suggested by Karl Marx (1987):

In so far as there is only a local connection between small holding peasants, and the identity of their interests begets no community, no national unity, and no political organization, they do not form a class. They are consequently incapable of enforcing their class interests in their own name, whether through a parliament or through convention. They cannot represent themselves, so they must be represented. Their representatives must, at the same time, appear as their masters, as an authority over them. (p. 332)

Georg Lukacs (1971) defined class consciousness as being introduced to the peasantry by an outside revolutionary party. In contrast, Rosa Luxemburg (as cited in Bottomore, 1983) argued that leaders evolved out of the class struggle, itself, and that it is through such struggle that class consciousness is raised (p. 81). However, the argument also can be made that insofar as peasants exist in a relationship that is subordinate to dominant elites who extract surplus from them, the peasants form a class "in themselves," but, to the degree that they accept their status, without struggling to change the systemic causes of their grossly inequitable position, they are not a "class for themselves."

Turning to Indonesia, Stoler (1985) investigated the conditions that promote the formation of a *class-for-itself* and supra-class movements that unite peasant groups. She critically examines the historical documents dealing with Sumatra's plantation belt from a bottom-up perspective. Before global capitalism, Indonesia came under the influence of the tributary mode of production in partnership with India, then China, and later the Middle Eastern Islamic empire, the latter of which overrode India and China as a tutelary power. Muslim traders sought to win the allegiance of Indonesian princes who ruled the peasantry that supplied them with surplus wealth. Stoler suggests that it was through this background that the Dutch colonizers moved. They worked, directly, under the auspices of local princes to extract the islands' rich natural resources for export to Europe. However, she stipulates, the Dutch empowerment of preexisting hierarchical figures and structures of authority was a process that was shaped not so much by colonial design as in reaction to local movements coming up from below (p. 6). Issues of contestation and change, not institutional stability and cohesion as the hegemonic colonial discourse would have it, instigated the development of capitalism in Indonesia.

Take Java, for example, where peasants—due to their economic situation—had no other recourse than to produce crops for export, while they remained in their villages living in relation to a larger state apparatus held in place by a layer of indigenous civil servants. In other words, Java's culture was subtly subverted. In contrast, Deli was made up of labor settlements owned by the companies who ran them. In these settlements, masters and workers left most of their cultural baggage behind, as new relationships of hegemony were formed. Java and Deli illustrate two divergent conditions in the relations of production, which gave rise to two distinctly different types of labor movements. In Java, collective resistance movements were organized under the umbrella of religious organizations. In Deli, to the contrary, largely, individual acts of labor protests evolved out of the context of a plantation economy that enforced gender-specific policies of recruitment, wage payment, and job allocations that, effectively, worked against the formation of traditional collective action. On company-owned plantations, opportunities for mass organization and protest were negated because workers were

frequently moved from place to place, intentionally set apart from one another. It is no wonder, states Stoler (1985), that “ties between workers were short-lived and not conducive to collectively planned and sustained action. Assaults, on the other hand, by individual or a handful of workers usually required little planning or long term cooperation” (p. 85). Hence, labor protests on plantations did not emerge as a struggle between clearly defined classes but, rather, as fragmented acts of resistance. Daily confrontations between laborers and their bosses represent the different ways in which sublimated class interests were expressed along gender, ethnic, and racial lines.

The Japanese colonization of islands, however, brought in new conditions and possibilities for these peasants to address felt wrongs. For example, the Japanese, largely due to the miserable circumstances of plantation workers, decided to allow the workers to cultivate small plots of land to feed themselves and reproduce, in order to work for the occupational forces. This started a new “squatter movement” where peasant families began to settle down on small farms around the peripheries of large plantations. Stoler (1985) argues that this movement actually was a form of mass protest, but it had its own repercussions (p. 97). The Japanese took advantage of peasants by taking their produce and forcing them to produce more than they would otherwise. After colonialism, the conditions on the plantations did not really change. For example, there was no real change in the working conditions or productive relations on the Deli estates (p. 45). There was not much difference between the quality of life of an indentured worker and a wage worker. In other words, there was no transition from a precapitalist system to a capitalist system. Stoler explains that it is through the loopholes in recruitment policies that precapitalist, unpaid forms of labor exaction are continued and maintained (p. 209). Unlike in the past, however, when the plantation estates had to ensure the reproduction of their laborers’ subsistence needs, contemporarily, the availability of a large, landless labor pool of temporary workers, beyond the skeleton crew, has freed companies from providing them with social security. That is, farming communities at the margins of large plantations are not operating in terms of a production mode that is contrary to that of the plantation economy. These farmers are not part-time peasants and part-time proletariats; rather, they are an intricate part of the plantation estates. They are a preexisting part of a preexisting economic and social system that has already been subsumed into the logic of the capitalist reproduction of the plantation economy.

Similarly, in the Philippines, students of the peasantry have been involved in a long debate over the direction of agrarian change. Benjamin Kerkvliet (1977, 1990) takes us back to the beginnings of the early American colonial regime in the Philippines, at the turn of the 20th century. At that time, peasantries were steeped in patron-client relations that were uniquely negotiated out of local colonial conditions. The relationship between landlords and peasants was

an unequal one, but because it was flexible and enabled peasants in time of urgent need to obtain aid from their landlords, it was acceptable. Peasants needed their landlords and landlords depended on them to legitimate their power and authority over local resources, by working the soil. Peasants could opt for alternative courses of action if their landlords treated them unfairly. They could collectively negotiate better working conditions or move on to new places where other landlords promised to protect them. In short, there was a system of checks and balances. But this traditional feudal mode of production changed with the coming of the Americans, and the imposition of the capitalist mode of production. The once symbiotic relationship between landlords and peasants was transformed into an impersonal relationship. Kerkvliet (1977) argues that this change caused peasants to rebel to regain earlier patron-client ties (p. 25).

The American colonizers brought capitalism. They utilized landed and official elites to promote their American business interests. This empowering of local elites provided additional legitimization of their authority. Hence, landlords could change the terms of agreement between themselves and their peasants, and they could relinquish their pledge to provide social security to those who worked the land. In time, peasants became transformed into tenants and waged workers, sharing similar work conditions, and began to organize to protect their own interests. Kerkvliet (1977) suggests that peasant unions were formed to reestablish traditional patron-client bonds (p. 25). However, Nadeau (1999) argues that peasants sought not so much to return to the past as to proceed forward in the context of capitalist relations of production by unionizing, much like workers in the early-20th-century United States had done. They tried to promote their own interests in the face of their newly formed competition, property owners, who also were the local political officials. Their efforts can be seen not so much as an attempt to realign patron-client ties as to contract better conditions of employment.

In the United States, union workers struggled for better working conditions from owners of property, the latter of whom resorted to tactics within the strictures and confines of their culture to retaliate against or negotiate with them. In Cagayan Valley, organized peasantries faced landed officials who were further solidified into power by outside colonial powers. For example, the American colonizers sent military and paramilitary forces to suppress peasant rebellions at the local levels. They armed landed elite warlords with monetary and military might that was superior to that of the peasantries who were struggling to create a structure of support for themselves. Kerkvliet (1977) argues that the working class in Manila opposed joining forces with the peasants because they thought themselves to be the vanguard of the revolution, rather than the peasants (p. 265). Another possible explanation, however, is that labor divisions taking place within the ranks of the working classes in the cities and the countryside came

about as a result of their fiercely competing against each other for immediate, short-term gains, rather than their long-term interests as a class in and for itself.

Going a step further, Willem Wolters (1983) questioned whether Ferdinand Marcos's 1972 declaration of martial law was able to change the pattern of Philippine rural politics into class-based parties, as it claimed to do (p. xi). One of the government's justifications for instituting martial law was to replace the personalized system of politics by a well-organized authoritarian system. Wolters, alternatively, suggests that the Philippine state is not structured along traditional patron-client lines; rather, traditional relations have been changed into new types that do not correspond to the traditional model. There continues to be patron-client ties between the president and upper-class politicians, and between these politicians and local brokers who bring in the votes, but the relationship between local elites and peasants is no longer one of mutual reciprocity. Wolters explains that these new relations between the political bosses and peasant voters are grounded on specific short-term, instrumental, impersonal transactions (p. 228). They are completely different from the multifaceted and dyadic relations that bonded landlords and tenant farmers in the past. Rather, into the 21st century, capitalist-oriented landlords try only to outwit tenant farmers, and make a profit from them, while tenants, without any viable means of income, are still thinking in terms of a subsistence economy.

Wolters (1983) explains that patron-client relations do not form a unifying state structure in the Philippines; rather, they are a structure tied in to wider processes of state development. He argues that in the Philippines and, by extension, Southeast Asia, relatively unified countryside classes, complete with a degree of class consciousness and organization, have not yet appeared. However, this question of whether or not peasants are self-consciously aware of their own class interests remains contentious. Philippine peasants have organized themselves on their own behalf. This has been demonstrated in our previous discussion on peasant rebellion in Luzon (Kerkvliet, 1977, 1990). Other examples include, but are not limited to, the 1986 people-power movement that overthrew the Marcos regime (Bonner, 1987; Poole & Vanzi, 1984) and the progressive, basic Christian community movement (McCoy, 1984; Nadeau, 2002).

Conclusion

Articulation of modes of production theory for the study of peasant societies came under widespread attack after the fall of the Soviet Union, in the early 1990s. Mode of production theory was faulted for being irrelevant and overly deterministic in terms of the end result of capitalism being socialism, and then communism. Also, critics claimed that this general theory lacked a concept of individual agency. However, late 20th-century theorists, using a mode of

production approach, addressed newly emerging issues of agrarian and social change. They conducted fieldwork and examined pertinent changes occurring in actual communities with unique configurations of culture, resulting from local interactions that existed in relation to global capitalism. It is not that their critics were incorrect in calling for more progressive theories to account for questions of individual agency and contingent issues of gender, ethnicity, culture, and class. Rather, they failed to also recognize the importance of looking at rural communities, historically and contextually, in relation to the changing modes of production around which they are oriented.

FOOD

Plants and Animals

FRANCES D. BURTON

University of Toronto

Today the world population is 6.7 billion people, according to the U.S. Census Bureau (2009). In 1900, there were “only” 1.65 billion people on earth, 2.5 billion by 1950, with a projected 9 billion by 2050. While a number of factors have affected this exponential increase, not the least of which is reallocation of resources and labor (Boone, 2002), the abundance and distribution of food has played a major role, spurring technology to increase production and distribution. The result is the food crisis emerging in this early part of the 21st century.

Leading to this crisis, there are four major “events” in the history of food use. The first is cooking—the act of using heat to transform a substance from one state to another. This is an *emergent* behavior, as no other primate does anything like it. The second event, equally as dramatic, is the domestication of plants and animals; the outcome has been increasing control of resources (plants, animals) to the point of manufacture. This manufacture has included husbandry procedures, breeding, sterilization, and the like—and most recently, genetic engineering. The third event, directly related to manufacture, is the dispersion of foods throughout the world, which is a continuous process beginning at the time of domestication and continuing today, albeit now in the form of globalization. The “typical” diets of China, Italy, France, or anywhere are the result of diffusion and dispersion of these domesticated plants or animals, known as *domesticates*

(Sokolov, 1991). The fourth event is the industrialization of food. This is an ongoing event beginning in the latter part of the 18th century with the invention of canning (Graham, 1981) and continuing today in the form of frozen meals, new packaging materials, ways of reconstituting foods, and, in the near future, creating animal “meat” by tissue engineering (Edelman, McFarland, Mironov, & Matheny, 2005). The purpose of this chapter is to describe the events concerning the human use of food in the past (prehistory to the 1700s) and present, and speculate on the trends for the future.

The Past

We are primates, descended from a long line that began around 80 million years ago (Ackermann & Cheverud, 2004). As a group, primates are *omnivores* and consume nuts, seeds, leaves, stalks, pith, underground roots and storage organs, flowers, insects, lizards, birds, eggs, and mammals. The source of nutrients, or its emphasis, varies from group to group so that it is possible to classify primates by food intake. Table 25.1 illustrates these groups.

Prosimians, or lower primates, tend to be insect eaters while certain types of these primates prefer lizards or small invertebrates; monkeys—both Old and New World—rely on fruits with a significant input from insects or small vertebrates. Apes eat from a variety of ladders (food supplies)

Table 25.1 Primates by Food Intake

Category of Eater	Principle Food
Faunivore	Vertebrates
Insectivore	Insects
Gummivore (also gumnivore)	Gums, resins
Herbivore	Leaves
Frugivore	Fruits
Graminivores	Grains
Omnivore	All of the above and more

depending on type: orangutans eat fruit, gorillas eat stalks and pith, and chimps eat fruit and hunt for mammals—but none eat one type to the exclusion of all else. Physical specializations to extract nutrients from the source vary greatly. Some primates ferment their food; others reingest it.

The shape of teeth and jaws, and the length of gut and digestive tract, also affect different emphases of diet. Fruit eaters, for example, are equipped with molars that are not shaped for crushing or grinding, but are small in relation to their body size (Kay, 2005). Some leaf eaters, like colobines or howler monkeys, have sacculated stomachs containing bacteria that aid in digestion. One type of lemur is probably coprophagous; that is, like rabbits, it ingests its own waste pellets to extract semidigested nutrients. The length of the gut in primates that eat any kind of animal is 4 to 6 times its body length, while that of a leaf eater is 10 to 30 times its body length (Milton, 1993).

Primates, unlike some other mammals, require certain vitamins. The most important substances, vitamins B₁₂ and C, must be obtained from outside sources. In the case of B₁₂, it must be extracted from animals including insects (Wakayama, Dillwith, Howard, & Blomquist, 1984), and for vitamin C, from fruits and a little from muscle meat. Genes controlling the manufacture of these substances were reassigned (*exapted*), as it were, to other functions when the anthropoid group of monkeys, apes, and humans split from prosimians. The genetic information is affirmed by the fact that some prosimian relatives of the earliest primates are still able to synthesize these substances (Milton, 1993).

The model for human evolution derives from the behavior and physiology of African apes, particularly the two kinds of chimpanzees: the bonobo and the common chimpanzee. These primates are more active than either gorillas or orangutans and a good deal more sociable than the orangutan, also known as the red giant of Asia. Their choice of diet is considered an important factor in their activity, as larger primates tend to rely on leaves and foliage, as do gorillas, who have a range of only around 300 meters per day. Fruit eaters are not only more active than foliage eaters, they are more eclectic in their diet, including nuts, seeds, berries, and especially insects of some sort because fruits are an inadequate source of protein (Rothman, Van Soest, &

Pell, 2006). They are also considered to be more “intelligent,” as witnessed by recent studies of New World capuchin monkeys, and Old World macaques and chimpanzees. Chimps can take in as much as 500 grams of animal protein a week (Goodall, 1986; Milton, 1993).

Animal protein is considered high-quality food, and the importance of high-quality protein to the evolution of the human brain cannot be underestimated (Leonard, 2002). From only 85 grams (3.5 ounces) of animal protein, 200 kilocalories are obtained. In comparison, this amount of fruit would provide about 100 kilocalories, and leaves would provide considerably less—about 20 kilocalories. The daily range of chimpanzees can extend to about 4 kilometers per day, and their societies are highly complex social groups. It is this complexity that enables them to conduct their hunts, coordinating members as they approach their prey using glances, piloerection, and pointing. Since primates evolved from insectivores at a time when fruits and flowers were also evolving, their ability to exploit this new resource demonstrates the most important characteristic of primates: flexibility.

Primates can readily adapt to extreme conditions like drought. Under harsh conditions, primates will seek (as indeed, humans do) what are called *fallback foods*. These are foods like bark, or even figs, that are less desirable because they lack ingredients such as fats or sweet carbohydrates (Knott, 2005). Primates have a remarkable repertoire of methods to deal with changes in food availability: They can change their diets; they can change their location; they change their behavior according to the energy they take in (Brockman, 2005).

This flexibility in adapting behavior to changing circumstances was a decisive advantage for the primates, as they implemented the underlying knowledge about resources with the ability to remember locations of specific foods. Equally as important is the ability to evaluate the probability of encountering predators in these locations. The ability to adapt to environmental and social changes depends not only on genetic evolution but, as Hans Kummer (1971) noted, on cultural processes arrived at through group living. The behavioral mode responds more quickly to dynamic situations than does physical evolution.

Gathering, Hunting, and the Beginnings of Food Control

The ancestors of humans continued the food-gathering techniques of their primate predecessors, gathering invertebrates and small vertebrates, as well as plant materials, in the trees, on the ground, and below ground. As prey gets larger, the techniques shift from one individual working to a concerted, group effort. The former is seen in the behavior of capuchin monkeys and baboons, and the more sophisticated planning and coordination is well documented

among chimpanzees. With greater reliance on meat, there are more changes in the primate body—the more reliance on protein, the more prevalence of the hormone ghrelin. Ghrelin is active in promoting the organism to eat, and therefore causes an increase in body mass and the conservation of body fat (Cummings, Foster-Schubert, & Overduin, 2005).

The secretion of ghrelin stimulates the growth hormone as it increases body mass. Human brains require huge amounts of energy—as much as 25% of our total energy needs. Most mammals, in contrast, require up to about 5%, and our close relatives, the other nonhuman primates, need about 10% at the most (Leonard, 2002; Leonard & Robertson, 1992, 1994; Paabo, 2003). The brains of our other close relatives, the australopiths, were apelike, measuring about 400 cubic centimeters (cc) at 4 mya. Our ancestor, *Homo*, experienced rapid brain expansion from 600 cc in *Homo habilis* at 2.5 mya, to 900 cc in *Homo erectus* in only a half-million years. This value is just below the lowest human value of 950 cc.

Somewhere near this period of time, *Homo erectus* began using fire to cook. While the association with fire may have been long-standing (Burton, 2009), its use in transforming plants and animals from one form to a more digestible one appears to have begun after 2 mya, and according to some, the date of reckoning is 1.9 mya (Platek, Gallup, & Fryer, 2002).

Tubers are underground storage organs (USOs) of plants. They became more abundant after about 8.2 mya, when the impact of an asteroid cooled the earth creating an environment favoring the evolution of C4 plants over C3 ones (trees and some grasses). The USOs are often so hard or so large that they cannot easily be eaten, and contain toxic substances. Heat from a fire softens the USO, making cell contents accessible, and it also renders the toxic compounds harmless.

For some years, Richard Wrangham and coworkers (Wrangham & Conklin-Brittain, 2003; Wrangham, 2001; Wrangham, McGrew, de Waal, & Heltne, 1994) have been proposing that cooking was the major influence in human evolution. As explained, the application of heat made USOs more nutritively accessible. Recently, in an experiment to test this hypothesis, captive chimpanzees, gorillas, bonobos, and orangutans were offered cooked and uncooked carrots, and sweet and white potatoes. Apparently there was a strong tendency for the great apes to prefer softer items (Wobber, Hare, & Wrangham, 2008). While monkeys dig for corms and the like (Burton, 1972), the finding that chimpanzees use tools to dig up USOs (Hernandez-Aguilar, Moore, & Pickering, 2007) underscores the appeal of this hypothesis. In addition, there is evidence that *Homo* had already been using tools for over a half-million years when cooking probably began. The inclusion of “meat” in cooking had to have begun by 1.8 mya because there is substantial evidence of big-game hunting by this date. Equally important to Wrangham and colleagues is the consideration that the jaws and teeth of these members of *Homo* could not

have dealt with the fibrousness and toughness of mammalian meat (Wrangham & Conklin-Brittain, 2003). This is despite the fact that apes and monkeys regularly partake of raw flesh; all primates eat insects, and many eat small vertebrates like lizards.

Insects are not termed meat, although their nutritive value is comparable. Certainly the early *Homo* was eating mammals. Recent evidence from *Homo ergaster* shows that this hominin was infested with tapeworms by 1.7 mya and that these parasites came from mammals (Hoberg, Alkire, de Queiroz, & Jones, 2001). The remains suggest that either the cooking time at this site was too short, or the temperature was not high enough to kill the parasitic larvae, but also that these hominins were utilizing fire as an instrument of control in their environment. The knowledge base of our ancestors was extensive: It had to be for them to prosper, and it included knowledge of medicinal qualities of plants in their habitat.

Food as Medicine

It is now well attested that animals self-medicate (Engel, 2002; Huffman, 1997). Plants are used externally as, for example, insect repellent or poultices on wounds, and internally against parasites and gastrointestinal upsets. They may also regulate fertility, as recent evidence suggests that the higher the fats versus protein or carbohydrate, the more males are born (Rosenfeld et al., 2003), and the higher the omega-6 versus omega-3, the more females are born (Fountain et al., 2007; Green et al., 2008). The fact that the animals seem to know the toxic limits of the substances they use and consume is also significant (Engel, 2002).

Domestication of Plants and Animals

As knowledge is passed from generation to generation, it crosses lines of species. *Homo erectus* became *Homo sapiens*, and their knowledge base was a compendium of all that had gone before that could be remembered. Hence, the knowledge base included the breeding habits of plants and animals, their annual cycles, and where and when to find them, as well as what dangers were associated with them.

Somewhere between the advent of *Homo sapiens*, at the earliest around 250,000 years ago, and first evidence around 15 kya, this knowledge became translated into domestication. The process of domestication was first delineated by Zeuner (1963). Foreshortening of the muzzle, lightening of the fur, and crowding of the teeth are characteristic of this condition. There are even changes in the part of the brain relating to fear, as there is a relaxation toward the fearful stimulus—in this case with humans—under domestication (Hare & Tomasello, 2005). Because human care is extended to the domesticate, a relaxation of natural selection occurs as nonadaptive traits are supported. This process is seen in sheep, and laboratory and

pet mice, as well as dogs, and whatever other animal has been domesticated.

Evidence of diets having components of domestication is attested to by microwear patterns, detected with an electron microscope. These can be found on teeth; isotope analysis of the ratio of C3 to C4 plants, since the latter include more domesticated plants; biomechanics; and anatomical characteristics, such as tooth size or length of shearing crests on molars. Researchers also experiment with various kinds of abrasion and compare these to the “unknown”—the fossil. Biomechanics, an engineering type of study, analyzes forces and examines tooth and bone under the conditions of different diets.

While earlier in our history, only about 30% of the dietary intake would have come from eating organisms that ate C4 plants, under domestication, the number of animals as well as C4 plants increased. This is known from isotope analysis, which evaluates how CO₂ is taken up by plants, and which can estimate the proportion of C3 to C4 plants in the diet. What’s more, the nature of the diet itself can be understood.

How Domestication Occurred

Descriptions of domestication follow different theoretical models. Terms like *center*, *zone*, or even *homeland* relate to a view of process and dispersion. How many separate areas of independent domestication there were relative to subareas that received the domesticate or knowledge on how to domesticate also depends on the scholar. A general consensus is that there were seven separate areas where domestication took place: the Middle East, sub-Saharan Africa, Asia, Mesoamerica, South America, eastern North America, and from the Near East to Europe, with firm evidence dating from between 12,000 and 10,000 BCE in the Fertile Crescent of west Asia. The time of transition between hunting and gathering and cultivation of plants and animals is well documented at a number of sites. One, in the Levant, at Ohalo II near Haifa, has evidence for the earliest brush dwellings (Nadel, 2003) and is fairly typical of this transition period. It is dated radiometrically to 19,500 BP (or radiocarbon years before present, RCYBP), which gives a calibrated date of between 22,500 and 23,500 BP (Nadel, 2003). In this Upper Paleolithic, or Epipaleolithic site, evidence from dentition suggests an abrasive diet emphasizing food based on cereals, fish, and a variety of local animals, especially gazelle. In addition to wild barley, wheat, and fruits, small-grained grasses were well represented in the remains (Weiss, Wetterstrom, Nadel, & Bar-Yosef, 2004). The Ohalo II people occupied the site for at least two seasons, likely spring and autumn (Kislev, Nadel, & Carmic, 1992) and perhaps throughout the year (Bar-Yosef, 1998) in brush huts along the lakeshore. These sites at the end of the Upper Paleolithic along the Mediterranean, and in Europe during the Mesolithic, indicate that plants were relied on as

dietary objects and may well have been cared for around campsites to ensure their growth.

The specifics of how domestication occurred in each region differ (Bar-Yosef, 1998). Classical theories seeking to analyze the how and why of domestication focus on the environment, population growth, the organization and management of small-scale societies, trade, and changes in the daily schedule (Sutton & Anderson, 2004). Extending in time from the 18th century, the discussion of these is too complex and lengthy to be included here. More recently, Boone (2002) invoked an energy-budget model, consonant with contemporary notions of evolutionary demography and ecology. A scenario then emerged based on archaeological evidence that the climate was becoming increasingly unpredictable. These dramatic changes in climate, some of them a result of asteroids (Firestone et al., 2007), caused big game to decrease. The subsistence base changed to accommodate the lessened availability, requiring the diet to become more diverse. Fishing became important as groups moved to rich coastal areas, especially along the Mediterranean (e.g., the Levant and Turkey). Activities changed as a consequence, since traditional jobs were now replaced and the need to “follow the herds” was replaced with sedentism, itself a complex phenomenon defined by activities at a given locale as well as infrastructure developed there (Bar-Yosef, 1998).

While populations over most of prehistory had overall zero growth, the cultural processes that emerged with hominines affected mortality and population increase (Boone, 2002), culturally “buffering” local climatic and environmental changes. Brush huts and other shelters are emblematic of this. Larger groups encouraged specializations to emerge. A concomitant to climate change was the decrease in big game. These had provided substantial amounts of protein, and some, because of their size, had little or no predator response, making them particularly easy for small people with limited technology to overcome (Surovell, Waguespack, & Brantingham, 2005). So proficient had the hominines become that these efforts apparently caused massive extinctions of megafauna worldwide, in particular, proboscideans (Alroy, 2001; Surovell et al., 2005).

The actual effect humans have had on megafauna elsewhere, however, remains controversial (Brook & Bowman, 2002), and the demise of big game may indeed owe more to an extraterrestrial impact around 12 kya and its concomitant effect on climate (Firestone et al., 2007). At the same time, humans were obliged to include in their larder a wide variety of foods that either were not as palatable or required a great deal more effort for the caloric return—rather like the choices of fallback foods that nonhuman primates make under poor environmental conditions. The heads of cereals (wheat or barley, for example) need to be gathered, dried, ground, and boiled to make satisfactory “bread.” They can be, and are, eaten whole, with the consequence of heavy dental abrasion (Mahoney, 2007). The circular process of exploiting new or different resources

required techniques and technology to extract nutrients, and in turn, the new methods provided access to new food sources (Boone, 2002): Between the 7th and the 5th millennia, for example, milk was being consumed by farmers in southeastern Europe, Anatolia, and the Levant. The evidence comes from comparing the residue left on pottery sherds—that of fat from fatty acid from milk to carcass fats (Evershed et al., 2008).

In his discussions of the San, Richard Lee (1979) noted that the cultural practice of reciprocal food sharing, as complex as it was, functioned as storage in a climate where there was no other means: As perishable meat was given away, it ensured the giver a return portion some days later. Had the giver kept the entire kill, undoubtedly most of it would have spoiled. Stiner (2001) references Binford's suggestion that the development of storage systems was one of the technological "inventions" that must have accompanied the broadening of the diet so that the new variety of seeds and grain could be kept for some days. While hunter-gatherers, even until the end of the old ways (until 1965), would gather grain heads as they walked from one camping site to another—an observation documented in the Australian government's films on the Arunta—the development of implements to break open the grain heads, removing the chaff and pulverizing the germ, perhaps preceded domestication. As grains and grasses became more important in the diet, the gathering of those that failed to explode and release their seed grain became the staple domesticates. The advent of domestication has been dated at the various areas illustrated in Table 25.2.

Table 25.2 Areas of Domestication

Area	Date
Mesoamerica	8000 BCE to 6000 BCE
Middle East = Turkey; Iraq/Iran; Levant (Syria, Jordan, Israel)	10,000 BCE to 8000 BCE
East Asia = China, Thailand	6000 BCE
West Africa	6000 BCE

Domestication of Plants

Early domestication developed in different ways in different areas, as local people responded to local exigencies in different conditions and with different cultural standards (Evershed et al., 2008). Gathering and colonization were how plants and animals came to be domesticated, with some evidence that people practiced cultivation in naturally growing areas of desirable plants. By removing competitors, distributing water, or protecting from predators, the people were able to enhance the growth of the desired plant. Because plants were gathered and brought back to home base, some

seeds took root nearby. Awareness of the relationship of these seeds to the burgeoning plant spurred the next stage. Those plants that were gathered often had less efficient dispersal mechanisms. Their seed heads did not break off, and their seeds did not blow away. This was the case for flax, peas, beans, and many others, facilitating their cultivation. It seems a natural progression to the next step, outright sowing.

Gathering of seeds, and keeping them for the next season, was the final and significant step in the process of domestication, but it requires surplus as well as foresight and storage facilities. The seeds that would become the next season's crop were selected for some attribute they possessed: The plant had produced more, the seeds were less volatile, less able to disperse, or predators had been kept from taking them. Forms of plants that were more suitable were selected, probably initially unconsciously, and later intentionally—skewing the genetic mix in favor of domestication.

Domestication of Animals

The supposition about animal domestication includes various ideas: Perhaps the cubs of hunted mothers were brought home and raised; some kinds of animals "followed" people home where making a living was easier; animals were kept in corrals or tethered to allow captive ones to mate with the wild until the population grew substantially so that taking them was easier; or animals showing traits such as aggression not favorable to people were eliminated from the gene pool. The "big five" of domesticated animals—pigs, cows, sheep, chickens, and goats—were domesticated in different regions, independently from one another (Diamond, 2002), whereas domestication of plants seems to have diffused through areas. The animals that became domesticated were those that had behavioral traits that permitted it: They were gregarious and lived in herds where following the leader was part of the repertoire. Diamond (2002) suggests that it is the geographic range in which domesticates were found that influenced whether there were single or multiple areas of origin. The range of the big five is so great in each case that they were independently domesticated throughout, whereas the plants had a more limited range and so both domesticates and process diffused.

A population boom is clearly recorded at the centers of domestication (e.g., the city of Jericho in the Near East had up to 3,000 people living in it by 8500 BCE, according to the original researcher, Kathleen Kenyon, although that number has been revised downward [as cited in Bar-Yosef, 1986]). In these centers, there were an impressive number of people supporting themselves on a variety of domesticated plants such as einkorn, emmer wheat, and barley. The city of Teotihuacan in what is now Mexico had a population of 200,000 just before the Spaniards arrived (Hendon & Joyce, 2003). The abundance of food has its repercussions in population size with a concomitant development of trade specializations.

Over time, however, the benefits of agriculture become somewhat overshadowed. Zoonoses from association with farm animals increased. Tapeworms were known from 1.7 mya along with hookworm and forms of dysentery. Because settlements were often near bodies of still water such as marshes or streams, malaria became endemic. The development of agriculture and its concomitant population increase encouraged a variety of contagious diseases in the human population. In addition, noninfectious diseases became increasingly apparent: arthritis; repetitive strain injury; caries; osteoporosis; rickets; bacterial infections; birthing problems; and crowded teeth, anemia, and other forms of nutritional stress, especially in weanlings who were weaned from mother's milk to grain mush. Caries and periodontal disease accompanied softer food and increased dependence on carbohydrates (Swedlund & Armelagos, 1990). Lung diseases caused by association with campfires, often maintained within a dwelling without proper ventilation, plagued humanity as well (Huttner, Beyer, & Bargon, 2007). Warfare also makes its appearance as state societies fight over irrigation, territory, and resources, and have and have-not groups vie for their privileges (Gat, 2006). Hunter-gatherers were generally not only healthier, but taller. The decrease in height is probably a result of less calcium or vitamin D, and insufficient essential amino acids, because meat became more prized and was only distributed to the wealthy. Women suffered differentially, as males typically received the best cuts and more, especially when meat was not abundant (Cohen & Armelagos, 1984).

The more mouths to feed, the greater the incentive to develop farming techniques to increase supporting output. Implements changed, human labor gave way to animal labor, metal replaced wood, carts and their wheels became more sophisticated, but above all, selection of seed and breed animals became more trait specific as knowledge grew. The associated decrement in variety began early and has continued to the present.

The Present

The changes that have taken place in the use of plants and animals are momentous. The idea of change promoted the advances that mark the 18th century. As has too often been the case, warfare encouraged new technology. Napoleon's dictum that armies run on their stomachs inspired competition to find a way to preserve food for his campaigns. Metal, rather than glass, was soon introduced to preserve food in a vacuum (Graham, 1981). It did not always work: Botulism and lead poisoning from solder used to seal the tin played havoc with health. (Currently, the bisphenol in the solder is also a concern.) Nevertheless, the technique was not abandoned, especially as it meant that food could be eaten out of season. "Exotic" foods from elsewhere could now be introduced from one country to another. The ingredients of Italian spaghetti are an obvious case in point:

noodles from China, tomatoes from Mesoamerica, and beef originally from the Fertile Crescent combined in one place at different dates. For very different historical reasons, the Conquistadors brought much of it back to Europe after Columbus's momentous voyage. Diffusion of crops and techniques had occurred since they were first developed, evident in the "Muslim agricultural revolution" at the height of Islam from 700 CE to the 12th century (DeYoung, 1984; Kaba, 1984; Watson, 1983). During this period, China received soybeans, which arrived in c. 1000 CE, and peanut oil—both staples in the modern Chinese diet. Millet had been more important in China than rice (just as in contemporary west Africa, corn is replacing the more proteinaceous millet), and tea was a novelty until the Tang dynasty.

In "the present," the kind of foodstuffs that could be dispersed elaborated the inventory. The Industrial Revolution, with its harnessing of fossil fuel (coal) to produce energy (steam), further encouraged the process as travel time diminished. Food could be eaten—fresh—out of season and brought from thousands of miles away. The refrigerator truck could take food from its source, usually unripe, and deliver it thousands of miles away. With this new mechanism, the food *value* in the produce is diminished, but the extravagance of eating produce out of season remains.

Rivaling the distribution of foodstuffs in its impact on human history is the continued control of breeding. Indeed, Darwin's great work proposed "natural" selection in contrast to husbandry, or "artificial" selection. Before the *gene* was known and named—properly a 20th-century achievement—"inheritance" in humans was sufficiently understood in the form of *eugenics* (with its dubious history) as put forth by Galton in the late 1880s. When Mendel's findings were recovered in 1900, Bateson named the gene (1905–1906), and Morgan discovered the chromosome (1910), genetics got seriously under way, and culminated, in the context of this chapter, in the Green Revolution.

By the 1960s, famine had become a major world issue, with increasing frequency and severity: the Bengal famine of 1942 to 1945; the famine in China between 1958 and 1961, which killed 30 million people; and the famines in Africa, especially Ethiopia and the west African Sahel in the early 1970s (Sen, 1981) rivaled the famines recorded in ancient history and throughout modern history, especially in the late 19th century. Although the causes of famine are usually environmental, for example drought or pests, the underlying causes are often economic and political (Sen, 1981). In the United States, the President's Science Advisory Committee (1967) issued a report noting that the problem of famine, worldwide, was severe, and could be predicted to continue unless and until an unprecedented effort to bring about new policies was inaugurated (Hazell, n.d.).

In an attempt to bypass the underlying issues by producing more food for starving millions, the Rockefeller and Ford Foundations initiated what was named the Green Revolution. This was a dramatic change in farming techniques introduced to have-not countries of the time: India,

China, and nations throughout Asia and Central America. Mexico had initiated this decades earlier, in the early 1940s, when Norman Borlaug (1997) developed high-yielding, dwarf varieties of plants. Production increased exponentially, and seed and technology from the “experiment” in Mexico was soon exported to India and Pakistan. At the occasion of his Nobel Prize being awarded in 1970, Borlaug noted that wheat production had risen substantially in India and Pakistan: From 1964 to 1965, a record harvest of 4.6 million tons of wheat was produced in Pakistan. The harvest increased to 6.7 million tons in 1968, by which time West Pakistan had become self-sufficient. Similarly, India became self-sufficient by the late 1960s, producing record harvests of 12.3 million tons, which increased to 20 million tons in the 1970s (Borlaug, 1997).

To sustain these harvests, however, petrochemicals had to be employed, and land had to be acquired. The new genetic seeds were bred for traits requiring fertilizers, pesticides, and water. Since the mid-1990s, the enthusiasm for the Green Revolution has waned as the numbers of the hungry have increased worldwide, and production has decreased. According to the International Rice Research Institute (IRRI) (2008), the global rice yields have risen by less than 1% per year in the past several decades.

The explanations for the decrease vary, but among the most important is the fact that soil degradation results from intensity of farming, and petrochemicals that do not “feed” the soil itself. Depletion in soil nutrients requires stronger fertilizers; pesticides select for resistant pests and diseases, which in turn require stronger pesticides. Poorly trained farmers overuse the petrochemicals, exacerbating the situation. Irrigation itself causes a serious problem: The evaporation of water leaves a salt residue that accumulates in the soil. There is a concomitant loss of fertility estimated as 25 million acres per year, that is, nearly 40% of irrigated land worldwide (Rauch, 2003). In addition, new genetic breeds have not addressed social factors: Water supplies are regional, and irrigation requires financial resources; and farmers with greater income buy up smaller holdings and can afford to purchase industrial equipment. Access to food was not enhanced by the Green Revolution, especially in Africa (Dyson, 1999), where imports are approximately one third of the world’s rice (IRRI, 2008). It is access to food, more than abundance or pest resistance, that mitigates famine, dramatically demonstrated by Sen (1981). Determining access falls into the hands of government—implementing social security programs, maintaining political stability, and legislating property rights. The small farmers then move to cities, which become overcrowded, and lack employment.

While access has improved in some areas, the increase in population—often occurring exponentially—requires yet greater production. The response has been what, at the end of the 1990s, some have termed *frankenfood* (Thelwall & Price, 2006), or genetically engineered seed. This combines traits from very different species to enhance the

plant. Thus, cold-water genes from fish are put into wheat to enable it to grow in regions not hospitable to the plant, or plants are engineered to resist a herbicide that would otherwise kill it as it destroys competitors. Transgenic genes might allow insemination for a variety of plants into soil that has become infertile due to salinization, and thereby extend productivity to regions where production has long ago ceased (Rauch, 2003).

Genetically modified (GM) plants are spreading throughout the world, even as some countries refuse them entry. The powerful corporations and governments that endorse their use see them as a panacea: New varieties for new climate issues, which themselves, like global warming, have arisen as a result of human activity, not the least of which is the industrialization of food. In addition, farmers are restricted from using seed from engineered plants, even if they blow into their fields, as the seeds are, in effect, copyrighted and the use of them has caused expensive legal challenges (“In Depth,” 2004). While GM crops are less damaging to the environment than typical introduced species, as the numbers and distribution of these increase, the probabilities of them spreading, evolving, and mixing with local varieties increases (Peterson et al., 2000). Early “evidence” at the beginning of the century that transgenes had entered the genomes of local plants in Oaxaca, Mexico, was based on two distinctive gene markers. The studies were corroborated by government agencies but further controlled, and a peer-reviewed study of a huge sample of farms and corn plants did not find transgenes in this region (Ortiz-García et al., 2005). The question therefore remains moot, at least in Mexico, but the issue gave rise to the Cartagena Protocol on Biosafety (1999–2000), which regulates the movement of living modified organisms—plant and animal—whether for direct release or for food (Clapp, 2006). A number of countries in Europe and Africa have refused modified seed, although pressure on them to accept the seed continues. The Food and Agriculture Association’s (FAO) Swaminathan (2003) has urged India not to permit a “genetic divide” to exclude it from equality with other developing nations. Anxious that there not be a genetic divide between those countries that pursue transgenic organisms and those that do not, the United Nations World Health Organization (WHO) has echoed this concern (WHO/EURO, 2000).

Future Directions

Over time, selection for certain desired traits and hybridization of stock to develop specific traits (resistance to disease, etc.) has meant the loss of biodiversity in agriculture. Conservation of seed, by agencies like the Global Crop Diversity Trust, and seed banks, like IRRI in the Philippines, and the Svalbard Global Seed Vault in Norway, have been established in order to retain plant biodiversity. Their purpose is to have available strains that can reinvigorate domesticated species with genes from the

“wild type.” Because domestication reduces variation, these “banks” become increasingly important (Acosta-Gallegos, Kelly, & Gepts, 2007).

Certainly there will be more technological advances as the pressure for food continues and the area available for cultivation diminishes. The growth of genetic modification over the past decade has been exponential and is a harbinger of the future. The food crisis in the mid-1970s caused by oil prices, and the world summit on finding solutions, both had little permanent effect. The food crisis in the first decade of the 21st century has multiple causes, not the least of which is climate change. But that is not the cause: It is a concomitant, as Sen (1981) has argued. Newspapers and magazines detail the economic and political actions that seem paramount, and then a climate disaster hits and the crisis becomes full-blown. Australia, for example, has been suffering drought for over a decade, especially in its wheat-growing areas, but its economy can support basic food imports; Canada’s prairies were overwhelmed by a heat wave due to climate change, which reduced its 5-year production of wheat by over 3 million tons. Ironically, one of the major factors is that due to the Green Revolution, the health and diet of billions of people, in China and India in particular, has improved, but this has led to obesity (Popkin, 2008). Their demand for meat, which traditionally was an ingredient in a vegetable-based gravy over a staple, has escalated, and with it a shift from land producing for people to land producing for, especially, cattle. And, world over, the amount of arable land left has decreased from 0.42 hectares per person in 1961 to just about half this figure by the beginning of this century (as cited in Swaminathan, 2003).

Over the past two decades, the rise in the price of oil has caused an escalation of food prices, since transportation by ship, plane, or truck requires energy and global food markets require foodstuffs that once were kept local. Clearly another form of energy needed to be found, and the answer lay in the conversion of biomass to energy. The demand for biofuel, initially created from corn, kept acres out of food production and relegated them to energy manufacture. Currently the move is to find other sources of biomass—like algae, for example—to relieve the pressure on foodstuffs, and ultimately to use waste to create fuel. Then too, agglomeration of land into huge holdings has helped to make farming a business enterprise, subsidized by government and reflected in the market fluctuations in the prices of commodities, where 60% of the wheat trade, for example, is controlled by large investment corporations. The consequence has been that small farmers cannot compete with imports that are cheaper than what they can produce; production cannot compete with demand (IRRI, 2008). An even further result is scarcity in precisely those countries where the crops are grown, resulting in hoarding not only by individuals, but also by governments, for example, the ban on rice in India and Vietnam (IRRI, 2008).

Global organizations such as the G8 and the World Trade Organization (WTO), together with nongovernmental

agencies, individual governments, think tanks, and institutes, are “closing the barn door after the horse has escaped” with a variety of stop-gap measures. At the same time, there are clear and significant countertrends occurring. Not the least of these, and perhaps the best established, is the organic movement, whose origins followed the introduction of vast petrochemical use in the 1940s. Since then, the movement has grown out of the “fringe” to become “established.” In the mid-1980s, supermarkets’ recognition of a substantial market for certified-organic produce and meat broadcast the knowledge of the health implications of additives (from MSG to nitrates).

Of course, advances in technology and science focus on ensuring that there will be sufficient food for future populations. Livestock require vast amounts of land to produce the food they eat. By the early 1970s, the calculation was that conversion of cow feed to meat produced amounts to only 15% (Whittaker, 1972), and cows eat prodigious amounts of food. The agriculture department of Colorado State University, for example, reckons a cow eats up to 25 pounds of grain, 30 pounds of hay, and 40 to 60 pounds of silage—per *day*. One way around this is the virtual “creation” of meat. The future will see the industrial manufacture of meat through tissue engineering (Edelman et al., 2005). Using principles currently devised for medical purposes, cultured meat may actually reduce environmental degradation (less livestock, less soil pollution) and ensure human health through control of kinds and amounts of fat, as well as bacteria. Given the growth of the world’s population, in order to maintain health levels, the current trend of creating, nurturing, and breeding *neutraceuticals* will be expanded. The Consultative Group on Agriculture Research’s (CGIAR) Harvest Plus Challenge Program is breeding vitamin and mineral dense staples: wheat, rice, maize, and cassava for the developing world (HarvestPlus, 2009). Similarly, the inclusion of zinc, iron, and vitamin A into plant foods is under way in breeding and GM projects. The Canadian International Development Agency (CIDA) terms its efforts *Agrosalud* as it seeks to increase the food value of beans, especially with regard to iron and calcium content (Acosta-Gallegos et al., 2007).

There is a distinct interest in returning to *victory gardens*—those small, even tiny plots of land in urban environments that produced huge quantities of food in the United States, the United Kingdom, and Canada during World War II. By 1943, there were 20 million gardens using every available space: roofs of apartment buildings, vacant lots, and of course backyards. Together they produced 8 million tons of food (Levenstein, 2003). The beginnings of this movement are seen in the community gardens hosted in many cities, and in blogs and Web sites all over the Internet. Cities will also see the development of *vertical farms*—towering buildings growing all sorts of produce and even livestock. This idea, first promulgated by Dickson Despommier, a professor of microbiology at Columbia University, has quickly found adherents (Venkataraman, 2008). One project,

proposed for completion by 2010, is a 30-story building in Las Vegas that will use hydroponic technology to grow a variety of produce. The idea of small plots, some buildings, and some arable land—in effect, a distribution of spaces to grow in—is consonant with the return to “small” and local: the hallmarks of the *slow movement*.

The future may see a return to local produce grown by small farmers, independent of the industrialized super-farms, utilizing nonhybridized crops from which seed can be stored. The small and local is part of the slow movement, which originated in Italy in the mid-1980s as a protest against fast food and what is associated with it. Its credo is to preserve a local ecoregion: its seeds, animals, and food plants, and thereby its cuisine (Petrini, 2003). It has grown into hundreds of chapters worldwide with a membership approaching 100,000 and has achieved this in only two decades. In concert with this movement is a new respect for, and cultivation of, traditional knowledge. The World Bank, for example, hosts a Web site on indigenous knowledge (Indigenous Knowledge Program, 2009) providing information ranging from traditional medicine, to farming techniques (e.g., composting, terracing, irrigating), to information technology and rural development.

The best example of small, local, and slow, along with exemplary restoration of indigenous knowledge, comes from Cuba. When the United States closed its doors to Cuba in the late 1950s, the Soviet Union became the chief supporter of Cuba, providing trade, material, and financial support. With the fall of communism, and the collapse of the Soviet Union in the 1990s, Cuba could no longer rely on the imports of petrochemicals that had been traded for citrus and sugar and upon which agribusiness depended. Large-scale state farms therefore were broken into local cooperatives; industrial employees were encouraged to work on farms, or to produce gardens in the cities much like victory gardens. A change in the economic system, permitting small-scale farmers to sell their surplus, encouraged market gardening and financial independence. Oxen replaced tractors, and new “old” techniques of interplanting, crop rotation, and composting replaced petrochemicals. Universities found practitioners and taught traditional medicine and farming techniques. It may not be feasible for small and local to exist everywhere, yet the future will see some of each as expedience requires.

PART IV

LINGUISTICS

LINGUISTICS

PATRICIA N. CHROSNIAK

Bradley University

Of the many areas of anthropology that entice researchers to study, language is one that draws significant and sustained attention. As far back as 1500 BCE, individuals in India speculated about language development, derivations, and use. Similar speculation was done in Europe among Greek philosophers at the time of Socrates and his followers. Evidence from over 30,000 preserved cuneiform writings has consistently raised curiosity regarding the spoken language of the ancient Sumerians prior to 2000 BCE, as have discoveries regarding original language types from other indigenous peoples, such as the aborigines of Australia and New Guinea.

The reasons and methods for trying to understand language have changed from one historic era to the next, making scholarly activity in the field known as *linguistics* as vibrant as each era. Knowledge of the changes in perspective about language development provides one key to unlocking the door to characterize the nature of human beings as well as unlocking the door to the evolution and growth of societies. For example, Franz Boas (1858–1942) used what became known as *descriptive-structural* linguistics in his studies of culture and anthropology in the early 20th century. His interpretation of *language* was, in the words of Michael Agar (1994), “just a ‘part’ of anthropological fieldwork, and the point of fieldwork was to get to culture” (p. 49). This sense of linguistics as a vehicle was shared by the students of Boas and became a primary interpretation for many years, especially through the influence of Leonard Bloomfield. One

can only imagine the kinds and degrees of meaning that are lost to us about peoples of the world due to the formal methods used in the study of language in the early 20th century and the relegation of language, as a research tool, as it was by Boas and Bloomfield. However, for the time, descriptive-structural linguistics was a significant advancement, albeit more of a part of anthropology rather than a separate field in itself. That changed dramatically in the latter half of the 20th century, particularly with the dynamic referred to by Noam Chomsky (2005) as the *second cognitive revolution* when the number of new research fields increased (e.g., cognitive psychology, computer science, artificial intelligence). The *first cognitive revolution* is a cognomen for the period between the 17th and early 19th centuries when classical thoughts and theories about language were proposed, especially by philosophers such as René Descartes, Gottfried Leibnitz, and Immanuel Kant.

In the 21st century, the methods of language study and characterizations of linguistics hardly resemble those of Boas and anthropologists in his era. Current scholars cannot capture all the characteristics of *language* in just one definition or modality to designate linguistics as one singular field of study. Multiple views of language and linguistics support a richer perspective about the study of language and people than one that identifies linguistic methods only as tools to find out about culture.

Philology in the 1800s was the ancestor to general linguistics. Those who identified themselves as philologists

were oftentimes recruits from the field of philosophy. Their studies provided historical perspectives about languages—classifying and categorizing them by phonology, morphology, and syntax (but not so much by semantics and pragmatics).

Much of the early linguistic research (i.e., up to the first half of the 20th century) was undertaken to find out about the speech of ancient peoples. Thus, there was a reliance on writings—as well as on the spoken word—as these survived and changed into modern eras. *Comparative linguistics* enabled scientists to look for patterns in spoken languages in order to find connections among them that might give some indication of evolution. Those involved in comparative linguistics were close cousins to researchers in the current subfield of *sociolinguistics*, which attempts to understand language use and its social implications as well as the consequences of language and literacy development and education among citizens of world nations and societies within them.

In the latter half of the 20th century, the pursuit of language understanding enhanced the identity of linguistics as a field constituted of several subfields, with each involving the study of specific human dimensions evidenced in language use. For example, *forensic linguistics* provides insights into language, law, and crime; *neurolinguistics* includes the relationships between language and the human nervous system. This latter field holds much promise for understanding individuals afflicted with aphasia and other communication disorders. It also provides answers regarding second-language learning and multilingualism. Another linguistic subfield, *computational linguistics*, is one that has supported the developments of the computer age. This field involves scholars from a wide range of related disciplines (e.g., logicians, computer scientists, anthropologists, cognitive scientists) in the study of natural language understanding to create models for incorporation in technological devices and instrumentation for crosslinguistic communication and translation. For example, the quality of voice recognition on the telephone, as well as the complexities of voice recognition responses, was unimaginable even in the early 1980s. Likewise, translations of written languages in computer search engines, such as *Google*, require sensitivity to meaning as well as to the interpretations of words and grammar between any two languages.

The branching off of language studies into a range of related linguistic disciplines demonstrates that there is no limit to the number and variety of questions that can be approached. Answers are constrained only by one's choice of definition, purpose, and characterization of language. Even so, the richness of language research, both past and present, shows that an answer to one question many times leads to new and more interesting ones. And, for the most part, language questions are now perceived to pose dynamic challenges in and among subfields of linguistics. For example, why should we be concerned about the extinction of languages? How did spoken languages evolve?

The Nature of Language

Studies of language by researchers who are designated as members of one of the several subfields of linguistics is limited by the particular theory or theories held by the particular researcher(s). Each theory is derived from the definitions of elements or characteristics of language that are of interest to the individual. Definitions of language chosen by linguists will influence the direction in which research will proceed; however, among the linguists, there is much cross-disciplinary understanding that continuously reshapes arguments and individual theories.

Definitions

There are a great variety of scholarly definitions for language as well as for *languages*. Each reflects the theoretical perspectives and areas of study of the specific group (i.e., subfield) of linguists. If one were to ask for a definition from those who are not considered academics, however, they more often than not would associate language with spoken communication. Joel Davis, in his discussions about the *mother tongue*, explains that there is somewhat of a dilemma for linguists to pose a singular definition to language because of the multiplicity of characteristics and the use of one's own language to describe language in general. To capture the nature of language and define it, linguists attempt to study language structure (form) as well as language use (*function*). Studies may reveal things in single languages or singular situations or may uncover things by comparison of one language to another language or other languages.

20th-Century Delineations

Those who look at the structure of languages do so to establish a foundation for exploring distinct parts and compositions of specific languages in order to see what might be common among them. Van Valin explains that from the beginning of the 20th century, those who were curious about “linguistic science,” such as Boas and his contemporary Ferdinand de Saussure (1857–1913), were especially focused on identifying language systems to support the further study of language use. This positioned the definitions of language within a construct that came to be known as *structural linguistics*. In the 1930s, Leonard Bloomfield reinforced the idea of structuralism, claiming that the main object of linguistic study should involve grammatical principles that have little or nothing to do with observations of what individuals know or think about their language.

In the second half of the 20th century, as researchers from fields such as psychology, cognitive science, and sociology began to take interest in language studies, definitions of language could be distinguished as representative of one of two major linguistic areas, *formalism* or *functionalism*. The former area involves linguistic study of

the systematic, organized ways that language is structured. The latter area is more concerned with language use and the reasons why individuals choose to speak in certain ways and not in others.

Formal Linguistics

Franz Boas, Ferdinand de Saussure, and Leonard Bloomfield are among those who are acknowledged as formal linguistic researchers in the first half of the 20th century. Their theories and the field of structural linguistics led the way to expanded ideas about language study. Boas is considered to be the father of American anthropology, and as stated above, his use of linguistic analyses was only as a tool to get to culture. Although Saussure did not write down his ideas in articles or books, his lecture notes distributed among his students became a text after his death titled *Course in General Linguistics*. Language researchers give recognition to Saussure for the growth of linguistics as a science, and his work has been a central one for the development of the subfield of sociolinguistics. Bloomfield is best known as a linguist, although some classify him as an anthropologist. Of his many writings, his book *Language* was revered for its discussions of structural linguistics and comparative work to characterize languages.

The work of these three scholars—Boas, Saussure, and Bloomfield—left an indelible imprint on the field of linguistics. In their wake, there began a strong desire among young language researchers to pursue studies in formal linguistics. However, none was to compare to Noam Chomsky who moved formal linguistics into a new home, that of generative transformational grammar.

Noam Chomsky

A political activist and formal linguist, Chomsky designated two particular foci for characterizing and, thus, added to the definitions of language. In his book *Aspects of a Theory of Syntax*, he distinguishes between language *competence* and language *performance*. Previously, those researchers who were identified with structural linguistics ignored or paid little attention to language competence which, as stated by Van Valin (2001), “refers to a native speaker’s knowledge of his or her native language” (p. 326). Structuralists were more concerned about language performance, or how speakers used the language forms to communicate. In Chomsky’s work and that of others who ascribe to the newer area of formalism, there is more of an involvement with explorations of cognition, and this situates language competence as the main focus for striving to define language. Those who study *generative transformational grammar* in the tradition of Chomsky look for linguistic characteristics that are universal to all languages (e.g., all natural languages have nouns and verbs). Language is approached by exploring its generative capacity using a logical system of transformations to manipulate syntax.

Chomsky’s work drew attention to distinctions between the *surface* and *deep* structures of sentences. For example, he notes that the difference between the following two sentences is at the level of deep structure; both are composed of the same syntactic elements in the same order at the surface but differ at the deep level:

John is easy to please.

John is eager to please.

A critical part of the linguistic theories of Chomsky concerns how humans are “wired” for language. Having critiqued the work presented in B. F. Skinner’s *Verbal Behavior*, Chomsky reinforced his own belief that humans have innate knowledge of grammar as evidenced in the ways that individuals can generate new, never before uttered sentences.

This particular view of universal grammar and linguistic nativism contradicted the work of Edward Sapir and his student Benjamin Whorf; both had proposed a theory of linguistic relativity. The Sapir-Whorf hypothesis states that the cognition of individuals is influenced by their linguistic experiences within their given cultures. In other words, people in different cultures have different worldviews that have been tempered by the ways that their languages are structured and used.

Language Competence and the Sentence

In the 1960s, Thomas G. Bever and D. Terence Langendoen characterized language competence in this way, “A person knows how to carry out three kinds of activities with his language: He can produce sentences, he can understand sentences, and he can make judgments about potential sentences” (Stockwell & Macaulay, 1972, p. 32). In the previous comment, there is the singular concentration on the role of the sentence. In formal linguistic research, the sentence has been the central grammatical vehicle through which characteristics of language are identified. Although all languages are the subject of study, it is particularly in English and many other SVO languages (i.e., subject-verb-object sentence ordered) that the sentence has provided a foundation for analyses.

Formal linguists who are designated as *psycholinguists* have long held that designing research at levels of discourse beyond the sentence is especially unwieldy, and it may be difficult to resolve a hypothesis with absolute certainty. One psychologist, who demonstrated this point in his work regarding the interpretation of written texts in the 1980s through the 21st century, is Karl Haberlandt, a scholar in the field of memory and cognition.

The previous discussion requires a clarification about the definition of *sentence*. Formal linguistics looks at the syntax of sentences and the rules by which the grammar of a language allows for the order of words in sentences. For example, English transitive sentences commonly follow

the order [s]ubject, [v]erb, [o]bject, but there may be variations of this order that are acceptable in English conversation. French follows a SVO pattern but is SOV when personal pronouns are used (e.g., *Je t'aime*, "I you love"). Consider also the ordering of adjectives in English, for example, *three enormous green avocados* versus *green enormous three avocados*.

Although not a member of any of the subfields of linguistics yet mentioned here, Richard Montague is a linguist known for his attempts to quantify language by matching the logic of set theory to characterizing the semantics of sentences. Although his life was a short one, his legacy of Montague grammar remains to challenge those who respect formal linguistics and considerations of the ordering of language.

Functional Linguistics

The second area of focus from which we might posit definitions of language is that of *functionalism*. Individuals who are involved in this particular area propose theories of language use that may or may not allow for grammatical connections. Van Valin classifies the functional linguists as extreme, moderate, or conservative. Those who are in the first category do not admit to any use for grammatical (i.e., syntactic) analysis in their studies. To them, all language study is necessarily at the level of discourse, and observations of language grammar are restricted to the discourse. Those who are conservative functional linguists study language by adding on language use components to formal linguistic grammars. They keep the syntactic structures as the main part of the design of their research and amend them with discourse rules. Susumu Kuno is a well-known functional linguist who proposed a *functional sentence perspective* that guided a part of his research at Harvard University.

Moderate functional linguistics is especially represented by the work of M. A. K. Halliday. This subfield of linguistics is particularly appealing to anthropologists since it encourages comparative studies of communication and discourse without completely discounting the need for reference to grammatical theories. Moderate formal linguistics includes the consideration of semantics and pragmatics within the analysis of spoken human discourse. Dell Hymes (1996), credited with naming the linguistic subfield of *anthropological linguistics*, commented on the nature of language and provided a functionalist perspective of grammar in which he criticized Chomskian theories of formal generative grammar. This perspective demonstrates the thinking of the moderate functional linguist:

The heart of the matter is this. A dominant conception of the goals of "linguistic theory" encourages one to think of language exclusively in terms of the vast potentiality of formal grammar, and to think of that potentiality exclusively in terms of universality. But a perspective which treats language only as an attribute is unintelligible. In actuality language is in large part what users have made of it. (Hymes, 1996, p. 26)

One important functional linguist and anthropologist who had studied under Boas, and whose work was particularly vital in the latter half of the 20th century, is Joseph Greenberg (1915–2001). He is credited with providing the first thorough classification of African languages. Greenberg looked for language universals through language performance, rather than through formalistic analyses such as those of Chomsky. Since his work resulted in characterizing languages in this way, Greenberg is also mentioned in discussions of *typological universal grammar*.

Classification of Human Languages

The classification and categorization of human languages is particularly complex. First, there is the complexity derived from the theories and definitions of the linguists who are influenced by their own subfields of linguistics. Second, there is the complex weave among the topics of language evolution, language modification and change, and language death that in some respects is an uncompleted textile, metaphorically speaking. Each of these areas is connected to the other in simple and intricate ways, and they continue to enkindle disagreements among researchers who want to classify languages. When, why, and how does/did language evolution occur? What are the causes and correlates of language change? Are there any simple reasons why languages die? How do languages differ regarding interpretation and communication both between and among cultures?

In the last quarter of the 20th century, it became somewhat clear that no one subfield of linguistics could provide full answers to those questions that concern the classification of languages. Thus, some linguists have joined forces with individuals who have opposing views from their own or who are experts in allied fields. For example, anthropological linguists do well to partner with formal linguists, neurolinguists, and archaeologists to search for the origins of spoken language. Researchers such as Marc Hauser, Noam Chomsky, Morten Christensen, and Simon Kirby have commented on the need for cross-collaborative efforts to study the evolution of language and languages, and they have been collaborative themselves.

Structural and Comparative Linguistics

Philologists who, for the most part, were later to be known as *comparative philologists* and, subsequently, *comparative linguists*, started out with questions concerning spoken languages and their origins. One of their main areas of inquiry was guided by material gleaned from artifacts that survived from ancient civilizations; most of these included writings and monuments from the Sumerian civilization dating between 5000 and 2000 BCE. Researchers hypothesized about modes of spoken language by evaluating ancient patterns of writing, that is, by separating out

demarcations from other elements of what might be a grammar. They also strove to classify spoken languages by documenting those that occurred in various parts of the world, creating models of word structures and grammars as well as looking for consistency and similarities from one geographical area to another. This kind of work, of the philologists and comparative linguists, was, however, once limited by the Société de Linguistique de Paris in 1866 as a response to the proliferation of ill-conceived explorations into the evolution of language prompted by the publication of Darwin's *On the Origin of Species*. It was not until the last decade of the 20th century that research on the origins and evolution of languages had a resurgence among a new breed of anthropological linguists, who were not at all like their comparative linguist predecessors, as well as among teams of researchers from fields such as computer science, neurology, biology, and formal linguistics. Though still using theories derived from formal linguists, new paradigms for research included language competence and communication theories.

In 1997, Philip Parker produced a statistical analysis of over 460 language groups in 234 countries, showing the connections between linguist cultures and life issues in their societies (e.g., economics, resources that defined cultures, and demography). He used variables such as the availability of water, transportation, and means for communication to see patterns regarding the development of nations, especially in third world countries. Parker's work can be studied to understand the difficulties involved in trying to classify languages as well as in identifying new languages or finding those that are going extinct.

Sociolinguistic Perspectives

Those who identify themselves as sociolinguists are concerned with the study of how individuals use language to be understood within particular communication contexts. This includes research about sports, courts of law, teen talk, conversations between individuals of the same or different genders, and even ITM (instant text messaging). Sociolinguists primarily concentrate on spoken languages or on gestural languages, such as American Sign Language. However, several scholars have become curious about written languages, especially about literacy. Rather than using formal linguistics, as did the structural linguists, sociolinguists use observations about the human condition, human situations, and ethnographic data to understand language. When their research includes formal linguistic analyses, it is to demonstrate language interpretations and comparisons of language use within particular social contexts.

Sociolinguists are well acquainted with the theories of Saussure. Although Saussure was only 2 years old when Darwin wrote *On the Origin of the Species* (1859), linguists in the early 20th century have remarked that Saussure showed an awareness of Darwin's ideas in his lectures on language change and evolution. At that time, those

linguists who were concerned with anthropology or language growth and language interactions within societies more than with the formal characterization of languages attended to linguistic performance rather than to linguistic competence. This was the period of structural and comparative linguistics. Until the early 1950s, the term *sociolinguist* was not used. In the following two decades, researchers were involved in what now is commonly identified as sociolinguistic studies, but these individuals were not fully recognized within the subfield of linguistics called sociolinguistics until well into the 1970s.

Sociolinguists are especially concerned with the processes involved in language use in societies. Their research designs are commonly ethnographic. Dell Hymes has been identified as the father of the *ethnography of communication* approach used in sociolinguistic research. As an anthropologist, Hymes observed that those in his field and those in linguistics needed to combine theoretical dispositions to fill in the gaps in each other's research. He saw that the legacy of Boas resulted in many anthropologists thinking about the use of linguistics in their work only at the level of a tool as Agar has interpreted it. Hymes also saw that linguists were focusing on what he thought was too much formalism. An ethnography of speaking would enable those in each field to get a fuller picture of the language processes used by individuals, as well as reasons for their use, processes that are associated with one of a variety of social constructs—politeness behaviors, courts of law, and the deference to the elderly.

Deborah Tannen's research, concerning gender differences in conversations in the United States in the 1980s, involved the use of video to compare the conversational behaviors of children, teens, and adults who were paired by gender and put into a room for a short time with only their partners. Her work has added much to understanding the effects of communication behaviors, by environment and human nature, along the continuum to adulthood. Although Tannen could have dissected her subjects' conversations using formal grammatical methods, she was much better able to answer her research questions by analyzing the processes, both verbal and nonverbal, that they used. In fact, the nonverbal behaviors were especially revealing.

Tannen's previous research had prepared her for her gender comparison study. In one early piece of research, she participated as a collaborator with several other linguists to observe and subsequently characterize differences in verbal interpretations of a film by individuals from several nations around the world. This led to the publication in 1980 of *The Pear Stories*, edited by Wallace Chafe. Tannen compared the narratives of Athenian Greeks to those of American English speakers and concluded that the style and form of interpretations vary according to how people of a given culture adopt the conventionalization of rhetorical forms used in their culture. She supports her claims with research from sociolinguists John Gumperz and Dell Hymes. Her comments about cultural stereotypes in this

early study are one reason that this work should be reread in the 21st century, especially by political scientists and those concerned about cultural misunderstandings derived from translations between the languages of two nations, particularly when the conversations have consequences for peace between these nations:

The cultural differences which have emerged in the present study constitute real differences in habitual ways of talking which operate in actual interaction and create impressions on listeners—the intended impression, very likely, on listeners from the same culture, but possibly confused or misguided impressions on listeners from other cultures. It is easy to see how stereotypes may be created and reinforced. Considering the differences in oral narrative strategies found in the pear narratives, it is not surprising that Americans might develop the impression that Greeks are romantic and irrational, and Greeks might conclude that Americans are cold and lacking in human feelings. (Tannen, 1980, p. 88)

Language Mixtures

The concept of language mixtures is one that has been identified through sociolinguistic research. It includes areas of oral communication accommodation between people who speak different native languages as well as the use of new “half-languages,” as McWhorter calls them—that is, pidgins and creoles. As people migrate, voluntarily or as a consequence of a historical situation (e.g., the great potato famine, the slave trade), they have a need, to a greater or lesser extent, to communicate with those who do not speak their language. For example, the United States experienced large waves of immigration from the mid-1800s to the 1920s. As these new Americans populated cities on the East Coast and continued to settle throughout the United States, they maintained their original cultures in ethnic neighborhoods and were comfortable speaking their native languages. Schools accommodated these immigrants, providing instruction in English as well as in dominant European languages. Across the neighborhoods, individuals tried to communicate for economic reasons and for socialization. Sometimes, the elderly preferred to speak only their mother tongue, even insisting that their children or grandchildren do so whenever in their presence. Regardless, these new citizens created what linguists call an *interlanguage*, which includes words and expressions from both the new language and their mother tongues.

Interlanguage is defined in one of two ways. It may be that an individual creates or mixes terms between the native language and the target language. A Polish immigrant might use an expression such as “Ja będę iś do marku” (“I will go to the market”), substituting the first syllable of the English word, *market*, in the Polish word, *rynku*, and retaining the final syllable of the Polish word. (*Rynku* is the Polish word for market.)

A second way that interlanguage occurs is in situations where each individual in a conversation uses clever verbal

manipulations. It may be that the speaker imposes the syntax of the native language on the order of words in the new language. For example, Larry Selinker, an expert in interlanguage, gives an example where an Israeli says, “I bought downtown the postcard.”

As individuals become bilingual, they will switch between the two languages in their attempts to be understood or to clarify for the listener what they mean. This behavior is called *code-switching*, and over time, individuals who are in constant communication may create new words and expressions that possess characteristics of each or both languages.

Studies of interlanguage and code-switching provide information regarding the development of new languages but especially new words. Researchers such as Joshua Fishman have observed a special form of language mixture that evolves slowly within speech communities—that is, groups or societies that use one variety of their native language. An example of this situation, called *diglossia*, is a language vernacular. Some languages have one formal language variety and one or more informal ones. Vernaculars are often called the “common language” of the people. What is very interesting about diglossia is that in some places in the world, as in some parts of Africa, two speech communities may live side by side and never mix. Speakers of one language will continue to use their mother tongue when addressing individuals who speak another language. Yet the latter will understand the former but never adopt any of the morphology, phonology, or grammar of those speakers.

Pidgins and Creoles

Pidgins are formed when speakers of one language interact with those of a second language for particular purposes. As with language mixtures, they are called *contact languages*, and for the most part, they developed during the colonial periods when European traders sailed to countries in Africa, as well as to South America, and to islands in one of the great oceans. However, pidgins may arise anytime speakers of two languages have a particular need to communicate. They are characterized by a mixture of words from each language (e.g., French and Ėwé, an official language of Togo) in a somewhat “abbreviated” kind of grammar. Frequently, pidgin languages die out as individuals become bilingual or if there is no longer a need for communication between speakers of each natural language. Many pidgin languages that prevail become regularized from one generation to the subsequent one, and they take on well-defined morphological and syntactic rules. When this happens, they are then called *creole* languages. McWhorter observes that, just as natural languages may occur in one of several varieties, creoles, too, may have more than one variety. Creoles often have the same generative properties as natural languages. One very well studied creole language is *Tok Pisin* of Papua, New Guinea. It is estimated that between 4 and 6 million people speak it.

Linguistic studies regarding language mixtures, including pidgins and creoles, have been a source of valuable information to historians and geographers as well as to anthropologists and sociologists. Besides gaining an understanding about more recent history, especially the colonial eras and migrations in modern times, researchers have been able to hypothesize about the structures of and changes in societies where there has been contact with groups from countries and nations distant from themselves. Those linguists who promote theories of linguistic relativism are able to better understand the effects of language change brought on by social interactions among peoples from different parts of the world. As moderate functionalists, they are also able to evaluate language use by integrating generative functional linguistics into their evaluations.

Linguistics and Politics

An edited text by Joseph, DeStephano, Jacobs, and Lehiste (2003) draws on research that is particularly important to sociolinguistic studies—that is, the nature and relationship of languages that may or may not share the same cultural space. In *When Languages Collide: Perspectives on Language Conflict, Language Competition, and Language Coexistence*, linguists from diverse subfields share essays regarding, as the editors say, “a variety of language-related problems that affect real people in real situations.” Although each one represents the views and perspectives of particular researchers, taken together, they give a powerful message showing that the complexities of language and languages are entities that are indicative of the complexities of human behavior and the structure of societies.

As is the case with so many texts in the subfield of sociolinguistics, *When Languages Collide* permits much reflection on the multiple roles of language through the paradigms of both formalism and functionalism. It especially provides thought regarding language endangerment and societal change. Among the topics discussed are language ideologies (i.e., the role of governments in determining language use), language resurgence (e.g., increased speakers in the Navajo nation), and language endangerment. Joshua Fishman, an eminent sociolinguist, expounds on the growth of literacy and the political structures of society. His chapter is especially intriguing since most of his other research involves studies of spoken language. Julie Auger describes the growth of literacy among people in the border areas of Belgium and northwestern France. In this area, a fragile language, Picard, has a growing literary tradition in spite of the fact that few individuals speak it.

Language Extinction

Just as there has been a resurgence in studies about the classification of existing languages and cultures, there have also been linguists and anthropologists who have tried to understand the reasons for language endangerment and the extinction of languages. They have attempted to keep

records about endangered languages, looking at linguistic structures and geographic areas where endangerment predominates. David Crystal, considered one of the world’s foremost experts on language, has compiled research about the language survival situation and reasons for language extinction. In *Language Death*, Crystal (2000) gave calculations that show that in 100 years between 25% and 80% of the world’s languages will be extinct. As of 2005, the actual number count of known languages (spoken and signed) was estimated as 6,912. Thus, approximately 1,728 languages, as a lower estimate, could be extinct by the year 2105. He states that currently 96% of the world’s population speaks only 4% of existing languages.

Research about language death is a relatively new pursuit. Just as societies have become concerned with ecology, global warming, and survival, they are becoming more aware of the case of linguistic ecology. There currently exists an International Clearing House for Endangered Languages at the University of Tokyo and an Endangered Language Fund in the United States. A new subfield of linguistics, *ecolinguistics*, has been designated for concentration on issues of language diversity and language death.

Reasons for extinction include the lessening of the numbers of peoples who speak the language, as in Northern (Tundra) Yukaghir, Russia, as well as language assimilation into a language that predominates in a geographic area. Only around 120 individuals in Northern Yukaghir speak the indigenous language of the villages. It is believed that this language is at least 8,000 years old. All of the community of 1,100 people can speak a second language, Yakut, which is the name of the Russian republic in which they live. The two indigenous languages are spoken by the elderly at home. In *Ethnologue: Languages of the World*, Gordon (2005) noted that these people have no ethnic identity due to their assimilation with other groups in the area, such as the Yakuts and the Evens. Yet the Northern Yukaghirs do share cultural bonds as explained in the research of Elena Maslova, a formal linguist.

Salikoko Mufwene has summarized the work of linguists, such as David Crystal and Jean Aitchison, regarding language death, decay, murder, and suicide. He also has conjectured about the possibilities for language persistence and language ecology. To do so, Mufwene looks to the social dimensions of language characterization as he has researched it within the subfield of sociolinguistics. He, like other linguists who are concerned about societies and cultures, takes a historical perspective and includes questions and answers from work on migration and colonization in particular areas of the world (e.g., Sub-Saharan Africa). His research adds a special dimension to the subfield of sociolinguistics, which he calls *sociohistorical linguistics*.

Psycholinguistics

Psycholinguistics is a subfield of linguistics in which researchers study psychological processes involved in language development and use. The primary focus for the

psycholinguist is language behavior, and this may include studies of memory, cognition, speech processing, auditory processing, and reading. This subfield, just as sociolinguistics, is a relatively young one. From the late 20th century to the early 21st century, there has been an exponential growth in the number of psycholinguistic studies concerned with cognition and language processing. What is particularly interesting about this field is its focus on the individual as a speaker, writer, and thinker.

Members of the subfield of psycholinguistics are typically identified within the field of psychology and to some extent in educational psychology. Since a primary goal is to understand connections between the mind and language, there appears to be much more collaboration of psycholinguists with others in allied fields than there is among other subfields of linguistics. Perhaps this collaborative nature exists because a large body of psycholinguistic research has to do with language acquisition. Those involved in developmental psycholinguistics have provided a wealth of research regarding language learning in infants and children, cross-linguistic issues in language development, and correlates of brain development and language maturation.

Although most psycholinguists follow the theories of formalism, many may be identified as functionalists. This is especially true among developmental psycholinguists who study child discourse, bilingualism, and language education. Since psycholinguists have a proclivity for collaboration, researchers who are in fields of applied linguistics (i.e., fields that study language use in a variety of situations) tend to be collaborators with psycholinguists and educational psychologists. For example, Evelyn Hatch, a researcher in second-language learning and discourse, uses a variety of research theories that relate to the theory of knowledge known as constructivism. Annette Karmiloff-Smith, who did much early work on children's narrative interpretations, focuses on the fields of developmental psychology and neuroscience. It has been stated elsewhere that Daniel Slobin's contributions in developmental psycholinguistics have enabled the field of linguistics in general to understand language acquisition among children in nations that represent a range of spoken language families.

Other concerns of psycholinguists have to do with language perception and language processing. A correlate of these areas is that of *forensic linguistics*, a growing subfield that has, as one of its areas of focus, the study of language interpretation and expression in matters of the law and crime. Knowledge of the use of memory and language perception is important to forensic linguists, and they are able to draw from the larger subfield of psycholinguistics for their own research.

Language Identification and Tools of Linguistic Studies

The large family of linguists includes those who are driven to research using formal theories and those who are

motivated by paradigms of functionalism. At one end of the spectrum are the conservative formal linguists, whose interests are in how the mind uses language and the identification and description of universal principles of grammar, as well as those that are unique to every language group. At the other end of the spectrum are the extreme functionalists, whose work is to uncover meaning in the conversations (verbal discourse) of individuals and to see deductively what is similar and what is different in the language use of peoples. Some linguists look at their research through the lens of the historian or anthropologist; others look through the lens of computational models, as these models are able to mimic natural language. And others take a route of applied linguistics to bring research down to a utilitarian level, as in forensic psychology and in psycholinguistics as a component of educational psychology.

Researchers may be especially concerned about the actual language or languages for study, or they may be more concerned with the individuals in societies and the conditions of their lives that are determined by their language or languages. Whether a sociolinguist or a computational linguist, the resources used in linguistics include words, sentences, conversations, gestures, body language, writings, and a range of nonverbal signals. Linguists separate and manipulate these resources in the main categories of *phonology*, *morphology*, *syntax*, *semantics*, and *pragmatics*. These categories apply to analyses of spoken language as well as signed languages, of which there are 119 known throughout the world. Of these, American Sign Language (ASL) is most studied by formal linguists, as well as sociolinguists and other functional linguists.

Languages are also delineated as *natural* or *contrived*. Simply put, a natural language is any human language that has developed naturally over time. Invented languages are not a significant area of study by linguists, although this area can be of value regarding computer paradigms. Computational linguists and those involved in the field of artificial intelligence study natural languages and try to figure out how to simulate these in computer technology.

There are many linguists who believe that a research paper of Steven Pinker and Paul Bloom (1990), "Natural Language and Natural Language Selection," was the main driving force for the spread of legitimate studies about language evolution into the 21st century. As stated previously, there had been a moratorium on this area of research imposed by the Société de Linguistique de Paris in 1866 due to an unwieldy number of studies of questionable integrity that arose after the 1859 publication of Darwin's *On the Origin of Species*.

Phonology

Phonology refers to the sound system of a language. Descriptive linguistics, during the time of the structural linguists, provided a large body of information regarding the articulation of speech, the classification of speech sounds in natural languages around the world, and the

characterization of the brain areas in which receptive and expressive language originate and function. Regarding ASL, linguists only began to characterize phonology (which involves facial expression and physical involvement other than the hands) in the latter half of the 1900s, especially after ASL was acknowledged as a real language.

Through linguistic studies in the early 20th century to the present, there has been much research in developmental linguistics regarding language acquisition and the growth of language as it occurs contrastively in the speech development of infants and children throughout the world. Slobin's research, comparing the expressive language of children in countries where languages belong to different language families (e.g., Turkish, Korean, Estonian, English), has proven invaluable for further studies of language acquisition. For example, he observed that initially all infants babble similar sounds, but those that are not common in the speech of a particular language drop off and are "forgotten" as the infant says his or her first words generally around the age of 12 months.

Research on the history of the phonology of languages, such as that of John McWhorter, provides a window into the possible ways that languages have changed as well as the development of new languages. McWhorter gives an example of the movement from Latin to French. In the Latin word for woman, *femina* (FEH-mee-nah), the accented syllable remains and the two weaker syllables are dropped as this word becomes *femme* (FAHM) in French. McWhorter comments that new words and languages develop with the "erosion" of sounds from the parent language to the new one.

Change in the phonology of languages is believed to be a very slow process, as is the modification of vocabulary forms. These precede changes in grammar. However, research by Atkinson, Meade, Vendetti, Greenhill, and Pagel (2008) indicates that there may be rapid bursts, which they call *punctuational bursts*, that occur at the beginning of the development of "fledgling languages" that may be derivatives of older languages. These characteristics are then followed by a period of slower development. The authors observed this in their studies of the languages of three language families and hypothesized that it holds for phonology, morphology, and syntax.

Anthropological linguists are especially curious about the studies of phonology to find out when humans first began to speak. Biologists as well have proposed theories based on the findings of archaeologists and paleontologists regarding the evolution of humans. Although there is evidence from fossils that the anatomical parts for speech were in place 150,000 years ago, scientists question when vocalization was cultivated for the use of communication. Even though the physical structures were available in the middle Paleolithic era, archaeological evidence of social organization suggests that the liberal use of speech and verbal language might have more reasonably started around 40,000 years ago during the Upper Paleolithic explosion.

One of the reasons that linguists from several sub-fields might find it worthwhile to collaborate with other researchers—particularly those in speech perception, audiology, neuroscience, and computational linguistics—is that each has expertise regarding different aspects of phonology. One possible goal of the collaboration might be to enable applications of new knowledge about phonology to support the development of instrumentation or technology to fulfill a medical or engineering purpose. For example, the development of the cochlear implant by individuals such as Graeme Clark involved a team of experts from 10 fields, including electronic and communication engineering, speech processing, speech science, and psychophysics.

Morphology

Morphology is a branch of grammar that describes the combination of sounds into words, the development of the lexicon of a language. As with phonology, morphology is rule driven. Crystal (1985) explained that there are two divisions of morphology, *inflectional* morphology and *derivational* morphology. The study of the structure of words is especially interesting since they are representations of actual entities in a language that involve meaning. Early structural linguists were able to look at the use of words and the growth of language lexicons in order to situate them within the grammar of a language. For example, Boas, in his *Handbook of American Indian Languages* (1911), called attention to the way that Eskimos (Aleuts) take a single root word and combine it with other morphological components to designate different words for *snow* according to their unique experience of it in Alaska. This point has frequently been discussed by others, including Benjamin Whorf, who used it to support his theory of linguistic relativism.

In generative linguistics, morphology and syntax are considered central foci for grammar. Crystal explains that the same syntactic rules apply to the structure of words, as well as they do to phrases and sentences.

Sometimes, one may hear the comment, "I don't have a word for that in my language." And sometimes, it may take more than a single word to describe a concept captured in another language by a single word. As with the example above regarding *snow*, linguists may argue for linguistic relativism using similar comments. What intrigues linguists is the way that words may represent degrees of meaning for an entity. For example, alternative verbs for *walk* give different impressions of movement in a conversation or text (e.g., *strut*, *saunter*, *shuffle*). Linguistic studies about conversations and word use provide information regarding the growth of languages and language change, even at the level of morphological analysis.

Wierzbicka explains that polysemous words (i.e., words that have many meanings) are a special case for the study of languages. It is not that there may not be an equivalent word in one language available in another but that a particular usage of the word is not permitted. She gives the

example of the word *freedom*, comparing it in five languages. In English, *freedom* can be used in the context of freedom *from* (interruption), freedom *to* (speak), and freedom *of* (choice). In Polish, the word *wolność* is used to represent moral and political issues, matters of life and death. Unlike English, it cannot be used in a context such as *freedom of access*, *freedom of movement*. It can, however, be used as *freedom of conscience*.

Syntax

Syntax refers to the grammar of a language. The study of syntax involves knowledge of the rules that govern the ways that words combine to achieve meaning in a given language. It is at the level of syntax that so much of the work of linguistics has been especially important. Whether in formal or functional paradigms, linguists have concentrated on the sentence and on syntax as primary characteristics that separate humans from the rest of the animal world. The work of Chomsky has contributed not only to the formal understanding of language structure but also to the enabling of researchers to understand something that makes humans special. Belletti and Rizzi (2002) stated it this way:

The critical formal contribution of early generative grammar was to show that the regularity and unboundedness of natural language syntax were expressible by precise grammatical models endowed with recursive procedures. Knowing a language amounts to tacitly possessing a recursive generative procedure. (p. 3)

Formal linguistics, as well as psycholinguistics, makes heavy use of syntactic and morphological structures in its research. There are several methodologies for syntactic, grammatical analysis. Besides those that are based on Chomsky's generative transformational grammar, there are mathematical methods, such as that of Montague, and methods that probe universal grammar, such as that of *optimality-theoretic syntax*.

In the case of discourse analyses, those who might be considered conservative functionalists, using the definitions of Van Valin, sometimes combine methods—more of a formal approach to observations of syntax in conversational discourse.

Semantics and Pragmatics

Semantics refers to the study of meaning. Pragmatics refers to the connections between specific contexts and meaning. Although these two are specific areas of linguistics, together they have provided for theories of understanding and human cognition.

The field of semantics has been especially important to modern language philosophy and logic. Philosophers such as Rudolf Carnap (1891–1970) and W. V. O. Quine (1908–2000) delved into language philosophy with consequences for those studying artificial intelligence. Quine, in

particular, explored the works of Chomsky and formalism in an attempt to verify his own direction regarding logic and language. Semantics also includes studies of speech acts and conversational implicature. John Searle, a prominent language philosopher who is identified with the free speech movement at Berkeley, has contributed greatly to speech act theory. This theory involves the search for meaning in what individuals say, and that requires further understanding of language contexts as well as linguistic culture. Conversational implicature is one component in speech act theory and has to do with particular conventions of speech in which there may be complicated underlying meanings. For example, a request at dinner, “Can you pass the salt?” does not require a yes/no answer but rather an acknowledgment in action by the guest. An understanding of speech act theory enables anthropological linguists to draw connections regarding the development of cultures as they observe commonalities in the use of language within particular cultural environments (e.g., traditions of rights of passage to adulthood and interactions in the marketplace).

Applications of meaning to grammar have practical consequences for computational linguists as well as for understanding political and other spoken and written discourse. Thus, those in the subfields of psycholinguistics and sociolinguistics have provided much evidence, regarding the role of semantics in a wide range of grammatical and conversational contexts, among a wide number of diverse cultures around the world.

Concerns that have arisen due to linguistic and philosophical theories regarding semantics have to do with variations in both speaking and writing. Two of these areas are ambiguity and referencing. In many spoken languages, such as English, listeners accommodate much ambiguity in conversation. For example, sentences such as “Bill told John that he loved Mary” are well tolerated. Spatial relationships and nonverbal cues help listeners disambiguate referents in statements such as “Here it comes,” when contextualized within a situation such as a baseball flying into the spectator section of a ballpark.

Pragmatics plays an important role regarding semantic interpretation. Subfields in both formal linguistics and functional linguistics concentrate on identifying and interpreting the meaning of statements as they are applied to the real world. Areas of speech acts, conversational implicature, ambiguity, and referencing all involve consideration of real-world contexts. For example, a sentence such as the following is usually understood because of an individual's prior knowledge of how the world works: “Sarah pulled the rug next to the chair and then sat on it.” In this sentence, a psychological principle known as parallel processing influences the listener's determination of the referent for the pronoun *it*. One wants to match the rug as the referent; however, pragmatically speaking, it appears more sensible to choose the chair.

Studies of meaning in linguistics, whether at the philosophical level or that of human culture and society, involve

each of the areas of phonology, morphology, and syntax to greater and lesser extents. Although these areas are often dealt with separately in research, they also may be used in one of several combinations or pairings.

Conclusion

It is particularly important for those in the field of anthropology to recognize and understand a wide range of linguistic theories in order to support their investigations and the works of cultures and societies. Rather than considering linguistics as an ancillary tool for research, as was the case with Boas, the new anthropologists of the 21st century need to consider the constitutive nature of language to humanity. The range of characteristics that constitute the matter of linguistics is so broad, however, that researchers of necessity need to collaborate in order to address their particular questions. Further study of the involvement of linguistics in the field of anthropology will require of the individual much reading in subfields, such as those described in this chapter.

COMMUNICATION AND SYMBOLISM

JOHN DOUGLAS RHOADES

St. John Fisher College

Communication and symbolism are the two cornerstones of cultural anthropology. Their analyses will continue to occupy a major portion of the field throughout the 21st century and, in fact, as long as there are humans and anthropologists. Humanity exists in continual processes of inter- and intracommunication as for all life forms, but for humans these processes are crucially important. The essential nature of our existence is created and maintained through the special means by which we communicate—language. Language enables humans to exist in a complex and seemingly limitless symbolic world that, while related in many interesting ways with the world of other life forms (growth and mortality, diurnal and seasonal cycling), is distinctively separate and unique to humans. Cultural anthropology is the attempt to study and describe human symbolic forms and their patterns, as well as the manner in which these function to facilitate human life. Symbols exist in shared usage, and so the study of symbols and the study of communication are but two sides of the same coin. A “symbol” that is not included (with some frequency) in the communicative activity of a community is not operable as part of its symbolic world and thus does not exist for that community. Communication itself has symbolic status; none of its many forms can be neutral—outside the world it creates. The communicative nature of symbols and the symbolism of communicative activity will continue to be robust areas of research and discovery.

Within the last decade of the 20th century and rapidly growing through the beginnings of the 21st, however, enhanced electronic media and advanced intelligent systems have introduced a significantly new dimension into human communicative abilities, which will be referred to here as cyberspace and the Internet. From continuous audio and video linkages with a limitless number of others around the globe to “entering” into virtual realms that enable persons to take part in another life in “cyberspace,” communicative exchanges and the symbolic systems these entail will likely be subjected to considerable modification.

20th-Century Studies of Communication

The past century has been an enormously productive one in regard to the analysis and description of human communication. Building on the ideas of Ferdinand de Saussure, early structuralists delineated the phonological and morphological building blocks of speech by refining and applying the concepts of the phoneme and the morpheme. In addition to the rigorous description of hundreds of indigenous languages, anthropological linguists using this body of data worked on the problem of language histories and the division of current languages into families of related languages with the concomitant contribution to cultural history. Another achievement was the demonstration that not only was language separate from physical

type, but also it was of equivalent complexity regardless of cultural complexity; in Edward Sapir's (1921) phrasing, "The lowliest South African Bushman speaks in the forms of a rich symbolic system that is in essence perfectly comparable to the speech of the cultivated Frenchman" (p. 22).

The second half of the 20th century was dominated by those who followed Noam Chomsky (1957) toward looking at the processes by which sentences are generated from an underlying assemblage of semantic, syntactic, and phrasal elements and their (re)arrangements through transformational cognitive processes. For both of these approaches—structural and generative—the symbolic role of communicative forms played little role. There was a concern with meaning, but it was really limited to its employment (1) as part of a method to uncover linguistic units (such as the use of the semantic difference necessary for identifying phonemic minimal pairs) or (2) as a lexical tagging element to prevent the generation (however correct in regard to the sequence of general syntactic classes) of semantically inappropriate sentences. A sentence such as "He ain't heavy, he's my sister" should not be generated due to the lack of semantic fit between the male pronouns and the term for a female sibling. But the interesting issue was not considered: how this expression could be used appropriately in regard to humor or sarcasm, for which the sentence might carry a distinctive symbolic weight in a particular discourse occurrence or strategy, or why it was in English if a possible choice of using, for example, Spanish, existed. This interest often was characterized under the name of pragmatics to distinguish it from the "true" or internal language systems of phonology, semantics, and grammar. Internal structure of language code, however absorbing as a research problem, is not by itself the salient element in human communication; it is the manner in which these code features are employed in human interaction within a cultural context.

The question of how speech was used in social expression and how it was evaluated by its users was raised in the last several decades of the 20th century under the banner of the sociology of language, or sociolinguistics, and the ethnography of language, or ethnolinguistics, and thus rapidly became the dominant orientation of linguistic anthropology. The research question was not so much how speech forms were constructed but what they signified as choices or alternatives in a complex field with several varieties of codes ranging from dialects, registers, and jargons within one "language" to different languages.

Joshua Fishman's (1968) work on minority language maintenance in the United States formed the field of sociolinguistics: language choice as a social issue and the interplay between national politics and ethnic identity. This was certainly not a new issue in the 20th century, but this work applied a more sophisticated understanding of language structure and employed a greater methodological rigor in determining the social and cultural place of a language in the communicative life of a community. The linguistic

implications of social behavior (and vice versa) were engaged as a valid research agenda. Numbers of speakers of each speech variety were tallied for different communities, language questionnaires were administered to identify how varieties were used across social space, frequencies of linguistic usage were measured, and diachronic studies were planned to determine how the allocation of speech forms was being maintained or shifted. In other words, speech behavior was considered to be a necessary concomitant to social behavior and their covariation a serious research objective.

Complementing the sociological approach was the more anthropological approach of Dell Hymes (1962) called the "ethnography of speaking." Here, the focus was on the cultural models that guided the speech behavior of the members of a community. What was it that a speaker (and hearer) needed to know about (and know how to carry out) in order to behave in an acceptable manner as a speaker? Essentially, what was required to be a human member of a community of communicators? Knowledge was required about different genres of speech acts, beliefs about kinds of speech and their speakers, when to talk in turn or interrupt and when to remain silent, using profane or sacred utterances, whom to speak with or about, what places are associated with which kinds of topics, and how to allocate the different available speech varieties in order to be polite or dominating. The ethnography of speaking was an ambitious undertaking that dealt with a very large and complex array of communicative knowledge and was committed to doing it across cultures. A crucial element in much of these studies was the determination of the symbolic value of the different codes and speech varieties that humans employed in their daily social communions. As much as language consisted of an intricate system of the arrangements of sound, meaning, and syntactic elements, it was not simply an elaborate tool to be used or not based on the vagaries or whim of the moment. It was a part of human identity and heritage, our past and what we stood for; as a first language, it was all that the phrase "mother tongue" connoted in terms of a powerful personal and ethnic identity.

Consequently, a large and continuing number of studies deal with language as a symbolic marker of ethnicity. Using a language is a social condition of being a particular kind of human, not only in the Whorfian sense of affecting how the world is perceived but also in the social sense of valid communicative membership in a community of other users. Language becomes a symbol of a state that transcends the act of speaking, one that defines one's place in the world and essential identity. In this vein, we shall examine three selected studies that may provide a base for looking into the 21st century: Jack Goody on writing, Ruth Finnegan on the nature of communicating, and Sol Worth on the growth and personal availability of visual representations of self.

Goody (1987), in *The Interface Between the Written and the Oral*, examined the potential changes that the advent of literacy had on humanity. Contesting the common assumption that the impact of literacy was one of

improvement, in the sense of a progressive change toward much greater rationality and enhanced thought, Goody's discussion deals with a much more complex intertwining of the effects of literacy (one should say "literacies") on human cultures. Certainly, the ability to physically store the products of human communication, whether or not these are phonetic or lexical, has the result of permitting the retrieval of certain kinds of communication without relying on the presence (and willingness) of the person(s) who produced the original communicative event. It also enables more time for reflective consideration of the contents of the communication, as well as analytic operations that are based in having access to a large number of written materials. It also opens a new realm of symbolic discourse whose topics are specific to written materials: pagination, fonts, first editions, citation, and bibliographies. It also adds to the symbolic notion of precedence and truth; Commentary A may not be accepted as "true" in contrast to Commentary B if B is written while A is oral.

It would be a mistake, according to Goody (1987), if oral communication were thus relegated to an inferior or less capable rank. Orality can support rationality and logic, and literate productions can certainly be false, or judged as less binding than oral communication. Yet, as we shall see below, this idea that the new medium of writing radically transformed human thought and brought into existence an enhanced human capability is pertinent to the consideration of communication in cyberspace, in particular communicative participation in Web-based domains.

Ruth Finnegan (2002), in *Communicating: The Multiple Modes of Human Communication*, wrote of the holistic dimensions of human communication, especially the aspects beyond speech and writing. We (other than those with sensory impairments) are enculturated to communicate in a field of visual, scent, and touch signals as much as sound. Furthermore, each of these categories of signaling is itself an array of different kinds of signals. Sound, for example, is not only simply what is produced by the vocal tract (however complex) but also what is produced by part of the human environment of speech communication—the rustling of a brocade garment, a babbling infant, the crackle of a hearth and the bubbling of a kettle, as well as the large variety of metalinguistic claps, coughs, whistles, and sighs. All of these signals overlap and are mutually reinforcing. Human communication is thus a global activity, and while one or another of the multiple channels for communicative signaling may be selected, with the others excluded or ignored, whatever might be gained with the narrow focus on one signal type must be lost through the attenuation of others. Cyberspace communication at the beginning of the 21st century necessarily possesses the symbolic limitation of sounds without touch, visual graphs, or images without scent, and the proxemic dimensions of a (small) two-dimensional screen (although three-dimensional simulation is often available). This dilemma will undoubtedly result in a number of avenues for further study, possibly the

technical development of packaging together multiple signaling capabilities or even a nostalgic return to the symbolic value of face-to-face communication.

Finally, Sol Worth (1999), in "Toward an Anthropological Politics of Symbolic Forms," has written a prescient article on the implications of a world in which individuals have open access to, and creative ownership of, visual productions (at a time when this capability was vested in videotape and hand-held photographic cameras, not the Web). The potential of individuals from all over the earth being able to produce and distribute their own symbolic representations of their world was predicted to be transformational, not only for anthropology in particular but also and essentially for humanity in general. This transformation would be vested in the creative, even idiosyncratic, elaboration of visual symbols. It would liberate humanity from a slavish reliance on what powerful publishers feel we should see to what everyone wants to show us. In its orientation, Worth's piece is remarkably similar to Michael Wesch's recent 2007 account of the inevitable tidal surge of Web-based productions on such sites as YouTube, which lists over 1 million hours of short visual programs every 6 months! That this capability will usher in a new era of human interconnection, information accessibility and transfer, and associated cultural forms is presented as a given. The issue is what will anthropology be able to do to incorporate this kind of world in its research agenda?

20th-Century Studies of Symbolism

Symbolism is coextensive with human life; we are "symboling" beings, and we exist in a symbolically constructed world. There are innumerable topical areas within cultural anthropology, but all of them, in one way or another, deal with our use of symbols in constructing meaning, in maintaining a sense of common bond with others, and in conceptualizing the structure of our world and how it operates. Rather than be limited to examining the content, or referential aspect, of symbols, linguistic anthropology has focused on relationships between this communicative content and the social forms with which they exist (praxis). Symbolic content is open-ended and productive, which provides symbols the power to be broadly adaptive and specifically useful in new contexts. Symbols are public in the sense that they are shared and continuously communicated, and they have emotional salience for those who employ them. Studies in the role of symbols, once the challenges of delineating their semantic and system properties are met, have looked at the contributions these have for human life. Victor Turner's (1967) *The Forest of Symbols: Aspects of Ndembu Ritual*, an examination of the use of symbols in the ritual process and how these are employed to resolve social conflict, is one example of this approach. Symbolic meaning that is able to unite disparate factions (at least temporarily) can be seen

as a common human use of the emotional efficacy of symbols. However, this function depends on the presence of symbolic commonality among the members of a community, and this cannot be taken for granted. Many studies of how symbols are used have shown that there may be considerable variation within a single community about the interpretation of symbolic content and an ongoing negotiation of this interpretation. Throughout the past century, American anthropology considered the effect of culture change, especially acculturation, on the shared value of symbols. The openness of symbol content also means that their content is subject to change and, in the acculturative process, different segments of a community—perhaps generational—will likely change their understanding of, even adherence to, certain symbols. This process is tied to the introduction of different channels of communication during culture change. As discussed above, writing may come packaged with new and different symbols. Written texts may be symbolically associated with “truth” or “importance.” In a similar vein, many assume that the new communicative technology of the Web will introduce new symbolic content. Following Worth (discussed above), one might have a sense of “freedom” from the constraints of social context or political authority.

Another dimension to the study of symbolism is the question of whether or not it has certain immutable properties that are assumed to be tied to the cognitive structure of the human brain. Claude Lévi-Strauss (1967), in *Structural Anthropology*, proposed that symbolic systems were composed of an essential duality—manifested, for example, as cooked-raw, wild-domesticated. Whether or not these structures are genetic, in the brain as opposed to in the mind, a considerable amount of research has gone into studying symbolic systems. One result has been the objection that descriptions of these systems may represent a more coherent array of meanings than are present or used by the members of a community. This difference is not based on culture change but rather on the idea that symbolic activity by humans incorporates a constant amount of ambiguity and uncertainty, especially in the presence of mutually incompatible symbolic meanings. This property gives rise to the orientation that symbols can, and should, be employed creatively and that it is a human privilege to expand symbolic reference and manipulation to their fullest limits. The presence of computer-assisted advanced communication technologies, such as virtual reality MOOs (multi-user object oriented domains), clearly is consistent with this orientation.

Some Current Studies of Communication and the Web

It is clear that anthropology will necessarily incorporate electronic forms of communication as part of its research agenda into human behavior and cognition. This should not be surprising, as it has already dealt with the presence of

literacy, radio and mass media, and e-mail. In fact, this kind of study is already in place and is growing, although now without certain methodological obstacles. Here we will examine three selected studies of Web-based activity and what their objectives and methods have been.

David Hakken (1999), in *Cyborgs@Cyberspace? An Ethnographer Looks to the Future*, presented the approach that advanced information technology (AIT), of which the Web is a prime example, should be examined as a (new) part of the human technological tool kit. His approach is based on the conclusion that humans have been “cyborgs”—part natural human, part technology-based device—for much of our species’ evolutionary development. Although there exist polar approaches that view AIT as either a benefit to our cyborgic nature or as a detriment to our natural need for socially vested information, Hakken steers between these in order to examine how various human groups actually make use of the Web and electronic communication (EC) systems. This practical, ethnographic approach is grounded in the anthropological axiom of firsthand observation. He starts with descriptions of particular groupings (e.g., a local government agency in Sheffield, England) and what their purposes are in embarking on the deliberate use of AIT. His analysis details what platforms are purchased, how access to these are set up, and who uses them and with what objectives. Planning strategies by user groups are observed as are the disputes that arise over such matters as costs, allocation of budget resources, and planning time lines.

One interesting conclusion that Hakken (1999) reached is that “computers” have often been assigned a symbolic efficacy beyond their capabilities. An economic challenge for a region should be solved by *having* “computers.” He sees many of the attempts to use AIT as “mixed” to the degree that some benefits were achieved while others were missed. A question of control was also raised. The symbolic promise of AIT is the freedom to access an unlimited amount of relevant information. However, in some cases, governments imposed strictures on this access. Software restrictions resulted in some kinds of access being more difficult than others, while in others, access to potentially useful databases were not open. In other words, computer-assisted practice was vested in the same kinds of social matrix as other kinds of social development projects with some due to technical issues and some even due to personal pettiness. The conclusion is that AIT does not significantly depart from existing human cultural and symbolic parameters. Hakken uses the term *culture-centered computing* to emphasize this point. Ethnographic methodology is quite suitable for this kind of study since the researcher is participating in the activities of a social group and can observe what they are doing in regard to this technological development. People can be asked about their activities, especially about the meanings they place on aspects of their activities and the devices they are using. The ethnographer is able to make useful inferences

concerning the operable symbolic system and check these against further behavior. New symbolic forms and rearrangements of the symbolic system will appear, especially in regard to “information” and “occupation,” but this is not a radical departure from the kinds of symbolic adaptation to new technology that has occurred throughout the human past.

Daniel Miller and Don Slater (2000), in *The Internet: An Ethnographic Approach*, contributed a somewhat different but related view of the impact of EC technology. Focusing on one locality, Trinidad, they investigate the particular manner in which Trinidadians have taken to the Internet. In this case, there is a celebration of the perceived capabilities of the Internet as an eminently appropriate vehicle for the symbolically valued character of being Trinidadian, or possessing “Trini-ness.” On one level, the Internet simply provides an effective and inexpensive means of staying in contact with friends and relatives who are scattered over the world; but on another level, this particular channel is symbolized as being designed for Trinis since it permits a varyingly creative, even consciously flamboyant, means of expression. It is certainly not symbolized as a threat or as impersonal technology but rather as a satisfying stylistic choice. This perception may well develop in other cultures; in the United States, for example, an e-mail note of appreciation for a gift or favor probably is displacing a handwritten letter although likely not for the same symbolic justification. Here, it is probably perceived as convenient and maybe efficient but not necessarily satisfyingly “American.” In Trinidad, businesses, schools, and even churches have eagerly adopted Internet and Web presences.

Miller and Slater (2000) described the involvement with the Internet as transformational, an “expansive potential” to create and expand a successful Trini identity. However, the question that must be raised is, What will be the efficacy of this attempt to create a vibrant Trini identity using the Internet? It is not a matter of whether or not the effort is possible but rather if it is feasible. As Hakken (1999) has shown, not all development projects using Web technology may be successful. Moreover, creations that are in cyberspace may only be “there,” satisfying, no doubt, but with little other impact. However attractive and exciting these creations may be, unless they have a salient impact on the real world, they have the quality of chimera. This is not to suggest that Trinidad’s ongoing fascination with the Internet is in the category of a symbolic illusion similar to a millenarian cult but rather to point out that other than for the human activity of play, cyberspace or Internet creations should yield practical outcomes.

The final study illustrates this last point above—the “reality” of Web-based activities. Tom Boellstorff (2008) in *Coming of Age in Second Life: An Anthropologist Explores the Virtually Human* took the position that the “unreality” or “virtuality” of Web-based domains is precisely their great and transformational contribution to

human experience. Second Life is a private, fee-based server that provides the software platform to enable people, once they are logged in, to create a persona (avatar) that is displayed on a computer screen along with other environmental features within the limits of the server. Other avatars with (or without) clothing and accessories, structures, furniture, hills, lakes, trees, and animal life are presented in an active mode that depicts a model of a human setting. As the name of this interactive system implies, what is depicted is akin to “life.” It is decidedly not a human simulation since what can take place online includes such unhuman capabilities as flying or being immediately transported from one site to another, appearing and disappearing from an online event (i.e., going on- or off-line), and appearing as a nonhuman avatar. Furthermore, avatars do not have to eat, eliminate, sweat, grow old, reproduce, or die. Still, Boellstorff presents this realm as an appropriate, even advantageous, manner of human existence. His ethnographic study is fully online within the confines of Second Life. The avatars he interacts with, observes, and talks with (even administers questionnaires to) are presented in the same manner as if he were studying a community. There are clearly methodological questions when identity is not known and the strictures of life are absent, but it is the symbolic dimension that is of interest here. The symbolic values of creativity, spontaneity, freedom, and play are dominant. These symbolic attributes are present in real human interaction, but in a virtual realm there are no limits other than those of nondisclosure and abusiveness for which a member might be censured and even banned. The virtual realm is valued as an improved human condition. The technological ability to construct and maintain this kind of activity creates a new set of symbols or at least a new dimension to the symbols of human life. Presenting oneself as an animal avatar may be no different from performing as a mummer in an animal costume, yet according to Boellstorff, in Second Life there is a seriousness and commitment to the guises that appears to be a potential rejection of one’s real visage.

Internet Creations and New Symbols

The existence and rapid development of Web devices, along with their extensive communicative power, has certainly created the need for new symbolic forms. However, the challenging issue is not really the new lexicon and meanings of devices and operating systems (such as cell phone and blog) but the rapidity by which these appear and are cast aside for new ones (such as Blackberry and Wiki).

Of greater significance is the lack of boundedness of the social groups involved in change. Millions of users from around the globe interact and are potentially involved (as creators or judges) in the creation of new terms, new meanings, and new programs. Anthropologists accepted that “rapid” culture change had to be accepted as an essential

part of the reality of contemporary cultures, and therefore has been studied beginning in the early 20th century under the umbrella term of *acculturation*. But *rapid* then meant within a generation; what can anthropology do when it occurs in hours and is instigated out of an amorphous, unknowable assemblage of users? This very speed has become symbolic of a new age of human interaction, one in which Zipf's law (that speech becomes more efficient over time by shortening words) is somewhat prophetic. David Crystal's 2001 work, *Language and the Internet*, illustrates the many abbreviated graphical forms that appear in text messaging from acronym-like forms using the first letters of a phrase (lol for "laughing out loud") to inventive pictorial forms using sundry letters and punctuation marks, such as ":-)" for a wink or a joking reference and "emoicons."

Anonymity

The absence of apparent or definite personal identification is not new with EC. Printed material could be the writings of anyone either listed as anonymous or with a pseudonym, the product of a group such as a government agency, or simply not given any specific authorship. There is also the production of print materials that are purported to possess definite authorship but that are, in fact, the products of other authors. In other words, print materials contain an opportunity for lying, an opportunity less available in speech. Of course, spoken lies occur (as well as modifications of an objective truth, such as exaggeration, satire, rationalization, etc.), but some person must utter the lie, and there is some connection to the identity and social membership of that person along with the ramifications of having produced the false message. Print removes any direct or face-to-face connection between sender and receiver. Yet even print has some restrictions. The very mechanism of preparing, producing, and distributing the materials provides some identification—but only after the fact, not during the communicative process. The sender is writing in the absence of the receiver or receivers, and the receiver is reading in the absence of the sender.

Indeed, this separation has been offered as one of the important advantages of print and one of the reasons why it occupied a significant role as authoritative messaging. The sender, not distracted by the vagaries of interpersonal interaction, could construct (and importantly, refine) a message focused on the requirements of reason and order, and the receiver, again not having to consider the sender's personal characteristics, could carefully consider those elements of reason and order discerned in a reading (and importantly, rereading) of the printed material. As Goody has shown, printing revolutionized the communication of meaning. Reason, logic, proof, and analysis, although certainly not absent from oral discourse, were especially enabled by writing. The symbolic value of a superordinate authority, especially science, dogma, and scripture, could be achieved. In particular, this was the case when printed materials were

laboriously constructed by intensive personal labor, but even going into this century, a printed version carries greater weight than what has been only spoken.

Still, the characteristic of anonymity is not inherent in writing, simply a possibility. Whether directly, through explicitly and authentic authorship, or indirectly, by a discovery process that determines authorship, print materials are typically considered to be authored in the sense of there being a person responsible. This identification becomes much more problematic in Web-based communication.

On the Web, there is no necessary condition of a real, or authentic, social identity. Other than the specification of the Internet address (e.g., Yahoo, Aol, or Hotmail) the identification that is prefixed to the sender's production is usually a matter of personal creativity. Or at least, even if the list of alphanumeric characters in the prefix may have some one-to-one connection with identity, such as first initials and birth date (*abc778@—*), this does not provide specific or usable social information.

Even educational addresses may only give a first initial and part of a surname. Even this is not done in a standard sequence (e.g., it may be obvious that *smithk@—* represents a person whose first name starts with K and whose last name is Smith, but this allocation breaks down with *bardon@—* or with *woidat@—*). More to the point, while some e-mail addresses are explicit (*Mary_Smith@—*), this is not a requirement for the vast number of senders. Moreover, the personal identification is not readily, or ever, available, if the Internet service provider maintains secrecy as to its users (other than perhaps through a court order). Anonymity is, thus, easily ensured.

To what extent will this condition affect the nature of messages and their symbolic characteristics? This will be a challenge that a 21st-century ethnography of Web communication will necessarily have to confront. One might suggest that anonymity has created a sort of liminal arena of discourse. Aside from the possibility that a sender's actual identity may, in fact, be able to be disclosed, while online and in electronic discourse, the sender is not John Smith, residing at 123 Fourth Street, whose parents are Mary and James Smith, but *toosmart23@aol.com*. As *toosmart23*, he can submit messages that may be socially unacceptable were John Smith to say these in a conversation. And this very freedom from the norms of social discourse is celebrated as a particular advantage of EC. Unlike the contribution that reason and logic gave to written materials, which can be considered an added responsibility for writers, anonymity strips away social repercussion other than what may issue forth from other senders, equally anonymous. This can be proffered as liberating and creative, since one can submit whatever one wishes (within the limits that some EC providers may establish as guidelines) without any concern with an evaluation by one's community of kin, friends, business associates, and others.

Symbolism is inherently a social construct, as discussed above. Symbolic forms derive their significance not only from their relative positioning within a semantic system but

also, and more important, from their usage within the praxis of a social group or community. One of the achievements of 20th-century symbolic anthropology is that symbols do not have inherent or universal meanings or significance. Rather, their referent properties/attributes are vested, or negotiated, in their continuing application in the life of a community. And in cyberspace, there does not seem to be a community.

The absence of a real community does not make studying this form of communicative behavior unimportant. An electronic realm of discourse and interaction is derived from real persons, operating from real settings, and performing real behavior (on keyboard and/or mouse) but in a not-real realm. Certainly, there are absorbing research questions about what humans do in this kind of realm, and especially, the linkages between their real and nonreal worlds. However, a more intriguing question is what the symbolic characteristics of this nonreal realm will develop to be—even whether there will be a “development” in the sense of a progression toward some sort of cultural/symbolic charter generally accepted by those in the virtual realm (or their avatars), or whether there will be continually changing symbolic representations according to which persons (and their avatars) are present and likely tied to the apparently limitless permutations of creative virtual activities and relationships. It may very well be that people use their avatars to take their real-world symbols in limited and predictable directions. Many descriptions describe the virtual worlds they enter as not being too different, in essential attributes, from their real world. One enters, meets others, selects those who are interesting, jointly engages in interactive activities (such as playing a game or conversing or going to a party), and then departs. This is very much like an active party scene in a hip urban neighborhood—regardless of what the virtual form and behavioral capabilities may exhibit (animals, giants, or dwarves and flying, teleporting, or shape changing). Social symbols, such as prestige, sophistication, admiration, exclusion, cooperation, commitment, et cetera, are transferred and remain operable in the nonreal realm. In somewhat the same way as examining what humans do when they believe themselves to be alone and not observed, virtual worlds may provide an opportunity for persons to behave in ways derived from their anonymity. Yet there may be some inability for human operators to shed their real-life social personage and treat the nonreal interactions as free of any repercussions to their social selves. In other words, we may not be able to be completely virtual, independent of any derivative orientations from our real social condition. Web communication may thus only provide another environment in which to extend our already culturally delineated selves rather than becoming the transformational portal into a new order of being.

Virtuality

The ability to fly, to become any form of your choosing, and to construct objects literally by simply thinking about

them—these are attributes of a virtual realm. This is not, of course, new or new because of the Web. Storytellers have taken their listeners into similar realms, with concomitant morphing abilities undoubtedly from the first appearance of our capacity to symbolize. Dramatically compelling accounts of beings that could fly, change their shape, and bring worlds into creation by willing them to exist are widespread among human cultures. Indeed, it may be the case that the creative achievements of a gifted storyteller have yet to be equaled (if they ever will be) by the platform capabilities of a virtual realm, including the variegated input design products by its inhabitant avatars. Such is the power of human symbolic generation with our open and productive language system that an oral (or even written) performance of a creation myth cycle is able to create mental images of realms and actions perhaps not yet present in any virtual realm.

Yet descriptive accounts of cyberspace realms, such as *Second Life* or *World of Warcraft*, demonstrate that being an “inworlder” (player) provides a dizzying array of choices absent from the real world. Moreover, within some limits, these choices are individually realized, or idiosyncratic (other than those avatars that are run by more than one person in real life). In fact, this is supposedly the lure of virtuality—one can be truly free of real-life social controls and instead express one’s creative individuality.

This opportunity to operate as a virtual individual (even if the virtual platform offers, or even encourages, access to group or community interaction) raises some interesting questions regarding the function of symbols in the virtual world. While symbols can be studied in isolation from human social reality as systems of relationships among universal motifs or qualities (theft of fire from gods, nature versus culture, and so on.), during the 20th century, anthropology has preferred to examine how symbols served the societies who employed them. This functional approach (e.g., that of Victor Turner) would base a symbolic anthropology on ethnography. Even the semiotic approach of earlier linguistic anthropology (as with Sapir) would base the study of symbols on the language structure and the use of language by a community. Symbols were not “free-floating” essences whose significance derived from a primordial or panhuman meaning. Symbols had work to do in the operation of meaningful human life.

This pragmatic approach to the meaning of symbols will have to undergo considerable reworking in order to be applied in a virtual realm. Certainly, many areas of human life will necessarily be absent in a virtual world. Certain life cycle landmarks could not occur, such as reproduction, birth, puberty, senescence, and death, and therefore could have no (or only attenuated) symbolic form. Perhaps reproduction might be argued to have a similar symbolic nature in a virtual world since sexual activity is certainly present in the interactions among avatars. Consequently, avatars can be guided through a variety of sexual encounters, and these may be viewed as resulting in pleasurable (or not) outcomes. However, the symbolic content of reproduction

is much more extensive than sex (however much the act itself may constitute a powerful component of reproductive symbolization) and intertwined throughout much of a society's cultural system due to the physical concomitants of community existence. Awareness of connections to each partner's past, even the sensation of descent and the transmission of a life force; a place, not just for the sex act, but as a home with the presence of kin, children, in-laws, and neighbors whose activity can be sensed as well as the sounds and smells of sexual activity; the carnality of perspiration and effluvia; and especially, the likely biological result of pregnancy—all of these and more are necessarily absent. And shorn of its physical senses, this would not be the same kind of human world (e.g., Finnegan's emphasis on the importance of taking into consideration the other dimensions of communication).

Conclusion

Cyberspace is not likely to disappear from human experience. Anthropology will necessarily have to take an active interest in this experience and attempt to achieve a useful analytic understanding of its parameters. Studying it as an adjunct to human affairs, as a device and set of skills, and as what communities do with it (such as in Hakken, 1999) should not pose too many challenges to a rigorous ethnography of communication activity. Even the creation of new symbols and symbolic arrangements based on the probable development of new uses and applications should be achievable through participant observation.

The real challenges will come with having to deal with activity in a not-real realm of interaction with an involvement of very large numbers of anonymous users existing in a mode that encourages deception of artifice (if only for playful purposes). Boellstorff (2008) claimed to have begun and even partially achieved this kind of ethnography of this new world and its symbols. It will remain to be seen if there is even a possibility of replication and restudy, as there should be (whether or not actually done), in real-life ethnography. If symbols can be created and discarded literally at will and this is largely an idiosyncratic act of personal play, it should be extremely challenging to study cyberspace symbolic systems as exhibiting outcomes. Turner's work on liminality located the conditions of this realm within a symbolic system that provided parameters for the separateness of a particular liminal space and time. But when the realm itself—a virtual reality—is itself essentially liminal, it will be difficult to work out its symbolic properties. However, as growing numbers of people engage in this kind of activity, anthropology will have

little choice but to follow the kind of work done by cyberspace ethnographers, such as Boellstorff, and attempt to be observant participants in Web worlds.

STORYTELLING

KATIE ELSON ANDERSON

Rutgers University

Once upon a time, before words were written, before cultures and societies were observed and analyzed, there was storytelling. Storytelling has been a part of humanity since people were able to communicate and respond to the basic biological urge to explain, educate, and enlighten. Cave drawings, traditional dances, poems, songs, and chants are all examples of early storytelling. Stories pass on historical, cultural, and moral information, and they provide escape and relief from the everyday struggle to survive. Storytelling takes place in all cultures in a variety of different forms. Studying these forms requires an interdisciplinary approach involving anthropology, psychology, linguistics, history, library science, theater, media studies, and other related disciplines. New technologies and new approaches have brought about a renewed interest in the varied aspects and elements of storytelling, broadening our understanding of, and appreciation for, its complexity.

What Is Storytelling?

Defining *storytelling* is not a simple matter. Scholars from a variety of disciplines, professional and amateur storytellers, and members of the communities where the stories dwell have not come to a consensus on what defines storytelling. Scholars tend to place storytelling within the broader topic of folklore, a term also surrounded by

debate, but generally agreed to be the beliefs, practices, and tales of a people that are passed on primarily through oral tradition. The complexity of defining storytelling continues with debates regarding the meanings of the words *story* and *teller*. There is agreement that storytelling, in its simplest form, is the act of communicating an event (or sequence of events) to an audience, using words and/or physical movement.

This simplified explanation of storytelling does not capture the interactive, cultural, and living essence of storytelling. It is necessary to look at more details that include the origin of the story (oral or written); the *who*, *what*, *where*, *when*, and *why* of the performance; the type of story; and the emotional and cultural implications of the storytelling event. The finer points of these details are debated and discussed among those attempting to provide a definition of storytelling.

Traditional Versus Nontraditional

Much of the debate in the definition of storytelling stems from the acceptance or denial of the different types of storytelling. Some scholars accept only the traditional forms of storytelling, the strictly oral, that is, nonwritten communication of a story that has always been passed down orally, never written. The traditional forms of storytelling are considered to be the unadulterated forms of oral tradition, stories shared within a group passed down

through the generations by people regarded as experts in the telling of an event. The stories from this tradition are culturally significant, often religious or spiritual, and deeply tied to the traditions of the community. In traditional storytelling, there is usually a trained, experienced narrator or professional storyteller. Examples of traditional storytelling are myths and legends. Nontraditional forms of storytelling can be told by nonprofessionals, embrace different methods of delivery, and present stories that are not necessarily only oral traditions. Contemporary examples of nontraditional storytelling are urban legends, personal narratives or vernacular storytelling, and original stories crafted by a storyteller.

Oral Versus Written

The conflict between oral and written is often at the heart of the struggle to define storytelling. Purists will claim that storytelling is the continuance of an oral tradition only, excluding any texts that have been written. However, this exclusion is difficult, considering that many ancient oral traditions have been written down in order to be preserved and were never studied in their actual oral form. The only way that modern culture has access to such oral traditions, such as the epic poem *The Odyssey*, is through its written version. Walter Ong (1982) explored the relationships between the oral and the written in his book *Orality and Literacy*, which is often cited by current scholars who seek to present distinctions between oral and written storytelling. These scholars have explored and presented terms such as *oral literature*, *narrative literature*, and *literary tradition* to distinguish the oral from the written. Folklorist Jack Zipes (1994) pointed out that the oral tradition was not replaced by the literary tradition but rather there is evidence that the literary traditions are influenced by the oral traditions. Stith Thompson (1951) also spoke about the difficulty of separating written and oral traditions in his book. A purely oral tradition in storytelling not only excludes written traditions, but also overlooks new technologies. It is generally agreed that simply reading a text is not storytelling. However, taking that text and breathing life into it during a performance is considered by some to be as valid a storytelling event as recounting an oral legend.

Formal Versus Informal

Descriptions of storytelling are usually of formal events, such as a bard singing an epic poem or an elder teaching children their creation story. Early scholars and some professional storytellers will emphasize such formal events in their discussions of storytelling. However, there also exists the no less important act of informal storytelling. A formal storytelling event takes place when there is an audience that has gathered for the specific purpose of listening to a story. The storyteller has selected specific stories to share with the expected audience. Examples of formal storytelling include

epic poems performed in theater, elders in a community sharing experience with the younger members, teachers telling stories in the classroom, ghost stories at campfire gatherings, and storytelling at festivals. Informal storytelling is the kind of storytelling that takes place everyday with everyone. Everyone is a storyteller in informal storytelling. Recounting the day's events at the dinner table, passing an urban legend on to a friend, and sharing a family memory are examples of informal storytelling.

Historically, the descriptive details of storytelling fell to the folklorists and anthropologists, who were the greatest contributors to the earliest scholarly studies on storytelling. German folklorists Jacob and Wilhelm Grimm, British folklorist Andrew Lang, and American folklorist Stith Thompson were some of the first to look at folklore and storytelling academically. It is important, however, that the definitions provided by individuals from other disciplines (art, library science, history, psychology, and religious studies) and the storytellers themselves are not ignored. Such definitions emphasize the emotional, artistic, and professional element of storytelling. It is best to consider all of the details when working toward a definition of storytelling.

The National Storytelling Network broadly describes storytelling as "an ancient art form and a valuable form of human expression." This general description acknowledges the diversity and broad scope of storytelling. Its Web site (www.storynet.org) describes storytelling as containing the following five elements: interactive, uses words, uses actions, presents a story, and encourages the active imagination of the listeners.

While previous definitions of storytelling tend to be narrow and biased toward the discipline conducting the research, current attempts, such as from the National Storytelling Network, are more inclusive. Today's definitions are careful to acknowledge that all definitions of storytelling are relevant. Recent scholarship on storytelling does not attempt to dispute previous definitions but, instead, embraces the different theories for a complete interdisciplinary understanding of the term. Storytellers Carol Birch and Melissa Heckler (1996) attempted to bridge the "philosophical, professional, academic, regional and cultural divides" (p. 9) that take place when defining storytelling. According to them, one of the most challenging aspects of the study of storytelling is in its respecting all of the different models that are presented by the various groups who study and analyze storytelling.

One of the ways this challenge is met is by approaching the definition of storytelling by focusing on its function and history, emphasizing less of the aesthetic elements and focusing more on the role within society. These functions of storytelling include education (of children and adults), socialization, validation, explanation, passing on of historical and societal information, and entertainment. Understanding why people tell stories and what purpose the act of storytelling serves are important parts of

defining the term. The most widely read and accepted functional study is William Bascom's (1965b) "Four Functions of Folklore." These four functions are summarized in Leeming and Sader (1997) as providing escape from reality, validating one's culture, educating, and maintaining conformity. Other functional approaches include Margaret Read MacDonald's (1999) "Fifty Functions of Storytelling" and Robert Georges's (1969) "Toward an Understanding of Storytelling Events."

To accommodate the different types of storytelling presented in this chapter, the term *storytelling* will be broadly defined as the culturally important act of presenting an event or a series of events, true or fictional, through some form of communication (oral, written, or visual) to an audience that is or is not present at the time of the presentation. Storytelling is a vital part of all cultures past, present, and future. The details as to how and why it got that way continues to be debated and discussed.

Origins of Storytelling

Discussions regarding the history of storytelling frequently present the statement that storytelling has been called the oldest and the newest of the arts. Individual authors' interpretations of this vary, but it is apparent that storytelling has been around since humans have been able to communicate. In preliterate societies, the oral and visual traditions were the only way to pass on important historical and cultural information. The act of passing this information on to the next generation in songs, chants, pictures, dances, and stories is storytelling. As with the definition of storytelling, the theories on the origins of storytelling vary according to scholars of different disciplines. Each discipline focuses on specific theories and provides evidence to support them. Storyteller Ann Pellowski (1990) provided a nice summation of the many theories addressing the cultural, historical, and psychological significance of storytelling. These theories include the emergence of the storytelling form as a basic human need for sharing their experiences with others, a need to provide entertainment, a need for beauty and form, and a need to record history and social norms.

This need for beauty and form was met by talented and skilled individuals who could provide an aesthetic performance of the events. In the early days of storytelling, everyone was a storyteller, for example, individuals chanting, singing, and telling stories within family units and within their communities. It is theorized that as time went on, some people became better at telling stories and honed their skills in order to become professionals. These talented professionals are the earliest examples of traditional storytellers, known by different names worldwide. Parkinson (2009) presented descriptions of some, including bard (Europe), seanachie (Ireland), ashik (Turkey), and griot (West Africa). These individuals were charged with preserving history and culture while also entertaining through

formal storytelling events. A vital element of society, storytellers were held in high regard by their communities. The function of traditional storytellers has changed with the advent of written history, but these individuals continue to be necessary in order to educate and entertain.

"Tell Me a Story"

When discussing storytelling, the word *story* is generically used to describe the event being communicated. These events have also been called folk narratives, oral literature, or more specifically by their individual classifications, such as myth, legend, or folktale. In general, use of the term story is inclusive, though perhaps not altogether accurate. The *Oxford English Dictionary (OED)* defines story as, "a narrative, true or presumed to be true, relating to important events and celebrated persons of a more or less remote past; a historical relation or anecdote." This definition describes legends and myths, but it is at odds with the description of fairy tales and other tales that are not always presumed to be true and do not always relate important events or celebrated persons.

The term *narrative* is often used when discussing storytelling, so exploring the word narrative may lead to a better understanding of the meaning of story. The *OED* definition for narrative is "an account of a series of events, facts, etc., given in order and with the establishing of connections between them." This statement appears to describe the events. However, more flexibility is necessary in order to allow for modifications in the order of events and connections. The definitions provided by the *OED* do not sufficiently capture the essence of the word story in storytelling. The "story" in storytelling is alive, changing each time it is told, depending on the teller, the audience, the context, and the intent. This modification through time and culture is a significant aspect of the definition of story. The adaptability of a story to the needs and intents of a storyteller and an audience is vital to the nature of storytelling.

The dictionary definitions do not capture all of the meaning of the word story within the context of storytelling. In some cases, the word *folktale* is used in lieu of story. Used in this context, the term folktale is used to describe any type of story. This, however, leads to some confusion as the term folktale is also often used to describe a specific type of narrative. American folklorist and anthropologist William Bascom (1973) proposed the term *verbal art* to refer to a subcategory in folklore that included myths, legends, fables, riddles, and tales. This term, however, was never widely adopted. The word story remains the most accepted way to describe the traditional and nontraditional narratives performed by a storyteller.

Traditional: Märchen and Sagen

One of the first documented attempts at cataloging and classification of stories was by Jacob and Wilhelm Grimm

of Germany. The Brothers Grimm, or Grimm Brothers, have become synonymous with children's fairy tales, with much credit given to them for their compilation and presentation of traditional stories. In their publication, *Kinder und Hausmärchen (Children's and Household Tales)*, the brothers divide their collected stories into two categories, Märchen and Sagen. Märchen can best be described as enchanted tales, or fairy tales. While not all Märchen include actual fairies, the characters and events in these stories are magical, involving the supernatural and taking place in mysterious realms. Sagen is the term used to define stories that are historical, taking place in the actual past, with mostly human characters. The closest English translation for this term is "legend" and should not be confused with the word *saga*, which is used to specifically refer to the legends of Scandinavian cultures. Märchen is still widely used today to refer to any sort of tale that involves the supernatural and is used interchangeably with fairy tale, folktale, magic tale, and fable. Legend has generally replaced the use of the term Sagen to refer to the traditional, historical stories of a culture.

As others followed in the footsteps of the Grimm Brothers, more categories and subcategories were developed to classify the different types of stories that were encountered in the field. Some stories did not fit neatly into the Grimm Brother's categories and needed their own place. One such type of story is myth, which can be thought of as a combination of Märchen and Sagen as it is a historical, heroic story with magical creatures and a supernatural element.

The challenge of assigning stories to specific classifications was taken on by those who sought to collect, classify, and analyze them. These individuals were the earliest known folklorists. In the early 1900s, Antti Aarne, a Finnish folklorist, wrote, *The Types of the Folktale; A Classification and Bibliography*. She assigned a type number to the tales, attempting to classify the known stories of the time. In 1932, her work was updated by American folklorist Stith Thompson, and published as *Motif-Index of Folk-Literature: A Classification of Narrative Elements in Folk-Tales, Ballads, Myths, Fables, Medieval Romances, Exempla, Fabliaux, Jest-Books, and Local Legends*. The update to Aarne's classic work included further clarification of the type by looking at the individual elements of the story (location, characters, and lessons), along with the story as a whole. Each recurring narrative theme or motif of a tale was classified and assigned a motif number. It was in this classification of stories that the earliest scholars began to see similarities in the oral traditions around the world, prompting further scholarly study of the stories within a culture's folklore.

The classification of stories continues to challenge scholars today, especially with the emergence and discovery of new, nontraditional stories. William Bascom (1965a) proposed the use of the term *prose narrative* to describe a category within verbal art that included three

traditional types of stories: legend (Sagen), folktale (Märchen), and myth. Terms such as *fairy tale*, *fable*, *saga*, *tall tale*, *animal tale*, *hero tale*, and *epic* can generally be assigned to one of these three categories, though not all will agree with these distinctions. Some nontraditional stories, such as urban legends, are also found within these headings, but other nontraditional stories, such as personal narratives, require their own category.

Legend

While there is no direct translation of the Grimm Brother's classification *Sagen*, the English word that best describes the meaning is legend. The word *legend* has its roots in the Greek and Latin words for "to gather, to read." The direct translation of the German word Sagen is "to say." The combination of these concepts results in the basic idea of storytelling itself: gathering, reading, and saying. Earliest use of the word legend was in reference to the lives of Christian saints, which were written down but shared orally and considered to be true. Through time, however, use of the term legend began to mean the unbelievable or impossible, which is not an accurate description. In describing the events of individuals in present space and past time, legends are considered to be the most historical and believable type of story.

Legends may be considered the most historical type of story, but it is important to note that they are not history. They are historical in nature because they are assumed to be true, even if they are not verifiable. Legends take place in a specific time and location in the present world, unlike the supernatural worlds of other story types. The characters in legends are real people and true historical figures, but the events are not always true to history. The characters in legends can be common folk and unnamed individuals or specifically named kings and heroes. The events, while not historically accurate, are considered to be real events in the sense that they are believable and plausible. Common themes in legends are the struggle against evil and superhuman feats of courage, strength, and intellect. Legends are localized, deeply tied in with the religion and culture of a region. Folklorists, anthropologists, psychologists, and other scholars look to legends to help understand the history, religion, and culture of the legends' owners. Some examples of well-known legends are those of King Arthur, Johnny Appleseed, Davy Crockett, and Jesse James. Epics and hero tales, such as *The Aeneid* and *The Iliad*, meet the criteria for legend and are often included under the broader label of legend.

Folktales

The Grimm Brothers used the term Märchen to refer to tales of wonder and magic. They distinguished these from the historical Sagen because these magical tales are accepted as fictional narratives of less than likely to be real

events. A popular translation of Märchen is “fairy tale,” as many of the stories involve the actions of small magical beings known as fairies. The terms *fairy tale* and *folktale* have been used interchangeably. Specifically, only those tales that have fairies as characters are true examples of fairy tales, but the term has been broadened to include stories without small magical beings. The term folktale is used to refer to any traditional narrative, written or oral, that is assumed to be false. The broad term folktale includes tall tales, animal tales, fables, and fairy tales. The characters in folktales are usually humans alongside animals (some with human traits), trolls, ogres, fairies, witches, goblins, and other magical creatures. The events in a folktale take place “Once upon a time,” meaning that they do not refer to specific times and events as legends and myths do. This lack of specification is a key element of folktales, allowing for the appearance of the same tale across many cultures. For example, there are several instances of “Cinderella” stories in various cultures, each with its local customs and characters, all with the same underlying plot and theme. Folktales, unlike myths and legends, are not intended to be taken as serious lessons on history and culture. Their main purpose is to entertain, though there are examples of folktales, such as Aesop’s fables, that teach morals and warn against bad behavior.

Myth

Myths, like legends, are considered to be accounts of true events. Unlike legends, myths take place in a remote time and space. The events in myth occur in a world that exists well before the current world, or sometimes even in a different world. The characters in myth are supernatural, usually deities, animals, or humans with special powers. The word *myth* comes from the Greek *mythos*, “to make a sound with the mouth” and has been incorrectly used to describe untrue statements or beliefs. Despite their supernatural nature, myths are considered to be truths, in many cases, religious truths. Myths are deeply rooted in a culture’s belief system and tied to their spiritual and personal understanding of the world around them. Myths serve to celebrate origins, explain mysteries such as natural disasters, and soothe fears of the unknown. Well-known examples of myths are the stories of the Greek and Roman gods and goddesses, and the creation myths of North American Indians. Due to their religious and philosophical nature, myths have garnered the attention of scholars from those disciplines as well as folklorists and anthropologists. According to Segal (1996), anthropologists such as Franz Boas and Ruth Benedict have looked to myth to help explain cultures and their belief systems. While anthropologists and folklorists include myth within the realm of folklore, there are scholars who look at myth exclusively. These scholars consider themselves to be mythologists and their collection and study of myths to be mythology. Comparative mythology takes the extra step of comparing myths of different cultures, looking for universal themes and

origins. Important scholars of myth include E. B. Tylor, Max Müller, James Frazer, Joseph Campbell, and Jaan Puhvel.

Nontraditional: Urban and Contemporary

Nontraditional stories are those stories that are not considered to be a direct part of or a descendent of a communities’ oral tradition. They do not fit the description of myth, legend, or folktale, though they may share characteristics with these traditional forms. More contemporary in nature, nontraditional stories transcend the traditional model of story, adding deeper dimensions to the definition of storytelling. Not all of the mentioned forms of nontraditional storytelling are recognized by everyone to be true forms of storytelling.

Urban Legend

Originally, stories collected by scholars came from the oral tradition of rural areas. In the first half of the 20th century, scholars began to look to the stories, both oral and written, being passed around in cities. Scholars referred to these as urban legends, contemporary legends, or modern legends. The spread of urban legends takes place informally through casual conversation and different modes of media (newspaper, e-mail, etc.). Urban legends differ from traditional legends in that they lack specific names and times. The characters in the legends are often a “friend-of-a-friend’s friend,” the place is not always specified, and the time is the recent past. The details are vague, providing room for modification and adaptation. Like traditional legends, these stories are presumed to be true or at least based on true events. The themes are cautionary, usually warning and advising the listener, and less historic and heroic than traditional legends.

Early folklorists took note of the commonalities in urban legends among different cultures. In the past, it was less likely that these stories had been spread from culture to culture but more likely that the common themes were universal. Today, the origins of specific urban legends are less apparent as they are spread and modified so quickly in today’s global communication via e-mail, blogs, social-networking sites, and video-sharing sites. These legends are consistently changing and being adapted to the time and place where they are transmitted. Examples of different variations across cultures have been explored by American folklorist Jan Harold Brunvand (1981). His book, *The Vanishing Hitchhiker: American Urban Legends and Their Meaning*, was the first of many in which he provides descriptions and variations of common urban legends, such as the vanishing hitchhiker, spiders in the hair, and a murderer hiding in the trunk. The popularity of urban legends in the United States today is proven by the many books, Web sites, and even television shows that attempt to collect, prove, and debunk the myriad stories about that “friend-of-a-friend’s friend” and their unfortunate experiences.

Personal Narrative

Personal narratives are the individual stories of a person or group of people. They are presented in both formal and informal settings and through diverse mediums. An example of formal personal narrative is StoryCorps (www.storycorps.org), “whose mission is to honor and celebrate one another’s lives through listening.” StoryCorps provides people with the means to record and archive the stories of themselves and their loved ones. Another example provided is the theatrical performance of one’s life story, or vernacular storytelling (Preston, 1995). Informal personal narrative takes place everyday as part of daily conversation. Personal narratives are the true stories of real people, told by the actual person experiencing the events. Telling one’s own story is an important way to pass on family history, influence and teach younger generations, and even provide therapeutic or psychological healing.

Organizational Stories

The power and influence of a good story has not gone unnoticed by organizations. Organizational stories include stories told both within and without organization. Stories within the organization serve to inspire, educate, and help members make sense of the organization. The stories usually involve the leadership of the organization in day-to-day events. These stories can serve to validate the corporate culture through everyday examples as well as provide a personal side to management. Raspa (1999) provided an example where the CEO of IBM does not have his ID to gain entrance to a secure area. The guard refuses him entry, even though she recognizes him. He calmly waits while someone is sent to get his ID card. This story provides those within the organization with assurance and security as to the importance of doing their job, regardless of who is in front of them. Many organization stories have made their way into the public, such as the legend of how a Post-it note was created. Raspa describes how an employee was first denied permission to conduct the research but ended up doing it on his own time. When the successful product was launched, he was eventually rewarded for his diligence. Stories like these help the public remember a product and at the same time provide positive reinforcement about the company that makes the product. Some instances of organizational stories can actually be considered advertisements. Another form of organizational story is when individuals in leadership positions use personal narratives to inspire others. The story of great success through hardship is often repeated by politicians and business leaders in order to provide their audiences with an emotional connection and understanding of them personally.

Digital Stories

According to Fields and Diaz (2008), a digital story is a video that conveys a dramatic point, using any combination

of images, video, music, and voiceover. The majority of digital stories are personal narratives, as individuals and organizations use this technology in order to share events in their lives with a large audience. Digital stories are created by amateurs and professionals with a variety of tools. They take place formally and informally. In 1990, the Center for Digital Storytelling (www.storycenter.org/about.html) was founded in order to “assist people in using digital media to tell meaningful stories from their lives.” The center teams with communities and organizations to create formal digital story events, such as the Capture Wales project for the British Broadcasting Corporation (BBC) (www.bbc.co.uk/wales/audiovideo/sites/galleries/pages/capturewales.shtml). The center also provides information and workshops for teachers who are interested in using digital stories in the classroom and for individuals interested in creating their own digital stories. Digital stories are active and in some cases collaborated on by many individuals. This sense of community in creation continues in the presentation. Fields and Diaz (2008) explained that a digital story allows people to connect socially beyond their communities with a diverse and vast audience. Vastly different from the early scholars’ ideas of traditional storytelling, digital storytelling provides a new dimension to the study of storytelling.

The Study of Storytelling

The first acknowledged scholarly work about stories is Jacob and Wilhelm Grimm’s publication *Kinder und Hausmärchen* (1812). Prior to this publication, the legends and lore of a culture were not highly regarded by intellectuals. There are previous examples of collectors of tales such as Charles Perrault who collected and transcribed children’s fairy tales at the end of the 17th century. However, these collections were thought to be childish and primitive and not given much scholarly attention.

The Brothers Grimm are considered to be the first to introduce the fieldwork research method involved in collecting stories. They did not distinguish between oral and written stories; all the stories they encountered were transcribed. According to Kamenetsky (1992), there was some disagreement between the two when it came to presenting the collected stories. Jacob felt that the stories should remain unaltered, while Wilhelm wished to modify the stories to be more literary. The final outcome produced stories that were modified yet remained loyal to the tradition of the story.

The Grimms’s work inspired other scholars around the world to collect and present their country’s stories. Early collectors include Alexander Afansyev (Russia), Joseph Jacobs (England), Peter Asbjornsen (Scandinavia), and Jeremiah Curtin (Ireland). As stories were collected and presented, scholars began to see similarities in themes. These themes were cataloged and classified in Aarne and Thompson’s (1961) *The Types of the Folktale*. The collection of stories

and other oral traditions (riddles, songs, etc.) came to be known as folklore, and those who studied it were folklorists.

By the beginning of the 20th century, scholars had recognized connections between these stories and other academic disciplines, such as mythology (already its own academic field), anthropology, and ethnography. In Leeming and Sader (1997), it is stated that the British scholar Andrew Lang is attributed with being one of the first to recognize these connections. Other contributors to these connections include Vladimir Prop, James Frazer, Stith Thompson, and Franz Boas.

The connection with anthropology in American academia is evident in the fact that much of the early study of folklore occurred within anthropology departments. According to R. M. Dorson (1972), The American Folklore Society, founded in 1888, was sustained by anthropologists. As anthropologists began to see storytelling as a vital part of the cultures they observed, the study of folklore took on more prominence. Anthropologists such as Ruth Benedict and Franz Boas had previously explored the importance of myth in a culture. These studies were expanded to include all stories as being valuable to culture. Dorson (1972) explained that Franz Boas encouraged his students to collect and analyze the oral literature of a culture. This action made the collecting of stories a valid part of anthropological fieldwork. The connection between anthropology and folklore is also evident in the statement by Dorson (1972) that members of the English Folklore Society referred to themselves as anthropological folklorists.

For many years, folklore studies were included within anthropology departments and courses. It is stated in Leeming and Sader (1997) that American folklorist Stith Thompson taught the first folklore class at Indiana University. While also working on the update of Aarne's classification system, Thompson and his students began working toward the legitimization of folklore as a separate academic department. At the same time that folklore was working to establish itself in the world of academia, storytelling was becoming popular in libraries. According to Pellowski (1990), by 1927 most libraries had begun to conduct scheduled storytelling events. The storytelling in these events was based on the written word, with librarians being trained to make the stories come to life. These practitioners of storytelling in libraries and other public places are no less important to the field than the academics who research it. Librarians and storytellers such as Augusta Baker and her students Ellin Green and Anne Pellowski have contributed a great deal to the discussion and definition of storytelling.

Brunvand (1976) explained that, in the 1950s and 1960s, folklorists began to flex their independence from anthropology departments. Folklorist Richard Dorson was a strong advocate for folklore as an independent discipline. He replaced Stith Thompson at the Indiana University where the first Department of Folklore was established in 1963. With the establishment of more departments and

courses specific to folklore, academics from different backgrounds turned toward folklore. This led to different perspectives and new ideas, and during the 1960s, the traditional study of folklore was challenged.

Early scholars of folklore focused on the oral and written traditions of mostly nonliterate cultures. The focus of these scholars was on the actual text of the stories. Collectors transcribed and recorded the words, often ignoring the context of the story's performance. In the 1960s, American folklorist Richard Bauman introduced a method of looking at the text within its performance. Bauman (1986) encouraged his peers to include the teller, tale, audience, and occasion in looking at the whole storytelling event. This method has been adopted by most researchers today. Descriptions of this method of fieldwork are included in Jaber Gubrium's *Analyzing Narrative Reality* (2009) and Bauman's *Story, Performance, and Event: Contextual Studies of Oral Narrative* (1986).

As more recent studies focus on the performance and emotional aspects of the field, storytelling has moved from being a part of the field of folklore to being recognized by some as its own interdisciplinary field. Already appearing in library science departments due to the tradition of children's storytelling, courses on storytelling are now being taught in departments of communication arts, anthropology, folklore, liberal studies, education, media studies, information studies, theater, art, writing, psychology, and even business and management. Courses range from the history and theory of storytelling to its technique and practice. A few schools worldwide offer advanced degrees in the field.

The theory and practice of storytelling are not limited to academia. Professional storytellers have been learning and studying storytelling along with trained academics. Before there were professional organizations, storytellers passed their knowledge and skills through inheritance, guilds, and apprenticeships. Today, storytellers learn the art in a variety of additional ways. Pellowski (1990) described five ways in which storytellers are trained: through inherited function or office, apprenticeship by guild, apprenticeship by individual, school (formal and informal), and imitation. Storytellers perpetuate their art through workshops, festivals, publications, and organizations. Publications include practical advice and how-to guides on conducting effective storytelling events.

While American universities were trying to determine where folklore and storytelling should reside, professional storytellers were trying to keep the art of storytelling alive. According to storyteller Joseph Sobol (1999), a storytelling revival took place in the United States beginning in the 1970s. In response to this renewed interest in the art of storytelling, the first National Storytelling Festival took place in 1973 in Jonesborough, Tennessee. Two years after this successful festival, the National Association for the Perpetuation and Preservation of Storytelling was formed. Currently known as the National Storytelling Network

(renamed in 1994), this organization is a place for storytellers to connect with each other in order to share, learn, and improve the art of storytelling. Special interest groups within the network address contemporary uses of storytelling, such as storytelling in organizations, uses of storytelling in higher education, and therapeutic storytelling. Internationally, organizations are also addressing the importance of storytelling. In a global environment, more people are able to connect through the universal human need to tell a story. The International Storytelling Center (www.storytellingcenter.net) focuses on the power of storytelling to elicit understanding among cultures and change in the world.

The power of storytelling is universally accepted by both academics and professionals. They do not, however, always agree on the theories, approaches, and definitions of storytelling. As storytelling studies develop, the paths of academics and professionals are getting closer, bringing the emotional and spiritual to the theoretical and practical. There are examples of individuals who have been able to bridge the divide between the academic and professional worlds by teaching and performing. Helping to build this bridge is a journal that, according to its inaugural issue (Sobol, Gentile, & Sunwolf, 2004), seeks to “create a marriage of emotionally connected research and intellectually open, exploratory storytelling.” The editors and reviewers of *Storytelling, Self, Society: An Interdisciplinary Journal of Storytelling Studies* are both academics and professionals. Using both perspectives, the journal seeks to explore the applied fields of storytelling (organizational, educational, therapeutic, etc.) while remaining dedicated to the artistic and performance studies of traditional storytelling studies.

Current Trends

The importance and value of storytelling to all cultures has been proven by a number of researchers in a variety of areas. As a distinct part of every culture, it can be determined that storytelling is vital to all human civilizations. Traditionally, the term *storytelling* has conjured up images of children’s bedtime stories, rural folk spinning yarns, epic poems, and tribal chants. All of these images are indeed examples of storytelling, but storytelling is no longer limited to these images. Storytelling also takes place everyday in our own here and now. Storytelling occurs around us—influencing, teaching, healing, and entertaining us. Storytelling’s ability to enrapture an audience has brought it the attention of politicians, corporations, therapists, and governments. Current trends involve the application of storytelling in untraditional places and uncustomary ways.

Stories have always appeared everywhere in the day-to-day events. Now however, they are showing up in unconventional areas, such as in the corporate boardroom, in advertizing, on the campaign trail, and on the therapist’s

couch. Corporations are embracing storytelling as a means not only to define their culture for their workers, but also to present themselves in a positive way to their consumers. Advertisements for a variety of products include stories of the designers, creators, and users. Politicians have recognized the importance of storytelling to connect with audiences. Political candidates attempt to personalize their cause, providing personal narratives of their own while also presenting the stories of their supporters and constituents. Therapists are acknowledging the healing powers of storytelling and listening to stories, as people attempt to make sense of their surroundings.

Education has always been a function of storytelling, and storytelling has always been a part of education. Current trends, however, place a stronger emphasis on the use of storytelling in education. While stories have been included in the classroom during story hours or free time, stories have begun to appear within the curriculum of all subjects. Educators, like politicians and corporations, see storytelling as a tool to inspire and influence. Not only are stories being presented to students, but also students are learning how to create and share their own stories through digital storytelling.

As with many disciplines, current trends flow toward the new technology that is available. Storytelling and storytelling studies are no different since they are spreading to a digital platform. While nontraditional areas are embracing storytelling, storytellers, both amateur and professional, are embracing new technologies to continue to entertain and engage audiences in traditional and nontraditional ways.

Technology and the Future

Storytelling began as a way to educate and entertain using the current forms of communication available to humans: words and gestures. As communication technology developed, so did the nature of storytelling. With the written word came the ability to write down the stories and share them among other communities. As technologies grew, so too did the reach of storytelling. Stories have been spread over the phone, via fax, in e-mails, on radio, television, film, and through other forms of media. New forms of communication have allowed not only for the broader dissemination of stories but also for unique experiences for both the teller and the listener. Storytelling is no longer limited to the live performance of an event in front of a single audience. It is an understatement to say that the Internet has had a profound effect on storytelling. With the emergence of collaborative and communicative applications, known as Web 2.0, storytelling has reached more listeners and inspired more creators while also providing a connection between the two. The rise of technology has been blamed for a decrease in the oral tradition and a loss of traditional storytelling. However, recent examples might

argue that technology is strengthening both traditional and contemporary storytelling by making it available to a larger audience.

Audio

As soon as the technology became available, collectors of stories began to record the spoken words of storytellers. These recordings were used for the purposes of transcription and not often made available to other researchers or the public. Fortunately, with the change in emphasis from text to context, researchers began to share the audio events. Audio has allowed not only for improvements in fieldwork but also for the sharing of stories in the way in which they were intended. The act of storytelling implies that there is a listener. Audio technology allows for listeners, even if they are not present at the time of the telling. Recordings and radio have been the usual technology for transmitting stories. Recently, podcasting has become a fixture in the storytelling world. Podcasting is similar to radio but without some of the limitations of radio. A listener is not limited to the time that the event is being produced but has the option of listening at a more convenient time. Podcasts may be downloaded and used with mobile technologies. Podcasting is performed by both professionals and amateurs, as recordings can be created by and are easy to use with inexpensive software. Public libraries have embraced podcasting as a way to expand their storytelling services to a wider audience rather than only to those who can attend the events in person. Podcasting has provided exposure to storytellers who were once known only locally, making their stories available globally.

Visual

Some of the earliest examples of storytelling are pictographs and drawings. Humans were able to convey historical and culturally important events through pictures. Technology today has allowed for a return to this simple form of storytelling. Digital technology allows for the ease of capturing and sharing digital images. These images can be put together to form a story or a sequence of events. Sites that provide global sharing of pictures such as Flickr (www.flickr.com), provide a forum for the telling of visual stories.

Video has had an influential role in both the study of storytelling and storytelling itself. With an emphasis on the entire context of a story performance, the addition of video technology to fieldwork has greatly improved a researcher's ability to analyze an event. Digital stories, or videos depicting an event or a sequence of events, are by far the greatest example of the effect of technology on storytelling today. The emergence of digital stories has provided a new dimension to the world of storytelling. Professional, amateur, traditional, nontraditional, formal, and informal stories all meet in digital space, sharing

audiences and crossing boundaries. Video-sharing sites, such as YouTube (www.youtube.com), return storytelling to the age when everyone was a storyteller, providing the platform for anyone to share their stories.

Social

Storytelling is social in nature, bringing together a teller and a listener and connecting them with a shared emotional experience. New technologies are providing more outlets for the sharing of information, emotions, ideas, and day-to-day events. Social-networking software, or applications that allow for the sharing of pictures, Web sites, articles, audio, or video, are in heavy use today. These applications not only allow a person to share their stories but also provide a forum for comment, questions, and conversation. Social networks create communities and conversations, connecting the teller and listener as with traditional storytelling events. An interesting question for the future is whether the personal narratives told on blogs, microblogs, and social-networking sites can be defined as stories.

The Future

In a sense, storytelling is ageless and timeless. It has always been and is not likely to cease to be, as long as humans are able to communicate. The past is not forgotten simply because there is a new future. Instead, the future is built on past stories and previous studies. The role of the storyteller may not be easily defined, but there will always be a teller of stories. The definition of story may be disputed, but the fact that the events, however they are classified, are important to the teller and the listener is not argued. The future of storytelling studies is moving toward an interdisciplinary cooperation with storytelling professionals. Storytelling itself builds on its past while embracing technologies of the future. Specifically with the community-driven and social technologies, storytelling will be shared, created, and enjoyed by broader audiences than ever before. These social and sharing technologies offer an interesting outlook for the future of storytelling.

Conclusion

Telling and listening to stories bring a community together with a shared emotional event that helps them relate to each other and to the world around them. Along with the need to pass on vital cultural, historical, and moral information, there is an innate human need to provide explanations for things that are not understood. While storytelling perpetuates cultural heritage and helps individuals make sense of the world, it also fulfills a basic biological need for entertainment and escape. The function of storytelling has not changed but the means by which storytelling takes place has. Storytelling has moved

from the formal tradition of oration by a professional to a 3-minute video of a 10-year-old interviewing their veteran grandfather for a school project. The importance of storytelling continues today as it did in the past. Future storytellers may find other ways to present narratives of events, but their ancestors' traditions of storytelling will always be a part of the event.

MASS MEDIA AND ANTHROPOLOGY

SARASIJ MAJUMDER

Rutgers University

According to *Merriam-Webster's Dictionary*, a *medium* is a channel or an intervening agency by means of which something is conveyed or accomplished. By this definition, languages and rituals are probably the examples of the earliest forms of media because ideas of belonging are conveyed and contested through words, rites, ceremonies, and practices. Also, just as all other kinds of media, rituals, as Victor Turner (1974) noted, have a sensory aspect, that is, they engage our senses of sight and sound and have an ideological aspect. They convey important messages. Thus, the study of human society cannot proceed without looking at the media, and both the language and the ritual have been concerns of the anthropologists for a long time. Yet the study of mass media has to emerge as a separate subdiscipline in anthropology because of the improvements and spread of technologies of mass communication and mediation on an unprecedented scale in the post-World War II era. This ubiquity of media worldwide made it increasingly difficult for anthropologists to study rituals and interactions without looking at how they take place in settings saturated with information, images, sounds, and ideas dished out by different kinds of media, such as television, photography, film, radio, and the Internet. Such empirical urgency led the anthropologists to understand the significance of mass media in the lives of the people whom they study. Thus, to emphasize the centrality of mass media to life in the late 20th century, Arjun Appadurai (1991) invented the concept

of “mediascapes” in the early 1990s. During the same time, Debra Spitulnik (1993) pointed out a major lacuna in anthropological understanding of human society by announcing that “there is as yet no anthropology of mass media” (p. 293). Since the 1990s, anthropologists have been deeply engaged in study of mass media and have, thereby, contributed much to the understanding of the media-saturated world in all its aspects. Therefore, the theoretical understanding of media-related social practices has advanced so much that Spitulnik’s lament seems untenable in the 21st century. The following is a brief overview of the major theoretical and methodological contributions that the study of mass media has made to the general understanding of nationalism, globalization, modernity, and society.

Theory

The Anthropological Perspective on Mass Media: Questions the Anthropologist Asks

The invention of printing in the 1400s and appearance of newspapers in the 1600s were watershed moments in human history. Since then, developments and improvements in mass media technologies not only transformed the way space and time was experienced and imagined, but

they also changed intimate relations among individuals and groups. Therefore, an anthropological perspective on mass media is chiefly concerned with people's engagement with media and how that shapes their ideas of themselves and of the intimate and the distant, the places and peoples, and economic, political, religious, and cultural actions and their practices. Thus, ethnographic studies of production, transmission and reception of mass-mediated images, sounds, and ideas are concerned with how media technologies mediate between people rather than simply looking at the effects of media on individuals. The questions that anthropologists explore are: What meanings do individuals and groups make out of mass-mediated images and sounds? How do they negotiate ideas, practices of domination, power, and stereotyping embedded in the mass-mediated programs? How do media technologies enable new forms of social interaction? How do existing social formations, such as the nation, the state, and ethnic groups, get transformed? How does engagement with media transform the conceptions of space and time? How and to what effect do the marginalized groups use mass media?

Although anthropology came late to the study of mass media, the latter as a domain of inquiry had a profound effect on anthropology's core concept—culture. Faye Ginsberg, Lila Abu-Lughod, and Brian Larkin (2002) wrote that for many years mass media were seen as almost a taboo topic for anthropology, “too redolent of Western modernity for a field identified with tradition, the non-Western, and vitality and authenticity of the local culture” (p. 4). In the post-World War II era, anthropologists working in non-Western settings routinely encountered processes in which media played an increasingly important part. For example, Lila Abu-Lughod (1993), one of the pioneers of the subfield that emerged in recent years, came across rapid commercialization of local popular songs among the Bedouins in Egypt and observed the ensuing generational conflicts depicted in national media forms, such as radio soap operas. Abu-Lughod (1993) questioned the “otherness” of the non-Western societies, and it made her rethink the bounded character of one's field site. Such doubts, which challenged the fundamentals of anthropology, had serious implications for the axiomatic understanding of postwar social and political geographies. An analysis of porous boundaries meant that the anthropologists were more attentive to the flows and traffic of people, goods, images, and sounds across the geographical spheres that were also imagined in temporal terms of *modern* and *traditional*. Thus, rural and urban and/or first and third worlds came to share the same geographical and historical space. Consequent ruptures in anthropological theories and methodology of the 1980s and 1990s led to the development of the “anthropology of the present” (Fox, 1991). Anthropologists recognized that they work in societies where media were more central and that electronic media were influencing societies once considered beyond their reach. These shifts catalyzed a critical reorganization of the

concept of culture by unleashing the concept from its traditional “bounded” moorings.

Recognition of the role that the mass media played brought the mediated quality of culture to the foreground. Thus, Louisa Schein (2002) stated that “the way the people understand who they are and how they belong is never anterior to, indeed is inseparable from, the kinds of media they use or consume” (p. 231). In other words, self-understanding and identity is not given to one in its authentic form, but it is produced, of course, within relationships of power and domination and is constituted within a system of representation.

Representations

Representation and systems of representation are key concepts in the anthropology of mass media. According to Stuart Hall (1997), the meaning is produced, communicated, and understood within systems of representation. The systems of representations work like languages, not because they are spoken or written but because they all use some element to stand for, or represent, what we want to say and to express. They communicate a thought, concept, idea, or feeling. Sounds, musical notes, words, items of clothing, facial expressions, gestures, body movements, and digitally produced dots on the screen do not have any clear meaning in themselves, but they signify. They operate as symbols and carry meanings as vehicles or media. In short, they function as signs. It is in these webs of signification that we make sense of ourselves.

Thus, Hall (1997) framed the study of mass media in terms of production and reception or encoding and decoding of meanings within systems of representations. This encoding/decoding formulation allowed for multiple interpretations of media texts during the process of production and reception. However, Hall was quick to point out that representational strategies prevalent in media practice try to fix the meanings of images, sound bytes, and visuals. Power, Hall argued, works through such representational strategies, such as those that try to fix the meanings and thereby invoke an ideal viewer/listener. Nonetheless, Hall emphasized the active participation of the audience and actors involved in the production of media. Audiences interpret and read the media texts in ways other than what has been intentioned in the strategies of who control the production of the media text. Thus, meaning of mass mediated images and sounds are slippery. Hall brought to media studies a perspective that went beyond the model of mass media as simply a tool in the hands of the authorities to propagate their images and views of the world. Hall's model provided anthropologists with a theoretical framework to study production, dissemination, and reception of media ethnographically.

The Medium and the Message

While Hall emphasized the importance of participation and representations in communication, Debra Spitulnik (1993)

turned our attention to technological forms of mediation and social contexts in which such technologies are appropriated. While Hall's encoding/decoding model helps us to imagine an active audience, an attention to technologies of mediation helps us to realize how a medium shapes the social relations and the audience's perception. For Marshall McLuhan (1964), the message of any medium or technology is in the way it changes the scale or pace or pattern of human interaction and affairs. McLuhan connected the rise of the print media to increased individualism, social separation, continuity of space and time, uniformity of codes, and nationalism. McLuhan's contentions were reasserted by Benedict Anderson (1991), who showed that print media was one of the necessary factors for the spread of nationalist consciousness. Nationalist consciousness was not simply produced through the nationalist thought and rhetoric that the print media disseminated. Equally important, the print media enabled participation of millions of people in the practice of imagining an inclusive community.

This ability of the mass media to facilitate the imagination of social entities—larger than those arising from the immediate and concrete contexts—inextricably links the study of mass media with discussions on identities arising out of nationalism and transnationalism. The national frame of reference with which citizens of a nation tend to identify is partly produced through media productions, and the idea of nation is continuously in formation. Spitulnik (1999) showed that radio helped create the postcolonial nation in Zambia by formalizing language hierarchies in a multilingual state, influencing speech styles, signifying modernity itself, and even embodying the state. Similarly, Purnima Mankekar (1999) argued that the televised Indian epic *Ramayan* “might have participated in reconfigurations of nation, culture, and community that overlapped with and reinforced Hindu nationalism” in the early 1990s. The televised epic, Mankekar notes, was part of a sociohistorical conjuncture in which inclusion and exclusion within the Indian national community was constructed in terms of being a Hindu. Also, the media may transform nationalistic feelings for the purposes of specific commercial imperatives of selling commodities to a particular group. Arlene Davila (1999) examined the construction of “Latinidad” by the U.S. Hispanic advertising industry. Davila's work leads us to the consideration of the relationships between the media and capitalism and the state and corporate powers. One of the pioneering studies in this area was carried out by the American anthropologist Hortense Powdermaker (1950). While doing her fieldwork in a small town in Mississippi, Powdermaker was struck by the fact that going to the movies was the primary source of entertainment for her survey respondents and other residents of the town. This realization led Powdermaker to carry out an ethnography of the Hollywood film industry from 1946 to 1947. Although she produced a very dense and insightful ethnography of the Hollywood film industry, her theoretical conclusions

were partly influenced by the theorists of the Frankfurt school such as Max Horkheimer and Theodor Adorno. Powdermaker concluded that Hollywood represents totalitarianism because the overriding profit motive underlying formulaic and dehumanized Hollywood productions not only “mechanizes” creativity, but also makes the audience passive by making it conform to certain aesthetic standards of entertainment. Thus, for Powdermaker, the film industry was an organ of mass deception in capitalist society dominated by big corporations, which hinders the development of autonomous and independent individuals.

Media and Power: Transnationalism, Capitalism, and Multiple Modernities

However, the relationship between the media and the state and corporate interests are more complex than it is often thought. Media are also used by activists and indigenous groups, which is discussed later. But what implications do the contradictory interests of the state have for the media? Ruth Mandel (2002) studied the reception of a television serial called “Crossroads” produced by a private British company as part of a British government-funded project for teaching capitalism to communists in the post-Soviet state of Kazakhstan. Mandel shows how a Thatcherite propaganda tool for teaching privatization, market reform, and democracy to ex-Soviet citizens was repeatedly hijacked and transformed—even derailed—until ultimately it became, at least in part, the voice of a nationalized highly censored, state-controlled media empire not dissimilar from its Soviet predecessor. But such Kazakhstan state-censored broadcasts were also used to transmit diverse and competing messages outside the domain of the state censors. Similarly, Mayfair Yang's (1994) ethnography of post-Mao China draws attention to the contradictions arising out of the Chinese state's embrace of capitalism and encouragement of links for investment to overseas Chinese. The overseas, or pan-Chinese, connections thrive through films, popular music, and television from the mainland. Such transnational subjectivities and desires threaten to shake the authority of the communist regime.

Mayfair Yang's ethnography of media practices in post-Mao China brings a new perspective to the anthropology of mass media, which also studies how media productions circulate across the boundaries of nations. Anthropologists have tried to go beyond the dominant framework of cultural imperialism of the West or cultural resistance of indigenous people. The popularity of Hindi films in places beyond the Hindi-speaking part of the Indian subcontinent and in diverse locations, such as Egypt, Kenya, Japan, and Nigeria, underscores the significance of the alternative circuits of media flows that operate outside the West. Also, there are circulations of small media serving an audience of diasporic communities as Yang has shown. Another very important example of circulation of small media is the

circuit of Hmong videos that span across continents. Louisa Schein (2002) studied how the Hmong, who came to the United States after the end of the Vietnam War, have developed both a pop music world of their own and a thriving video industry. Through these videos, Schein notes that Hmongs not only create a community that transcends the boundaries of nations but also market it as transnational and emphasize the role of the Hmongs Central Intelligence Agency (CIA) recruits during the Vietnam War. Schein theorizes the effect of such media circuits in terms of the concept of “transnational subjectification.” While national subjectification is an understanding of oneself as a citizen of one nation, transnational subjectification is an anchoring of one’s identity in transnational interstitial space. For the Hmong such a transnational space has deep historical significance in terms of wars and conflicts with dominant groups in various nations.

The cultural imperialism model of looking at transnational media circulation has also been complicated by Richard Wilk (1994) in his study of the consequences of the introduction of direct access to U.S. television in Belize through a satellite hookup. Such access to U.S. television, Wilk argues, gave the people in Belize a sense of coevalness that disturbs their ideas about themselves making them feel backward or lagging behind the metropole. Instead, such access reinforced an idea of nationhood in the minds of people who could see the difference between Belize and the United States in terms of cultural difference rather than a historical time lag.

The cultural imperialism model has been further complicated by anthropologists of the media who discovered that ideas and practices generated by circulation of non-Western films, television serials, and popular songs create new sensibilities signifying modernity in various countries. In his study of media in northern Nigeria, for example, Brian Larkin (1997) used the concept of parallel modernities to describe the worlds of those who are not mobile but who, nonetheless, through media participate in imagined realities of other cultures as part of their daily lives. Larkin argues that spectacles and plots of Indian films and their indigenization in a local genre of *soyyaya* (“songs”) books as well as in locally produced videos offer Hausa youth of Nigeria a medium to consider what it means to be modern. Similarly, in Kathmandu, Nepal, circulation of Hindi and Hollywood films, “teen” magazines, pirated cassettes, and interactive radio shows create a transnational public sphere that provides the experience of modernity as a space of imagined possibilities defined by commodities (Liechty, 1994). Thus, media circulation, production, and reception occur within political, economic contexts that define access to cultural and material resources and occur within the constant gaze of the state trying to control its representations to the citizens. Yet new subjectivities and sensibilities and networks that surpass the national and state borders emerge to form a transnational public sphere that span geolinguistic regions and beyond.

As we can see, ethnographic studies enable subtle understanding of operation of power and actions of individuals and groups by looking at influences of state ideologies, histories of migration, and transborder connections on reception and appropriation of images, sounds, and ideas dished up by various kinds of media. Ethnographic focus on particular sites of production makes anthropology of mass media richer. Thus, recent work on media has been described as bifocal as it attends to both the institutional structures and the agency and circumstances of cultural producers. These works emphasize how producers of programs imagine the audience. For example, Barry Dornfeld (1998) demonstrated that the production of a 7-hour educational documentary series on childhood for American public television entails complex negotiations. The audience, Dornfeld shows, is not only anticipated but is also constructed and reconstructed at every stage of the production. Public television workers bring certain assumptions about the particular class fraction of “the American public” that they imagine and hope will watch their work.

Ginsburg, Abu-Lughod, and Larkin (2002) commented that media technologies are not neutral. Each new medium impresses on society not simply new interpersonal relations. But a medium transforms one’s relations to the body and perception and to time and space as theorists from McLuhan (1964) to Jack Goody (1977), Walter Ong (1991), Jean Baudrillard (1984), and Friedrich Kittler (1999) have argued. In recent years, Brian Larkin (1997) has examined the ways in which cinema halls were part of the construction of public space under colonial rule in Nigeria. Cinema halls along with other new spaces, such as libraries, parks, and theaters, created new modes of racial, social, and sexual interaction that raised anxieties about social hierarchies and spatial segregation in Nigeria.

Use of Media Technology in Anthropology

So far we have seen how anthropologists have engaged with questions of production and contestation of identities in a mass-mediated world. An equally important and closely related concern has been the use of media technologies in the production of truth. By emphasizing the mediated quality of truth, anthropologists not only question positivist celebration of value-free science but also turn the critical lens of inquiry on themselves as figures who authoritatively comment on others. Margaret Mead and Gregory Bateson introduced the use of camera (both still and moving) in their 1930s research on Balinese culture and personality. Although they disagreed on how to use camera, they accepted that the camera constituted a privileged medium for scientific research (see Askew, 2002). Similarly, Franz Boas encouraged the use of phonograph for documentation purposes. Use of media technology in early ethnography reflected the positivist concern for truth, objectivity, and science. Photography, however, was never an innocent technology. Photography was used

in categorization and classification of human subjects, especially the criminal, the mentally ill, and the culturally exotic. Yet careful scrutiny of who was photographed and under what conditions reveals in every case a whole host of precursory judgments that negates the purported objectivity of the medium (Askew, 2002). Similarly, by analyzing the photographs in *National Geographic*, Catherine Lutz and Jane Collins show that the magazine relies on two intertwined strategies in the marketplace of images. *National Geographic's* reputation is built on humanism—that under the skin all humans are basically the same. But this foundational idea contradicts the Western common-sense knowledge about the hierarchy of races. Thus, they demonstrate how photographs and the stories told through them in the *National Geographic* reflect the Euro-American notion that the people of color are poor, dirty, technologically backward, and superstitious. They further argue that photographs also distinguish bronze people from black by portraying the former as less poor and more technologically adept than the latter. An idea of a fatalistic link between skin color and progress underlie the so-called objective photographs of the *National Geographic*, contend Lutz and Collins.

Media and Activism

The use of media technologies and perpetuation of power and dominance has been a well-commented topic. The marshalling of media technologies in modernization and racialization projects, which often lead to genocides, is not uncommon. However, McLuhan and others viewed media technologies as tools available to disenfranchised members of society that can be used to undermine existing power relations and to instigate societal change. Since the 1980s, indigenous and minority peoples have begun to take up a range of media in order to talk back to structures of power that have distorted their interests and realities. Such cultural activism, as Ginsburg, Abu-Lughod, and Larkin (1997) called it, emphasizes the political agency and the ability to intervene in the production of the representations. George Marcus and Michael Fischer (1986) identified an activist imaginary in such cultural productions that tends to pursue not only broad-based social change through identity and representation but also produces a utopian desire for “emancipation” by raising fresh issues about citizenship and public sphere.

However, indigenous and marginalized use of media raises many debates and questions about representations of culture. Mediation of an objectified culture to an urban or Western audience can create political cultural assets that can be deployed to make moral and economic claims over land. But many scholars also question if the objectification also results in a paradox of primitivism that often distort the processes that indigenous people are committed to preserving. Ginsburg (1991) suggested that indigenous use of media presents a kind of Faustian contract with technologies of

modernity, enabling some degree of agency to control representation under less-than-ideal conditions. Daniel Miller (1992) accepted the objectification of indigenous or local cultures but said that an anthropologist's first concern is not to resolve these contradictions in theory but to observe how people sometimes resolve or commonly live out these contradictions in local practice.

Methodological Issues and Future Directions

Media and Methodological Issues in Anthropology

Anthropological studies of production, distribution, and reception of mass media not only help us see mass media in a different way, but the studies also have left a deep influence on the way anthropologists do fieldwork and conceive of culture. Thus, Abu-Lughod (1993) has argued that the study of media forces us to represent people in distant villages as part of the same cultural worlds we inhabit—worlds of mass media, consumption, and dispersed communities of the imagination. Yet William Mazzarella (2004) noted a contradiction in narratives of globalization. He points out that in the various discourses on globalization and its implication, there is a growing awareness of the role media and mediation in people's lives; however, there is also a simultaneous disavowal of mediation. This tendency, Mazzarella says, manifests itself in the ideas of “resurgence of the local,” “cultural proximity,” and “hybridity” (p. 352). The celebration of the local is based on the assumption that we value things, which we know from our immediate surroundings. Such assumptions and ideas give rise to a substantialist or essentialist or “unmediated” view of culture. Accounts and analyses based on such assumptions tend to portray the media as something that happen to or are imposed on already-constituted local worlds. The local, in this view, is composed of a certain set of cultural values and practices in which media intrude in beneficial or deleterious ways. But rarely is it acknowledged that mediation and its attendant cultural politics necessarily precede the arrival of what we commonly recognize as “media”: that, in fact, local worlds are necessarily already the outcome of more or less stable, more or less local social technologies of mediation.

Thus, William Mazzarella (2004) and Rosalind Morris (2007) proposed to push anthropology of media and globalization further in order to develop an anthropology of mediation. Mediation, Mazzarella claims, is the general foundation of social and cultural life. Mediation, for Mazzarella, does not simply constitute what we conventionally understand as our lives represented in television, newspaper, and radio; the ritual is itself already a medium that facilitates self-understandings by routing the personal through the collective or the impersonal, the near through

the far, the self through the other, and the real through the virtual. Therefore, study of mediation entails the study of the intersections, tensions, and collaborations of various systems of mediation, which includes ritual practices, as well as the production and consumption of images, sounds, and stories, dished out by the media.

The analytic of mediation helps anthropologists to do away with dichotomies such as outside and inside, global and local, technology and culture, or real and virtual. Thus, Daniel Miller and Don Slater (2000), in laying out an ethnographic approach to the study of the Internet, avoid treating the Internet as global technology that is appropriated in a locale or society. Their study of Internet practices in Trinidad shows that, contrary to the expectations, uses of the Internet are not opposed to “traditional” or “real” forms of relationship, especially kinship. The Internet, Miller and Slater find, is strongly continuous with those values that were developed first in kinship and later through the experience of mass consumption. Thus, they conclude that online and offline worlds penetrate each other deeply and in complex ways. People use the Internet to realize older concepts of identity or to pursue new modes of sociality.

In the next section, we will briefly touch on the ways of designing and executing an ethnographic project to study mass media.

Studying Media Ethnographically

The review of anthropological works on media studies gives us a range of perspectives from which one can come up with a hypothesis or a research question for carrying out an ethnographic research. For example, one may look at use of the newspaper as a source of information that forms political opinion and shapes political behavior and practice. With such a broad area in mind, the first step would be to narrow the topic of newspaper reading in two ways. One should identify one or more particular sectors of the society and sample population for studying the practices associated with newspapers in those sectors or groups. Nonetheless, one should be open to whatever one comes across. Miller and Slater in their study of the Internet used anything that seemed relevant to their understanding of Internet-related practices in Trinidad. Second, one should also try to identify an anthropological problem from certain theoretical perspectives, which has been discussed.

Carrying out the ethnography will require interviewing individuals and groups and observing them in their everyday settings. The questions that will be asked and the things that will be observed will partially depend on the theoretical framework one uses. But one must be open to details because it is the details that help one to contribute to the theoretical understanding of the mass media and the practices that they entail. The aim should not be to make statements that allow us to generalize about all people but to reveal something about the way that particular people behave in the world. The goal is to gain insight into some

of the characteristic ways people use media (e.g., news in case of newspapers) and the information that they give to relate to the wider structures and the people around them. Therefore, interviews should always be matched with what people do. Only by combining observation and interviews can one achieve what Daniel Miller (1992) said is the first concern of the anthropologists; it is not to resolve the everyday contradictions of individuals and groups in theory but to observe how people sometimes resolve or commonly live out these contradictions in various contexts.

Conclusion

In this short review of anthropology of mass media, we see that the study of mass media by the anthropologists has contributed as much to the understanding of media as it has enriched anthropology. Engagement with mass media has subtly shifted anthropology's focus from understanding human beings to how human beings understand themselves. The key point that all anthropological studies of mass media with their focus on production, reception, use, and appropriation of representations emphasize, is that the human interactions and identities have a mediated quality. Thus, the dichotomies between oral and literate cultures and societies with or without mass media or between immediate, or face-to-face, and mediated encounters are false dichotomies. Power, identities, and collectivities always emerge by routing or mediating the self through the other and the near through the far. Anthropology's primary task, therefore, is to look at how various technologies of mediation, such as television, radio, cinema, newspapers, and also rituals, languages, and symbolic practices, interact and to study the tensions and collaborations between these technologies and contradictions in self-understanding arising out of such interactions. Ethnographies must engage with how such tensions and contradictions are reconciled and lived with in different contexts and circumstances.

PART V

APPLIED ANTHROPOLOGY

APPLIED ANTHROPOLOGY

MICHAEL J. SIMONTON

Northern Kentucky University

This chapter explores the subject of applied anthropology. It was found to be most productive to do this from a historical perspective in order to see the formation of the discipline from its earliest, inchoate form to its current state. This method lends a processual understanding of how applied anthropology arrived at the state in which it is found in early 21st-century anthropology.

The chapter commences with a brief definition of applied anthropology in both its broader and more restrictive senses. What follows then is an examination of the origins of applied anthropology within the matrix of anthropology, generally, in the 19th century. The early history of the discipline through the post–World War II, or mid-20th century, era is explored in the next section. The mid-20th-century era was dominated by three subjects: the Fox Project, the Peru Vicos Project, and Project Camelot, which is treated separately. The section on the later 20th century leads into applied anthropology today, which is followed by a section on areas for future research.

Without doubt, some readers will question why particular topics are not presented in this chapter. To them, the reply is that some subjects were considered to be just as easily, and perhaps more fully, discussed in other chapters. In other cases, the sections were perceived as becoming too large to the point of confusing the discussions. In some cases, articles published in some applied anthropology

journals did not appear to do anything but describe situations without offering practical, applied solutions. It is hoped that this interpretation will not be taken personally by any authors or other scholars.

What Is Applied Anthropology?

Applied anthropology, in its broader sense, is distinguished primarily from academic anthropology as anthropological methods and data put to use outside of the classroom. This is not to say that all anthropological methods and data put to use outside of the classroom is applied anthropology; field research also is anthropological methods and data put to use outside of the classroom, but it can be used for academic purposes, as well as for practical application. Applied anthropology is used to solve practical problems outside of the academic world, and it has appeared under such names as action anthropology, development anthropology, practicing anthropology, and advocacy anthropology among others.

In its narrower sense, applied anthropology is distinguished from practicing anthropology. Practicing anthropology is the application of anthropology strictly outside of academia by nonacademics; applied anthropology can be practiced outside of academia or within academia by academics. To some, the differences are considered to be minimal, but to others they are of great importance.

Origins

Early in the 19th century, anthropology was a religious philosophy that examined how to view the place of humans in the cosmos. This began to change by the mid-19th century, and people who were to become the founders of what is called anthropology today began to look at the more earthly nature of humanity. One of these individuals was Lewis Henry Morgan. Morgan, who was an attorney, began to work with the Iroquois in the 1840s on legal issues involving railroad right of ways. This may have been one of the first, if not the first, application of the nascent but as yet still inchoate discipline.

Across the Atlantic, Sir Edward Burnett Tylor, the “father of anthropology” who defined “culture,” considered anthropology to be a “policy science” that should be implemented to ameliorate the problems of humanity. James Hunt, who founded the Anthropological Society of London, began to use the term *practical anthropology* by the 1860s, and in 1869, the Royal Anthropological Institute of Great Britain and Ireland (this was later to be titled the Royal Anthropological Institute) was formed.

In North America, the federal government formed the Bureau of American Ethnology (BAE) under John Wesley Powell in order to perform research that was intended to guide government policy toward Native Americans, and in 1879, Powell dispatched Frank Hamilton Cushing to the Zuñi pueblo to perform some of the first anthropological field research. By 1895, the BAE had hired anthropologist James Mooney to research a revitalization movement, the ghost dance. It also was in the 1890s that Franz Boas, the “father of American anthropology,” worked outside of academia with the Chicago Field Museum.

Early History

Boas developed a lifelong hatred of racism arising from anti-Semitic experiences he had had in school in Germany. This led him to attempt to dispel the prevailing racist notions of the day in anthropology. From 1910 to 1913, Boas applied anthropometry to disprove a basic racist assumption: Cranial shape was a factor of race. To accomplish this, he measured the heads of Jewish immigrants in New York City ghettos. Presumably, they were members of the dolichocephalic (longheaded) Mediterranean race, and indeed, the immigrants tended to fit that pattern. However, their children, born in America, were members of the brachicephalic (roundheaded) Alpine race. Apparently, they had changed race within one generation of having moved to America. Boas explained this anomaly as being the product of different diets between the parents and their children during their growth years and not the result of race at all.

Boas’s first PhD student, Alfred Louis Kroeber, and Kroeber’s students spent the first two decades of the 20th century conducting “salvage ethnology” to preserve

cultures that were, or already had, become extinct. The most famous of these cases, both within and outside of anthropology, is the story of Ishi, the last member of the California Yahi tribe, whom Kroeber brought to Berkeley to serve as the key respondent from a vanished people. In 1919, Kroeber applied anthropological techniques to discover the rapprochement between fashion and economic cycles in his hem-length study. He demonstrated that one could determine (and perhaps predict) economic cycles by the rise or fall of women’s dress and skirt lengths. The 1920s also found Margaret Mead (1928/1973) making recommendations on sex education to the American educational establishment in the last two chapters of her doctoral dissertation, published as *Coming of Age in Samoa*.

In Europe, it was common during this time for anthropologists to seek employment in colonial governments: Anthropologists from the Netherlands were employed by their government to provide ethnographic data on its Indonesian colony; Northcote Thomas used anthropology to aid in administrating the British colony in Nigeria; and Alfred Reginald Radcliffe-Brown served as director of education on Tonga. Somewhat later, in the 1930s, Edward Evan Evans-Pritchard (1969), in the employment of the government of the Anglo-Egyptian Sudan, spent several research periods among the Nuer to determine why they did not consider it necessary to uphold their treaty with the British government, among other projects. Also in the 1930s, Radcliffe-Brown first used the term *applied anthropology* in the article “Anthropology as Public Service and Malinowski’s Contribution to It” (although the term already had appeared in 1906 in a degree program at Oxford). Bronislaw Malinowski himself, had coined the term *practicing anthropology* for nonacademic anthropology.

In 1932, President Franklin Delano Roosevelt appointed the anthropologist John Collier to Commissioner of the Bureau of Indian Affairs (BIA). Collier then employed fellow anthropologists Julian Steward, Clyde Kluckhohn, and others in the applied anthropology office to investigate Native American cultures and to counsel the BIA in regard to the Indian Reorganization Act. The anthropologists served as intermediaries between the BIA and Native Americans during the drawing of tribal constitutions and charters. Also in the 1930s, Edward Sapir’s student, Benjamin Lee Whorf, applied anthropological linguistics to the analysis of fire insurance investigations, and anthropologist W. Lloyd Warner was hired by the Western Electric Company to study worker productivity in its bank-wiring facility. Warner employed qualitative ethnographic techniques, such as participant observation and informal interviewing, that previously had been used in nonindustrial, non-Western societies in one of the first applications of “industrial anthropology.”

The 1940s brought about the efflorescence of the field with the founding of the Society for Applied Anthropology (SfAA) by Margaret Mead, Conrad Arensburg, and Eliot Chapple. They published the journal *Applied Anthropology*

to counter what they saw as academic bias against practical, nontheoretical work. In 1949, the name of the journal was changed to *Human Organization*, and the SfAA code of ethics was created. Despite this, Melville Herskovits taught in the late 1940s that applied anthropology was racist and should not be practiced, according to one of his former students.

Today, a variety of organizations specialize in applied anthropology. The Consortium of Practicing and Applied Anthropology Programs (COPAA), chaired by Linda A. Bennett of the University of Memphis, lists and gives a brief description of some of these organizations on its Web site, including the COPAA, the SfAA, and the National Association for the Practice of Anthropology within the American Anthropological Association.

The COPAA also lists regional organizations, which include the Washington Association of Professional Anthropologists; the High Plains Society for Applied Anthropology; the Chicago Association for Practicing Anthropologists; the Sun Coast Organization of Practicing Anthropologists; the California Alliance of Local Practitioner Organizations that embraces the Southern California Applied Anthropology Network, the Bay Area Association of Practicing Anthropologists, and the Central Valley Applied Anthropology Network; and the Mid-South Association of Professional Anthropologists. It was during World War II that Margaret Mead headed a group of anthropologists who served in the Office of Strategic Services. In addition to Mead, Ruth Benedict, Ralph Linton, Julian Steward, and Clyde Kluckhohn, among others (including such interdisciplinary notables as Erik Erikson), worked on the Committee on Food Habits, the Culture at a Distance national character project, the War Relocation Authority, and others, in order to aid in the U.S. war effort. A description of their work and methods was published (Mead & Rhoda, 1949) after the war as *The Study of Culture at a Distance*. Following the war, anthropologists also worked for the U.S. Pacific protectorates' administrations.

Mid-20th Century

The Fox Project

In the late 1940s, Sol Tax of the University of Chicago wanted to develop a program that would give field experience to anthropology students. To do this, he began the Fox Project in 1948 to look into social organization and leadership in the Fox/Tama settlement, which was facing acculturative pressures from the neighboring Euro-American community. Although they tried to become involved in the amelioration of the acculturative process, they had no authority to do so. Thus, they developed a theoretical agenda that became known as "action anthropology." In 1953, the group consulted with the Fox project and developed a framework for action that was funded by a private

foundation. University of Iowa students joined the University of Chicago group, and together they created the Fox Indian Educational Program and began the Tama Indian Crafts industry.

About the time that the Fox project was nearing its completion in 1952, Edward Spicer's book, *Human Problems in Technological Change*, was published. That same year Allen Holmberg began Cornell University's 14-year experiment: the "Peru Vicos Project." Cornell University had rented Vicos, a feudal estate in Peru, as a living laboratory to study social engineering on the Quechua-speaking peasantry, to test theories of modernization, and to develop models for community advocacy and culture brokering.

1964: Project Camelot

Project Camelot had the potential to be a low point in the application of anthropology in the late 20th century. In December 1964, the Office of the Director of the Special Operations Research Office of the American University in Washington, D.C., announced a new program to be funded by the army and the Department of Defense. The program extensively would employ anthropological fieldworkers in government research for 3 to 4 years. In theory, it was a project that was intended to develop a systems model that would enable the prediction of social changes that in turn could develop into political movements in third world nations that might threaten the United States—specifically in Latin American countries (where a field office was planned) but with plans to expand globally. Its objectives were to formulate means to predict civil wars and revolutions; to identify means to prevent civil wars, insurgency, and counterinsurgency movements in particular societies; and to develop a system of field methods to collect the information to accomplish the two previous objectives. The budget was expected to be in the \$1.5 million range annually.

Some anthropologists feared that applying anthropology to aid Latin American government's repression of political movements was unethical and would hinder development of societies in those countries. A more horrific potential outcome to the field ethnographers was the possible executions of their field respondents. In response to the outcry from the social science community, Project Camelot was cancelled in July 1965.

Nonetheless, not all social scientists found Project Camelot to be totally objectionable. Beyond the satisfaction of the obvious and never-ending quest for research funding, which it would have provided, albeit from sources that are suspect to many in the academic community, there is the less obvious appeal of ethnography finally having some input into government international policy, something that had been called for over decades. Likewise, many anthropologists in that era had gotten their starts in the military by having had their first international experiences during the second World War and their educations financed by the government issue, or GI, Bill. Rather, it

was the possible outcomes of their research that convinced the community to object to Project Camelot.

Also in the 1960s, medical anthropologists working with the Foré tribe of New Guinea traced the origins of a deadly neurological disease, *kuru*, to cannibalism by using traditional qualitative techniques, such as collecting life histories; Margaret Mead testified before Congress on birth control and marijuana, and she coined the term *generation gap* to describe a global phenomenon that had never occurred previously in human history; Jules Henry's *Culture Against Man* described the Orwellian nature of popular advertising in American society; Jomo Kenyatta applied his PhD in anthropology from the London School of Economics under Malinowski to running the government of Kenya, with its diverse ethnic makeup, as its first president under the slogan *Harambe*, or "let us pull together" in Kiswahili. Oscar Lewis conducted his "family life histories" in Mexico City (*The Children of Sanchez*) and New York (*La Vida*) and described the poor as living in a self-perpetuating "culture of poverty." Although this was criticized widely as an attempt to blame the poor for their condition, it also could be said that Lewis was acknowledging the wisdom of people who lived on the edge and their ability to survive and fully exploit their economic niches.

James P. Spradley conducted a Herculean application of ethnoscience to "tramp" culture in Seattle in the 1960s to determine the emic structure of the society in order to make recommendations for improved treatments to social workers, police, psychiatrists, and alcohol treatment centers. It was published as *You Owe Yourself a Drunk: An Ethnography of Urban Nomads* in 1970. In 1969, George Foster wrote the first textbook on development and change agency, *Applied Anthropology*, in which he cited changes in human behavior as a primary goal in order to solve social, economic, and technological problems. He followed this up in 1973 with *Traditional Societies and Technological Change*.

Late 20th Century

In 1974, the University of South Florida began the first master of arts degree program to focus specifically on training students for careers in applied anthropology. The options available to those students form a wide range of topics that define applied anthropology. Among them are archaeology, Cultural Resource Management, economic development, educational anthropology, immigration, medical anthropology, race, gender, ethnicity, and urban policy and community development. Among the reasons for such theoretical breadth is the realization that many master of arts students do not choose to pursue a doctor of philosophy degree, and this curriculum, then, qualifies them to work in specialized professions outside of academia. The reader will note that work outside of academia is known as practicing anthropology, and in 1978 the

University of South Florida first published the journal *Practicing Anthropology*. Graduate programs in applied anthropology are becoming more widespread in the United States since that time; for example, the master's program in applied anthropology at California State University, Long Beach, has three program options: communities/organizations, health, and education. Northern Kentucky University's anthropology program is long known for its award-winning Web site with information on where undergraduate anthropology majors, who cannot or do not choose to attend graduate programs, can find jobs outside of academia; currently, it is in the process of developing a master's program in applied anthropology.

Programs in Applied Anthropology

COPAA lists member programs on its Web site for those interested in pursuing a career in applied anthropology. The Web site notes that there are other programs that are not currently COPAA members. Among the universities in consortium are the University of Alaska, Anchorage; American University; University of Arizona; California State University, East Bay; California State University, Long Beach; University of Florida, Gainesville; The George Washington University; University of Georgia; Georgia State University; Indiana University-Purdue University at Indianapolis; University of Kentucky; University of Maryland; University of Memphis; Mississippi State University; Montclair State University; University of North Carolina at Greensboro; University of North Texas; Northern Arizona University; Oregon State University; Santa Clara University; San Jose State University; the University of South Florida; the University of Texas at San Antonio; and Wayne State University.

The first doctoral program in applied anthropology was begun at the University of South Florida (USF) in 1984. Although the master of arts curriculum had been intended for nonacademic professions, the PhD curriculum trained students for university careers, as well as for practicing anthropology. USF's Center for Applied Anthropology combines these two objectives in ventures such as the Human Services Information System database and the Alliance for Applied Research in Education and Anthropology.

In the 1960s and 1970s, Napoleon Chagnon and James Neel conducted genetics research for the American Atomic Energy Commission in an ethnographic setting. Chagnon was the ethnographer, and Neel was the geneticist. Their work was designed to determine the effects of the forces of evolution (such as the founder effect) on small populations in order to determine how genes might affect survival following a nuclear destruction of modern civilization. Their research took them to the Orinoco River basin in southeastern Venezuela where they established contact and conducted research among the Yanomamo, an isolated, horticultural, tribal society. Out of this research came

Chagnon's ethnography, *The Yanomamo: The Fierce People*. From its very early days, the project was heavily documented on film, and their classic documentary, *The Yanomamo: A Multidisciplinary Study*, became a standard in both cultural and physical anthropology classrooms. In the film, Chagnon and Neal become aware of a measles epidemic sweeping up the Orinoco Basin toward the Yanomamo. They acquire a vaccine that contains a weakened strain of the live virus and conduct mass inoculations of the Yanomamo against measles.

Although their work was met with criticism from the outset, none was quite as virulent as the later criticism contained in Patrick Tierney's 2000 book, *Darkness in El Dorado*, and its aftermath. Tierney claimed that Chagnon and Neel had been conducting Josef Mengele-like genetics experiments on the Yanomamo by injecting them with the live measles virus to see who would live and who would die—not, as shown in the documentary, to protect them from an epidemic. The author of this chapter recalls sweeping condemnations of Chagnon and Neel from the anthropological community on several Internet electronic mailing lists originating throughout the United States at that time based on *Darkness in El Dorado*—although the book had not yet been released. By that time, Neel was dead, and although Chagnon was retired, he filed a lawsuit against Tierney in which he and Neel eventually were vindicated. Currently, calls are being made in anthropology to disband the “El Dorado Task Force” set up to investigate this case.

In the 1980s, Philippe Bourgois conducted field research among Hispanic crack (“rock” cocaine, which is smoked) dealers in the Harlem area of New York. This was not an update of Elliott Liebow's *Tally's Corner* nor of Oscar Lewis's *La Vida*. Rather, it is what Bourgois refers to as a “culture of terror” that exploits an underground economy. Bourgois argues that this renders the crack dealers unexploitable by the larger, legal society as they pursue their interpretations of the “American dream.”

Across the Atlantic, anthropologists and other social scientists began to influence government policies in the Republic of Ireland in the late 1980s, according to Thomas Wilson and Hastings Donnan, via what are called the economic and social partnerships with government. This should not be confused with hegemony as may have been the case with the 1960s American “military-industrial complex.” Rather, in a country in which anthropology traditionally had been practiced by foreign scholars investigating semi-isolated rural communities, it was a remarkable innovation for anthropologists and other academics to have creative input, with their governmental partner, in the policies that led to the Celtic Tiger economy in what had been one of the poorest countries in Europe and the social structural transformations that allowed the “boom” to filter down to the public at large. Anthropologists also have been called on more recently in Ireland to assist the government with ethnic minority issues, especially those of the indigenous minority, the travelling community.

Since the beginning of the 1990s, nonacademic jobs for anthropologists have increased, and more anthropologists have found themselves involved in the business world, especially in marketing, although the irony of this may not be lost on those who were students when Jules Henry's anti-Madison Avenue research, published as *Culture Against Man*, was a popular textbook in the 1960s and 1970s. Much of the new material centers around *cultural miscues* that corporations and individuals make in advertising—physical gestures, slang, and so on—when acting cross-culturally (e.g., Chevrolet's attempt to market the *Nova* automobile in Latin America where the homonym of the name means “does not go” or Gerber's attempt to market baby food with an infant's picture on the label in parts of Africa where labels routinely showed the containers' contents for consumers who could not read). Other business-oriented approaches fall more along the lines of the Western Electric bank-wiring study (noted above) conducted by W. Lloyd Warner in the 1930s.

Nonetheless, some members of the anthropological community still consider business anthropology to be “colluding with the enemy,” according to Jason S. Parker of Youngstown State University in a recent article in the *Society for Applied Anthropology Newsletter*. Parker points out that these same critics, who stigmatize those applied anthropologists that work in business, are not offering any jobs to their recently minted bachelor's degree graduates, who must then look elsewhere. Parker argues that the anthropological perspective can benefit the employees, as well as the corporations, through the inclusion of their input in the manufacturing processes.

Ann T. Jordan has written a persuasive argument for the use of anthropology in the business world in her book *Business Anthropology*. Jordan cites a number of cases in which anthropologists have ameliorated conditions that had the potential to lead to labor disharmony through managerial insensitivity to working conditions. Likewise, she explains that cross-cultural conflicts and misunderstandings on the job could easily be avoided with anthropological input.

Applied Anthropology Today

Louise Lamphere suggested a convergence of applied, practicing, and public anthropology in 2004. Lamphere argues that anthropologists in the 21st century should collaborate with each other, as well as with the groups that they are investigating, on archaeological research, health, urban, and environmental topics to unify their work on critical social, educational, and political issues. The traditional research populations increasingly want greater degrees of jurisdiction over what is written about them, and applied anthropologists, especially those influenced by the feminist critique, have advocated more collaboration with their respondents on ethnographic publications and

museum exhibits in order to express more emic perspectives. This joint participation in the research and presentation process (whether by publication or museum display) fosters skills and generates capacities for indigenous change within communities.

Charles Menzies erects a paradigm to foster these joint ventures based on his work with the Gitksa Nation in British Columbia, which consists of four stages. First, the anthropologist opens a dialogue with the community that may suggest modifications to the research protocol. Then, research continues to grow and change in consultation with the respondents—who now are becoming “coethnographers.” Next, the research is conducted jointly between academics and members of the society. Finally, the data and results are analyzed by the joint team and the reports are coauthored. Lamphere advocates training students to conduct collaborative research of this nature as anthropologists increasingly find themselves employed by nonacademic public and private organizations.

21st-century anthropologists increasingly find themselves involved in policy-making jobs in areas as diverse as libraries and the army. The University of Rochester library hired anthropologist Nancy Fried Foster, under a grant from the Institute of Museum and Library Services, to study undergraduates’ term paper research, to steer library renovations, and to make suggestions on the redesign of its Web site. Foster used traditional anthropological research methods to discover that not only are many students extremely uncomfortable with the increasing technological changes that universities are forcing on them but also that they use the libraries to escape from them.

Anthropologists and the Military

A recent *Society for Applied Anthropology Newsletter* reports that anthropologists increasingly may become involved in work with the military via a program called the Human Terrain System under the Department of Defense (DoD). According to Susan L. Andreatta, president of the SfAA, the DoD wants to employ graduate-level anthropologists in Iraq and Afghanistan. Opinions on this are divided, but one may note that the Society was founded by anthropologists who worked for the war effort in the 1940s.

The anthropologist and senior consultant to the Human Terrain Systems project is Montgomery McFate. William Roberts of St. Mary’s College, Maryland, describes her argument as one in which a military that has greater understanding of indigenous civilians in war zones will reduce loss of life and cultural destruction.

Also, archaeologists may be involved with the military on sensitive issues. As of this writing, archaeologist Laurie Rush serves as a cultural resources manager at the United States Army’s Fort Drum, where she works with the Integrated Training Area Management unit of the DoD’s Legacy Program to develop a consciousness

for archaeological treasures. This project arose out of a British Museum report that detailed the construction of a helicopter pad by U.S. Marines on the ruins of the ancient city of Babylon, the destruction of a 2.5-millennia-old brick road, and the filling of sandbags with artifacts. Part of Rush’s program involves building models of archaeological sites, mosques, and cemeteries for soldiers to train to avoid.

Forensic Anthropology, Ethnic Cleansing, and Political Dissidents

Television programs such as *Crime Scene Investigation (CSI)*, *CSI: Miami*, *CSI: New York*, and *Naval Criminal Investigative Service (NCIS)* have sparked an international interest in forensics. This, in turn, has led to a student population interested in forensic anthropology. Cable television’s Discovery Health channel has created a true-life version of the *CSI* phenomenon with its *Forensic Files* program, which features cases solved by forensic anthropologists, such as Elizabeth Murray of the College of Mount St. Joseph in Cincinnati who works regularly with law enforcement agencies across the country.

The *ABC News* and *Christian Science Monitor* Web sites occasionally report on the applications of forensic science. They describe forensic anthropologists and archaeologists who have been involved in the identification of the remains of the nearly 3,000 victims of the September 11, 2001, attack; Jon Stereberg, a forensic archaeologist, has tried to trace the evidence of 1992 gas attacks in the clothing of victims in the Balkans; and Clyde Collins Snow, a retired forensic archaeologist, has investigated grave sites in Guatemala, Bosnia, and Iraq. Currently, forensic specialists, such as Ariana Fernandez, are examining the bodies of Kurdish people who were found in mass graves and who are believed to have been massacred in a genocide attack during the Saddam Hussein regime in Iraq.

Tourism

The travel and tourism industry is in dire need of the services of anthropologists, and this is becoming an attractive employment option to anthropology graduates, according to Susan Banks, an anthropologist involved in the travel industry. Too often, tourists will go to exotic locales where they believe that they are seeing the actual types of lives lived in those places, unaware that they are being fed a fabricated culture designed, not to expose them to life in other places, but to screen them from the true ways of life found in those locations. Commonly, tourists are discouraged from visiting local towns and actually learning something about the countries that they have visited. Anthropology can offer a remedy to this problem and provide some much-needed income to the local economies. Exploitation

and insensitivity to indigenous people by culturally uninformed tourists does little to change the image of the “ugly American.” Likewise, the international sex trade both exploits and victimizes indigenous peoples and furthers the spread of dangerous diseases, such as HIV/AIDS.

Environmental degradation of local ecologies is another problem of culturally ignorant tourism. For this reason, Susan Charnley, in an article in *Human Organization* in 2005, suggests a change from nature tourism to ecotourism. She cites the case of Ngorongoro Conservation Area (NCA) in Tanzania. Nature tourism involves traveling to pristine locations where tourists can experience and enjoy nature; ecotourism involves traveling to natural areas that conserve the local ecology while respecting the rights of the local cultures and encouraging sustainable development. Charnley makes the case for the increasingly difficult position of the Massai people since the creation of the NCA and the negative effect it has had on their economy. Charnley argues for culturally appropriate involvement of local people in tourist destinations in ways that will provide actual benefits to their communities. These benefits would include social and political justice and involvement in decision-making processes that directly influence their lives.

A selection of articles from *Human Organization* from the first decade of the 21st century includes such topics as the administration of federally managed fisheries, including a discussion of the role of James A. Acheson who was the first applied anthropologist hired by the National Marine Fisheries Service in 1974 to conduct policy research and implementation through conservation and stewardship of marine ecosystems.

Another article described the importance of beer parties among Xhosa labor cooperatives on homesteads in South Africa. An article that has to do with changes in gender relations and commercial activities, as the global market expands to countries such as Mali, explores how the outside world can force local peoples to change the structure of their society by giving advantages to one gender over the other when that may not have been the case previously. Another article illustrates what the author of this chapter sees as a parallel between the popular use of family trusts in the United States in the 1980s and 1990s and a move from individual land tenure to collective, kin-based ownership on Mokil Atoll in Micronesia, as the region's political, economic, and demographic transformation has imperiled the rights of absentee owners. By placing the land ownership in the kin group, it is protected from individual alienation.

A 2007 article by Kathryn Forbes is especially topical in the current social, economic, and political climate of the United States today. Forbes's article examines how the regional land use of ideologies and popular images of farm workers has contributed to a housing crisis for Mexican agricultural laborers in Fresno County, California. Stereotypic descriptions of Mexican farm workers have resulted in the formulation of zoning codes that exacerbate

demographic segregation in Fresno County. Most farm workers live in rural areas, which are more economical and more convenient to their sources of income but where there are fewer retail outlets—including groceries. The arrival of seasonal laborers, combined with a lack of affordable housing thanks to local policymakers, has engendered a regional overcrowding crisis for Mexican farm workers. Forbes's role in this discussion is similar to the review of the roles that anthropology can play in public policy cited by Wilson and Donnan (2006) in Ireland.

Future Directions

Forbes's article is especially relevant to the United States today as the influx of immigrant labor, thanks in part to the North American Free Trade Agreement (NAFTA), has made the appearance of Hispanic laborers a topic of vituperative discussion on national radio talk shows and political campaigns. This is a point that falls clearly within the purview of social science rather than politics as anthropological demographers and gerontologists clearly can demonstrate that not only does the country require immigrant labor because of statistical “full employment,” but also it needs to save social security from the influx of baby boom retirees.

The bankruptcy of social security was predicted in university classes as long ago as the 1970s. The increase in life spans, coupled with the potentially disastrous demographic effect of a baby boom generation that will retire to be supported by a much smaller (thanks to the introduction of the birth control pill in the 1960s) birth dearth/baby bust cohort, has the potential to lead to economic disaster for the latter group as their increasing social security taxes erode their quality of life. The baby boom retirees' social security taxes must be replaced from somewhere—if not by eroding the birth dearth/baby bust cohort's quality of life, then by an influx of tax contributors, for example, immigrant laborers.

Anthropologists are in a unique position to act as the social partners of policymakers on this issue not only by means of their demographic and gerontological expertise but also by their ethnographic contributions to allay the concerns of the extant non-Hispanic population of the United States over its possible perception of cultural drowning by immersion in a neo-Hispanic society *del Norte* (“land of the north”).

Likewise, anthropological expertise in indigenous Latin American medical beliefs, such as *hot* and *cold*, *wet* and *dry* bodily conditions derived from the ancient Mediterranean medical concept of *humors* where illnesses were believed to be caused by an imbalance of humors; folk illnesses, such as *susto* (“fright”), a culture bound syndrome found in southern Mexico in which an individual who does not recover from an illness is believed to have had a terrible fright in the past that prevents recovery from

the unrelated illness (Rubel, O'Neill, & Collado-Ardon, 1991); and cultural sensitivities to variations in conceptions of sexual modesty and familial responsibilities will form a necessary component in the rapprochement of the two larger cultures although this may be difficult in cases of smaller subcultures.

Other areas for future research in applied anthropology include human trafficking (briefly cited in the discussion of tourism); indigenous rights (e.g., salmon fishing among the native Northwest coast peoples in North America, cattle grazing in the Burren in County Clare, Ireland, or the effects of water control on the Marsh Arabs of southern Iraq); anthropometry and gender (in the cultural sense, not the linguistic sense) stereotypes and gender rearing roles; cultural relativism versus cultural interference, including whether or not Muslim women need to be "saved" or if Western hegemonists even have the right to do so; genital mutilation (male as well as female); the role of nongovernmental organizations (NGOs) in distributing information and treatment of HIV/AIDS; food waste, diet and health, and body image; intelligent design, globalization and high-tech industry; and the role of biology and culture in psychiatric illnesses, to name but a few of the possibilities open to applied research in anthropology.

In an article titled "Making Our Voices Heard—Ethical Dilemmas and Opportunities," in the November 2007 *Society for Applied Anthropology Newsletter*, Mark Schuller of Vassar College gives a good review of the future of applied research in anthropology. Schuller writes that many anthropologists believe that their contributions are considered marginal and irrelevant and are passed over in policy making based on a review of the leading anthropological journals and newsletters. He argues that applied anthropologists with a holistic viewpoint can inform policymakers regarding the integrated structural correlation among debt and poverty, education, health care, and local welfare via their engagement with local communities. Schuller calls for local, global, and ethical analysis of current concerns to make anthropology applicable in the "real" world. He suggests that a good way to apply anthropology is through teaching; his students investigate public policies and then send letters to the editors of newspapers in order to introduce anthropological viewpoints into current policy discussions.

Schuller has been keyword-searching "anthropology" on Google and reports that he has found at least two stories a day in which anthropologists are interviewed or have authored stories in media outlets. Among the included issues that his students or other anthropologists have written about in daily news publications is the part played by anthropologists in clandestine activities, inequalities of globalization, the State Children's Health Insurance Program (CHIP) health care bill, the UN Declaration of the Rights of Indigenous Peoples, No Child Left Behind, prison reform, disclosure of hormone content in milk, Hurricane Katrina "fatigue," and the cancellation of international debt in impoverished nations of South America.

In the same issue, Amanda Stronza of Texas A&M University describes a new program in applied biodiversity science, which also will tackle poverty and cultural inequality. The interdisciplinary research program integrates cooperation between social and biological sciences and conservation organizations at the applied level. Research topics are to incorporate biodiversity with local legislative policy in partnership among academia, governments, NGOs, and local societies in four regions of the Americas.

Conclusion

This chapter has explored the subject of applied anthropology. It was done from a historical perspective in order to gain a processual understanding of how it arrived at the state in which it is found in early 21st-century anthropology.

A brief definition of applied anthropology was followed by a review of the origins of applied anthropology in the 19th century and a history of the field through World War II, the Fox Project, the Peru Vicos Project, and Project Camelot. The section on the later 20th century led into applied anthropology today and topics for future research.

Some topics were not presented in this chapter as they are more fully discussed in other chapters in this book. The author has expressed the opinion that some articles published in some applied anthropology journals do not appear to do more than describe situations without offering any real, useful solutions that are likely to be applied by the nonacademic. This is not to say that practical solutions to problems that have been described have not been made in many cases—They have. Rather, it is a call for anthropologists to do what they do best: engage with communities. It is hoped that my interpretation will not be taken personally by any authors or other scholars.

LAW AND ANTHROPOLOGY

OLIVER W. LEMBCKE

Friedrich Schiller University in Jena

Law is a cultural achievement of humankind. On the basis of rules that are typically connected with sanctions, it is meant to prevent or overcome social conflicts. The nature of these rules can generally be distinguished by their purpose: They either serve the purpose of deciding legal cases (rules of decision) or the purpose of conducting a legal process (rules of conduct). The foundation of the rules, too, can vary. Some legal cultures base their rules on (unwritten) traditions (common law), usually replenished with precedents of case decisions by the judge's dispensation of justice (case law). In contemporary legal systems, however, the foundation of legal decisions is above all provided by the state legislature (statutory law). In modern judicial terms, the sum of legal norms, which forms a more or less coherent legal system, can be described as objective law. The (legally guaranteed) authorizations of the individual member of this legal system (e.g., the citizen), on the other hand, are subjective rights, guaranteed, for instance, in the form of civil rights.

The social function of preventative conflict avoidance or reliable conflict resolution can be fulfilled, lastingly, only when law is also able to offer criteria in terms of content to justify legal decisions. Since ancient times, law has therefore been characterized not only by its sanctions but also by its reference to justice. At the beginning of Justinian the Great's *Digesta* (533 BCE), a collection of the works of Roman legal scholars, it is stated in that respect: "Law is the art of the good and the fair" (*ius est ars aequi et boni*

[*Digesten*, 1.1.1. pr.]). Similar definitions can be found in other legal cultures that have not been influenced by Roman law. Yet law also involves the "authorization to coerce" (Kant, 1996, p. 25), as we learn from Immanuel Kant (1724–1804). Both sides, coercion as much as justice, have at all times during the history of humankind decisively influenced the development of law. One essential reason for the continuously tense relationship between these two dimensions of law is the strong correlation between law and human life. Friedrich Carl von Savigny (1779–1861), a distinguished German legal scholar and the founder of the so-called Historical School of Law, once noted rightly that law had no intrinsic content; it is directed toward and, at the same time, dependent on the life of human beings. This fact displays the anthropological foundation of every law. Moreover, it bears legal consequences that are concisely expressed in a canon of ancient Roman law: No one can be obligated beyond his or her capabilities (*ultra posse nemo obligatur*). This principle is rooted in the insight that a legal norm that asks too much of an individual is simply unjust.

Anthropological Foundations of Law

From the viewpoint of evolutionary biology, the development of law shows itself to be a matter of adjustment to the benefit of our own species' self-preservation and reproduction. This concept is above all based on the

findings of primatology. This science informs about the phylogenetic background of *Homo sapiens* and allows conclusions to be drawn about the emergence of normativity in human relationships. The phenomenon of reciprocity is of major importance in this context; it can, for instance, be observed in the social behavior of chimpanzees, our closest relatives. To meet the basic challenges of self-preservation and reproduction, chimpanzees live in social groups. The advantages are obvious: The offspring is more effectively protected, and food is more efficiently secured. Our species develops affection for the building of societies, an *appetites societas*. Not unlike human associations, though, living in groups is never without disadvantages. These occur whenever competition arises within the group in the struggle for scarce supplies that ultimately decide on the individual fate of the group members. Chimpanzees have obviously developed the ability to ensure a regulated exchange of goods among each other. The disposition to share goods among one another considerably depends on whether the “beggar” was, in a reversed situation, also willing to share his food or to provide the “proprietor” with other “services” (e.g., “grooming”). Generosity will generally be answered likewise; parsimony will be socially sanctioned. Chimpanzees appear to have a highly developed long-term memory for social relationships; it lays the foundations for an equipment that stabilizes the social order and that sanctions deviance, for instance, through the building of coalitions. To a certain extent, the success of social associations is the result of “chimpanzee politics” (de Waal, 1982).

But are these observations of altruistic behavior compatible with the genetic self-interest that constitutes the fundamental axiom of evolutionary biology? They are and in two ways: First of all, it should be noted that the thesis of a “selfish gene” (Dawkins, 1989) does not refer to the individual or the population. These are only “agents” of the “victorious” genes, which survive at the expense of the less suitable genes. Biological evolution is genocentric. Natural selection in principle awards features that encourage survival and reproduction—not only of single individuals but also of relatives. This is at least applicable to highly developed creatures in social associations. Here, organized forms of family support have been observed. The basis to this *nepotistic altruism* is consequently the self-interest of each individual’s genetic programs. Their purpose, the reproduction of genetic information, is achieved through the fitness of the family. Nepotism is oriented toward this fitness.

The self-interest of nepotistic altruism for the family is different from *reciprocal altruism*, which, under two conditions, can also include nonrelatives: First, in the long run, solidarity must pay off for the individual, for example, when food supply is dependent on good fortune during the hunt. In this case, solidarity serves to diminish the individual risks of life; if there is no shortage in food resources, then solidarity generally vanishes, too. Second, the mechanism of reciprocity must work out. While nepotistic altruism

involves the danger of a bad investment, reciprocal altruism involves the danger of an exploitation by “free riders.” In both cases, the problem expands with the size of the group and thus endangers altruistic behavior—in the end, to the disadvantage of everyone.

From the standpoint of evolutionary biology, it is evident that (moral and legal) normativity has biological roots. Norms of reciprocity help to perform the adjustment that could not be performed within the parameters of egoistic behavioral patterns. Reciprocity is the beginning of a moral consciousness that distinguishes between factual and normative behavior. But it requires stabilization by means of specified rules and sanctions. Human ability to establish a legal system and the simultaneous need to live in such a system reveals humanity’s special position in nature. This has been evident since the natural sciences have contributed to the self-enlightenment of humankind: In terms of the objective parameters of natural science, there is not much that could distinguish humans from other life-forms. Subjectively, however, our species can do nothing other than turn itself into the center of its environment; humanity has no alternative but to build its world according to its own criteria. Max Scheler (1874–1928) tried to grasp this situation in his concept of the “openness to the world.” It is meant to denote human independence from organic bondages. Man or woman is instinct driven, but also he or she possesses the ability to say “no” in order to postpone or to sublimate his or her urges. The resulting opportunity and necessity is not merely to live but to lead his or her own life. Like Nietzsche, Arnold Gehlen (1904–1976) regards a human as the “not determined animal.” Man or woman cannot be sure of his or her surroundings; he or she lacks the protective instincts. As a result of his or her biologically deficient vesting, there are no natural habitats; everything and everybody can turn into an enemy. Consequently, a human is a being whose life is constantly at risk. Thus, humans have no choice but to create their own relations to the world and to themselves through active performance. Her or his nature is culture; this is how she or he compensates for her or his “deficient constitution.” And yet woman or man is not only defenseless against her or his environments, but she or he is also dangerous. Undetermined but driven by her or his physical desires, she or he is latently threatened by degeneration. Hence, man or woman not only has to lead his or her life, but he or she also has to be led, namely by institutions. Institutions make up for his or her absent instincts; they support man or woman by obliging him or her to behave in a given way and, at the same time, relieve him or her from the burden of incessant decisions.

Institutions can evolve and persist wherever things that are taken for granted are valued accordingly. The modern world, however, is marked by an increasing absence of customs and by a growing plurality of values. Customs and values as institution-building factors are replaced by law that is in fact free of contents but still has a stabilizing

effect. Humanity's modern world is literally a world of law. The close connection between human nature and human culture, entailed by humankind's lack of instinct and world-openness (i.e., the idea that humans are not limited by their environment but can transcend it), leaves humankind no choice but to build humanity's life on law.

Ethical Foundations of Law

Moral and ethical claims of today's norms have evolved from the social history of humankind. Most notably, this is true of custom. It provides tradition with a generally binding authority to which law, too, was subject for a long time. Old law was good law. Nowadays, it is typically the other way around. Accordingly, a later law overrules an earlier law (*lex posterior derogat legi priori*). In the course of time, law has emancipated itself from customs and has become more independent. Nonetheless, law remains dependent on acceptance, approval, and discernment. The phenomenon of an increasing juridification of social life should not be regarded only as a process of law's emancipation from ethics and morals. On the contrary, in the question about the right law and about its connection with justice, the bond between law and the prelegal foundations of human social existence recurs.

Juridification is a process that commences whenever social norms lose their effect. Above all, habit and custom belong to the social norms; fashion, too, can be part of it. While habit lives on permanence and repetition, fashion is, and must be, ephemeral in order to consistently reinvent itself. Its aim is disparity; chic and elegance is not for everyone but only for the few. Habits are unspecific in this regard; one has a habit, or one does not. But a particular habit can only rise to a common law if it is shared not only by the individual but also by the majority. In the English language, this is expressed in the differentiation between habit (of the individual) and custom (of the group) (French *habitude, coutume*; Latin *habitus, consuetudo*). As opposed to habit, custom, just like the law, claims to be valid for every member of a given group. It is therefore oriented toward equality. Religion constitutes its own category of ethical norms.

The Greek term *ethos* illustrates the close bond between habit and custom as it is related to "habitation": One can get accustomed to various habits. However, habit requires more than just a superficial adaptation; namely, it requires a certain inner attitude. From this, a basic attitude can evolve that shows "character." This, too, is covered by the meaning of *ethos*. Accordingly, character always has to be formed first. The virtue whose *ethos* keeps law and ethics together is uprightness. It illuminates the ethical meaning of being right; namely, being right is to strive for the establishment of a system based on law. A dogmatic attitude, however, destroys such an order as it gives the desire to be right precedence over the right itself.

Moreover, it is part of the ethical foundation to give reasons, not only for a court judgment but also for all forms of institutionalized legal decisions. The obligation to state reasons directly results from a particular concept of justice and consequently from an ethical commandment. As per Aristotle (*Nicomachean Ethics*, V 3, 1129b), justice is "perfect virtue, though with a qualification, namely that it is displayed toward others." It is perfect, "because its possessor can practice his virtue toward others and not merely by himself." For the judge, who can decide in favor of only one party, this means an obligation to state reasons above all toward the unsuccessful party. The winner of a lawsuit does not usually care too much for grounds; thus, the loser will ask for the grounds. Owing to the judge's commitment to law, these grounds must be deduced from positive law. The reason for the grounds, however, is not of a legal nature but of an ethical one; this is to ensure a continuously peaceful social existence of those who were having a conflict with each other while insisting on their (assumed) legal right. The realization of fair proceedings alone, which allows each side to present their views and to be heard (*audiatur et altera pars*), contributes to this appeasement. A prudent judge will attach less value to the applause of the successful side than to the silence of the unsuccessful one. The procedural law obligates the judge only to the stating of reasons. The quality of these reasons is up to his or her professional ethics. It requires an appropriate translation of the judicial into the layperson's language and a comprehensive conveying for the unsuccessful side. In some cases, the latent tension becomes tangible between law's rationality and predictability on the one hand and the respective demands for material justice of all litigants on the other hand. For an appropriate decision, much will then depend on the judge's ability to meet the ethical foundations of law.

This problem has a long history. Basically, there are still two opposing notions: Legal positivism takes the stand that the legal concept is to be understood as not including moral or ethical elements. Law is regarded as being separated from these values. Following the logic of this separating thesis, law can have any given content. The positivistic legal concept solely depends on whether a law was created in accordance with regulations and whether it is socially effective. Those who, beyond that, require the legal concept to create a just law, follow the tradition of the theory of natural law. They associate law with a claim for correctness in terms of its content that cannot be given up without giving up the legal concept itself.

Characteristics of Law

In the course of time, law has occurred in many places in various shapes. Not only norms have changed and multiplied, but also legal institutions have been extensively transformed. Yet there is no shortage of attempts to define the characteristic element of law. Three approaches are of particular significance.

The first concept holds that law's characteristic is founded on its abstract rules. This view can advert to a long historical/cultural tradition, such as Hammurabi's Code (ca. 1760 BCE) or the Roman Twelve Tables of Law (ca. 450 BCE). The theories of natural law have also contributed to this opinion. Through Stoicism, natural law had first found its way into the philosophy of ancient Greece and later into the works of the ruling classes of ancient Rome. Cicero, for instance, adapted the idea that human life is subject to the purpose of a highest law. This legal concept is the starting point for a hierarchy of law, with the three components being eternal law (*lex aeterna*), natural law (*lex naturalis*), and human, or positive law (*lex humana*, or *lex positiva*). In antiquity, eternal law was understood as unchangeable and inevitably valid for everyone. Positive, or human law, contains all those norms that determine the social life of the respective society. Natural law, in turn, comprises all norms that humans and peoples reasonably share.

The notion of a legal hierarchy has gone through many enduring transformations. Among others are those that were introduced by Christianity, particularly by the influential doctrines of Augustine of Hippo (354–430) and Thomas Aquinas (1225–1274). Both do not interpret the *lex aeterna* as a cosmic principle but rather as the expression of God (there still are disagreements as to whether this must be interpreted as divine reason or divine will). *Mutatis mutandis*, the concept of a hierarchy, can also be found in modern legal systems. Examples include the precedence of international law over national law, the special status of human rights in democratic states, or the enhancement of the constitution (e.g., by the Supreme Court in the famous decision *Maryury v. Madison*, 1803) to the “supreme law of the land.”

Modern legal theory has seen many attempts to describe law as a coherent system of norms. The most notable representatives include, among others, John Austin, H. L. A. Hart, Ronald Dworkin, and Hans Kelsen or, more recently, Robert Alexy and Joseph Raz. Within the transatlantic discourse, the theory of Kelsen (1881–1973) has proved particularly influential. The center to his analytical reconstruction of an objective legal system is a norm pyramid: An individual legal norm derives its validity from a higher norm and itself validates a lower-ranking norm. To solve the problem of an infinite regress, Kelsen introduced the so-called *hypothetical basic norm*. This norm serves as a transcendental-logical condition for the coherence of a legal system. A norm is part of a legal order only when it can be deduced from the basic norm.

A fundamentally different view was held by Eugen Ehrlich (1936), which he also developed through the examination of Kelsen's “pure theory of law.” According to Ehrlich, it is important to comprehend the “living law.” By this, he understands those rules that the citizens actually comply with. This law had to be differentiated from the “laws in the books,” as well as from laws and their concretion,

through legal practice. For all these norms could not force a certain human behavior but are themselves dependent on the effective rules of social behavior. Bronislaw Malinowski has made a similar attempt to define law from the reality of community life and, above all, referred to the obligating power of reciprocity.

The third version sees law as those principles that can be deduced from the decision of legal authorities. Significant preparatory work to this was, among others, produced by Karl N. Llewellyn and E. Adamson Hoebel. Oliver Wendell Holmes (1897) put this concept in a nutshell: “The prophecies of what the courts will do in fact, and nothing more pretentious, are what I mean by the law” (p. 461). While in the first version, law is determined by norms and the legal system, in the second version, law is determined by social effectiveness. The former could be termed *normativism*, the latter *vitalism*. The third version regards itself as belonging to *realism* as it defines law according to the actual behavior of authorities. As opposed to the other two approaches, legal disputes become the center of attention. From this perspective, law is different from politics, as well as from customs and morals.

The realistic approach, just as the vitalistic approach, regards law as a social phenomenon. But it is not only the community's compliance, which this approach examines, but also the realistic approach does not differ from custom. The focus is mainly on the authorities' actions in case of conflict. These do not perform only a regulating function qua mediator but also offer an orientation for the citizens. Normativism and realism generally agree about the regulating function of law. To realism, it is less a result of norm parameters than it is the task of the institution, which finally has to apply the law to a case. For the obligation of legal application, especially in the light of social changes, the judge needs the faculty of judgment and creativity. However, the judge's role is usually confined to understanding the social dimensions of a dispute between opponents, to transforming it into a legal relationship, and to settling it by means of law. Lawsuits are about the actual claims of the parties involved as well as the reestablishment of a symmetric legal relationship among them. Advanced social interventions are the responsibility of the government. In modern societies, politics typically makes use of the law to realize its targets. Yet by using the law as an instrument, politics also submits to the legal form that is, above all, the prohibition of arbitrariness (which is guarded by jurisdiction in modern constitutional states, above all by administrative and constitutional courts).

Its connection with authority also distinguishes law from other social behavioral norms, such as customs and morals, whose sanctioning mechanisms are, typically, hardly institutionalized. If and to what degree sanctions occur, in the case of norm violations, are not certain. The authority of law, on the contrary, is decisively based on the certitude that law is also enforced. It otherwise represents dead law. By no means does a sanction always have to

imply coercion or physical force. A sanction's form is not essential but the effective implementation of the decision is. For example, the Inca civilization's prevailing penalty for community members consisted of corporal punishment, including the death penalty. However, the Inca nobles were punished with public exposure and removal from office, as they feared social death more than physical death. Modern constitutional jurisdiction is another example of effective sanctions: Constitutional courts cannot force the government to comply with their decisions. Finally, it is the court's authority with regard to constitutional issues that the government submits to. If it does not comply, then the government's action would most likely result in a bad public reputation for intending to practice unlawful politics in a state based on the rule of law. However, this requires the court to present itself to the public as a reliable guardian of the constitution by making equitable and wise decisions.

Evolution of Law

Ancient and Modern Law

With the establishment of modern statehood, law changes its character. Ideally and typically, the differences can be described as follows: Prestate societies often aim at solving conflicts by reaching a consensus among the opponents during negotiations. If they fail in this attempt, then physical force is usually applied as a means of self-help. Law in modern societies, on the other hand, provides for judicial proceedings in litigations. In case of need, law is enforced by state power. Modern states can resort to a differentiated system of institutions. On the norm level, law is abstract and impersonal; it is valid for everyone in the same way and it does not regard differences in status or reputation. Thus, individuals have to take responsibility for their actions. He or she knows what to expect when violating a norm. Punishment is based on this transparency and predictability. For what reasons the individuals comply with the rules is insignificant to the law.

This distinction between exterior behaviors and inner motives is largely unknown in prestate systems. In the case of norm violation, the entire person will be regarded, not only his or her actions. Strictly speaking, the individual is not only solely responsible for his or her own behavior but also is part of a family that is just as much affected by the dispute. Every sanction has to bear this in mind. Finally, it is less about a personal punishment than it is about compensation in order to maintain the social system.

Owing to these differences, there is a long history of debates between historians and ethnologists about law as to whether the norms of prestate societies should be regarded as law or customs. By now, the views tend to accept that (in these orders) laws, morals, and customs cannot be reasonably discriminated. These elements,

rather, display a process in the course of which the several fields slowly differentiate.

Law in Segmentary Societies

The order of segmentary societies is organized through extraction and kinship. These societies usually consist of small communities (villages, tribes, etc.), which live in separated areas. They lack a central political authority; each community autonomously governs its social life. The regulating norms form a mixture of religion, custom, and law. In hunter-gatherer societies, the need for legal regulations is only very low and primarily occurs in the spheres of matrimony and family. Violations of the incest ban are punished as a severe offence against the community. Adultery, assumed or actual, is among the most prevalent conflicts. Property, on the contrary, is seldom a cause of quarrel. Hardly anyone owns something that would not be owned by the others. There are scarcely incentives for covetousness; probate disputes play no role at all.

The necessity for regulation increases with the change to agriculture and settledness. The population grows and with it the significance of lineages and clans. These are the actual bearers of rights, which now increasingly refer to property and particularly to real estate. The land or the livestock belongs to the clans; they are the owners, but individuals are not. Without their association, the individual is not only poor but also defenseless. In the absence of a state monopoly on force, it is the lineages that guarantee the individual's security, namely through the threat of a blood vendetta.

To threaten in this manner with a maximum of vengeance follows the principle of deterrence. De-escalation is therefore a major requirement for all sides. There is no norm violation that could justify an endangerment of the community as a whole. A blood feud not only destabilizes the system within but also weakens the community outwardly. Although the individuals may not live in a so-called state of nature, the respective communities do. There is no valid law or custom beyond the community "segment." In this no-man's-land, life is, as Thomas Hobbes put it, solitary, poor, nasty, brutish, and short. The responsibility to maintain peace within the community is all the higher; law is oriented toward this. In case of a norm violation, it is therefore less relevant to impose sanctions than to compensate for the detriment incurred or to requite in the same way through the *ius talionis* ("an eye for an eye"). If very serious crimes are committed, then the community as a whole unites against the culprit in order to prevent a spiral of violence. Furthermore, various norms are provided to obviate violence and to secure peace: Among the most famous are the asylum by the leopard-skin priest, purification ceremonies, and negotiations of expiatory payment, and so on.

This kind of self-regulation without political order can be kept alive only within small spaces. With spatial extension, a political form of governance evolves that is in effect founded

on the precedence and subordination of lineages and clans. The reasons for these processes can vary, but they mostly lie in the person's charisma to which certain skills are attributed. The respective clan can turn into a chiefly lineage if it succeeds in connecting the myth of a special governance competence with the myth of a special derivation (of gods or heroes). A chiefdom can comprise multiple levels, each with one hierarchical top (headman, headwoman, chief). The paramount chief is distinguished by a series of privileges to which only he or she has access (tributes, trade with prestigious objects, claims on the prey, etc.). For it is he or she who exclusively possesses direct admission to the gods. Owing to the paramount chief, the gods are well disposed toward the people and present them with fertility, rich harvest, and victory in case of war. It is also the paramount chief who makes the final decision to end disputes. These cases are of particular importance, and that is why his or her judgment usually avoids a distinct decision. The paramount chief, too, is primarily concerned about fathoming out possibilities for reestablishing social peace. To this end, it can now and then be advisable not to make his or her own decisions but to consult the gods directly through oracles or ordeals.

Yet the paramount chief's status is fragile for three major reasons: His or her competition arises from within his or her own family, as every member of the chiefly lineage is principally able and entitled to take over the rule; although the paramount chief can protect himself or herself from a coup with personal life guards, she or he cannot prevent enemies from having the same guns at their disposal (bow and arrow, spear, and shield cannot be monopolized, but they can be independently produced by anyone); and finally, it is not in his or her hands whether the gods maintain their well-disposed attitude toward her or him. Plagues, crop failures, and other forms of disaster inevitably initiate considerable doubt about his or her rule. Rise and fission of this kind of political rule are very close.

Law in Premodern States

The premodern state differs from segmentary societies and from the chiefdom in its institutionalization of political order. The information and decision-making processes become structured and are organized hierarchically. First and foremost, this is done by the establishment of a bureaucratic administration. The introduction of the written form of communication permits the collecting and processing of larger amounts of information. Archives provide experiences for future decision making, and reforms can be compassed on a grand scale. Information is gathered from bottom to top, but decisions are carried out from top to bottom. This rationalization creates space for delegation and results in a differentiation of politics: It is not only guidance, for it also turns into an organization whose routines ensure the functioning of the political association.

The organization's effect can be felt in every scope of the state; taxes lose their character of donations, which are

connected with the expectation of reciprocation (they become charges, which are mandatory duties for the financing of the state). The level of physical force within the society is lowered; it becomes illegal to take the law into one's own hands or to feud with another citizen. The state monopolizes the instruments for the use of force, regulates the equipment of the army, supervises the arms production, and arranges for the logistics of the forces. The power to secure peace and order is not anymore in the hands of clans but rather lies in the organizing authority of politics. Lasting changes can also be observed in the field of jurisdiction: The establishment of the written form fundamentally alters the character of law. The gain in clarity is accompanied by a loss of flexibility. This generally results in an enhancement of the written text in law; some states (e.g., imperial China) even cultivate a legalistic tradition. Yet the character of the legal culture also depends on the institutionalization of jurisdiction. In ancient Rome, courts continue to play an important role under the modified conditions of the written form. In the democratic *polis* of Athens, however, courts are an instrument of self-help for the parties of the litigation; moreover, their character as true mass events (up to 500 judges participate in a usual hearing) necessitates a strict formalism that has not displayed much impact on the development of law contents.

Just as in segmentary societies, the law of premodern states significantly contributes to the preservation of the social order. This order, however, is marked by social differences in status. The chiefdom was already based on relationships of precedence and the subordination of clans; in premodern states, the social stratification increases. Law is primarily a question of status. The upper classes possess exclusive access to public offices and hence to political power. The lower classes, including peasants, tradesmen, and merchants, hardly possess any rights. Slaves are without any rights at all; the homicide of slaves by someone who is not their owner, at the most, results in a responsibility to compensate for the loss. Other parts of the society are also excluded from law, as they are not able to claim their own rights. Among them are mainly women and children but also wards (clients). All of them are subordinate to their protector according to Roman law, the *pater familias*, or the patron, who represents them before the court or at other institutions. Within this static order, the individual scarcely has opportunities for advancement. One is born into one's fate, and this fate is cemented by the law. Correspondingly, being marginal is the significance of legislation. Law does not serve to regulate social transformation but rather to secure a social order that is founded on inequality.

Law in Modern States

Caused by dramatic social upheavals, the processes that lead to an increased concentration on lawmaking accelerate during the 16th century. Law is still seen, in general, as

an expression of divine will, but as a result of religious division, the certainty about the content of this will begins to dwindle. Rather, this issue becomes the object of a dispute that irrevocably splits the Christians' unity and leads to the destruction of Europe during the Thirty Years' War. More and more, the idea prevails (which had already been proclaimed by Bodin, Hobbes, and others) that law alone cannot ensure peace. Peace also requires politics, more specifically, a sovereign power that holds the reins of law and justice in its own hand. Thus, law becomes an object of human creation and an instrument of a constantly growing political will to create. This is the beginning of the politicization of law. From the mid-16th century to the early 19th century, law serves more and more to consolidate the peacekeeping system of the territorial state, to reduce privileges, to control jurisdiction, and to centralize administrative structures. In the course of these developments, legislation continuously increases in importance; as a consequence, the relationship between law and politics begins to shift. Law, formerly an expression of the concept of justice, becomes less important as a binding parameter for political orientation. Whatever remains of the concept of justice is turned into nonbinding natural law, which does not endanger the legislative sovereignty of the ruler nor its peacekeeping, system-securing effect.

With the rise of the bourgeoisie as a political power, the situation changes as was manifested in America's War of Independence (1775–1783) and in the French Revolution (1789–1799). The claim to power as a divine right is challenged just as vehemently as the state's unrestricted authority. Instead, all of a sudden, it is a "self-evident" truth "that all men are created equal [and] that they are endowed with certain unalienable rights," as the Declaration of Independence written by Thomas Jefferson stated in 1776. The firm belief that society can rule itself for the greater public good is the common core of the different strands of liberalism. To the liberals, law becomes a guarantor of individual liberty, that is, equal rights for everyone and not privileges just for the few. After all, it is the people, the citizens, whose cumulative effort forms the whole of society. Accordingly, people must also be granted the right to political self-determination as put forth by Abbé Sieyès in his famous pamphlet *Qu'est-ce que le tiers État?* (1789). It has since been the legacy of the Enlightenment era that political power can be justified only when its claim to power is democratically legitimized and legally limited. This is only one element that contributed to the process of the juridification of politics.

The other main element is the constant expansion of legislative activity in response to tremendous social transitions, for the most part caused by the Industrial Revolution. While the growing social demands intensify the political process by increasing the number of political decisions as well as their purview, an internal hierarchy is established within the European legal system. It differentiates between two principal levels of law: statutory law, which is enacted

by the legislative power, and constitutional law, which is enacted by the constituent power. Constitutional law provides a regulatory framework for the establishment and purview of statutory law, but it is kept safe from a hasty interference of politics. The creation of a constitution itself differs fundamentally in its historic importance from the everyday passing of laws in a constitutional state. Most states store their own historical "constitutional moment" (Ackerman, 1989) in their collective memory. Furthermore, amending the constitution requires in most countries a much more complicated and consensus-oriented process than changing laws. This internal hierarchy between constitutional law and statutory law enables a mutual dependence of politics and law. It empowers the lawmaker to act politically, swiftly, and effectively in order to change or adapt the law according to his or her own ideas and to even create a completely new legal situation. Nevertheless, he or she must adhere to the constitutional requirements.

Law of the International Community

The sovereignty of states, which arose from the close connection between politics and law, is also of major importance in international relations. Sovereignty dominated classic international law, which came into being with the Peace of Westphalia in 1648. Until the beginning of the 20th century, international law was primarily interstate law, resulting from agreements among individual states. Rules and institutions at the international level were subject to the principle of unanimity; nothing could be implemented against the will of a state. In this regard, every state was equal in sovereignty. The sovereignty was primarily documented in the right to wage war (*ius ad bellum*). The disaster of World War I, however, led to a change of views. The League of Nations (1920) was a first attempt to transform the unrestricted right into a partial ban on war. The Briand-Kellogg Pact (1928) went even further and aimed at a general outlawing of war. But not until after World War II was the time ripe for a substantial modification of classic international law: With the Charter of the United Nations (1945), a general prohibition of force has been introduced, complemented by a global obligation to ensure peace. The multitude of transnational players and international organizations has already at the time of the Cold War (with its debilitating consequences primarily for the UN Security Council) resulted in an advancement of international law. It has become an "international law of cooperation" (Friedmann, 1964, p. 251). International human rights are increasingly established as the critical criterion for international politics.

Since the end of the Cold War, the challenges of globalization can no longer be ignored: It is manifest in the daily, global forms of communication (e.g., the Internet) and traffic (e.g., the international employment market); it appears in the form of ecological problems (e.g., climate change), which overtax the individual states as much as economical issues (e.g., unregulated financial markets).

The state's power is no longer sufficient to protect against threats coming from inside and outside its territory (e.g., international terrorism). As these key words illustrate, the sovereignty of the state is put into question. It once was the expression of the connection between law and politics in a state; now, however, social systems and political fields begin to disengage themselves from state-defined (territorial) frameworks. Politics is increasingly dependent on transnational players, which are organized in networks and equipped with their own negotiating power. Foreign relations are no longer a government's prerogative.

From this, crucial challenges for international law follow whose further development is part of the paramount tasks of the international community; international law has to enhance and consolidate those processes that stay abreast of the diversification of players as well as of the extension of activity levels (this also includes the divers regional orders as an autonomous level within world politics). This will require a reconsideration of the relationship between universalism and particularism in international law. The crucial question in this regard is, How much legal pluralism is possible, and How much constitutionalization of international law is necessary on the way to an effective legal order that would be worthy of the name "law of mankind"?

On the way to this effective legal order, international law has already partly developed into a regulatory law of the international public order. The sovereignty of the state is no longer an insurmountable barrier toward the international protection of human rights. The international community can and must intervene in case of gross human rights violations. This self-commitment of the international community constitutes a major break in international law. It will succeed in justifying this, though, only if the interventions themselves form an inevitable step toward the juridification of international politics. The guiding principle of legal reason is to exit the state of nature as Immanuel Kant stipulates. And he adds that as long as a free society based on law is not realized, it can, under certain circumstances, be permitted to coerce another person to exit the state of nature and to enter into the civil society organized by the rule of law. The obligation of international law is to clarify the conditions of these permitted compulsory measures. This would be a main contribution to the strengthening of international law's legitimacy.

Conclusion: Functions of Law

Abstractly speaking, the specific function of law is to protect the (normative) structure of expectations within a group against disappointments. This is primarily done by means of sanctions, which are imposed in case of disappointed expectations. At the same time, sanctions serve as incentives for the community members to fulfill the generalized expectations. The prerequisite for a socially effective, or "living" law, is not merely its standardization but also its institutionalization. Both developments are closely connected; they facilitate a division of legal work

that is of major importance above all for the modern law. Under the conditions of an increasingly complex society, the uncertainty is growing as to what is expected of the individual and if this expectation is shared by others. Law tends to reduce this uncertainty by providing general rules of conduct, which are directed at everyone. The more abstract the standardization of behavioral rules becomes, the more necessary is the individualization of case decisions by appropriate institutions. The history of law is therefore as much a history of standardization as a history of institutionalization.

The invention of a triangular relationship is of crucial importance for the institutionalization of law. It consists of two conflicting parties and one impartial person, or institution, with the obligation to settle the dispute. The character of the third person can vary (judge, chief, council of elders, etc.), but its function relieves community life in several ways that can ideally and typically be summarized as follows: First, the mediation by a neutral third person represents an alternative to the logic of mutual vengeance. On principal, this contributes to a decline in violence and consequently strengthens a community's integration capacity. Second, the function of the judge marks the beginning of an institutionalization of social roles that structure the distribution of power within a group. Socially accepted behavior and legally protected expectations connect and stabilize themselves in the respective roles; and the roles themselves forward the anticipation of sanctions and typically increase the self-domestication of the group members. This supports the interplay of leadership and followers and decreases arbitrary behavior on both sides. Third, the repetition of the application of the law and the law enforcement are augmentative, in terms of the reliability of expectations, provided that the dispensation of justice will lead to the same or to very similar results in the concrete case. This incentive can encourage the authority's self-commitment to precedents. Furthermore, it can be a stimulus to the development of legal equality within a group, for law lives (as opposed to the privilege) not on the exception but on the rule.

Sir Henry Maine (1822–1888) regarded the transformation from law based on privileges to law based on equality as the evolutionary principle that is ultimately decisive for every legal system. His formula "from status to contract" is nowadays regarded with skepticism because of its strong teleological connotations that do not leave much room for cultural diversity. But it still expresses a valid idea: Law displays a tendency toward formalization itself. The exceptions to the rule are also put into a legal form and are, consequently, incorporated by the law. It does not turn blind to the necessity of exceptions; however, as part of legal rules, they require an intense substantiation. The limits are typically reached when the exception is reinterpreted to become the rule. Such cases raise problems of justice that let law appear to be arbitrary and thus illegitimate. According to its own intention, law forms the counterpart to arbitrary decisions as it can otherwise not fulfill its function of protecting expectations even in the case of norm violations.

The problem of arbitrariness illustrates that law's main function, its protection of expectations, can be concretized and differentiated into a regulating function and a directing function; one is oriented toward stability, the other one toward justice. Both functions are connected: To the same degree to which a political order is based on acceptance by the citizens, the question about the legitimacy of law gains in influence for a system's stability. Examples of historically far-reaching consequences include the great revolutions of the United States (1776), France (1789), and Germany (1898), a comparatively young example. Below these major caesuras, the pursuit of legitimate law continues. At all times, this has also been a quest for (social) justice and has thus fostered the struggle for law in modern legal systems.

For some, the field of tension between the ideal of legal equality for all citizens and the socioeconomic inequalities in modern societies presents itself as a productive challenge; to others, on the contrary, law is merely an instrument that is supposed to conceal or stabilize social inequalities in the interest of the ruling classes. These differing ideological views explain that, with institutionalization progressing, law is attributed further functions within the political system: on the one side, the function of authorizing political power; on the other side, the function of controlling political power and civilizing it. Historically, the state's gain in power by the combining of law and politics has evoked countervailing powers that are, nevertheless, dependent on law: Liberalism and constitutionalism see law as a suitable instrument for confining politics' claim to authority. This balancing of law and politics is based on a constant mutual adjustment that has led to a considerable juridification in all areas of modern social life.

FORENSIC ANTHROPOLOGY

SARA ROFOFSKY MARCUS

Queensboro Community College, City University of New York

Forensic anthropology involves the identification of an individual. As such, it can be considered a *medico-legal subspecialty* of both physical anthropology and forensic science. Forensic anthropology focuses on the study of human osteology in order to make a positive identification, while physical anthropology focuses on the study of our species in terms of primate evolution, human genetics, and biological variations. A difference between physical anthropology and forensic anthropology is the age of the human remains. Physical anthropology is interested in all ages, while the focus of forensic anthropology is specific to human remains that are less than 50 years old. A second difference between physical anthropology and forensic anthropology is that while each analyzes human remains, forensic anthropology does so in order to meet a specific objective of identifying the dead through biological characteristics and, if possible, determining the circumstances of unexplained death. Forensic anthropology focuses on differences in the human skeleton to determine specific physical traits, such as age, sex, height, weight, health, anomalies, and ethnic background.

These differences came to light particularly in 1972 when the American Academy of Forensic Sciences (AAFS) established a physical anthropology section. Membership in this section entailed exclusively forensic applications of anthropology rather than all anthropology in general; the 14 members in 1972 became known as forensic anthropologists. This led to the establishment in 1977 of the

American Board of Forensic Anthropology (ABFA) (www.theabfa.org/index.html) with sponsorship by the AAFS and the Forensic Sciences Foundation.

Origin of Forensic Science

Forensic sciences were practiced before they were identified as forensic anthropology or even forensic science. Forensic science was first documented in France in 1910 with Dr. Edmond Locard's establishment of a center where scientists studying biology, physics, and medicine came together to examine evidence for criminal investigations. This group analyzed materials and shared resources in an attempt to reconstruct crime scenes. Eventually known as a criminalistics laboratory, or crime lab, this model was followed in 1914 by the city of Montreal. The center in Montreal followed Locard's philosophy, called Locard's *exchange principle*, the foundation of the field of forensic science. Montreal's center was run by a physician and thus became known as a *medico-legal lab*, a subspecialty of medicine. The structure of this model lab became popular, and in 1923, the first lab based on this model was established in the United States by the Los Angeles Sheriff's Department. In 1932, the newly established Federal Bureau of Investigation (FBI) set up its own lab, which could be accessed nationwide, although unlike the lab in France, contributions were minimal from different areas of science such as biology, chemistry, and physics.

Over the last 100 years, physical anthropologists have assisted with medico-legal investigations. Many physical anthropologists, especially from the Smithsonian Institute, acted as advisors to medico-legal officials through published articles and law enforcement bulletins during the 1930s and 1940s. In the 1960s, Lawrence Angel joined the Smithsonian staff and continued as a consultant for the FBI, including the launching of a training program for the forensic applications of skeletal biology.

Forensic Anthropology

The Need for Forensic Anthropology

There are five main objectives in forensic anthropology: (1) Determine ancestry, sex, age, and living height; (2) attempt to identify the nature and causative agent if evidence of traumatic injury to human bone exists; (3) render a determination of postmortem interval; (4) assist in locating and recovering remains so that all evidence relevant to a forensic investigation is recovered; (5) provide information useful in obtaining a positive identification of deceased persons (Byers, 2002, p. 1).

Forensic anthropology is needed to restore names and identities to unknown human remains from murder, mass disaster, or other found human remains. Forensic anthropologists assist both in the identification of bones and also in the recovery of bodies. Besides identifying the bones, forensic anthropologists also analyze trauma to the bone in order to gain necessary knowledge on the cause and manner of death. Nafté (2000) asserted that identifying remains may actually prevent the time and expense of a large-scale legal investigation. Forensic anthropologists not only process and analyze human remains in a laboratory but also are called on to assist in locating and recovering remains as well as to interpret any ante-, peri-, or postmortem (pre, during, or after death) movements or modifications of the remains.

Development of Forensic Anthropology

Forensic anthropology can be divided into three time periods, according to Rhine (1998): formative (early 1800s–1938), consolidation (1939–1971), and modern (1972 onward). Prior to the 1970s, those physical anthropologists working particularly with the medico-legal and forensic aspects of anthropology had no official name. The father of American forensic anthropology is Thomas Dwight, a Harvard anatomy professor in the late 19th century who published *The Identification of the Human Skeleton, a Medicolegal Study* in 1878. In his book, Dwight discussed how an examination of human bones could lead to the determination of gender and stature of the remains.

During the formative period (early 1800s–1938), one of the first known cases occurred. In 1849, Dr. Jeffries Wyman

of Harvard University identified human remains in order to help solve the death of a prominent Boston-area doctor, George Parkman. In this case, Dr. John White Webster, a colleague of Dr. Wyman, was accused of the murder based on evidence that on November 23, 1849, Parkman went to claim money owed to him by Webster. This date was the last time anyone saw Parkman alive. Less than a week later, a janitor at the Harvard Medical School called the police on discovery of what appeared to be human remains in a stone vault underneath Webster's office. While officers suspected these approximately 150 bones, some of which were burned, and set of false teeth belonged to Parkman, the police left it up to a team of doctors and dentists to prove it in court. On examination, the doctors were able to testify that these remains matched a person of Parkman's age, build, and height. Three hours of deliberation led to a guilty verdict for Webster.

More forensic anthropological activity was recorded during the consolidation period (1939–1971), such as the identification of servicemen killed on the battlefields during World War II and the Korean War. The work of the physical anthropologists called on by the United States Army during World War II for the identification of skeletal remains for repatriation led to the establishment of the Central Identification Laboratory (CIL) at the Hickman Air Force Base in Hawaii in 1947.

The third, or modern period, which began approximately 20 years ago, is when the application of forensic anthropology to the investigation of human rights violations increased dramatically, mostly due to the reinstatement of democratic governments along with higher levels of public awareness and social action. Requests for such action have been from countries such as those in Latin America, Africa, the Middle East, and Eastern Europe. One team in particular demand is the Forensic Anthropology Team of Argentina (EAAF), which has established its own precedent by becoming involved in other missions worldwide; this team is very much in demand due to their expertise, particularly in presenting evidence for war tribunals.

Methods in Forensic Anthropology

The process of forensic anthropology can be described, according to Mercedes Doretti of the EAAF, as three parts: interviews, excavation, and analysis (Burns, 1999). However, interviews are less likely to be conducted by forensic anthropologists as the bones are often already decomposed and witnesses are not easily located. In addition, many forensic anthropologists prefer to work with as little preconceived knowledge as possible to avoid tainting their conclusions and findings. The three parts identified by Doretti can be redefined into two types of methods: data gathering (interviews and excavation) and data analysis (analysis). The data is gathered from skeletal remains, while the analysis answers questions posed by forensic-anthropology protocol.

Data Gathering

Data is gathered using four techniques: anthroposcopic, osteometric, chemical, and histological. Anthroposcopic data is gathered visually, including through the use of X-rays, and involves such characteristics as ancestry, sex, age, and stature. Osteometric data involves the measurement of human bone on an objective scale using calipers or an osteometric board in an attempt to quantify many of the anthroposcopic characteristics. Chemical data is gathered through the examination of chemical makeup of certain structures of the skeleton, including mitochondrial DNA (mtDNA) and associated matter such as the ground beneath the skeleton. Histological data is gathered through the study of the microstructure of teeth and bone.

Data Analysis

There are five methods to analyze the data from the skeleton: decision table, range chart, index, discriminant function, and regression equation. The last two methods come from statistics.

A decision table helps the researcher judge the importance of conflicting information to arrive at a single conclusion. In a decision table, options are listed across the top of the table, while characteristics for determining these options are listed down the left-hand side. A forensic anthropologist marks the columns where characteristics observed indicate agreement with the option at the top. The name of the column (option) with the most marks is the one most likely to be correct.

A range chart provides multiple ranges of estimates so that a central tendency can be determined. To use a range chart, a forensic anthropologist charts the ranges of features observed. Where the most overlap on the chart occurs is the data range that is most likely to be correct. These are particularly useful for parameters in which multiple sources of data are encountered such as time since death and age at death.

An index is a method to standardize skeletal measures for two dimensions. This method was developed so that numerical expressions of the shape of a structure can be compared between two groups. An index is a simple yet powerful statistical method for quantifying anthroposcopic traits. When two measurements express visually identifiable characteristics, the forensic anthropologist will divide one into the other, multiple the quotient by 100, and arrive at an index.

A discriminant function is a method for calculating a numerical expression of shape that can be used when more than two measurements are available. A forensic anthropologist would use a discriminant function whenever there are discrete categories to determine to assist in distinguishing between two or more predetermined groups. These might consist of gender or hair color.

A regression equation is a method by which one value can be predicted from the values of other measurements.

While regression equations are included in the five methods to analyze data from skeletons, these are often incorrect because they do not account for the increasingly unknown nature of points away from the middle line of a set of values, and they do not consider that other samples might yield other values.

Facial Reconstruction

Facial reconstruction is a subset of the methods of forensic anthropology. In facial reconstruction, the forensic anthropologist works to recreate the facial characteristics to assist in identification. This is considered a last resort, one to use only if a search of missing persons' files has not revealed a potential match. Traditionally, this was done manually by molding and casting the original skull, applying spacers to indicate the amount of tissue thickness at various places on the facial skeleton, and filling in the areas between and around these spacers. Today, preferably, computer software is used to produce faces on images of the skull. However, in other cases, artists drawings, restoration of disrupted or damaged tissue put back on the skull, or photo/portrait superimposition is also used. There are still problems found by forensic anthropologists and other practitioners such as predicting individual characteristics not apparent on the skull regardless of the method used.

There are three software programs commonly used: CARES (computer assisted reconstruction and enhancement system), FACE (composite picture software), and Faces (face recognition software); each of which uses radiographs or photographs of faces or skulls, which are then digitized. Using banks of stored features from both cadavers and living samples using magnetic resonance imaging (MRIs) and computerized tomography (CT) scans, a face is then electronically restored or reconstructed.

Human Skeleton

Forensic anthropologists should be familiar with every feature of the human skeleton, including the range of variation between individuals and the differences between human and nonhuman bones. The familiarity is needed to assist in the critical matter of identifying human skeletal remains. The bones to be familiar with include the 29 bones of the head (cranium, inner ear, mandible, and hyoid) and the 177 bones of the postcranial skeleton below the head. This number varies, however, based on age and other circumstances, all of which the forensic anthropologist needs to be aware of. In particular, a child's skeleton will have more bones since not all bones found in a younger body will have fused together to create the bones found in the adult skeleton. Forensic anthropologists need to be familiar with the landmarks and features, growth and development of each of these bones and their components to help determine age and other characteristics of the skeleton.

The postcranial skeleton can be further subdivided into the torso and limbs. The torso includes the ribs, vertebra, scapulae, clavicles, sternum, pelvis, and sacrum. The limbs include the arms (the humerus, radius, ulna) and legs (the femur, tibia, and fibula). The pelvis, composed of three portions (ilium, ischium, and pubis), contains information critical to determination of age at death or gender in adults.

When referring to bones in the human skeleton, it is necessary to use specific terminology to assist others in locating the same bones one is referencing. This is done by thinking of the skeleton standing (or lying on its back) with arms at the sides, palms forward, and thumbs to the outside. This position was chosen, in part, due to the fact that in this position none of the bones cross each other, and it is possible to consistently describe the relationships between bones (Adams, 2007).

Identification Process

Identification occurs after the forensic anthropologist has gathered all of the data and analyzed this data through various methods. The identification is rarely definitive but rather provides a guide or range from which identification can be drawn. As time passes, modeling and remodeling of bones within the skeleton records events in the person's life such as growth, disease, and environmental change, providing a lasting record of past events, lifestyle habits, and occupational stress. Earlier in life, generally within the first three decades of life, the growth and maturation of the human skeleton is most reliable for its relation to the time and sequence of age change as it relates to sex and race differences.

Definitive identification is rare based solely on the skeleton as there are external factors that can affect the records stored in the bones, for example, nutritional deficiencies, diseases, medications, pathological conditions, anomalies, and more. The markers on the bones indicating occupational stress provide an additional means of identifying a person from a skeleton, which is particularly helpful in aiding law enforcement officials in their search for a missing person. The most important details in the identification of an individual person occur in the head: eyes, ears, nose, and mouth.

How Bones Change

Though living bone is mainly inorganic, it is a dynamic tissue that is capable of responding to a wide variety of stimuli. As such, it is in a constant state of change. Modeling is the change, or growth and development, of living bone that takes place from approximately the third intrauterine month to approximately 25 to 30 years of age. Remodeling, or changes in the density, shape, and size of bone, takes place throughout the person's life. Remodeling is due to factors such as aging, exercise, diet, injury, trauma, disease, and occupational stress. In particular, there can be

lesions due to occupational stress. These lesions manifest in four ways: modifications to areas of insertion, osteophytosis, discrete markers, and stress fractures.

The forensic anthropologist needs to be aware of the different responses of bone to stress during and after life. The type and patterning of a fracture can help establish the sequence of damage to skeletal material.

Age

The forensic anthropologist can estimate the age of the decedent through knowledge of changes to the skeleton that occur both during growth and deterioration. There are several methods to determine age at death that require special instruments such as cortical bone loss, counts of bone histological structures, and the Gustafson method on teeth. Byers (2002) asserted that the "methods for determining age are not accurate enough to be usable in forensic situations" (p. 192) although the age for individuals under the age of 12 years is said to be estimable from the lengths of the long bones combined with the development and eruption of teeth and fusion of primary and secondary ossification centers. In adolescents, the forensic anthropologist can also estimate the age of the skeleton at death through the amount of union in various epiphyses. In adults, the forensic anthropologist needs to be aware of changes in pubic face, auricular surface, the sternal ends of ribs, and the amount of suture closure in the skull. In general, the age of a skeleton is more accurately determined the younger the decedent was at time of death.

Gender

In determining gender, the statistics are generally higher than for most other characteristics. There is a 50% chance of a correct guess without other information available. The pelvis is where the strongest and most accurate indication of male versus female is found as the pelvis of a woman is generally broader than that of a male. When examining the pelvis, particular attention should be paid to the bone of the anterior pelvic area (the pubis) as the lower margin of the pubis forming the border of the subpubic angle is wider in a female than a male. This margin is determined using the ischium-pubic index, the only commonly used metric method for distinguishing sexes. If the pubis is missing, then the skull difference can assist in determining the gender, but there is a certain amount of overlap in the middle of the size differences.

Stature

The stature of a skeleton is determined by adding together the measurements of many bones in the skeleton. It is very important to obtain as many bones as possible and to correctly identify each bone. The bones measured to determine the stature include the skull and the combined

heights of the vertebrae, the femur and tibia, and articulated calcaneus. Although it is less accurate, forensic anthropologists commonly calculate stature based on the lengths of the long limb bones solely: the humerus, ulna, radius, femur, tibia, and fibula. Because it has been documented that persons lose stature with age, estimates of living heights among persons determined to be 45 years or older at death need to be adjusted downward.

Race/Ancestry

When determining the race or ancestry of a skeleton, the forensic anthropologist depends on the skull. The skull has the most traits to use in determining the race or ancestry. Without a skull, there are a limited number of postcranial skeleton traits to use. This categorization is often the most difficult and least precise due to problems of inconsistency between racial categories. Forensic anthropologists depend on the categories for race/ancestry most widely used by law enforcement agencies: Caucasian, African, Asian, Native American, and Hispanic.

Handedness

When examining the skeleton, the forensic anthropologist often can estimate the handedness of the decedent by comparing the right- and left-upper-limb bones. The side with the largest and most modified bones is generally the dominant side.

Basis of Examination and Evaluation to Identify the Dead

Krogman and Iscan (1986) provided a guideline that forensic anthropologists follow today when examining and evaluating to identify the dead. Krogman and Iscan suggest beginning with “the big four”—stature, age at time of death, sex, and race/ethnicity. Once this information is determined as well as possible, the forensic anthropologist should then continue with the “accessory” information—weight/body build, duration of interment, cause of death if registered in the bones, and a final registry of miscellaneous details of individuality to assist in identifying the decedent such as fractures, amputations, and so on.

The Human Genome (DNA)

The human genome provides the ability to chart any person’s genetic makeup. However, particularly for forensic anthropologists, this is not always possible to obtain. When it is obtainable, often it is the forensic biologist who processes the DNA, not the forensic anthropologist. The human genome, or DNA, is, according to Bass and Jefferson (2007), the “gold standard” for making a positive identification. However, they note, this is not always the

fastest or most efficient method to obtain a positive identification. There are still older methods that are much faster and more affordable than DNA testing. Advances in the analysis of DNA extraction from archaeological bone allows for personal identification. However, the DNA preserved from crime scenes or other evidence may be affected by human errors that will affect the quality of the DNA, degrade the DNA, or be in minute quantities. As the DNA falls apart due to degradation, the pieces become smaller and smaller, which causes DNA analysis to become harder and harder.

Newer DNA analysis is based on DNA (such as mitochondria) that is not located in the cell’s nucleus as it was in the past. Cells have organelles just as bodies do; these organelles are called organelles, existing in the cell but outside of the nucleus. Select organelles have their own packets of DNA, such as the mitochondria. This DNA, called mtDNA, is carried on the mother’s side and survives in numerous quantities in hairs, bone, and teeth, according to Houck (2007).

Other Evidence

Other evidence gathered can be from the location itself, scraps of clothing or human remains beyond the skeleton, and interviews with people. In collecting evidence through interviews, one needs to be sensitive to the culture of those being addressed as this can vary from place to place, culture to culture, and country to country.

Collecting Evidence

There are four major steps in collecting evidence: location, mapping, excavation (if needed), and retrieval. The forensic anthropologist is not always involved with these steps although it is helpful and often time and cost saving to have the forensic anthropologist involved from the start rather than relying on the findings of others. Locating the remains is the first step of the process. Next is mapping, which includes drawings, photographs, videos, and other methods of recording the location and the process itself from locating to retrieving to relocating the remains to the forensic anthropologist’s laboratory. The excavation includes searching and collecting the bones and other materials considered necessary for the forensic anthropologist’s work, while the retrieval includes packing and transporting the materials to the forensic anthropologist’s laboratory.

It is helpful, from the start, to make an inventory of what is found. This inventory will help establish the number of sets of human remains. If there is more than one left femur, other limb bones, or skulls, then this is a general indication of collocation (arrangement) of more than one human skeleton, or commingling. Additional vertebra, ribs, or sesamoid bones (bones that grow in tendons) are not indicators of commingling as it is not

abnormal for an individual to have one or more of these. The recording of the process, along with the proper usage of methods of collection and retrieval, will enhance the reliability and success with which the case can be resolved.

Interpreting and Applying Evidence

When interpreting evidence to assist in making an identification, attempts made by humans to disguise or destroy remains can cause problems. Problems can also be caused by any other postmortem damage from a number of sources, including human dismemberment to prevent identification or to show disregard for the victim, and nonhuman animals; heat such as fire; and weathering, burial, and water. The effects of fire include charring, cracking, discoloration, warping, and shrinkage, while weathering—due mainly to sunlight—manifests itself through cracking and warping. Burial has similar effects to weathering and low-temperature burning, whereas water causes abrading and scattering of skeletal elements. The overlap of effects can also cause problems in interpretation for cause of death or postmortem damage that has occurred.

There are three types of bone disease (deformative, lytic, and proliferative) as well as four types of skeletal anomalies (accessory ossicles, nonfusion anomalies, accessory foramina, and miscellaneous anomalies) that the forensic anthropologist needs to be aware of to better help determine what has happened to a bone.

One of the main interpretations by the forensic anthropologist is the manner of death, or the manner in which a person died. There are five recognized manners of death: homicide, suicide, accident, natural, and unknown. It is the forensic anthropologist's job to avoid as much as possible an unknown cause of death, unless there is insufficient evidence to prove one of the other four manners of death.

While determining the type of bone injury, the forensic anthropologist should also attempt to determine the timing of the bone injury: during life, or *antemortem* trauma; around the time of death, or *perimortem* trauma; or damage done after death, or *postmortem* damage. This timing will help establish if the bone trauma discovered is the cause of death.

The bones can tell a lot about the cause of death. There are four types of bone trauma that can indicate the type of death: blunt, sharp, projectile, and miscellaneous. In the analysis of a blunt force bone trauma, the forensic anthropologist must start with a complete description of the injury, including the type (fracture or infraction), the bone affected, which side of the bone, and the placement in the bone of the injury. Next, the forensic anthropologist should attempt to determine the size, shape, and weight of the causative instrument. Of particular note, a fracture of the hyoid bone is the main osteological consequence of death

by strangulation, which is caused by hanging, ligature, or manual strangulation. Sharp trauma results from narrowly focused dynamic compression forces applied to the surface of a bone, such as evidenced in punctures, incisions, and clefts. A projectile bone trauma needs to be analyzed by a forensic anthropologist who understands a number of characteristics of firearms and ammunition such as size (e.g., caliber gauge), velocity, and bullet construction. The forensic anthropologist, when examining a gunshot wound to the bone, should also determine, to the best of his or her ability and knowledge, the causative weapon, the placement of the firearm, and any other information that can be accurately determined.

The forensic anthropologist should create a report that is stated clearly. The report should be generated after careful examination, research, and reflection and based on notes taken throughout the process. The length of time it takes to create a report depends on the complexity of the case. Regardless, the forensic anthropologist's report should provide as much detail and precise data as possible at the time of writing, although modifications for further clarification can be made if needed. This report "records physical observations on the remains, identifies important biological characteristics, and identifies and differentiates changes in the remains due to natural and cultural forces" in a way that is understandable to the medico-legal officer in charge (Pickering & Bachman, 1997, p. 35). The report should be presented in two parts. The first part of the report should be approximately one page in length and should briefly describe the results in a readable form to the nonforensic anthropologist and include a description of methods used and discuss details of the results obtained from the analysis.

The second part of the report consists of six sections. Part 1 presents background, including names, dates, and places as they apply to the case, including how the forensic anthropologist was summoned, what was done prior to the summoning of the forensic anthropologist, and who was present during the analyses. In Part 2, the general condition of soft tissue that is present and the state of preservation of osteological material along with any photos of the body, which are included as an appendix to the report, can be referenced here. Part 3 is a complete inventory of osteological and odontological remains, including the number of individuals present. Part 4 presents each of the four aspects of demography (ancestry, sex, age at death, and stature) in separate subsections that fully describe how these characteristics were determined. Part 5 explains antemortem, perimortem, and postmortem injuries using photographs, line drawings, and other supportive material. Part 6 includes any recommendations for further testing outside the realm of the forensic anthropologist, which can include searches of missing persons' files or the names of ethnic enclaves to approach for information on the decedent. Appendices can include supportive photographs and tables.

Expert Witness

1948 was the turning point in the United States for the forensic anthropologist to be accepted by the legal system as an expert witness. Today, forensic anthropologists are being asked to offer expert testimony for both prosecuting and defense attorneys.

A biological profile is the information presented by the forensic anthropologist as testimony in a court of law. The human skeleton or other human remains are *not* part of an exhibit in a court of law. Therefore, a well-documented analysis or conclusion with verbal testimony, written statements, photographs, and slides are the supporting facts and exhibits in the court of law.

The forensic anthropologist must always be certain, whether in the report or when testifying as an expert witness, to present the data and opinion honestly. Particularly in court, this must be done so as to ensure that the judicial process is not affected by the forensic anthropologist's presentation of the data and opinion. It is imperative for the forensic anthropologist to differentiate between evidence or data and opinion or interpretation. This evidence-opinion dichotomy is one of the most important distinctions for a forensic anthropologist to make before presenting findings for others' use.

There are three types of opinions a forensic anthropologist may form: speculation, possible, and probable. Speculation is based on few or no data and should be given only if specifically asked and never in a written form. A possible opinion is one that is based on a characteristic or event that is possible but is too unlikely to be taken seriously. A probable opinion is one with the highest level of certainty,

Ongoing Advances in Modern Forensic Anthropology

In 1986, the Forensic Anthropology Data Bank was created at the University of Tennessee in Knoxville to help identify the race or ancestry of a skeleton. The Forensic Anthropology Data Bank contains measurements and observations of thousands of individual skeletons analyzed in forensic cases and from museum collections. This vast data helps the forensic anthropologist to detect previously unrealized subtleties. This data bank is the foundation for FORDISC, a computer tool that analyzes these subtleties to confirm or challenge an anthropologist's findings. FORDISC enables the user to enter measurements from a current case to help estimate sex, ancestry, and stature.

Forensic anthropology has become used more for identifying victims of current disasters, such as 9/11, and mass disasters, such as hurricanes and earthquakes. Forensic anthropology has also become used more and more as a way to gather evidence of victims who can no longer speak, those who are dead—such as in cases of human

rights violations worldwide. Forensic anthropologists are stepping outside serving not only the community in which they work but also serving internationally, traveling to large-scale conflicts to work with governments.

Future Use of Forensic Anthropology

Forensic anthropologists are being called on more and more to assist in the identification of victims of homicides, mass disasters, and political atrocities (Camenson, 2001). As the methods to identify human remains become more accurate and exacting, older cases will be reopened for further analysis by forensic anthropologists to assist in solving cold cases.

PALEOPATHOLOGY AND ANTHROPOLOGY

CHRISTOPHER DAVID CZAPLICKI

Canisius College

Paleopathology, an application of biological anthropology, offers us an interesting perspective into the lives of the ancients. When skeletal remains are all that are left from many ancient civilizations, paleopathologists rely on strict skeletal analysis to offer insight into ancient civilizations. Combining scientific inquiry with educated reasoning can give anthropologists an idea of the daily activities of individuals; their diet, health, and environment; and even more, specifically, the cause of death of each individual. This can offer anthropologists insight not only into the prevalence and evolution of a disease in a past civilization but also into what trends to expect from the same or similar diseases today. While paleopathology can focus on more recent cases from a forensic anthropological standpoint, most paleopathologists focus more specifically on what can be learned from the remains of individuals long gone. Often, these remains consist almost entirely of bone. However, in more unique cases, such as with “Ötzi the Iceman,” tissue structure remained incredibly preserved over thousands of years (Fowler, 2000). This allowed anthropologists astonishing insights into human life in the Copper, or Chalcolithic Age.

Paleopathology started as a subspecialty with the emergence of archaeology. However, in the beginning, most archaeologists were concerned with artifacts instead of skeletal remains, since the latter seemed to have little monetary value compared to golden relicts. On the few occasions that attention was paid to human remains, usually

only the skull was studied (Waldron, 2001). A series of measurements, known as cranial fixation, were taken while the postcranial skeleton drew little attention from even the most senior of archaeologists, who were after greater riches (Jarcho, 1966). At roughly the same time, paleopathology was being looked at from another front: medicine. As the United States continued to move westward in the middle to late 1800s, doctors began to take interest in the skeletal remains of Native Americans. One of the first studies, published in 1876, looked at the prevalence of syphilis in Native American skulls (Jones, 1876). Little advances were made into the field of paleopathology until the first decade of the 1900s, when archaeologists began excavating Egyptian temples. Under the direction of George Reisner, over 6,000 bodies were examined although the pathological findings were not well reported (Waldron, 2000). Again, the field seemed to fade into obscurity for several decades until the emergence of Calvin Wells, one of the most respected and imaginative paleopathologists in history. With a strong passion and enthusiasm for the field, he drew on his medical training and enthusiasm for the field, he drew on his medical training to work with archaeologists to study the history of human disease. His book *Bones, Bodies and Disease* (Wells, 1964) was a landmark publication in the field and advanced the field of paleopathology to the level it is today.

To detect the subtle signs of illness in skeletal remains, paleopathologists must receive extensive training to master this art form. During undergraduate studies, most receive a

broad background in anthropology overall, taking classes in biological anthropology, cultural anthropology, archaeology, and linguistics (Klepinger, 2006). Alternatively, paleopathologists may graduate with a bachelor's degree in the sciences, with a heavy emphasis on anatomy and the human body. They should have knowledge of the basic sciences and mathematics. Some may include medical training in their studies, as paleopathology is a survey of the history of disease. Many then go on to pursue a master's degree as well as a doctorate in biological anthropology, with a strong emphasis on the human skeleton, osteopathy, and the skeletal record. Unfortunately, there are currently no regulations in place on the practice of paleopathology and forensic science. Thus, quality control is an issue as amateur sleuths, with inadequate training, can attempt to interpret skeletal remains.

Human Osteopathology

Paleopathology can be broken into several general components: arthropathy, infection, oral pathology, trauma, and tumors (Aufderheide & Rodríguez-Martín, 1998). Arthropathy, or disease of the joints, includes some of the more common findings of paleopathology, including simple arthritis and gout. Serious infections can often leave their mark on bones, especially debilitating chronic diseases, such as syphilis and tuberculosis. Oral pathology, which examines diseases of the oral and maxillofacial regions, may offer insights into not only dental practices and oral health but also diet. Trauma is one of the most obvious abnormalities in bone to identify, even to an untrained observer. Fractures and breaks can be examined, and paleopathologists are often able to determine if the individual lived beyond the initial injury based on bone-healing patterns. Lastly, tumors, or neoplastic osteosarcomas, may not be as obvious as some may be led to believe. Although obvious outgrowths may be observed in the bone itself, many times these tumors can be subtle, remodeling the internal bone structure before the cancer metastasizes to different parts of the body.

Arthropathy

From a pathological perspective, changes in the joints appear to be most common when analyzing fossil skeletons (Waldron, 2001). While this can include many rare and unusual disorders, most paleopathologists are more familiar with common ailments, including osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, and gout.

Osteoarthritis is a very common disorder in the living (Resnick, 1981). Many of the joints in our body are bathed in synovial fluid, including joints of the knee, hands, toes, and neck. This fluid acts as a lubricant for the constant pressures placed on the ends of our bones with each movement. Many of our bones also have a layer of cartilage on their ends, also acting as a shock absorber. This cartilage

may degenerate from the normal wear and tear through time, and is replaced by less plastic bone in an effort for the joint to repair itself. This new bone, forming on the ends of the bones, is known as an *eburnation* and is the classic indication of this illness when examining fossil skeletons. This can cause pain and inflammation in the effected joint, making every movement very painful. However, although this disease may actually be pathologically present in many individuals, some are completely unaware of its presence and have little or no pain.

Rheumatoid arthritis, similar to osteoarthritis, involves destruction of the articular cartilage (Abdel-Nasser, Rasker, & Valkenburg, 1997). This occurs from an autoimmune response in which the body produces antibodies against the synovial membrane enclosing the joint. This inflammation of the membrane spreads to the cartilage and bone, causing deformities and, in some cases, fusing the two bones. Paleopathologists can distinguish rheumatoid arthritis from osteoarthritis by the lack of new bone formation during the degenerative process. This can often be difficult, however, as arthritic bones tend to be fragile and damage easily during excavation or from erosion over time. Therefore, care must be taken to be sure the degenerations observed are truly from rheumatoid arthritis and not simply erosions of points of entry from blood vessels and nerves. New techniques in radiography have been helpful in confirming this diagnosis. Since this disorder targets the synovial membrane, the joint margins are affected first, then rheumatoid arthritis invades the rest of the joint surface. If radiographic studies show the joint surface has degenerated but not the joint margins, then paleopathologists can conclusively say that the skeleton did not suffer from rheumatoid arthritis.

Ankylosing spondylitis, unlike the previous two joint diseases, affects the spinal column as opposed to the synovial joints of the body (Waldron, 2001). This disease presents with a fusion of the spinal column, starting at the sacrum and moving slowly upward toward the cervical vertebrae. In this disorder, which has been linked with a genetic abnormality, no vertebrae are skipped in the disease's progression, helping to distinguish it from other spinal fusion disorders, such as reactive arthropathy. Due to the gross morphological changes to the spinal column, and even to the rib cage in some cases, paleopathologists can easily arrive at this diagnosis. Needless to say, this disease is extremely debilitating to those persons who are afflicted.

Gout is an extremely common disease in which uric acid crystals are deposited in the joints, leading to painful inflammation in the affected areas (Ball, 1971). If this becomes a chronic problem, the deposits may become large tophi, leading to erosions in the joint. This disease is most commonly presented in the joint between the phalange of the large toe and the first metatarsal. Paleopathologists can diagnose gout with the use of X-ray imaging, which will show asymmetrical degenerations in only a single area of

the skeleton, with no osteoporosis associated as with other joint diseases.

Infectious Diseases

As most diseases directly affect body tissue, which is rarely if ever preserved, the signs of an infectious disease may not be apparent to a paleopathologist (Waldron, 2001). Relative to the overwhelming number of potential infections, very few present themselves in the bone. Aside from very rare diseases, such as Proteus syndrome, several widespread diseases do in fact make their mark on the bone: tuberculosis, leprosy, and syphilis.

Up until the creation of streptomycin, tuberculosis was one of the deadliest diseases known to man. Caused by *Mycobacterium tuberculosis*, tuberculosis is an airborne illness characterized by primary lesions in the lung (Bauman, 2009). After the initial infection, the *Mycobacterium* may lie dormant for many years within a lesion in the lung tissue, with the patient being relatively asymptomatic. This period, which is variable among patients, will end when the lesion ruptures, releasing the bacteria back into the lung tissue. The bacteria will continue to spread throughout the body, most notably in areas of the chest, lymph nodes, and skeleton. If the infection reaches the bone, then degeneration of the tissue is observed, most commonly in the spine and hands. In the hands, a condition known as tuberculosis dactylitis is observed, characterized by extreme inflammation in the fingers. In the spine, the anterior portion of the vertebral column is destroyed, creating a distinct angulation known as *Pott's disease*. If the disease continues to progress, then this angulation may ultimately lead to a complete collapse of the spine. It is this dramatic change to the spine that paleopathologists rely on to make the diagnosis of tuberculosis. However, since the prevalence of this gross anatomical change is much lower than the overall prevalence of the disease, paleopathologists are looking for new techniques in order to identify tuberculosis in skeletal remains. One such technique is the extraction of *ancient DNA*, or aDNA, from *M. tuberculosis* remains within the skeleton (Taylor, Goyal, Legge, Shaw, & Young, 1999). This DNA can be replicated, using the polymerase chain reaction, and analyzed to confirm the presence of the disease. An even more inventive technique is the extraction of mycolic acids from skeletal remains, which make up the outer layer of the bacteria (Donaghue, Spigelman, Zias, Gernaey-Child, & Minnikin, 1998).

Of the infectious diseases studied by paleopathologists, none have had such a profound clinical impact as the study of *leprosy* (Møller-Christensen, 1965). Caused by *Mycobacterium leprae*, the bacteria initially infect the peripheral nerves (Bauman, 2009). If the immune system cannot overcome this initial infection, then the disease may progress systemically, affecting bones throughout the body, especially the hands, feet, and skull. In both the hands and feet, the phalanges are absorbed. In the skull, the anterior

nasal spine is also absorbed, creating a round, wide opening for the nose. The front teeth are also absorbed. These distinct changes in the skull are known as *facies leprosa* (Møller-Christensen, 1965) and are telltale signs for any paleopathologist looking to make this diagnosis. Study of the remains of skeletons with leprosy paired with the remains of skeletons with tuberculosis can help to explain the history of these two diseases in humankind. Since both diseases are caused by a strain of *Mycobacterium*, partial immunity from one disease occurs when infected with the other. Since the incidence of leprosy seemed to suddenly decline in Europe at around the same time the incidence of tuberculosis rose, paleopathologists hypothesize that the emergence of tuberculosis created immunity to leprosy throughout the population. However, extensive studies must continue to estimate the true prevalence of the diseases at that time in order to support this theory.

The disease *syphilis*, caused by *Treponema pallidum*, has several distinct stages of progression (Bauman, 2009). Transmitted sexually, the primary infection of syphilis is characterized by chancres, or sores, in the genitalia, or occasionally, other areas of the body. This may occur after a short incubation period following the initial exposure. Secondary syphilis, which usually begins several months after the primary period, is characterized by more numerous and painful lesions that occur in moist areas of the body, as well as in the palms of hands and on the soles of feet. It is at this stage when the host is most contagious. From secondary syphilis, the patient may enter a latent stage in which there are no signs or symptoms of the disease despite its presence in the body. The bacteria can remain dormant in this stage for many years, and some patients never progress to tertiary syphilis, the final and most debilitating stage. In tertiary syphilis, *granulomas*, or inflammatory balls created as an immune response, occur throughout the body in an attempt to destroy the bacteria. Since these granulomas, also known as gummas, can occur in any tissue, any organ system can be affected. Thus, a variety of symptoms are observed in patients at this stage. From a paleopathologic perspective, gross anatomical changes to the bone are the most profound changes. Erosion and healing of the skull is cyclic as the disease progresses, creating what is known as *caries sicca* (Hackett, 1976). Bone depositions can also occur extracranially, especially on the anterior surface of the tibia. In some cases, especially in infants, the deposition is so severe in this area that it is known as *sabre tibia* (Waldron, 2001).

Trauma

Trauma, or body-altering physical injuries, can often have very distinct presentations in skeletal remains (Waldron, 2001). Fractures and breaks can be identified with relative ease by even the most inexperienced paleopathologists. These fractures can be further analyzed to see if they resulted in death or if the specimen received

medical attention based on the presence or absence of healing patterns. When observing fractures, there are many different types based on the style of break and how the bones interact with the surrounding tissues.

One of the most common type of fracture is, unsurprisingly, named the *simple fracture* (Müller, Nazarian, Koch, Schatzker, & Heim, 1994). In this fracture, the surrounding tissue may be damaged; however, the skin is not broken, giving it the additional name of closed fracture. Due to these criteria, paleopathologists can only suspect this type of fracture with little to no bone displacement, such as with small hairline or incomplete fractures where the bone ends never separate. The alternate type of fracture, where there is enough displacement to break the skin, is known as a *compound, or open fracture*. These are much more susceptible to infection, since the exposed bone ends may come into contact with pathogens in the environment.

Within these broader fracture types, there are many other fracture types, usually related to how the bone broke (Müller et al., 1994). For example, a *transverse fracture* refers to the angle of the breakage in relation to the axis of the long bone: 90 degrees. Similarly, an *oblique fracture* is a fracture that occurs diagonally in relation to the axis of the long bone. Different types of forces also result in different types of fractures. For example, *stress fractures* are caused due to repeated stress on the bone and not necessarily from acute trauma. This type is common in the feet of long distance runners, which are constantly feeling the forces of stress between the body and the pavement. Another type is a *depression fracture* in which the outer layer of the bone, the cortex, is driven into the inner bone and underlying tissue. Since most long bones cleanly break with enough force, depression fractures are most commonly seen with fractures of the skull. Another notable fracture type, which is only seen in immature bones, is the *greenstick fracture*, in which only the outer cortex of the bone is fractured while the inner, immature bone bends.

While healing rates can be highly variable throughout the different bone types and different patient ages, healing does take place in well-defined stages, which can help paleopathologists determine how long, after the initial injury, the patient survived (Waldron, 2001). Within the first 4 to 8 weeks, union between the fragments usually takes place, holding the two together. During this time period, it is very important that the two ends be aligned anatomically correct to ensure proper healing. If this is not established, especially in the long bones of the limbs, then a patient will likely experience an extreme deficit in limb functionality. After this period of union, it will usually take an additional 4 to 6 weeks until the bone can support the weight, or handle the forces it once could. Interestingly, many studies of skeletal remains with severe breaks have found the bone to be properly aligned, leading paleopathologists to believe that even the earliest civilizations knew the importance of proper alignment in the healing process (Waldron, 2001).

While many types of trauma observed in past civilizations are acute injuries, such as fractures, there are also many documented instances of *ritualistic trauma*. One such type is *trephination*, in which a hole is drilled into the skull with a specific instrument designed specifically for that purpose (Margetts, 1967). Similar to burr holes performed by surgeons to release cranial pressure during hemorrhaging, it is believed that trephination may have been performed on individuals with chronic headaches and brain injuries. However, unlike burr holes, which are based on science and performed in an effort to relieve cranial pressure, trephination was performed in hopes of releasing the evil spirits from the body of the patient, thereby, hoping to cure them. The paleopathologist generally has no trouble identifying trephinations in skeletal remains, which often have more clean-cut holes relative to depression fractures. Often, there are signs of healing, indicating that this procedure, if not successful, was at least not immediately fatal.

Another ritualistic trauma performed is *artificial cranial deformation*, which can include the flattening or the elongating of the skull. Paleopathologists have dated skulls with these abnormalities to 45000 BCE (Trinkaus, 1982). It is believed that these abnormalities are related to either a social class or to very specific groups or clans, as with the ancient Mayans. Since the sutures between cranial bones do not fuse during youth, intentional deformation begins early in life (Tubbs, Salter, & Oakes, 2006). It was often achieved by tying stones or boards to the head with a great deal of pressure, forcing the bone to slowly remodel itself over many years.

Tumors

In modern medicine, it is difficult to find a dirtier word than *tumor* or *cancer*. This group of diseases has sidestepped the best efforts of countless scientists as the battle against cancer continues. A tumor, or neoplasm, is a mass of cells, dividing uncontrollably due to faulty genetics or molecular cues gone wrong. This rapid cellular division can cause an accumulation of mutations, spreading and changing faster than modern medicine can keep up with. While this certainly is not true of all cancer types, as great strides have been made against breast cancer, cervical cancer, and prostate cancer, many other cancer types still have scientists scratching their heads in dismay. While relatively rare compared to other cancers (roughly 200 deaths a year), primary bone tumors generally occur in areas of the bone still undergoing division, such as the growth plate of the long bones (Waldron, 2001). Since bone growth ends in adulthood, primary bone tumors, such as osteosarcomas, generally occur only in children under 20 years of age. These can be difficult to initially diagnose, which is the very key in successful treatment. Usually, osteosarcomas are not detected until metastasis to other regions, resulting in more distinct symptoms. From a paleopathology perspective, little

information can be found on osteosarcomas throughout time due to their extreme rarity even today.

Secondary bone tumors are much more common and occur from the metastasis of cancer from other regions of the body. These secondary tumors can present themselves anywhere, although they are most common in the spine, pelvis, femur, and skull (Waldron, 2001). In this type of cancer, malignant tissue invades the bone, replacing the normal bone tissue with the rapidly dividing malignant tissue. Therefore, in examining fossil skeletons, a variably shaped hole marks the site of tumor invasion, which is quite distinct in appearance compared with other holes such as those caused by bullets. Since the tissue decomposed long ago, paleopathologists can only guess the type of cancer the individual suffered from, except in one unique cancer type.

Unlike other secondary tumors from other cancer metastases, prostate cancer invasion actually causes deposition of bone instead of degeneration. It is believed that similar proteins, activated in both prostate cancer cells and normal bone stromal cells, activate osteoblasts to begin bone deposition (Koeneman, Yeung, & Chung, 1999). While this interaction still isn't entirely clear, the results are striking for any paleopathologist to observe, with prominent neoplasms on the bone surface.

Oral Pathology

Built to withstand the constant mechanical and chemical stresses of a typical human lifetime, it is no wonder that teeth can remain remarkably intact over thousands of years. Generally, being the only piece of skeletal remains that has come into direct and constant contact with the environment, teeth can provide paleopathologists with quite a bit of evidence on the lifestyle and activities in the daily living of an individual (Klepinger, 2006). With fairly standard growth rates for younger skeletons, anthropologists can gain a rough idea of the age of the skeleton when they passed. While this may be important for statistical studies, paleopathologists are most interested in the diseases that have affected the teeth through time.

Cavities are a nuisance that a good portion of the population has experienced at one point in their lives. With an increase of acidic beverages and sweets in our diet, fluoride is removed from the teeth, causing weakness and demineralization of the teeth. This breakdown, coupled with acid production by bacteria in the oral cavity, causes the formation of dental caries, or cavities. These decompositions can be quite apparent in the dental record of our ancestors as the lesions form deep between the teeth. In more dramatic cases, the cavities may have advanced all the way into the root of the tooth, which, if allowed to continue to spread, can even cause an infection in the maxillary sinus. If an infection occurs at this level, gross anatomical changes are apparent in the teeth as well as small changes within the sinus that can be viewed with fiber optics (Waldron, 2001). It is interesting to note that

the prevalence of cavities in the dental record increases with the amount of sugar introduced into the diet at the time (Moore & Corbett, 1971, 1973, 1975).

While cavities may be somewhat rarer in more dated specimens, an *oral calculus* is relatively more common. These are formed by the mineralization of the teeth, leaving deposits on the teeth (subgingival) or gums (supragingival). Since mineralization forming calculi are directly opposite of the demineralization of cavities, it is no wonder that the two seem to exist in inverse proportions in the fossil record (Waldron, 2001). Studies on these calculi have shown bacterial presence within the calculi, along with the remnants of any other debris that may have been in the oral cavity (Dobney & Brothwell, 1986). Whether this can include food remnants, offering insight into the individual's diet, is the subject of further research.

Periodontal disease, associated with poor oral hygiene, is characterized by bone loss around the teeth due to a high level of bacteria in plaque. This decay can be horizontal and occur across all levels or vertical, occurring at each individual tooth at varying rates (Rogers, 2008). If the decay reaches a certain point, then the individual will begin to lose teeth, which is quite evident in the fossil record. This can easily be distinguished from any teeth lost after death due to the presence of new bone growth around the tooth socket in an attempt at repair. It is important to note that all tooth loss is not necessarily from periodontal disease but can also be caused by trauma, scurvy, leprosy, or other illnesses. Thus, care must be taken to closely examine the surrounding bone structure for degeneration before a correct diagnosis can be made.

The Iceman

In September 1991, two German tourists, Helmut and Erica Simon, were hiking along the Italian-Austrian border on a Similaun mountain when they came across a corpse sticking out from the snow (Fowler, 2000). He was crudely removed, the excavation team not realizing he was more than a stray backpacker caught in bad weather. Causing quite a bit of damage during the process of excavation, including damage to the hip and limbs, the mysterious man was brought to an Austrian morgue. Because of suspicion over the ancient-looking objects found with the corpse, including a copper axe, unfinished bow and arrows, and a stone knife, archaeologist Konrad Spindler was called to examine the body. It didn't take long for the archaeologist to confirm that this was no ordinary corpse.

Dated to be from 3300 BCE (or roughly 5,300 years old), Ötzi the Iceman is one of the oldest specimens ever recovered with tissue structure still intact (Fowler, 2000). This has allowed scientists, anthropologists, and paleopathologists a unique opportunity to look at not only skeletal remains but also organ and tissue remains. Attributed to the cold glacier environment, Ötzi is remarkably preserved, an almost

completely unheard of phenomenon in the archaeological realm; he was lying completely safe in a shallow trench as the ancient glacier moved over his frozen body. This relatively unchanging condition of Ötzi's icy tomb has allowed DNA and histological analyses, giving paleopathologists a very detailed overview of his health.

Due to the importance of this archaeological find, painstaking care was taken to ensure Ötzi's preservation (Fowler, 2000). This made research rather difficult, as Ötzi must be kept in a constant state of humidity and temperature, mimicking the conditions he spent the last 5,300 years in. Thus, paleopathologists, who normally rely on skeletal interpretations, had to rely on X-rays and other diagnostic tests to discover Ötzi's ailments. Strictly from a paleopathological standpoint, Ötzi was not in the best of health when he died. X-rays of Ötzi's chest revealed broken ribs, with both complete fractures and hairline cracks. Doctors closely examined the films and reported no signs of healing around the bones. Due to Ötzi's semidehydrated state, they could not detect the normal inflammatory response associated with breaks that occur right at death. Thus, doctors could not ascertain whether these fractures occurred at death or over the next 5,300 years. Doctors also noted several healed fractures on the left side of Ötzi's rib cage, perfectly aligned, which he had probably lived with for some time.

Also, thanks to the dehydrated state of Ötzi's remains, computerized tomography (CT) scans had limited use in analyzing his corpse (Fowler, 2000). Many of Ötzi's internal organs were dried and shriveled, showing up as nothing more than wisps on CT films. Even the brain was nothing more than a fragile ball, bouncing around inside the cranium. However, CT scans did provide researchers a good idea of the age of Ötzi when he died. Due to the slow rate of fusion of the cranial-plate sutures, researchers noticed that, while these sutures were closed, they were still slightly visible, leading them to believe Ötzi was between 25 and 30 years of age. The aorta could also still be analyzed on CT films and showed some signs of arteriosclerosis—surprising for a man of his young age. The use of CT scans also revealed some arthropathies, most notably osteoarthritis. While this was again a surprising find for his age, researchers believe it was the difficult lifestyle of the Iceman that seemed to hasten the onset of these degenerative diseases.

Since full autopsies would have completely jeopardized the longevity of Ötzi's preservation, tissue samples were carefully taken to be analyzed. Extractions from his gastrointestinal tract found the presence of *Trichuris trichiura*, a type of whipworm (Dickson, Oeggl, & Handly, 2003). Although Ötzi showed none of these signs, severe infections of this parasite can result in diarrhea, blood loss, and even rectal prolapse. Ötzi also had 3 Beau's lines on his one remaining fingernail, an indication of three recent illnesses at least 6 months before death. It is believed that Beau's lines form after cellular division stops in the nail bed, creating distinct horizontal lines across the nail. This

can be caused by systemic illnesses, such as infections, poison ingestions, and severe traumas resulting in shock.

While most paleopathologists deal with cases that are no longer of any forensic significance, Ötzi again provided a new challenge in determining the cause of death. Many initially assumed he froze to death in the cold glacial region, exhausted and looking for refuge from the inhospitable environment. In fact, researchers published a report in *Science* that, although speculative, made more sense of death by freezing (Seidler, 1992). Konrad Spindler had another theory. In 1993, he proposed that Ötzi may have actually been fleeing for his life. Based on the unfinished condition of his weapons and the signs of injury throughout his body, Spindler believed that Ötzi may have been fleeing his village from a massacre, which was documented as common in the Copper Age (Spindler, 1994). However, many felt that this story was stretched so that Spindler could reach higher sales for his *Iceman* book, which was to be released that year. Because of this, for many years, his theory was dismissed by his peers, despite being very well liked in the "popular imagination" (Fowler, 2000). However, a high resolution CT scan in 2001 revealed an arrowhead lodged in his shoulder (Dickson et al., 2003). Now realizing foul play was a legitimate factor, anthropologists took a closer look at the body, finding more and more signs of trauma in the hands, wrist, chest, and head, all of which showed no signs of healing. While it is possible that he bled to death from the arrowhead lodged in his shoulder, most anthropologists have now come to the conclusion that he was killed from a blow to the head, whether by an attacker or by falling from blood loss.

Mummies

When people think of mummies, many think of the cloth-wrapped mummies of Egypt, which have long been of interest to archaeologists and anthropologists. Part of a very unique culture and way of life, Egyptian mummies and tombs have been studied and researched a great deal since the early 1900s. However, mummies as a class have a much broader definition that includes many other specimens found outside of Egypt. The process of *mummification* "involves the transformation of once-living body or tissue into a state of arrested decay" (Aufderheide, 2003, p. 41). Thus, by this basic definition, we can broaden our view of mummies beyond Egypt, and in fact, mummies have been found throughout Europe in Spain, France, Germany, Austria, Italy (including the Iceman); throughout South America in Peru, Chile, and Argentina; throughout Africa and Asia; and even in the United States. Because the mummies found in each individual region have their own unique properties and cultural relevance, these are of much more interest to the cultural anthropologists, while paleopathologists are much more interested in the diseases that plagued these individuals.

To understand how paleopathologists study mummies, it is important to first understand how they are preserved. Decomposition occurs in several phases (Aufderheide, 2003). The first is the release of normally regulated digestive enzymes within the cells, which begin non-specifically digesting cellular structures. Bacteria then begin to further digest body tissues, aided by larger organisms, such as maggots and scavengers. Thus, mummification must somehow block these processes in order to preserve the integrity of the body. Since enzymes must operate in an aqueous environment, the drying out of a body, or desiccation, is one of the most common methods employed in the mummification process. This, unsurprisingly, occurs in dry arid regions, such as the deserts of Egypt, the Gobi desert of Mongolia, and the dry regions of Peru and Chile. This is not to say that heat is the only method employed when drying a body. Freeze-drying techniques used by mountainous peoples, such as the Incas of the Andes (Schobinger, 1991), are also used. With this technique, water slowly leaves frozen body tissue via sublimation, a process in which the ice passes directly to water vapor, bypassing the liquid phase. The Iceman was so well preserved by this method. These cold temperatures can also block enzymatic action, which requires a narrow optimal temperature range for functioning. Most bacteria can only thrive in a narrow temperature range, and thus, frozen specimens tend to be very well preserved. A third method, although less common, uses honey or other concentrated solutions to coat the body. Due to osmosis, the water will leave the body to enter the more concentrated solution. Furthermore, honey has been found to have antimicrobial properties, furthering the preservation of a body (Aufderheide, 2003). Heavy metals, such as arsenic, copper, mercury, and lead, can also block the activity of many of these enzymes by binding them and changing their structure, thereby rendering them useless. An example of this is the “Copper Man” mummy from CE 1000, found in a copper mine in Northern Chile (Bird, 1979). This mummy is remarkably intact, which many attribute to the copper found throughout the viscera. However, many point to the dry conditions of the mine and region as the true reason for his excellent condition (Preston, 1980).

The dry conditions of these tissues have given paleopathologists difficulty in diagnosing any illness beyond the skeletal structure, which is otherwise usually still quite reliable. Many organs are desiccated or degenerated to a point beyond recognition, and even the anatomical position is not an entirely reliable marker in organ identification (Aufderheide, 2003). Despite these limitations, many techniques used in autopsies of the recently deceased can be employed in the study of mummies. For example, mummies can be systematically dissected; this enables examining of overall morphological changes to various organs, looking for any telltale signs of disease. Histological sections for microscopic analysis can also be taken,

employing a variety of stains to analyze various cellular structures. In mummies, where structural integrity must be absolutely preserved and dissection is not an option, radiographic methods may be employed. While this may include simple X-rays to look at bone changes, CT scans can also be used to create three-dimensional reconstructions. Magnetic resonance imaging (MRIs) are rarely used as the desiccated remains do not respond well to this imaging technique thereby providing little additional resolution over cheaper and faster CT scans. Endoscopy, in which a flexible camera is sent into the body for pictures of biopsy retrieval, is also used in the study of mummy pathology. This is again used to preserve the integrity of the remains, limiting gross mutilation while still allowing researchers to take samples of various organs for histological or chemical analysis, which can include DNA composition and amino acid racemization.

Due to the mummification process, gross anatomical changes in the organs are not reliable markers of disease. Histological techniques are a paleopathologist’s best chance at identifying an infectious disease in mummies (Aufderheide, 2003). For example, tissue samples from the spinal cord may show dried pus and the presence of small bacilli, leading many to the diagnosis of meningitis. Similar samples can show a myriad of other infectious diseases throughout the body, including trachoma in the eye, caused by *Chlamydia trachomatis*; *Mucocutaneous leishmaniasis*, a parasitic infection of the mucous membranes; myocardial infections; and various pulmonary infections. Paleopathologists must also rely on histological techniques when identifying neoplasms. Again, since gross anatomical changes of various organs cannot be markers for disease, histological sections must be examined for the presence of cancerous cells, which have a characteristic appearance in comparison with normal differentiated cells. DNA analysis for the presence of genetic abnormalities is also slowly starting to come into use and is certainly an area of further research. For example, Huntington’s chorea, a neurodegenerative disorder that is inherited in a dominant fashion, would only be able to be detected by these means, as the brain is almost always atrophied beyond normal analytical means.

Areas for Further Research

With the possibility of the discovery of significant archaeological finds on any given day, paleopathologists will certainly have ample specimens to analyze for years to come. This can include unique case studies like Ötzi the Iceman, Egyptian kings, or the bog people. Alternatively, paleopathologists can concentrate on more “normal” findings, providing a much better picture of the daily activities of an ancient population. It was earlier discussed that epidemiological studies must continue looking at the incidence of leprosy and tuberculosis over time. These studies

can and have been applied to the incidence of any of the aforementioned diseases, and this is always an area that can be expanded on as more skeletal fossils are recovered from the fossil record.

One of the most exciting new areas in paleopathological research is the emergence of a chemical analysis of skeletal remains. Many papers have already been written that looked at the presence of heavy metals, most notably lead, in skeletal remains (Waldron, 1983). The composition of other elements can also be examined, although they must be present in high enough quantities in the diet and bone (Ezzo, 1994). As technology advances, new extraction techniques will be employed, allowing paleopathologists access to proteins in the fossilized bone for analysis. For example, if paleopathologists can find molecular factors for a disease, such as the rheumatoid factor, then they can confidently make the diagnosis for this illness and many others.

With the completion of the human genome project, the ability to extract aDNA has even more relevance than ever. Although using aDNA as a focus for experiments does pose a challenge due to the general poor quality of most samples and large missing segments, it does show a great deal of potential for future research (Cano, 1996). By examining very specific gene fragments, researchers can watch the evolution on a genotypic level of our own species over time in the fossil record. Gene studies can also be made to look at migration patterns, as highly conserved genes unique to individual populations are tracked over time in the fossil record. Never before have paleopathologists had access to such detailed information, and the potential in this new field is quite limitless as technology continues to advance in genetics.

Conclusion

The field of paleopathology will continue to provide answers for anthropologists, while introducing even more questions about our past. As new technologies are used in the interpretation of skeletal remains, we can expect to gain a great deal of insight about not only the diseases that affected us but also the story of our species and our evolution over time. But why search for the answers to these questions? The famed paleopathologist Calvin Wells (1964) put it well when he said,

Disease and injury mirror more faithfully the haps and mishaps imposed by the vagaries of life and struggle to survive. If we seek the genetic affinities of an individual or group, details of normal anatomy and physiology are usually our most rewarding study; for the more intimate knowledge of how people have responded to the aggression of their environment pathology is a surer guide . . . The intricate relationship between a people's way of life and the diseases they endure is the chief reason for the study of paleopathology. (pp. 17–18)

MEDICAL ANTHROPOLOGY

ARVILLA CHAPIN PAYNE-JACKSON

Howard University

Medical anthropology is the discipline in anthropology that addresses disease and the health care systems developed to cope with disease. Medical anthropologists study the spectrum of cultural and biological factors that have contributed to health, disease, and health care systems throughout human experience from cross-cultural, historical, and evolutionary points of view. They address a wide variety of health and health care issues including cultural barriers to therapeutic and preventive health care; issues of bioethics; the effect of pandemics, epidemics, and natural disasters; the impact of public policy on health care, practitioner-patient communication in hospitals, clinics, private, and ethnomedical practices; nutrition; perceived etiologies and their effect on therapeutic approaches to healing; differences in the cultures of biomedical, ethnomedical, and other alternative health care systems; ethnographic studies of healers, their patients and families, and their support systems; different types of practitioners (biomedical, alternative, ethnomedical, religious) and the science and technology and medicines used in their practices as well as how cross-cultural and societal differences shape biological and psychological reactions to suffering. Medical anthropology is highly interdisciplinary lending itself to ecology, geography, economics, linguistics, medical sociology, biochemistry, genetics, serology, anatomy,

paleopathology, epidemiology, medicine, nursing, and public health, among other disciplines.

Medical anthropology is distinct from other social sciences in three ways: (1) It covers a wider temporal and geographic scope of the experience of human health from paleontological and archaeological research through the ethnographic studies of modern day health care systems. (2) It attempts to identify and understand both the socio-cultural and bioecological factors that define and characterize health, illness, and disease. (3) It uses an extensive combination of both qualitative and quantitative methods. Quantitative methods help identify disease patterns, standard patterns of social behavior, and social and economic factors that affect disease and health. Qualitative methods help ascertain the fundamental, unspoken cultural ways of life and values that form the foundation of a society's health care system and help decipher the relationship between a society's normative, or ideal culture (what people say things ought to be), versus real culture (what people actually do) (Joralemon, 1999, p. 13).

History of Medical Anthropology

Four contributing sources to the foundation of medical anthropology have been (1) biological anthropology,

(2) ethnographic studies of health care systems, (3) the culture and personality movement of the 1930s and 1940s, and (4) the post–World War II international public health movement, which has led to a global consciousness of the effect of disease on societies.

Early Studies

The Exotic

The early pre–World War II ethnographic studies of medical traditions and health care practices of non-Western societies focused on the magico-religious beliefs (magic, sorcery, witchcraft, and religion) in relation to health and sickness, underlying perceived causes of illness (natural, spiritual, or occult), types of practitioners, and the corresponding healing practices. E. E. Evans-Pritchard's *Witchcraft, Oracles, and Magic Among the Azande* (1937) is a classic example from this era. His and other studies of the time provided insight into the underlying cultural premises of medical knowledge, procedures, customs, rituals, and roles of the different types of practitioners (natural, spiritual, and occult) as well as the relationship between the environment, how people made a living, the political and social organizations in a society, and perceived causes of illness and disease.

William H. R. Rivers (1924), a British physician and experimental psychologist; Erwin H. Forrest Clements (1932), an anthropologist; and Ackerknecht (1942, 1971), a physician and anthropologist, are three well-known scholars who made significant contributions to the early studies of health care. They were influenced by historical diffusion and functional theory, the dominant approaches used by anthropologists in the early 20th century. Diffusionists attempted to establish classification systems for given cultural domains (e.g., etiology of illness) and the subtypes within that domain (e.g., natural, spiritual, and occult). Once a domain and its subtypes were determined, they were used to identify the cultural domains in other societies and trace their diffusion from geographic centers. Functional theory treated cultures as a whole made up of parts with each part contributing to the maintenance of the society as a whole.

William H. R. Rivers (1924) was the first to attempt to systematically relate the practice of medicine to other characteristics of culture and social organization. In a series of lectures at the Royal College of Physicians (1915–1916), he presented a classification of the cultural domain of etiology of illness. The model was based on early 20th-century attempts to classify discernable explanations of disease causation in traditional, or *primitive*, medicine as being either magical or religious. He identified three types of disease causation: (1) those caused by human agents through the use of magic and sorcery; (2) those caused by a spiritual or supernatural agency, such as deities, spirits, or breaking of taboos; and (3) those that result from a natural agency or

natural processes. He also related perceived disease etiology to type of curer or practitioner sought out for treatment.

Rivers's (1924) findings were based on two basic propositions. First, that medical practices in primitive medicine are not random, meaningless, and disconnected customs but rather that they are based on “definite ideas concerning the causation of disease . . . [and are] both logical and systematic and in some respects more rational than our own” (pp. 51–52). Second, that traditional primitive medical practices and beliefs comprise a social institution, “a social process, subject to the same laws, and to be studied by the same methods as other social processes” (p. 55). Despite these revelations, which ran contrary to the scientific view at the time, primitive medicine continued to be treated as being unscientific due in part to the magico-religious nature of the perceived etiologies and treatments (see Foster & Anderson, 1978; Good, 1994). Rivers saw primitive medicine and modern medicine as two separate, incompatible entities of study in which magico-religious beliefs and practices of primitive medicine could not be considered in the same realm as naturalistic-scientific modern medicine (Wellin, 1977).

Anthropologist Forest Clements's work “Primitive Concepts of Disease” (1932) undertook a systematic diffusionist “culture-trait” approach to the analysis of non-Western medical beliefs and practices. He identified five etiological categories: sorcery, breach of tabu, object intrusion, spirit intrusion, and soul loss. The distribution of these traits was then mapped on a worldwide basis and the chronological sequences, pathways of diffusion, and geographic centers for each of the traits were postulated. Clements's work added credence to the concept that all cultures develop systems of health care that define disease (see Wellin, 1977).

Erwin Ackerknecht (1942) is attributed with being the first to establish medical anthropology as a subfield of anthropology. He applied functional theory to the ethnographic study of medical beliefs and practices of non-Western cultures. He was influenced by British functionalists, the French sociologist Marcel Mauss, Boasian tradition, and in particular Ruth Benedict at Columbia University. Many of the essays Ackerknecht wrote during the 1940s and 1950s are included in *Medicine and Ethnology: Selected Essays* (1971). He explored from a cultural relativistic perspective how the perceived cause of a disease reflected lines of social tension in a society and how the threat of being accused of causing an illness by witchcraft or sorcery could operate as a powerful sanction to maintain the status quo by preventing deviation from social norms.

Ackerknecht (1942) was among the first to argue that disease concepts were culturally constructed: “What is disease is, in the last instance, not a biological fact but a decision of society” (p. 167). He differed from Clements in that he focused on the total cultural configuration of a society, not individual cultural traits. He also did not see

primitive medicine as a single entity but rather that each culture had its own system. A medical system was viewed as an integral part of a society as a whole but varied from society to society in how it was interrelated to other parts of a society. Disease in non-Western cultures was seen to be an artifact of customs and beliefs and divorced from the nature and distribution of disease and adaptation to the environment. He also saw primitive medicine as a totally separate entity from Western “scientific-based” medicine (see Wellin, 1977).

Physical (Biological) Anthropology

Physical (biological) anthropologists have contributed to the understanding of how human evolution and cultural factors influence disease and human health. The biological approach examines morphological, physiological, and genetic variation among people living in different kinds of conditions. Their interest in human biology, human growth and development, genetics, and serology parallels areas of interests of biomedicine. Biological anthropologists share common interests with medical anthropologists in their study of “the distribution of disease, physiological adaptations to disease and social factors related to health status” (Brown, 1998, p. 2). Evolutionary theory concerns understanding disease in the past and understanding what past diseases may tell us about contemporary health issues. The second biological approach concerns morphological, physiological, and genetic variation among people living in different kinds of conditions.

Culture and Personality

The culture and personality movement of the 1930s and 1940s brought anthropologists and psychiatrists together to study how personality and the sociocultural environment are interrelated. A wide range of topics were investigated during this time: (a) the nature/nurture debate, (b) sibling rivalry, (c) instinct, (d) aggression, (e) culture-bound syndromes, (f) the cross-cultural applicability of Freud’s theory to mental illness, and (g) the universality of biomedical-psychiatric categories (see Pool & Geissler, 2005).

Studies during this period were primarily theoretically oriented but others focused on how to improve health care. Ruth Benedict’s (1934) *Patterns of Culture* is a seminal theoretical work of the period. According to Benedict, each culture selects a few personality traits from the pool of characteristics of “human potentialities” that become the unique personality of a culture that in turn influence the personality traits of people living in that culture. Representative studies that focused on improving health care included the Leighton’s (1941) study of introducing modern health care to the Navahos, the Devereaux’s (1940) study of therapeutic fitness on a schizophrenic ward, and Joseph’s (1942) description of how cultural differences about the roles of biomedical

physicians and Indian patients in Southwest America hampered therapeutic interaction.

International Public Health Movement: Post–World War II

Anthropologists began work in the international public health field in the 1930s and 1940s. In 1942, the United States partnered with several Latin American countries to address public health concerns. But it was the international public health movement after World War II that helped to crystallize the role of anthropology in the study of disease and medical health care systems. Applied medical projects during this period attempted to solve health problems in particular cultures. Among the early backers of public health projects was the Rockefeller Foundation sponsoring applied projects, such as Philips (1955) hookworm campaign in Ceylon. After World War II, the applied roots of medical anthropology were extended through cooperative foreign aid programs initiated in countries in Asia and Africa. The early programs were administered through the International Cooperation Administration and later through the United States Agency for International Development and the United Nations World Health Organization (WHO). The primary goals of the programs were to stamp out epidemics, improve water supplies, and identify factors that hindered and/or facilitated the carrying out of and success of the aid programs. It was also during the 1950s that anthropologists were first assigned to official positions in international health organizations: Cora DuBois at WHO, Benjamin Paul at the Harvard School of Public Health, and George Foster at the Institute for Inter-American Affairs, among others (see Baer, Singer, & Susser, 1997).

Among the most influential works of the post–World War II movement was Benjamin Paul’s edited work *Health, Culture and Community: Case Studies of Public Reactions to Health Programs* (1955). This work was a major contribution to the field of applied anthropology and public health. The focus of this work was to investigate “the immediate situation where medicine and community meet” (p. 4). He introduced social science methodology into the study of medical health care systems. His work revealed that in order for Western-based medical intervention programs to be successful it was necessary to take into account local beliefs about how health and illness are defined and manifested and the perceived causes of and treatments for illnesses. He was concerned with examining how a traditional medical system reacted to the introduction of new health-related practices and how traditional practices in turn influenced the contributing medical system. Other works during this period that contributed to the development of the field of medical anthropology were Caudill’s (1953) survey of anthropological studies in the field of health care in “Applied Anthropology in Medicine” and Scotch’s (1963) general literature review of medical anthropology.

As a result of the work of medical anthropologists in the international public health arena, several universals of medical systems were identified: (a) Every culture has a medical system; (b) disease is pathologically defined, but illness is culturally defined; (c) medical systems have both preventive and therapeutic sides; (d) medical systems provide the etiology of an illness and the appropriate treatments; (e) a disease theory system answers the question, Why did this happen to me; (f) medical systems play important roles in approving of and supporting social and moral cultural norms including the control of aggression; (g) disease theory systems play a role in the conservation of medical practices; and (h) traditional medical systems often play an important role in national identity and pride (Foster & Anderson, 1978, pp. 38–47).

Society for Medical Anthropology

The brief history of the Society for Medical Anthropology is found on two Web sites: the Society for Applied Anthropology Web site (www.sfaa.com) and the Medical Anthropology Web site (www.medanthro.net). While the beginning of medical anthropology can be traced back to the turn of the 20th century, it was not until the 1960s that a more formal organization began to take shape and is known today as the Society for Medical Anthropology. The earliest origins of the Society for Medical Anthropology are traced to the Roster of Anthropologists, Physicians and Others Who Have Special Interests in Medical Anthropology—the name of the organization at the time. The group changed its name to the Organization of Medical Anthropology (OMA) in 1967. At the 1968 annual meetings of the American Anthropological Association (AAA), the OMA offered its first workshop and changed its name to the Group of Medical Anthropology. At the 1970 American Anthropological Association (henceforth AAA) Annual Meetings, the OMA was renamed the Society for Medical Anthropology (SMA) and adopted its constitution and officially became a section of the AAA. Today, the SMA is one of the largest sections in the AAA.

The major journals affiliated with the SMA include *Medical Anthropology Quarterly*, *Medical Anthropology, Culture, Medicine and Psychiatry*, *Social Science and Medicine*, and *Ethnomedizin*. The SMA has close ties with the Society for Applied Anthropology; the Association for Anthropology and Gerontology; the Society for the Anthropology of Food and Nutrition; Medical Anthropology Students' Association; AIDS and Anthropology Research Group; Alcohol, Drug, and Tobacco Study Group; Bioethics Interest Group; Clinically Applied Medical Anthropology; Complementary and Alternative Medicine (CAM); Integrative Medicine Group (IM); Council on Anthropology and Reproduction; Council on Infant and Child Health and Welfare; Council on Nursing and Anthropology; Critical Anthropology of Global Health Study Group; Disability Research Interest Group; Global Health and Emerging Diseases Study Group; Pharmaceutical

Studies Group; and Science, Technology, and Medicine (STM) Group (www.medanthro.net).

Today: Global Health

The works of medical anthropologists have contributed to both the theoretical and empirical understanding of the relationship between culture, medical knowledge, and practice. Several basic themes and questions addressed by medical anthropologists today are (a) the development of systems of medical knowledge and health care; (b) the roles of healers in the well-being of societies through the study of patient-practitioner relationships and the relationships between different types of health practitioners; (c) the integration of alternative and complementary medical systems in culturally diverse environments; (d) the interactions among and impact of biological, environmental, and social factors on health and illness at both individual and community levels; (e) the impact of general political and economic forces on the health of individuals and communities and the interplay between social structures (e.g., political and economic arrangements), ecological settings, and disease-causing agents; and (f) the effects of biomedicine and biomedical technologies (www.en.wikipedia.org/wiki/medical_anthropology).

Basic Concepts and Terms

As in any discipline, the jargon used has specific definitions that often vary from the lay definition of those terms. Baer et al. (1997, pp. 4–12) discussed several basic concepts and terms used in medical anthropology in the study of health care systems and issues related to health, disease, and illness: health, disease, illness, curer/practitioner, medical system, medical pluralism, biomedicine, and ethnomedicine. The basic definition for each term is given below.

In 1978, WHO defined *health* as “not merely the absence of disease and infirmity but complete physical, mental and social well-being” (Baer et al., 1997, p. 4). The limits of this definition have come under question by critical medical anthropologists who argue that the definition should be expanded to include “access to and control over the basic material and nonmaterial resources that sustain and promote life at a high level of satisfaction” (p. 4).

Medical anthropologists differentiate between *disease*, which is generally defined as a pathological or physiological disorder, infection, or malfunction of the body, and *illness* (*sufferer experience*), which is defined as a culturally constructed concept of how people conceive of a particular physical state as being deviant from the normal state (Baer et al., 1997, pp. 6–7). Brown (1998, pp. 8–9) summarized the conceptual significance of the distinction of disease/illness in the study of the social construction of illness behavior including the sick role, medical decision making,

seeking of treatment, and the social production of health (see Weller & Romney, 1988; Young, 1980).

Foster and Anderson (1978, pp. 148–153) identified six social roles of illness: (1) Illness provides release from unbearable pressure, (2) illness helps account for personal failure, (3) illness may be used to gain attention, (4) hospitalization may be a vacation, (5) illness may be used as a social control device, (6) illness may be a device to expiate sin.

In reaction to the existence of threats posed by disease, each culture develops a *medical system* that consists of culturally based learned behaviors and beliefs that include a theory of disease causation and treatment. *Curers* or *practitioners* are specific people with special knowledge who know how to diagnose and treat sickness. *Medical pluralism* is the coexistence of different medical systems within one society (Baer et al., 1997, pp. 7–11).

Biomedicine, also referred to as scientific, allopathic, Western, or cosmopolitan medicine, among other terms, focuses on the pathology and external causes of disease (e.g., germs, viruses, bacteria) and symptoms while emphasizing treatment of disease more than prevention (Baer et al., 1997, pp. 11–13). *Ethnomedicine* refers to the culturally constructed health care systems of any society. Other terms associated with ethnomedicine are terms such as *folk medicine* or *popular medicine*. Until the turn of the 21st century, biomedicine and ethnomedicine were treated as separate systems with the scientific-biomedical approach seen as uniform, objective, and not culturally constructed. Lynn Payer's (1988) study of biomedicine in England, Germany, France, and the United States clearly demonstrated that biomedicine is not a uniform medical system but is also a culturally constructed system of medical care that varies from one culture to another.

Approaches

Brown (1998, p. 2) gave an overview of the two basic approaches used by medical anthropologists to address questions related to disease and health care—the biocultural and cultural approaches. He points out that variation in theoretical orientations and application of different methods for research and analysis exist within each of these approaches.

Biocultural Approach

The biocultural approach examines the ways in which people adapt to their environment and how the changes they make in their environment improve or worsen their health conditions. Topics investigated from a biocultural approach include disease in human evolution, health and medicine, human biological variation, human growth and development, paleopathology, bioarchaeology, and the history of health and culture and political ecologies of diseases.

Cultural Approach

The cultural approach examines the underlying ideas, beliefs, and values used in the classification of illness and medical systems developed for the treatment of illness. Topics investigated include belief and ethnomedical systems, the social construction of illness and the social production of health, healers in cross-cultural perspective, culture, illness and mental health, and critical medical anthropology.

Applied Approaches

Applied medical anthropologists apply anthropological theory and method to specific medical problems. The two main areas of application in medical anthropology are clinical studies and public health. Clinical studies have focused attention on understanding the differences between patient- and doctor-explanatory models in an effort to improve communication and health outcomes. The public health area of application focuses on public health policy making, program development, and interventions that are culturally sensitive, address local needs, and secure support of local communities (Brown, 1998, pp. 16–17).

Pool and Geissler (2005) pointed out that “applied medical anthropology is aimed at solving health problems in particular settings. . . . Theoretical medical anthropology is aimed at understanding the functioning of medical systems as cultural phenomena and develop more general theories about underlying processes” (p. 31).

Theoretical Approaches

The classification of theoretical perspectives in the research of medical anthropologists varies. For example, Byron Good (1994) in *Medicine, Rationality, and Experience: An Anthropological Perspective* discussed four theoretical approaches: (1) the empiricist paradigm, (2) the cognitive paradigm, (3) the meaning-centered paradigm, and (4) the critical paradigm. Ann McElroy and Patricia Townsend (2009) in *Medical Anthropology in Ecological Perspective* discussed four theoretical approaches: (1) medical ecological theories, (2) interpretive theories, (3) political economy or critical theories, and (4) political ecological theories. Joralemon (1999) identified the cultural constructivist or interpretive approach, the ecological or ecological/evolutionary approach, the critical medical approach, and the applied medical approach. The following section summarizes the basic tenets of the primary theoretical approaches used by medical anthropologists.

Ecological/Evolutionary Theoretical Medical Approach

Until the 1960s, the theoretical orientation of studies in medical anthropology was based primarily on a sociocultural

approach. In the 1960s, the theoretical orientation shifted to a more biological approach. The ecological/evolutionary approach is a biocultural approach to the study of disease that applies the concept of human adaptation to the dimensions of disease. Examining the interaction among a population's ecological system, its health conditions, and its forms of adaptation provides ways to examine how humans adapt to different environments and social and cultural changes.

Alexander Alland (1970), one of the first proponents of the approach, argued that humans either do or do not adapt to environmental challenges by genetic, physiological, or cultural changes. Three basic premises underlying the medical ecological approach are (1) environmental adaptation is a measure of health while disease indicates disequilibrium, (2) disease mirrors human biological and cultural evolution, and (3) biomedical disease categories are universal. McElroy and Townsend's *Medical Anthropology in Ecological Perspective* (1979) is a work built on Alland's model extending the approach to include a more political-ecological orientation. This approach is closely associated with that of medical epidemiologists, ecologists, and medical geographers (p. 3).

The ecological model has been criticized for not recognizing the effect of the structure of social relationships on influencing which cultural constructions rise to power. Critical medical anthropologists raise two basic questions: (1) Whose social realities and interests are expressed in specific cultural constructs? (2) What were the historical realities that gave rise to them? They also criticize the ecological approach for considering only the external reality of nature and not the evolutionary history of hierarchical social structures that result in the evolution of the political economy of human society (Baer et al., 1997, p. 23).

Cognitive Theoretical Medical Approach

Farmer and Good (Pool & Geissler, 2005, pp. 34–35) define that the focus of the cognitive theoretical approach is to reveal and describe the underlying cultural conventions and ideas that structure people's interpretations of illness. This approach examines how societal and individual variations in the cognitive processing vary from one culture to another. Early studies focused on the classifications of symptoms of illness, diseases, causes of illness, and types of healers and how they are organized in relation to each other including patterns of health care seeking. Cognitive anthropologists examine cultural models of particular disorders, their cross-cultural variation, and the levels of consensus about them among individuals. Some focus on illness narratives, their cultural shaping, and the cultural models that underlie their production. They look for the relation of formal properties of illness models to the natural discourse, context, and performance characteristics of illness representations.

Criticism leveled at the cognitive approach focuses on illness representations being simply abstracted

“mentalistic terms” that do not take into account the social and historical factors that have contributed to the illness meanings. They admonish cognitive anthropologists for paying little attention to the pragmatic and performative dimensions of the illness models that are presented in formal, semantic terms. They also note that the methods used to elicit the cognitive models may, in fact, be an artifact of the methods themselves and the mode of elicitation (Farmer & Good, 1991).

Cultural Constructivist, Cultural Interpretive, Meaning-Centered Medical Approach

The cultural-interpretive theoretical approach to medical anthropology began in the 1970s when Arthur Kleinman (1978, 1980) argued that medical systems were cultural systems and that “explanatory models” could best explain how illnesses are understood by all those who participate in an illness experience—the individual, the family, the practitioners. Cultural-interpretive anthropologists explore the cultural construction of illnesses and the responses to disease. Explanatory models provide insight into perceptions held about etiology, diagnosis, pathology, physiology, possible consequences, and the appropriate treatments for an illness. An individual's construction of his or her explanatory model of an illness may differ from that of the practitioner as a result of cultural, ethnic, and social differences. The result is miscommunication between practitioners and patients. Kleinman advocated for medical anthropologists to work in clinical settings in order to elicit patient-explanatory models of illnesses and thereby facilitate doctor/patient relations and communication.

Good (1994) attributed the development of the cultural-interpretive approach as a direct response to the ecological/evolutionary approach. The underlying difference between the two approaches is that the ecological approach treats disease as part of nature and is therefore external to culture, while the cultural-interpretive approach sees disease as an explanatory model or cultural construction of human reality. Cultural-interpretive researchers work with patients and practitioners in clinical environments in their investigation of explanatory models. This differs from the methods used by researchers of the cognitive approach who used formal elicitation methods to determine the underlying codes and structure of people's interpretations of illness.

Byron Good and Mary-Jo Delvecchio Good developed the “meaning-centered approach” to the study of illness that builds on the basic suppositions of the interpretive approach (B. Good, 1977; Good & Good, 1980, 1982). “The meaning of illness for an individual is grounded in—though not reducible to—the network of meanings an illness has in a particular culture” (Good & Good, 1980, p. 176).

Critical medical anthropologists cite the interpretive and meaning-centered approaches for not paying attention

to the asymmetrical power relations in the clinical setting and how such imbalance in power contributes to the maintenance of social dominance (Baer et al., 1997, p. 25).

Critical Medical Theoretical Approach

The critical medical-anthropology approach combines Marxist theory and dependency theory to analyze the effect of the global political-economic systems on local and national health. Press (1990, p. 1001) listed three primary concerns of the critical medical anthropology approach: (1) How do capitalism, imperialism, and/or Western technology affect health care in third world nations? (2) What roles do logistics and availability of, allocation of, and access to biomedical resources play in both the non-Western and industrialized nations? (3) What is the role of biomedicine as a means of spreading world capitalism?

Critical medical anthropology addresses questions such as “(1) Who has power over agencies of biomedicine? (2) How and in what forms is this power delegated? (3) How is this power expressed in the social relations of the various groups and actors that comprise the health care system? (4) What are the principal contradictions of biomedicine and associated arenas of struggle and resistance that affect the character and functioning of the medical system and people’s experience of it?” (Baer et al., 1997, p. 27).

The critical medical approach focuses on practice rather than symbols and meaning and promotes experiential health versus the functional health associated with global political economies. Critical medical anthropology is concerned with how wealth, power, and socioeconomic status affect the patterns and distribution of disease and challenges the underlying suppositions of the biomedical disease model. It examines how the representations and misrepresentations of illness operate to strengthen the control of the wealthy and powerful as well as the forms of resistance by those who are suffering illness and distress. Critical medical anthropologists propose that an analysis of power relations in the delivery of health services should distinguish four major levels of analysis: (1) the macrosocial level, (2) the intermediate social level, (3) the microsocial level, and (4) the individual with a goal of synthesizing the macrolevel, the middle level, and the microlevel (Baer, 1990, pp. 1011–1012).

One problem Press (1990) cited for the critical approach is that it offers little insight into “on the ground medical organization, staff/patient interaction, and the culture of patienthood in specific cases of disease or illness” (p. 1001).

Critical Interpretive Approach

The critical-interpretive approach synthesizes the critical medical-anthropology approach and the explanatory model approach by incorporating a microlevel and macrolevel approach to understanding health care. The explanatory model provides insight at the microlevel into

patient beliefs, while critical medical anthropology reveals the social, economic, and political dimensions that influence health care. In the critical-interpretive approach, medical knowledge is not conceived of as an autonomous body but as rooted in and continually modified by practice and social and political change.

Nancy Scheper-Hughes and Margaret Lock (1987) challenged the nature of the biomedical separation of “mind from body, spirit from matter, and real from unreal” (p. 6) in their proposed critical-interpretive approach. Lock and Scheper-Hughes (1990) defined the task of critical-interpretive medical anthropology as first to “describe the culturally constructed variety of metaphorical conceptions (conscious and unconscious) about the body and associated narratives and then to show the social, political and individual uses to which these conceptions are applied in practice” (p. 44). They identify the body in three ways: (1) the individual body, or “body-self,” and the vulnerability of the body as it is experienced in health and sickness; (2) the social body represents the state of health of nature, society, and culture itself. If the body is healthy, then it is a model of “organic wholeness.” If it is sick, then it is a model of disharmony, conflict, and disintegration and vice versa; (3) the body politic represents the regulation, surveillance, and control of both the individual and collective body in “reproduction and sexuality, work, leisure and sickness” (Lock & Scheper-Hughes, 1990, pp. 45–70).

Methods

Most medical anthropologists are trained in cultural anthropology and use the cultural approach, theory, and research methods of anthropology in the study of health care, but they also draw on other social-behavioral sciences including biology, psychology, epidemiology, nutrition, clinical, and social sciences. Qualitative research uses a multimethod approach in data collection, also referred to as triangulation of data. Triangulation provides a method by which the researcher can arrive at an in-depth understanding of the phenomenon being studied by using a combination of multiple methodological practices, empirical materials, perspectives, and observers in a single study. This strategy adds rigor, breadth, complexity, richness, and depth to any research.

Among the traditional methods used by anthropologists in qualitative work are structured and unstructured interviewing, participant observation, direct observation, key consultant interviews, in-depth interviews, focus groups, life histories, systematic interviews, questionnaires, household and community surveys, mapping (physical and social), network analysis (clique and structural equivalency), decision modeling, and photography. Before the turn of the 21st century, new methods were being developed that allowed anthropologists to conduct rapid assessment of health care issues and concerns.

Trotter (1991) discussed the new methods developed for rapid assessment. Rapid methods are used “to identify key issues, cultural domains, health beliefs and sociocultural conditions that might act as either barriers to the success of the proposed health project, or to act as supporting mechanisms that would allow the project to succeed” (p. 187). The rapid-assessment techniques can be divided into three groups: (1) those that assist in determining the content and limits of cultural domains in the area of health care (e.g., free listings), (2) those used to determine the basic structural framework of cultural domains (e.g., triads, pile sorts, and scales), and (3) those that explore the consensual properties of a cultural domain (e.g., consensus theory approach) (Trotter, 1991, pp. 187–188; see also Bernard, 2002; Gladwin, 1989; Pelto & Pelto, 1996; Young, 1980).

Future Directions

Singer (1989) proposed that the four theoretical approaches used by medical anthropologists should be integrated to maximize their full potential in addressing health care issues. Baer et al. (1997) reported advances in the integration of three of the primary theoretical models. Medical ecologists moved toward a more political-ecological orientation. Interpretive medical anthropologists acknowledged, attempted, and produced work that took into account political and economic issues. Critical medical anthropologists became more sensitive to political ecology and the significance of political economy in the construction of meaning.

Integration of the different medical-anthropological theoretical approaches provides three major benefits to the study of health care and to the understanding of the factors that affect diseases, the effectiveness of treatments and health care delivery from local communities to the global community. Specifically, integration provides a means for medical anthropologists (1) to examine the ecological, biological, and cultural factors affecting diseases and their treatment; (2) to take into account the political and economic forces that have an effect on disease patterns and access to health care resources; and (3) to provide for the possibility of the needed health-based interventions (Joralemon, 1999, p. 12).

The 21st century offers multiple opportunities for interdisciplinary approaches to the study of health issues. Physician-anthropologist Cecil Helman (1994) called for future research to involve “adopting a much more global perspective—a holistic view of the complex interactions between cultures, economic systems, political organizations and ecology of the planet itself” (p. 338). But an interdisciplinary approach is equally important. Medical anthropology’s recognition of the interrelationship among disease patterns, a society’s belief and value system, and its socioeconomic structure lends a complementary approach to epidemiology’s study of the distribution and determinants of

disease (Trostle & Sommerfeld, 1996, p. 253; see also Glass & McAtee, 2006; Janes, Stall, & Gifford, 1986). Medical anthropology provides public health care programs with insights into local cultural beliefs and values. These insights help reduce barriers to interventions and foster an increase in cooperation between traditional and biomedical practitioners. Medical anthropologists working on the international projects provide insights into the culture of international health programs and policies and their effect on health care delivery. As the global community shrinks and epidemics and pandemics become more common, a fully integrated, interdisciplinary approach to health care will provide the most effective approach to meeting the challenges of global health care.

INFECTIOUS DISEASES AND ANTHROPOLOGY

RICHARD ALBERT STEIN

Princeton University

Infectious diseases accompanied humanity throughout its existence and shaped history more profoundly than probably any other single biological factor. The epidemic from 165 to 180 BCE, referred to as the Antonine plague, or plague of Galen, is said to have caused 2,000 deaths per day and was considered the most decisive event in Roman history. The second bubonic plague pandemic from 14th-century Europe, also known as the black death, thought to be the deadliest pandemic in history, resulted in an estimated 50 million deaths and the loss of one third of the population in Europe and the Middle East. Smallpox caused 3.5 million deaths during a 1520 to 1521 outbreak, and the 1918 to 1919 Spanish flu claimed 50 to 100 million lives worldwide. Some investigators proposed that the extinction of the Neanderthals approximately 30,000 years ago was caused by a transmissible spongiform encephalopathy, resembling kuru and “mad cow disease.”

While infectious diseases existed in the hunter-and-gatherer populations, many pathogens currently infecting humans have emerged with the development of agriculture. Evolution of the benign *Yersinia pseudotuberculosis* into the pathogen *Yersinia pestis* from 1,500 to 20,000 years ago, shortly before the first known pandemics of human plague, coincided with the development of agriculture that provided an abundant food supply for rodent hosts.

Several emerging, reemerging, and deliberately emerging infectious diseases have marked the past decades. Since 1976, over 40 emerging infectious diseases were

reported by the World Health Organization, and recent predictions estimate that from 10 to 40 new viruses will emerge by 2020. Certain infectious diseases, once presumed eradicated, have reemerged while others, historically confined to specific geographical areas, are surfacing in new locations. This was facilitated by a complex interplay of biological, social, political, and economical factors that include microbial evolution and adaptation, global ecosystem changes, human behavior, poverty, war, extremism, and intent to harm.

Ecosystem perturbations resulting from human activities often have far-reaching effects. The 1998 emergence of malaria in the Bure district in northwestern Ethiopia, a region that has not been affected for decades despite the presence of the disease in other locations in the country, coincided with the replacement of more traditional crops with maize in this area. Maize pollen represents an important nutrient for the larvae of *Anopheles arabiensis*, the main mosquito vector for malaria in the country, and larval mosquitoes were shown to develop more rapidly and produce larger adults in villages where maize pollen is more abundant. Restricting the plantation of maize in the immediate vicinity of homes or using genetically modified plants were proposed as important measures to control malaria.

Certain human interventions, despite intending to limit an outbreak, may have unpredictable effects. *Yersinia pestis*, the etiologic agent of plague responsible for several

pandemics throughout history, is spread among rats, which constitute the main reservoir, and from rats to other species, including humans, by fleas. Campaigns to eradicate rats were often followed by human outbreaks. This was explained, in part, by the fact that decreasing rat populations required infected fleas to find other organisms to survive, and thus, they more often bit and infected humans. More recently, human interventions, such as deforestation and urbanization, together with the growth of cropland that provides abundant food resources for rodents in deforested areas, changed the interaction between rodent and human populations and facilitated new plague outbreaks.

Certain infectious diseases come from the most unusual sources. For example, discarded vehicle tires provide a habitat for several mosquito species. Female mosquitoes lay their eggs inside moist tires, and the accumulating rainwater allows the larvae to hatch and subsequently develop into adult mosquitoes. The used-tire trade, a very profitable business, was linked to the worldwide spread of *Aedes albopictus*, a mosquito that represents a vector for at least 22 viruses and from its southeastern Asian origin has spread to North America, Europe, Africa, and South America. A study that examined over 4,700 used tires collected from roadside locations in Vietnam reported that over half of them contained water and 34% of those harbored mosquitoes, the majority of which were vectors for the dengue virus.

One of the most significant risk factors for infectious disease is the use of unsafe injections. Approximately 1.3 million deaths annually are attributed to hepatitis B and C and HIV that are transmitted by unsafe injections administered globally. In a study examining health care injections that did not include the ones performed as part of illegal drug use, Y. J. F. Hutin and collaborators estimated that in 2000, approximately 6.7 billion injections administered in several locations worldwide were unsafe. In addition, many investigators pointed out that a large percentage of injections performed worldwide are unnecessary. To understand the effect of unsafe injections, it is important to remember that the 1976 Ebola virus outbreak from Zaire, which infected 318 individuals and caused 218 deaths, was linked to unsafe injections and traced back to a patient who received injectable medication for fever.

Human infectious diseases are increasingly caused by zoonotic pathogens. These are pathogens that normally infect animals but occasionally acquire the ability to cross species barriers and cause disease in the human population. A recent review estimated that of 1,407 infectious agents that infect humans, 58% are zoonotic. Several conditions have to be fulfilled to initiate a zoonotic outbreak in humans and usually combinations of factors are required, of which crossing the species barrier is only one requirement. HIV crossed several times from animals to humans before it emerged as a pandemic. Human T-cell leukemia viruses (HTLV 1–4) emerged from their counterparts infecting nonhuman primates, and foamy viruses

from the same family repeatedly entered the human population. Ample evidence reveals that these viruses were transmitted during hunting and butchering that are part of a vast bush meat market in several African countries. As part of these practices, it is estimated that over 500 million wild animals are caught annually in the Congo basin, ape populations in Gabon declined by more than half between 1983 and 2000, and several species in western Africa have disappeared or are on the verge of extinction. N. D. Wolfe and collaborators termed this repeated transmission from animals to humans *viral chatter* and proposed that at high rates it can increase the diversity of viruses that cross species, facilitating the emergence of strains adapted to humans. For HIV, we know that viral entry into the human population was decisive but not sufficient. Other factors, including the sharing of contaminated needles, human trafficking, commercial sexual work, powerlessness among at-risk women in many countries and cultures worldwide, misinformation, risky sexual behavior, and the expansion of global mobility all made important contributions to the worldwide emergence of the pandemic and provide important lessons for future pathogens.

Deforestation

Human-induced land changes represent a major force driving the emergence of infectious diseases. Deforestation, which has been increasing over the 20th century and annually affects 2% to 3% of the forests worldwide, caused some of the major transformations in the global ecosystem. Within half a century, tropical forests have shrunk by half, a loss of approximately 9 million km², and several pathogens were linked to landscape changes.

Lyme disease, a bacterial infection caused by *Borrelia burgdorferi*, is the most common vector-borne disease in North America and is transmitted by ticks of the family Ixodidae. The white-footed mouse, *Peromyscus leucopus*, is the main natural reservoir for the bacterium. Several deforested areas have seen changes in the species composition: While certain species cannot survive, the white-footed mouse, which has a broad habitat tolerance, is not affected to the same extent, and its relative abundance increases. The “dilution effect model,” proposed by R. S. Ostfeld and F. Keesing, predicts that high species diversity dilutes the natural reservoir and reduces the infection prevalence of ticks. Any factor that decreases the representation of the white-footed mice, relative to other hosts in the community, would reduce the proportion of ticks that are infected. Therefore, one mechanism to reduce the prevalence of the infection is to reduce the relative abundance of white-footed mice. This can be accomplished by increasing the number of alternative hosts, which often are incompetent reservoirs. In support of this model, extensive evidence indicates that reducing the composition and biodiversity of host communities

increases the risk of human exposure to several vector-borne diseases. For example, L. J. Dizney and L. A. Ruedas (2009) revealed that in several forest areas in and around Portland, Oregon, the prevalence of sin nombre virus infection in deer mice (*Peromyscus maniculatus*), which constitute the main reservoir for this frequently fatal pathogen, drastically increases in areas with low mammalian species diversity.

Deforestation was associated with increases in malaria incidence in Africa, Asia, and Latin America. Several studies conducted in Kenya reveal higher outdoor and indoor temperatures in deforested areas, which together with other factors led to the increased vectorial capacity of mosquitoes, shorter development times of the parasite *Plasmodium falciparum*, and increased risk for human infection. The biting rates of *Anopheles darlingi*, the most important malarial vector in the South American Amazon basin, were more than 200-fold higher in sites experiencing extensive deforestation.

A Nipah virus outbreak that occurred in Malaysia between September 1998 and April 1999 was intimately linked to deforestation. In September 1998, several individuals associated with pig farming in Perak state developed acute encephalitis with a high mortality rate, around 38.5%. This was preceded by respiratory infection outbreaks among pigs within the same area. The infection spread to several states and to Singapore where it infected abattoir workers who handled pigs imported from the affected regions in Malaysia. The Singapore outbreak ended when pig importation stopped, and the outbreak in Malaysia subsided when infection control measures, including the culling of a million pigs, were adopted. Fruit bats of the *Pteroid* species represent the natural reservoir of the Nipah virus, and several factors were proposed to have contributed to the outbreak. This included massive deforestations from 1997 to 1998, which destroyed the natural habitat of fruit bats that, lacking their food supply, migrated from forests to fruit orchards. Pigs living around those orchards ingested bat saliva from partially eaten fruit infected with the Nipah virus, and the virus spread to domestic pigs and ultimately to humans.

Deforestation is just one of many environmental disturbances with a profound impact on infectious diseases. Other human activities, including agriculture and irrigation, significantly change the ecosystem. In 1985, a barrage was constructed at Diama to prevent seawater from entering the Senegal River and to make the river more suitable for irrigation. However, this changed water salinity and pH, which became more permissive for the growth of freshwater snails, the natural host of *Schistosoma mansoni*, a parasite that caused massive schistosomiasis outbreaks among people in the area. In the Thar Desert in northwestern India, malaria outbreaks were linked to mismanaged canal-based irrigation related to agriculture. And in Ethiopia, the incidence of malaria in children living within

3 km from dams was shown to be 7 times higher compared with children living from 8 to 10 km away.

Kuru and Creutzfeldt-Jakob Disease

In 1957, scientists studying the Foré people living in Papua New Guinea described, for the first time, a fatal progressive “neurodegenerative condition” called *kuru*, which from the local dialect translates as “trembling with fear.” Several pieces of evidence, including geographical clustering, distribution in age and sex groups, and local rituals to dispose of the deceased, revealed that this initially mysterious condition was transmitted by *endocannibalism*, also termed *transumption*, a practice in which the body of the deceased was consumed by relatives as a sign of affection and an expression of grief.

In some villages, kuru became the predominant cause of death among women. One of the early observations was that the disease mostly occurred in women and children: Men represented only 2% of the diseased while women represented 60%, and the remaining were children. This was explained by the endocannibalistic rituals in which women and children were the ones to consume the internal organs, including the brain, which contained the most infectious agents, while men never consumed these parts.

The main pathogenic feature of kuru is that, unlike in many other infectious diseases, the transmissible agent is an infectious protein called *prion*, which was isolated from the brain tissue of the diseased individuals and was shown to cause disease in experimental animals. The prion hypothesis proposes that the protein can exist under two forms, a noninfectious one, PrP^C, which is encoded by the host and can spontaneously be converted into an infectious form, PrP^{Sc}, a highly aggregated detergent-insoluble form that was extracted from affected brains. Once the infectious form is produced, it can transform noninfectious molecules into the pathogenic form. It is thought that PrP^C constantly undergoes minor conformational changes, and one or a few of the misfolded prion protein forms can associate and generate seed PrP^{Sc} structures, which leads to the autocatalytic formation of more PrP^{Sc}.

Examining the *PRNP* locus that encodes the prion protein revealed a polymorphism at position 129, which can encode either methionine (M) or valine (V). Individuals can be homozygous for either allele if they carry both chromosomal copies encoding the same amino acid (MM or VV) or heterozygous if each chromosome encodes a different amino acid at this position (MV). A study that examined Foré women older than 50 years, who repeatedly participated in endocannibalistic behaviors, revealed a drastic overrepresentation of the frequency of heterozygotes (MV) in this group as compared to other populations, indicating that being heterozygous provides resistance to the disease and a clear survival advantage. This polymorphism has a powerful influence both on kuru susceptibility and

incubation time. It is proposed that the practice of endocannibalism could have represented a selective force to eliminate homozygotes and select for heterozygotes, which were more resistant to the disease. One hypothesis is that the worldwide distribution of this polymorphism could very likely be the result of a constant exposure in our evolutionary past to animals that were constantly a source of prion disease or represent a testimony of endocannibalism in ancient populations. The polymorphism at position 129 results in one amino acid change (M versus V) in the protein and is thought to make protein-protein interactions more difficult between proteins that harbor this discrete change than between homozygous proteins, which aggregate more easily, explaining the selective advantage of heterozygous individuals.

More recently, in March 1996, another prion, causing the variant Creutzfeldt-Jakob disease (vCJD), attracted worldwide interest when it was reported that the progressive spongiform encephalopathy outbreak, discovered in cattle several years before, had spread to 10 humans. About 210 clinical cases were reported by late 2008, but due to the long and variable incubation, it is unclear how many people were infected. Importantly, all individuals who developed the disease are homozygous for methionine at position 129 of PRNP, which is one of the genetic susceptibility factors described. This human epidemic occurred in the wake of the bovine spongiform encephalopathy, or “mad cow disease,” that started to be reported a few years earlier in the United Kingdom. In 1986, a previously unrecognized progressive neurological condition was reported in cattle in the United Kingdom, with spongiform lesions appearing in the brain of the affected animals. Early during the outbreak, which is thought to eventually have infected 2 million cows, epidemiological investigations revealed that cases were reported from throughout the country, indicating the likelihood of a common-source epidemic rather than one that is propagated. The cause was proposed to be the meat-and-bone meal, a dietary supplement that was prepared from carcasses of sheep affected by scrapie and fed to cattle. *Scrapie*, a fatal neurodegenerative disease caused by a prion, has been recognized in sheep for about 250 years. This supplement was fed to dairy herds more often than to beef herds, and dairy herds exhibited a much higher incidence of the clinical manifestations during the “mad cow disease” outbreak. Feed manufacturers in the United Kingdom started introducing the meat-and-bone meal in the diet of dairy calves in the 1970s, a practice that was less prevalent or nonexistent in other countries. One step during the manufacturing process involved treatment with an organic solvent at 70 °C for 8 hours to extract fat. In the early 1980s, as many manufacturing plants reduced the use of organic solvents in this process, the fat content of the meat and bone meal increased significantly and is thought to have allowed prions, which are resistant to heat but can be inactivated by lipid solvents to maintain their infectivity. It is believed that prions have always been present in the

meat-and-bone meal, but were inactivated by the solvent treatment step, and changes in the manufacturing process made inactivation less effective, allowing it to cause disease. A ban on ruminant protein supplements, introduced in the United Kingdom in July 1988, led to the decline of the outbreak and confirmed the origin of the outbreak.

HIV and HTLV

For certain infectious diseases, it became clear that a multitude of factors facilitated the emergence and worldwide spread of these pathogens, and the HIV/AIDS pandemic provides an important example. Since 1981, HIV has caused an estimated 25 million deaths worldwide and was most recently implicated in 2.7 million new infections annually, becoming probably the most studied virus in history. Over 15% of the adult population is infected in Zambia, and as a result of the pandemic, life expectancy in Botswana decreased from 59 years in 1990 to around 44 years in 2003.

The mortality caused by the HIV/AIDS pandemic profoundly affected all aspects of biomedical and social sciences and even required that the validity of certain approaches that have classically been used in population studies be revisited. For example, since the infection often affects couples, mortality rates, usually determined from the number of deaths reported within a household, could be underestimated due to the disappearance of entire households, opening the need for implementing new demographic tools.

Two HIV types are currently known, and they differ in biology, epidemiology, transmission, and clinical progression of the disease. HIV-1 is distributed worldwide and responsible for the majority of disease, whereas HIV-2 is found mostly in Africa and India and is transmitted less efficiently. Extensive evidence, including molecular phylogenetic analyses, supports the view that HIV emerged from simian immunodeficiency viruses (SIV), their counterparts found in several species of nonhuman primates. HIV-1 originated from SIV_{CPZ}, a virus that infects chimpanzees (*Pan troglodytes troglodytes*) in western Central Africa and was introduced into the human population on at least three separate occasions, giving rise to the three phylogenetically distinct HIV-1 lineages, M, N, and O, present in the human population. HIV-2 was shown to have originated from SIV_{SM}, which infects sooty mangabeys (*Cercocebus torquatus atys*) and entered the human population on at least four different occasions. Most recently, a new HIV-1 strain, closely related to a virus that infects wild-living gorillas, SIV_{gor}, was described in a Cameroon woman and proposed to be designated group P. Chimpanzees and sooty mangabeys are hunted for food and kept as pets. Exposure to infected animal blood and tissues during hunting and butchering, animal bites, and the consumption of uncooked, contaminated meat were all proposed to have facilitated the cross-species transmission of the virus and its emergence in humans.

Cross-species transmission explains the origins of HIV but was not sufficient to establish a pandemic. HIV existed in humans for several decades before it emerged worldwide. Testing plasma samples collected in 1959 revealed that a male member of the Bantu tribe, who lived in Kinshasa, the Democratic Republic of the Congo, had anti-HIV antibodies, and the polymerase chain reaction subsequently amplified a fragment of the viral genome, confirming the infection. Phylogenetic analyses, using viral DNA isolated from a paraffin-embedded lymph node biopsy, originating from a patient in 1960 in Kinshasa, indicated that HIV could have infected humans between the late 19th century and the early 20th century. A constellation of additional factors was instrumental for the global spread of the virus. Some of them such as the high HIV mutation and recombination rates, compounded by its fast replication, are inherent to the biology of virus and make it one of the fastest evolving pathogens currently known. Most important, a complex interplay of cultural, social, economical, and political factors was instrumental in facilitating and fueling the pandemic. One of these factors, the high prevalence of other sexually transmitted diseases, particularly ulcerative ones, increased susceptibility to infection and continues to play an important role in HIV transmission worldwide. For example, gonorrhea and herpes infections both increase HIV transmission. Resistance to using condoms is often rooted in social and economic causes or in the advice of religious leaders with substantial influence in the respective communities and represents an important contributor to the pandemic. Several interview-based studies talk about the often-reported concern that requesting sexual partners to use condoms would bring distrust into the relationship. An established risk factor for HIV is the widespread use, in several African countries, of vaginal herbs that dry, contract, and heat the vagina to increase sexual pleasure but also create lacerations that increase susceptibility to infection. The worldwide crisis, created by an estimated 800,000 annual victims of human trafficking, 80% of whom are forced into becoming sexual workers, is compounded by the powerlessness of female sex workers in many countries and cultures. As biological, social, and economical factors made women in many countries more susceptible to infection, HIV incidence rates were reported to increase faster in females than in males in many locations worldwide. E. Esu-Williams (2000) described a "gender paradox" in relationship to HIV in Africa, pointing out that despite men often being the ones more likely to have multiple sexual partners, community stigma is directed toward women, who are blamed even when their young adult children become infected. The global mobility that made it possible to reach remote parts of the world within hours is another factor that greatly contributed to the HIV/AIDS pandemic. Due to the multitude of factors involved, it is becoming increasingly clear that medical and public health approaches are insufficient to address the pandemic, and adopting a combined perspective,

including cultural, social, and political interventions, is vital in managing the pandemic.

Contacts between humans and nonhuman primates were implicated in the emergence of another retrovirus, human T-cell leukemia virus (HTLV), with four representatives identified in humans. These viruses, together with their simian counterparts, STLV-1, -2 and -3, belong to the group of primate T-cell lymphotropic viruses (PTLV). HTLV seroprevalence varies worldwide. Over 10% of some populations in southern Japan and up to 5% in sub-Saharan Africa and several Caribbean and South American countries are infected. Infection rates are from 0.01% to 0.03% in the United States and Canada and even lower in Europe, with higher prevalence among immigrants from endemic areas and their families, intravenous drug users, and multiple-transfusions recipients.

HTLV-1, which was more intensively studied, is estimated to infect approximately 15 to 20 million people worldwide. While most infected people are asymptomatic, from 1% to 5% develop adult T-cell leukemia from 20 to 30 years after the initial infection, and others develop a progressive inflammatory neurological condition or rheumatoid arthritis. HTLV-2 is less pathogenic and was linked to neurological manifestations. It is unclear why certain individuals develop these severe medical conditions, while the majority of those infected remain asymptomatic. Transmission occurs by sexual activity, blood transfusion, contaminated needles, and from mother to child during breast-feeding and pregnancy.

Over 10% of the free-ranging primates in the rainforests of Cameroon harbor a variety of STLV strains, which were also identified in pet primates and in bush meat sold for human consumption. In fact, Africa is the only continent where all four viruses infecting humans, HTLV-1, -2, -3, and -4 and all three known simian counterparts, STLV-1, -2 and -3, were found.

Human HTLV infections emerged independently by the cross-species transmission, on several occasions, of their simian counterparts. N. D. Wolfe and collaborators reported that HTLV-1 strains, isolated from local villagers from Cameroon who hunted for primates, exhibited from over 97% to 98% identity at the nucleotide sequence level with STLV-1 isolates infecting free-ranging monkeys in the region. Bites and contact with the blood and body fluids of primates, during hunting and butchering, represent major risk factors that facilitate the cross-species infection of humans.

In addition to implications for human health, HTLV emerges as an important instrument in dissecting human history. In 1999, an HTLV-1 provirus was identified in a 1,500-year-old Andean mummy from northern Chile, and comparisons between several nucleotide regions of this virus and strains infecting present-day Japanese populations helped in understanding human migration from Asia to South America and reopened many questions, some of which are still controversial and insufficiently understood.

Influenza

Among microorganisms that reemerged periodically through history, an important representative is the influenza virus. In addition to annual outbreaks known as seasonal flu, which usually affect mostly the very young, the elderly, and individuals with underlying medical conditions, influenza regularly emerges in the form of pandemics that spread over extensive geographical areas and cause extensive morbidity and mortality in all segments of the population. The first influenza pandemic on which all authors agree occurred in 1580 and three pandemics, the 1918 to 1919 Spanish flu, the 1957 to 1958 Asian flu, and the 1968 to 1969 Hong Kong flu, occurred in the 20th century.

Three types of influenza viruses, A, B, and C, were described in humans. The single-stranded RNA viral genome contains 8 segments for types A and B and 7 for type C viruses, all required for infectivity. Two viral genes encode hemagglutinin and neuraminidase, the proteins that decorate the viral surface as “spikes” visible by electron microscopy. Hemagglutinin is crucial for viral attachment to host cell receptors during the initial stages of the infection, and neuraminidase facilitates the subsequent cell-to-cell spread of the virus. There are 16 hemagglutinin and 9 neuraminidase subtypes that represent one of the bases for classifying influenza viruses.

Two characteristics of the influenza virus are central to its ability to regularly cause disease. One of them, common for RNA viruses, is the high rate of errors during replication as compared to DNA viruses. The progressive accumulation of small errors in the influenza virus genome introduces subtle changes in the resulting proteins, a process that is known as *antigenic drift*, and occurs constantly in all three types of influenza viruses. As a result of these small changes, influenza viruses constantly gain the ability to reinfect individuals who already were infected during previous flu seasons.

A second type of change, called *antigenic shift*, that occurs more rarely, was described only in type A viruses and has by far more devastating consequences. The segmented influenza virus genome enables two viruses that coinfect the same cell to exchange one or more of their genes and create new viruses, a process known as *reassortment*. The 8 segments of two viruses can rearrange in 256 possible combinations, providing a great source of genetic diversity that confers new properties to the resulting strain. D. M. Morens and collaborators recently pointed out that it is more meaningful to think about influenza A viruses not as distinct entities but as “gene teams” that sometimes trade away one gene and gain new ones and acquire unique skills as a result.

The 1918 to 1919 Spanish flu infected 25% to 30% of the world’s population and caused an estimated 50 to 100 million deaths. Its origins are debated, but the virus was shown to harbor several segments originating from avian-like viruses. The virus responsible for the 1957 to 1958

Asian flu acquired three of its genes from viruses infecting wild ducks, and the strain that caused the 1968 to 1969 Hong Kong flu had two genes of avian origin.

The ability of influenza viruses from different species to undergo reassortment requires them to cross species boundaries. Despite widely held beliefs, human influenza viruses do not replicate easily in avian species, and avian viruses do not easily cause infection in humans. The biological basis of this host restriction is explained by the specificity of the interaction between *hemagglutinin*, which is the viral protein responsible for attachment, and *sialic acid*, which represents the influenza virus receptor on the surface of host respiratory epithelial cells. It was known for a long time that several types of sialic acids exist across species, but the significance of this phenomenon was not completely understood.

Human influenza viruses recognize sialic acid, which contain galactose bound by an α -2,6 linkage, and these receptors are found on human cells. Avian viruses have a predilection for sialic acid linked to galactose by α -2,3 linkages, and these receptors are mostly found on avian respiratory epithelia. This interaction is one factor that restricts influenza viruses to their respective species. However, sialic acid from pig tracheal-epithelial cells contains both types of linkages, and this explains their susceptibility to infection with both avian and human influenza viruses. Pigs are often described as “mixing vessels” that facilitate the reassortment of influenza viruses to generate new strains that infect other species.

Avian species represent the natural reservoir for type A influenza viruses. Both low- and high-pathogenicity viruses exist in birds, and mutations can convert low-pathogenicity strains into highly pathogenic ones. Ito and collaborators demonstrated that consecutive passages of an avirulent virus infecting wild birds can generate highly pathogenic strains with high lethality in chickens, accompanied by the progressive accumulation of basic amino acids at the hemagglutinin cleavage site, a widely reported feature of virulent viruses from several outbreaks.

Several influenza virus subtypes were documented in migratory waterfowl, particularly in wild ducks. In April 2005, an H5N1 influenza virus outbreak was detected among wild birds from the Qinghai Lake in western China, a major breeding site for migratory bird populations. Over 6,000 dead birds were found in this area over a 2-month period, and of several viruses that were isolated, all were lethal to chickens and most were highly lethal to mice. Moreover, between February and June 2006 over 2,400 dead birds were found in the region of Lake Constance, an important wetland habitat at the border between Germany, Austria, and Switzerland, and many tested positive for influenza A viruses. Several avian species exist at this location throughout the year, and many more migratory birds pass between October and March. Wild ducks infected with influenza viruses are often asymptomatic and were recently referred to as the “Trojan Horse” of H5N1 influenza.

In addition, Sharp and colleagues (1997) revealed that ducks can be co-infected with several subtypes of influenza A viruses, facilitating reassortment. Migratory birds should become a cardinal component of the global influenza virus surveillance. Wild birds can infect poultry and other domestic animal species, including pigs. This process is facilitated by habitat overlap, particularly in several Asian countries, where pigs and ducks are often raised in close proximity, and both are close to humans, facilitating reassortment and infection. Another practice that facilitates reassortment is the integrated pig-hen-fish farming where to reuse waste, pigs consume the feces of hens located in cages above them, and subsequently, pig manure is released into ponds situated below the pigsties. In this system, excess food from pigs and hens becomes available for the fish, and at the same time, their feces are used as pond fertilizers.

Several populations are at particular risk for influenza virus infections. These include individuals occupationally exposed to live poultry, swine farmers, and meat processing workers, who can be infected by the respective species and subsequently introduce the viruses in the community, exposing people who did not have direct animal contact. Surveillance, conducted at poultry markets in several countries, revealed that influenza viruses are present in live birds and/or meat products, and several studies that examined poultry and swine workers revealed that they have higher levels of antibodies against influenza viruses, indicating the potential to become occupationally infected.

Several reports described avian influenza virus infections in individuals who did not raise poultry and were not exposed in their neighborhood, and the only epidemiology-relevant events were visits to live bird markets within the days or weeks preceding the disease. Therefore, it appears that visits to poultry or animal markets are sometimes sufficient to become infected. In this respect, it is important to remember the role of feathers as a potential route of infection. Yamamoto and collaborators reported that viruses were able to replicate in the feather-epithelial cells of domestic poultry infected with H5N1 viruses, even in asymptomatic birds, opening the possibility that feathers can represent a source of infection. In fact, Marek's disease virus, a herpes virus that infects chickens, was previously shown to exist in high concentrations in many feather-follicle-epithelial cells, from sites where they can be shed into the environment. Certain human behaviors, such as increasing numbers of poultry kept in the vicinity of wild waterfowl, and extensive contacts between animal and bird species, and humans in and around the household and in wet markets, represent important risk factors facilitating influenza virus infections in animals and humans. Wet markets are live animal markets that sell poultry, mammals, and fish and animals reside in close proximity to each other and to humans, for days and sometimes weeks.

SARS

The first outbreak to attract global attention during the 21st century was the 2002 to 2003 severe acute respiratory syndrome (SARS) pandemic that infected over 8,000 people and claimed over 700 lives worldwide. The outbreak was caused by SARS coronavirus (SARS-CoV), a member of the coronaviruses, which includes representatives previously implicated only in mild respiratory infections.

The outbreak started in the Guangdong province in China, and the observation that many of the first patients in China were chefs or animal handlers raised the possibility that the outbreak involved zoonotic exposure. The initial investigation of animals from a market in Guangdong detected SARS-CoV-like viruses in several species, including palm civets, a raccoon dog, and a Chinese ferret badger. In addition, animal traders and workers involved in slaughtering animals at the same market had significantly more antibodies to the virus than did vegetable traders. The genomic sequence of two viruses isolated from palm civets had over 99% homology with viruses isolated from humans, revealing the possibility that market animals represent the source of human infections. Importantly, during the winter of 2003 to 2004, after the SARS outbreak ended, 4 new human cases were reported from the same province. Epidemiologic investigations linked two of the patients to a restaurant that served palm civets. One patient was a waitress who worked close to the animal cages located within the restaurant, and the other was a guest whose dining table was close to the civet cages. All six palm civets from the same restaurant tested positive for SARS; sequencing of the *S gene*, which encodes the "spike" protein that helps the virus attach to the surface of target cells on human or animal hosts, revealed that these civets were the source of the outbreak, as opposed to the continued circulation of SARS in the population. Civet cats thus emerged as a potential source that contributed to the SARS outbreak. Civets represent a culinary delicacy in southern China and this explains why food handlers, caterers, and chefs were overrepresented several-fold among the first victims during the outbreak.

However, while several subsequent studies confirmed that civets from animal markets harbor the virus, others failed to reach the same conclusion and reported that civets, particularly the ones growing on farms, were not infected. This pointed to the possibility that even though palm civets can harbor the virus, additional species could be involved. Taking into account that approximately 66 virus species were isolated from or detected in bats, the bat population was examined as a potential source of SARS. Two independent virological surveillance studies revealed that several species of horseshoe bats from China have high seroprevalence for a coronavirus that was called bat-SARS-CoV. Bats were able to support viral replication without becoming sick, indicating that they may represent the natural reservoir for the virus; sequence analysis of

several bat viruses revealed that they are closely related to viruses isolated from humans and civets. Subsequently, SARS-like coronaviruses were documented in bats from Europe, North America, and Africa. From bats, the virus can be directly transmitted to humans or first infect other species that subsequently infect humans.

The slaughtering of bats and the consumption of bat meat represent possible pathways for infection. Bat meat is considered a delicacy in Southern China and is believed to cure various ailments such as asthma, kidney conditions, and general malaise. Bat feces are sometimes used in traditional medicine in Asia. In many locations from southern China, such as the Guangdong province, considered to be the epicenter of the SARS outbreak, eating a wide range of wild animals, including civets and bats, is considered beneficial for general health and sexual performance. In many countries that have a centralized slaughtering system, contacts between the general population and animals are limited, and zoonoses usually emerge either occupationally among individuals who handle animals or recreationally among people who come in contact with animals in the wild. However, in other countries where people live close to the animal supply or regularly visit wet markets where several live species are sold and sacrificed in close proximity to humans, much larger segments of the population are exposed to the risk of zoonotic infections.

Foamy Viruses

Retroviruses, the same family that includes HIV, have a unique replication strategy as their distinguishing feature. These viruses harbor reverse transcriptase, an enzyme that uses the viral RNA genome to generate a double-stranded DNA molecule that becomes integrated into the host genome and subsequently replicates together with the host. Two retrovirus subfamilies exist: the Orthoretroviridae, comprising six genera and the Spumaretrovirinae, comprising one genus, the *Spumavirus*, or foamy viruses. *Foamy viruses* infect a broad range of mammals, including non-human primates, horses, cows, and cats. The highly vacuolated appearance of infected cells provided the name for these viruses.

Despite being discovered over 40 years ago, foamy viruses are still among the least characterized retroviruses. Of the seven known retrovirus genera, foamy viruses appear to represent the only exception to pathogenicity, and it is unclear whether this might change as new findings become available. The most studied representatives are simian foamy viruses, which infect nonhuman primate hosts and are thought to have coevolved with them for over 30 million years.

The first report of a foamy virus infection in humans was in 1971 when it was isolated from a Kenyan patient with nasopharyngeal carcinoma. The high amino acid similarity between this virus and a strain infecting

chimpanzees pointed toward its animal origin. High prevalence of foamy virus infection was reported among non-human primates, including rhesus macaques, African green monkeys, baboons, and chimpanzees. In all species, infection rates are higher among captive than free-ranging animals and in adults as compared to juveniles. Bovine foamy virus infections were reported in cows, and feline foamy viruses infect wild and domestic cats.

Animal-to-human transmission of foamy viruses can occur in two broad settings, occupational and recreational. Populations at risk for occupational transmission include zoo workers, veterinarians and laboratory workers in contact with primates, individuals involved in hunting primates, and employees in monkey temples. Owning primate pets, close contact with performance monkeys, ecotourism, and visiting monkey temples represent some of the routes facilitating recreational exposure. Calattini and colleagues reported that 1.8% of adults living in primate habitats from southern Cameroon had serological evidence of exposure, and N. D. Wolfe and collaborators found that 1% of individuals residing around primate habitats from southern Cameroon had antibodies against simian foamy viruses. W. M. Switzer and collaborators tested 187 lab and zoo workers recruited from five different institutions and revealed that 10 were infected.

Visiting monkey temples provides, worldwide, more human-primate contact opportunities than any other setting and increasingly emerges as a significant risk factor for infection. Taking into account that 700,000 tourists visit the four main monkey forests in Bali annually, M. Schillaci et al. estimated that approximately 2,100 visitors would become seropositive, and assuming that only 10% of them originate from North America and only 1% to 2% donate blood, they predicted 2 to 4 infected individuals would contribute to the North American blood supply at least once a year. These predictions were modeled based on only the four main monkey temples in Bali and did not take into account other sites on the island or in several other Asian and African countries.

Blood transfusion and organ transplantation represent potential transmission routes, but the risks are still unclear. A recent study reported that blood products transfused from an individual, confirmed retrospectively to be infected, did not infect any of the four recipients. Transplantation becomes relevant under two circumstances: Tissue and organ donors infected with foamy viruses could transmit the virus to recipients, and baboons used for liver transplantation could infect humans. In two human recipients of baboon liver transplants, simian viruses were identified in several tissues in the recipients. It is unclear whether human-to-human transmission can occur. Foamy viruses were not identified in blood samples collected from infected individuals' spouses, but very few individuals were examined so far.

The involvement of foamy viruses in human disease is controversial and unclear, and this, too, is partly due to the small number of reports. There is a contrast between the

in vitro ability of foamy viruses to induce rapid cytopathic effects in several cell types, and their apparent lack of pathogenic effects in infected individuals. While some studies implicated foamy viruses in Graves' disease, de Quervain thyroiditis, multiple sclerosis, amyotrophic lateral sclerosis, and myasthenia gravis, other reports did not replicate these associations, and many authors reported nonspecific or age-related symptoms among foamy virus-infected individuals. However, mice infected with various combinations of foamy virus genes were reported to develop neurodegenerative conditions.

It will be important to understand whether foamy viruses are linked to medical conditions in humans or whether they persist in the genome without causing disease. A third scenario, which deserves serious consideration, is also possible and becomes relevant, particularly when considering the recent report of the first two human co-infections with HIV-1 and simian foamy viruses in a blood donor from Cameroon and a commercial sex worker from the Democratic Republic of the Congo. Foamy viruses could shape other viral infections. Reports showing that foamy viruses make human T-cells become more permissive for HIV-1 binding and cell-to-cell transmission, together with mouse models indicating that foamy virus transcription factors can activate HIV in certain tissues, strongly support this possibility. Under this third scenario, even if foamy viruses turn out not to cause disease on their own, they could well become the pandemic that shapes another pandemic.

PART VI

METHODOLOGY

DATING TECHNIQUES

TORI M. SANEDA

Cascadia Community College

Situating things in time and space is critical for archaeology and paleoanthropology. Knowing when something happened helps us to understand how humans and cultures evolved. From John Lightfoot and Bishop James Ussher, who calculated the age of the earth using genealogies in the Bible, to Willard Libby, who developed radiocarbon dating and beyond, researchers have been working to establish a chronology of the past.

Absolute, or chronometric, dating techniques provide us with measurable dates—day, year, millennia, for example. Relative techniques provide a basic order to material recovered from a site; they give us an idea of its age—how old something is in comparison to something else. This chapter will cover a few of the techniques from each category. It is not meant to be a comprehensive overview of all dating techniques nor provide an in-depth discussion of the techniques. It is meant to be an introduction to some of the dating techniques available to archaeologists and paleoanthropologists.

Relative Dating Techniques

Relative dating techniques provide the researcher with an order of occurrence but not an absolute date—it is an age in relation to something else. Even though it does not provide a calendar date, it does not mean that the techniques are not important or useful. For sites where it is impossible

to recover the appropriate material for absolute dating techniques, relative dating is critical. It can also be used to make connections between sites and artifacts across time and space, as well as to examine site formation processes. Stratigraphy and the index fossil concept are the cornerstones of relative dating, providing a foundation for subsequently developed relative methods.

Stratigraphy

In geology, *stratigraphy* deals with the classification and mapping of observable units that form the earth's crust, using rock description, classification, and interpretation. Archaeologists use stratigraphy to establish relationships in time between artifacts and features. As such, stratigraphy is the cornerstone of archaeology.

Stratigraphy, or stratigraphic dating, is based on the assumption of the law of superposition. First noted by Nicolas Steno (1638–1686), the law of superposition states that geologic strata are progressively older the deeper one goes. Steno observed a layer of shell beneath ancient Rome and posited that it must be older than the ancient city since it was beneath the city. He reasoned that particles in a fluid would be laid down in distinct horizontal layers (strata), an effect he called the principle of original horizontality. For example, let us say that a layer of sediment, or strata, heavy in clay content is laid down (Strata 1). Perhaps through a flood, a layer of organically rich sediment with pebbles is laid

down on top of it (Strata 2), and then perhaps another layer of sediment (Strata 3) is laid down, and so on. In this example, Strata 1 is the oldest, Strata 2 is younger than Strata 1 but older than Strata 3, and so on. This may seem common sense to us today; however, it was a new idea in the 1600s.

The principles of stratigraphy established by Steno provided the first relative dating technique. Using the earth's own strata, it became possible to place things in the order they were deposited. Early attempts at establishing stratigraphic chronologies centered on stratigraphic observation—the noting of artifacts in relation to strata. John Frere (1740–1807) used the method to order stone tools found with extinct animal fossils, and Christian Thomsen (1788–1865) developed the three age system for Stone Age Europe. Boucher de Perthe (1788–1868) was the first archaeologist to employ stratigraphic observation in conjunction with archaeological excavations, ensuring stratigraphy's vital role in archaeology.

Stratigraphic observation and stratigraphic excavation differ in that stratigraphic observation is simply noting the occurrence of artifacts within geologic strata. Stratigraphic excavation requires the archaeologist to excavate a site using stratigraphic levels. This can be done in two ways: (1) arbitrary levels and (2) natural levels. An archaeologist may excavate a site in arbitrary levels: 10-cm- or 20-cm-deep levels, for example. Once sterile soil, or a level without artifacts, is reached, archaeologists note the various stratigraphic levels on the wall(s) of the excavated unit, generally in the form of a profile. A profile is created by drawing the observed strata using a line level and tape measure. Excavation using natural levels can be accomplished in a couple of ways. One way is to dig until you hit a change in the soil type. The other way is to divide the excavation unit into smaller segments—in half or quarters, for example. One segment is excavated using arbitrary levels. The next segment is excavated using natural strata based on the profile exposed when digging by arbitrary levels.

Archaeologists generally use basic stratigraphic methods: the observation and recording of the various strata, particularly noting soil composition and color as well as artifact content. Recently, some archaeologists have employed specialized stratigraphic measures developed by geoscientists in order to create deeper analyses: lithostratigraphy, which examines the composition of strata; biostratigraphy, which examines the fossils contained within strata; and chronostratigraphy, which looks at the age of rocks. Geoarchaeologists suggest a new unit of study: ethnostratigraphy, which is similar to the biostratigraphic unit but is focused on cultural artifacts instead of fossils. Ethnostratigraphy is not widely used because there is no standard of classification as there is with fossils.

Index Fossil Concept/Time Markers

William Smith (1769–1839), a British geologist, observed that fossils found in various strata indicate that

life forms changed over time. He demonstrated that by using these differing life forms, it was possible to associate strata from different places with one another. If the same life forms were found in the strata at two different places, then the assumption is that the strata were laid down at the same time. Smith's ideas are now known as the *index fossil concept*.

This concept was successfully adapted to archaeology by substituting artifacts for fossils. These artifacts, known as *time markers*, represent particular time periods. Oscar Montelius (1843–1921), Flinders Petrie (1853–1942), and Nels Nelson (1975–1964) used the principles established by Smith to date a variety of sites in Europe, Greece, and the North American Southwest. Montelius, a Swedish archaeologist, used the method to establish time markers for Neolithic, Bronze, and Iron Age Europe. Petrie used time markers from Egypt on Heinrich Schliemann's Mycenaean sites in Greece to establish dates. Nelson applied the methodology to pottery found at the San Cristobal site in New Mexico, establishing a master sequence that was used later by Alfred Kidder (1876–1960) in his development of a culture history for the North American Southwest. Nelson's work is especially important, as he carefully excavated a portion of the site, combining stratigraphic excavation with the time marker concept to create a relative order of occurrence for the pottery. This enabled archaeologists to track culture change over time.

The index fossil concept has become important for paleoanthropology, specifically for sites where no material exists for radiometric dating. In southern Africa and Chad, fossils are compared to fossils from sites in eastern Africa where radiometric dates were acquired.

Seriation

The index fossil concept is the basis for *seriation*. Popular in the mid-20th century, today seriation is used when chronometric techniques are not applicable. It is like the index fossil concept in that it uses time markers to establish chronological sequences; however, it differs in that it not only traces stylistic change over time but also examines the frequency of occurrence of the artifacts in question. It can be used on any type of artifact, but it is most commonly used on pottery and ceramics, as those artifacts are ubiquitous in the archaeological record.

Seriation is based on the assumption that cultural styles change over time. A master sequence of the frequency of use can be established to correlate sites with one another. This allows archaeologists to compare occupation sequences among sites in a region and track the popularity of styles across time. The frequency of occurrence, or popularity curve, is charted, creating a graphic representation that resembles the plan of a battleship. These curves are then compared to establish relationships between sites.

The methodology became progressively more quantitative in nature over time, where statistical measures were

used to track changing artifact attributes (characteristics), helping to refine seriation sequences. Seriation becomes a particularly robust technique when correlated with chronometric dates. In the North American Southwest, ceramic sequences have been correlated with tree-ring dating, which validates the seriation sequences established.

Amino Acid Racemization

Amino acid racemization was first observed in 1884; however, it was not until the 1950s that the process was recognized as a potential dating technique for fossils. In the 1970s, the technique was applied to archaeological artifacts, such as bone, mollusk shell, teeth, and avian eggs. At first glance, it would appear that amino acid racemization should be a chronometric technique, but for reasons outlined below, it is included with relative dating techniques.

Proteins are formed from amino acids that occur in one of two molecular patterns: L-enantiomer (L-types) and D-enantiomer (D-types). In living organisms, the L-type pattern is the most common, almost to the exclusion of the D-type pattern. This means that the organism is optically active (during the interaction of the amino acid with polarized light, the organism will rotate in the direction in which the light is vibrating as it passes through them) for the L-type molecules. Having only one type is thermodynamically unstable, so over time the amino acids will change until they are optically inactive, which means that the ratios of L-types and D-types reach an equilibrium, a process known as *racemization*. The rate at which the amino acids become optically inactive can be used to calculate an age for the artifact up to several million years. However, calculating an age is dependent on the rate of racemization, which in turn is affected by a number of factors, the most prevalent being the environment. If the temperature history of a site is unknown, then ages cannot be calculated. If items are from the same site, then one can assume that they share a temperature history and can be relatively dated with one another using the degree of racemization. Since it is difficult to determine the temperature history of an item, the relative technique is usually employed.

Fluorine Dating

Fluorine is a reactive chemical found in several elements, most importantly in ground water for archaeological and paleoanthropological purposes. As ground water leaches into materials, especially siliceous rock, bone, and teeth, fluorine ions replace calcium-based minerals. Fluorine ions are extremely reactive with other materials. This means that once it replaces minerals in an object, it is fixed in the material and begins to accumulate over time. The rate of fluorine accumulation can be measured and compared to objects from similar environments to construct a relative chronology.

Fluorine dating is dependent on the amount of fluorine in ground water supplies; therefore, the artifacts being dated must be from similar environments, if not the same, to establish an accurate chronology. The density of the material can also affect fluorine dating. Dense material absorbs fluorine ions more slowly than porous or spongy material. This can be corrected for by comparing the fluorine content to the phosphate content of the object.

Uranium (U) and nitrogen (N) testing can be done in conjunction with fluorine (F) dating to further refine the chronology. This technique, *F-U-N dating*, was used successfully to identify the Piltdown skull as a hoax. In 1911, fragments of a hominid skull and other vertebrate bones were found in England. Subsequent excavations recovered pieces of a human skull that had both modern and apelike characteristics. Fluorine analysis was applied to the skull bone, as well as to some of the vertebrate bones found associated with the human bone. These tests indicated that the cranial bones were much older than the jaw bones.

Patination

Rocks such as flint, basalt, andesite, and other fine-grained rocks that are exposed to moisture will develop a *weathering rind*, or *patina*. Over time, the rind pushes itself into the unweathered rock. Where the weathering processes are known, the rind may be used to calculate a sequence for a site, from as few as a couple of years up to around 500,000 years. For this method to work accurately, only rocks that have been exposed to the same environmental conditions should be compared. Since this can be difficult to determine, sequences should be verified using another dating technique if possible. In some cases, the patination can be used to calculate an absolute date—for example, obsidian hydration dating (see below for discussion).

Rock varnish is formed when clay elements bond with manganese and/or iron oxides on rock surfaces. The layers of varnish provide environmental information and can be used to estimate when the rock surface was first exposed to weathering. Many different patination techniques have been developed, including trace element trends, metal scavenging, and orange bottom varnish growth; however, they have not been used with much success. The cation-ratio (CR) dating method, on the other hand, has yielded some relative chronologies for rock—stone tools from sites in semiarid and arid conditions, for example.

Cations are positive ions that are impacted by various leaching processes. Cation-carrying clay materials are blown onto the rock surfaces where they chemically react with minerals of varying mobility to form a patina or varnish. It is known that cations of potassium + calcium/titanium decrease with age; hence, a relative chronology can be established by comparing the ratio of mobile cations to immobile cations. This method cannot provide a manufacturing date for a stone tool; it only tells us about how

long ago the rock varnish began to accumulate. CR chronologies need to be calibrated by using absolute dating methods, such as potassium-argon dating or radiocarbon dating. Once a chronology is established for a site, it can be used as a master sequence for relative dating purposes.

Palynology

Pollen analysis, or *palynology*, is another relative dating technique, as well as a method of environmental reconstruction. Developed in 1916, pollens found in lake sediments and ice cores can be used for cross-site comparisons to establish a chronology. When comparing two sites, if layers in the pollen diagram are similar, then we can infer that the sites were occupied at the same time. Concomitantly, we can reconstruct what types of plants were available in the local environment as well as develop a picture of the climate. For example, if there is a plethora of tree pollen, then the climate was warm. Pollen analysis is in effect a form of biostratigraphy.

Varve Analysis

Varves are annual series of sediments deposited in still bodies of water—a glacial lake, for example. Varves form seasonally. In winter, when glacial meltwater is reduced or stopped altogether, clay material slowly settles to the bottom of the lake, and during spring and summer, silt and sand are deposited, creating a series of dark (clay) and light (silt and sand) layers. This layering effect is sometimes referred to as laminated sediment. A chronology can be established by counting the varves and then correlating the thickness of varves across sites. Long chronologies can be established by following the tract of retreating glacial ice. Varves closest to the glacier are younger than those farther away.

Over the past century, scientists have found that one of the main problems with varve analysis is that it is possible that years can go missing due to natural processes. Therefore, it is necessary to recognize that the dates calculated using this methodology are minimum ages and whenever possible should be correlated with absolute techniques, such as dendrochronology. In addition to chronology building, varve analysis is useful for environmental reconstruction.

Chronometric Techniques

Since the 1940s, a plethora of *chronometric*, or *absolute*, dating techniques have been developed; these techniques are increasingly more accurate and help us to refine the chronological sequence of the past. In this section, we will look at several different types of chronometric techniques: natural rhythmic and chemical change, radiometric, and trapped charge dating.

Natural Rhythmic and Chemical Change Techniques

As the name implies, *natural rhythmic* and *chemical change techniques* measure either an inherent chemical change in an object or natural cycle. It neither relies on radioactive decay, as do several other prominent chronometric techniques, nor does it rely on energy emission. In this section, we will look at astronomical dating, dendrochronology, obsidian hydration, and archaeomagnetic dating techniques.

Archaeomagnetic Dating

Archaeomagnetism, a subfield of paleomagnetism, is both a chronometric dating technique and a relative dating technique. It is predicated on the fact that the earth's magnetic field changes periodically. Archaeomagnetism, which can date sites up to 100,000 years, can be used on baked clay, geological sediments, and igneous rocks. Appropriate samples are the key to getting a good archaeomagnetic date. *In situ* features must be used—kilns and hearths, for example—and the orientation retained. This is accomplished by establishing the orientation with a compass or transit, and then encasing the sample in plaster or fastening it to a plastic disk. Once the qualities of the natural remanent (permanent) magnetization are known, the direction of the ancient magnetic field can be determined.

About every 250,000 years, the polarity of the magnetic field flips or reverses. This reversal lasts approximately 10,000 years. In between the times of reversals, magnetic fields change approximately 1° every couple of decades at any given point on earth, with a maximum variation of roughly 20° (as it moves around the geographical north pole). This is called *secular variation*. This information coupled with the knowledge that some minerals (e.g., ferromagnetic minerals) have a remanent magnetization allows archaeologists and geologists to date sites.

Astronomical Dating

Archaeological data suggest that many ancient societies tracked the movement of the stars—for example, the Maya—and aligned structures with significant events, such as solstices and equinoxes at Stonehenge. Sometimes these data can be used to date buildings. Ancient Egyptian texts, for example, mention astronomical events, enabling Egyptologists to correlate historical events with calculable astronomical events. Based on information in Middle Kingdom and New Kingdom texts, archaeologists have been able to determine that the Egyptian calendar was based on 3 seasons, each consisting of 4, 31-day months, with 5 days left over. These months were anchored to astronomical events, such as when Sirius becomes visible above the eastern horizon, an event known as a heliacal rising, which happens to coincide roughly with the annual flooding of the

Nile in July. This event heralded the Egyptian New Year. Using information from Roman histories, we know that the Egyptian New Year and the heliacal rising of Sirius occurred in CE 139. Because we know the length of the period between heliacal risings and how it relates to the Egyptian calendar, it is possible to correlate a date mentioned in an ancient text with a date that is understandable to the modern archaeologist.

But what if no such texts exist, as is the case for the Old Kingdom? A relatively new method of dating, *precession dating*, has been used to date Old Kingdom features, such as the pyramids of Giza. To understand what precession is, think of a spinning top—If it is spinning fast enough, then it will not fall over and the tip stays in one spot. As it begins to slow down, the tip no longer stays in one spot; it begins to loop outward in a somewhat horizontal circle; that motion, the path of the tip, is called the precession.

How does this work for archaeology? Earth's precession can be traced over time. We know that currently the earth's axis is centered on a celestial pole around the star Polaris. We also know that the celestial pole itself moves around a pole centered in the Draco constellation and approximately how long it takes for this move to occur. Since these are known quantities, it is possible to calculate where the celestial pole was relative to stars at any given time in the past. Using this information, the changes in the alignment of the pyramids of Giza have been correlated with the earth's precession.

The pyramids at Giza as well as Snofru's pyramids at Meidum and Dashur are all aligned with the cardinal directions, each with an error of approximately < 1 degree off the previously built pyramid. For example, the Bent pyramid at Dashur, which was built after the pyramid at Meidum, has an alignment that is < 1 degree off of the Meidum pyramid, and so on. Since the Turin papyrus informs us as to how long various kings ruled, it is possible to estimate the duration of the construction of each pyramid, giving us a relative chronology for the pyramids. However, when this information is combined with information on the earth's precession, it is possible to assign calendar years to the construction of each pyramid.

While more testing is needed to see if other Egyptian pyramids conform to the pattern established by the aforementioned pyramids, the methodology does offer the prospect of dating archaeological deposits for which ancient texts do not provide the necessary information.

Dendrochronology

The science of tree-ring dating, or *dendrochronology*, was developed by Andrew Ellicott Douglass in the early 20th century. Douglass discovered that the ring-width patterns of different ponderosa pines were identical. To build a chronology for the North American Southwest, stretching from prehistory to modern times, he compared remains of ponderosa pines across sites based on the assumption that

tree rings of the same width were formed in the same year. Counting the number of tree rings provided the number of years that had passed since a tree was cut down. Today, dendrochronological sequences exist for other regions, including the southeastern and temperate United States, Western Europe, the Mediterranean, Australia, New Zealand, parts of Asia, southern Africa, Tasmania, and southern South America.

Dendrochronologists use cross-dating and chronology building. Cross-dating is the process of matching the ring pattern variability between samples. The process of building the dated ring sequences from the samples is called chronology building. Dendrochronology works by using a sample from a living tree and then working backward, overlapping samples until reaching the desired sample, often a piece of dead wood. Then, it is a matter of counting rings to determine the number of years that have passed.

Dendrochronologists use width and density of the rings as well as fire rings and frost rings to cross-date the samples. Dendrochronology has many applications and is useful in multiple disciplines, including oceanography, art history, and botany, to name a few. It has become a staple dating technique in archaeology; however, it is applicable only in areas where appropriate trees are available. Archaeologists also use tree rings to examine human behavior—tree use and environmental reconstruction, for example.

Obsidian Hydration Dating

From the moment it is formed, obsidian, a volcanic glass, will begin to absorb water from the atmosphere. A rind, or adherent hydrated layer, is formed and thickens over time. The density and refractive index of the rind is higher than the original glass, making it easily discernable from the original. The amount of time needed to create the rind's thickness is calculated using information on the chemical composition of the glass, as well as the relative humidity and temperature of the environment. Because a rind can form in only a few hundred years, *obsidian hydration* can be used on relatively young samples, as well as samples around one million years old. Thus, we can use the method to determine when an artifact was manufactured.

Errors in the measurement of the rind and determining the rate of hydration can cause errors in age determination. If the relative humidity of the environment of the site where the artifact was found is significantly less than 100%, then an additional correction must be made to calculate a date. This can be done in a couple of ways: (1) Use the rind thickness in conjunction with an artifact dated by using another technique such as radiocarbon dating, and (2) induce hydration experimentally. Most researchers use obsidian hydration and a second or third or more dating method to determine the accuracy of the obsidian hydration dates.

Obsidian hydration can also be used as a relative dating technique if only the chemical composition of the sample

is known. The chemical composition can be compared to samples found on other sites in order to determine occupation contemporaneity.

Radiometric Techniques

Radiometric techniques rely on the fact that unstable, radioactive isotopes decay over time into a different isotope. Through experimentation, the half-life, or the amount of time it takes for half of the original radioactive isotope to turn into a different isotope, of these unstable isotopes is known and can be used to calculate the age of the material. There are a variety of radiometric techniques; however, we will focus on those commonly used in archaeology and paleoanthropology: radiocarbon dating, fission track dating, potassium-argon/argon-argon dating, and uranium-series dating.

Radiocarbon Dating

Radiocarbon dating (^{14}C) is the backbone of chronometric archaeological dating. Developed by Willard Libby and a team of scientists at the University of Chicago in the mid-1940s, ^{14}C can be used to date organic material up to around 45,000 years. It provides a date for when something died and stopped taking in carbon.

Carbon-14 is created when cosmic radiation in the upper atmosphere produces a neutron that replaces a nitrogen-14 (^{14}N) proton. From there, ^{14}C is oxidized, which means it is attached to oxygen, to form carbon dioxide, which eventually makes its way into the earth's oceans and plants. When herbivores or omnivores eat plants, they take in ^{14}C . Carnivores and omnivores also take in ^{14}C when they eat herbivores. Once something dies, it stops taking in carbon and ^{14}C decays back into ^{14}N . Based on Libby and others' work, we know that the half-life of ^{14}C is 5,730 years.

The amount of ^{14}C in a sample is estimated by the amounts of the stable carbon isotopes, carbon-12 (^{12}C) and carbon-13 (^{13}C). A carbon molecule is comprised of around 99% ^{12}C and 1% ^{13}C . Only one in a million million atoms are ^{14}C . Once this estimation is made, we can measure the amount of ^{14}C in the sample and determine how much ^{14}C has decayed and how long it took.

When a date comes back from the lab, it tells us how many radiocarbon years old the sample is in relation to 1950 (the year the method was invented). The date returned is associated with a \pm number, which is the standard deviation for the number of times the lab ran the tests. For example, if the lab returned a date of $4,110 \pm 50$ BP (before present or rather before 1950), then we would say the sample stopped taking in ^{14}C between 4,160 and 4,060 radiocarbon years BP.

There are a few problems associated with ^{14}C dating. Carbon from the surrounding soil matrix can leach into organic material such as bone, obfuscating the correct date. A second problem involves the reservoir effect. The

reservoir effect refers to the problem of samples from aquatic sources, for example, mollusk shells. Radiocarbon dating was developed using atmospheric carbon; in water, carbon disseminates much more slowly, so it builds up in the material (a reservoir of carbon). For marine samples, that means the ^{14}C date could be hundreds of years too young. What the reservoir effect is for riverine samples is as yet unknown. A side effect of the reservoir effect is that dates for the bones of peoples who relied on marine and riverine resources for their primary subsistence could be off. Context of the sample then becomes important. If the lab is acquainted with the context of the sample and any other pertinent background information, then the reservoir effect can be corrected.

Another problem is that organic material takes in carbon in different manners. Not all plants take in carbon in the same way. Plants that live in arid and semiarid regions, with the exception of succulents, convert carbon dioxide into a 4-carbon compound. This means that these C_4 plants take in more oxygen than all other types of plants. If plant remains are not identified, then radiocarbon labs cannot make the appropriate corrections, and the plants will appear younger than they really are.

Radiocarbon dating was made more accurate through tree-ring studies where it was noted that ^{14}C dates and dendrochronological dates did not match. It was discovered that one of Libby's assumptions was wrong, ^{14}C production was not constant. Studies of bristlecone pine indicated that there were over a dozen changes in ^{14}C production over the past 10,000 years, most likely due to sunspot flare-ups. Corrections can now be made for this phenomenon known as the de Vries effect.

Accelerator mass spectrometry (AMS) links two technologies, particle acceleration and mass spectrometry, to push the date range of ^{14}C back to 55,000 years. This method directly counts carbon ions. One of the primary advantages of AMS over standard ^{14}C -dating techniques is that a much smaller sample can be used, thereby destroying a lesser amount of the artifact. Additionally, testing does not take as long as standard ^{14}C tests. While it was hoped that AMS would extend radiocarbon dating to around 100,000 years, the ability to prepare the samples without contamination from modern carbon still prohibits calculation of such a date.

Fission Track Dating

Fission track dating was developed in the 1950s and is based on the fact that as uranium 238 decays, it fissions and leaves tracks as the fragments move through parent material. The track density along with the amount of uranium present in the sample enables an age to be calculated. Thousands of tracks are counted; therefore, a large amount of ^{238}U is needed. The best materials for fission track dating are igneous materials, such as natural glass—obsidian and zircon.

One problem associated with fission track dating is that if the material is heated to a sufficiently high temperature, then the fission tracks can fade, making the sample appear too young; however, separating the sample into aliquots (equal parts of the original sample), and inducing fission tracks in one of the samples, creates a comparative method that allows fading to be corrected for. The step-heating plateau method is another way to correct for fading. Experiments have demonstrated that the density of tracks in an area (areal track density) of a natural sample is proportional to the track density in its irradiated aliquot. When both a natural sample and its irradiated aliquot are heated to a temperature where the areal track density of the samples reaches a plateau, the ratio value between the two samples increases until it reaches a plateau. The value of the ratio at the plateau can be used to correct for track fading. Similarly, the isothermal plateau technique, whereby a sample is heated at a constant temperature for a long period of time, allows for the correction of track fading.

Potassium-Argon Dating and Argon-Argon Dating

While first used to date hominin fossil deposits, *potassium-argon (K-Ar)* and *argon 39-argon 40 (Ar-Ar)* are now used in the natural sciences to date events back to the Precambrian era. K-Ar dating measures the buildup of decay of radioactive potassium 40 (^{40}K) into argon 40 (^{40}Ar) in volcanic and metamorphic rock. Potassium 40 is an unstable isotope. During the decaying process, one of its protons converts to a neutron. This process produces a ^{40}Ar atom, the quantity of which can be measured and a date calculated for when the rock cooled. Radioactive ^{40}K has a half-life of 1.28 billion years, making it more useful to paleoanthropology than radiocarbon dating with its limited dating range; however, K-Ar dating loses accuracy the younger the material. Radiocarbon dating can fill that gap.

Argon 40 is a noble gas, which means that no chemical bonds are formed when it comes in contact with other elements. Since noble gasses can escape from molten lava, it is assumed that when the rock cools, there is no ^{40}Ar left. Any ^{40}Ar present in the sample must then have formed after the rock cooled and became trapped. There are some conditions that can affect the accuracy of the date. Argon-40 could be trapped in the lava flow in unmelted rock. It is also possible that the rock was reheated, allowing ^{40}Ar to escape. Both of these instances would cause the date to be inaccurate.

Argon 39-argon 40 (Ar-Ar) dating can be used to date the same types of material as K-Ar dating. In this method, the measurement of ^{39}Ar is substituted for potassium. The primary difference is that the sample is irradiated at a nuclear reactor, which produces ^{39}Ar , an isotope not produced in nature. The irradiation processes cause ^{40}Ar and ^{39}Ar to be released from the rock sample. The quantity is then measured using mass spectrometry. Ages are calculated by comparing the ratio of $^{40}\text{Ar}/^{39}\text{Ar}$ to a standard ratio of a known age that is irradiated at the same time as the sample.

The advantage of Ar-Ar is that it does not have to rely on a separate K measurement; it measures Ar in a single sample. Additionally, a smaller sample can be used. It is more precise because the release of Ar is controlled through the application of increasingly higher temperatures.

Uranium Series Dating

Using the known half-life of several uranium isotopes, the ages of archaeological sites can be determined using the *uranium series (U-series) method*. Since uranium occurs naturally in material such as marl, caliche, carbonates, speleothems (e.g., stalactites and stalagmites), travertine, mollusk shells, eggshells, bones, teeth, and other materials, the technique is useful for archaeologists, especially for sites older than the upper range of radiocarbon dating.

There are three series of decay associated with U-series dating, only two of which are appropriate for archaeological purposes: (1) uranium series, ^{238}U with its decay products, and (2) actinium series, ^{235}U with its decay products. The third series, thorium, or ^{232}Th , and its decay products, is useful for dating geological events. The basic principle of U-series dating is that there is a decay chain that eventually ends in a stable isotope, lead 206, which is associated with ^{238}U , and lead 207, which is associated with ^{235}U . While the length of time that it takes for uranium to decay into lead is longer than the time frame for human evolution, the length of time for some of the decay products does fall within that time frame, thereby making the dating method useful for anthropology.

U-series dates for archaeological sites are determined in a couple of ways. At some cave sites, for instance, the archaeological material itself is not datable using the U-series method; however, speleothems in the cave are datable. Archaeologists can create an age range for the cultural material by dating speleothems above and below the deposit. Another way is to date the artifact itself such as bone or teeth. One problem with the latter is that bones and teeth not only absorb uranium during their formation but also can absorb uranium from the deposition environment, skewing its age. Reconstructing the U-uptake history of the artifact can mitigate errors that might occur because of the deposition environment.

Trapped Charge Dating

Trapped charge dating involves methodologies that measure trapped charges in a mineral such as feldspar or quartz. Background radiation causes the electrons of some atoms to change in a manner that causes them to become trapped in the flaws of the crystalline structure of minerals. The amount of trapped electrons increases over time and can be used to estimate the radiation dose of the object, which can then be divided by the annual dose of radiation to determine the specimen's age. In this section, we will

examine the three types of trapped charge dating used in archaeology: thermoluminescence, optically stimulated dating, and electron spin resonance.

Luminescence

Luminescence dating techniques, thermoluminescence (TL dating) and optically stimulated dating (OSL dating), measure the changes to the structure of crystals contained in minerals caused by exposure to natural background radiation. Developed during the late 1960s and 1970s, luminescence dating provides a way for archaeologists to date sites that radiocarbon dating cannot, as it is accurate up to 100,000 years, and perhaps as much as 300,000 years.

TL dating can be used on material that contains minerals such as feldspar and quartz that emit a light when heated quickly to 500° C—pottery, bricks, burned stone, flint, and so on. As an artifact is “exposed” to natural background radiation, electrons are released from the crystalline structure and caught in flawed parts of the structure, sometimes referred to as trapping sites or lattice deficiencies. This accumulation of background radiation in natural material must be zeroed for it to be useful for archaeological dating. Zeroing occurs when the natural material is fired. This releases the electrons that had already accumulated in the materials used to construct the object, for instance, a clay pot, so that when the firing is completed light-emitting electrons have been released. Over time, these electrons will begin to accumulate again as the pot is exposed to natural background radiation. When heated in a laboratory, the released electrons emit light that can be measured to calculate when the material was last heated to 500° C. Because the method measures the last time an object was at 500° C, context becomes critical to differentiate between the time of manufacture and possible refiring events.

OSL dating differs from TL dating in that it is used on soil, not fired artifacts. The same types of materials that TL dating relies on—for example, quartz and feldspar—are also used in OSL dating. When these materials are exposed to sunlight, their luminescence clock is zeroed, which is referred to as bleaching. When buried, the material begins to accumulate trapped electrons, which, like TL dating, can be measured. Unlike TL dating, OSL dating uses light, not heating, to release electrons. To arrive at a date, a light of a specific wavelength is passed through a sample. The trapped electrons are released and emit light. To ensure the accuracy of dates, the standard for OSL dating is to date the soil grain-by-grain.

Electron Spin Resonance

Developed for the earth sciences in the mid-1970s, *electron spin resonance (ESR) dating* is used in archaeology for dating tooth enamel, shell, and burned stone tools, although it is usable on other materials such as speleothems

and spring-deposited travertine. Accurate from 10,000 to 100,000 years, ESR dates the time when the artifact was buried. Like the other trapped-charge methods, context is critical.

ESR measures the quantity of trapped charges in an artifact. With this method, a sample is ground up and exposed to electromagnetic radiation. During the process, the sample is exposed to an external magnetic field. At a particular moment in the process, the trapped electron, or paramagnetic center, aligns itself parallel with the external magnetic field. When microwave radiation is introduced into the process, the paramagnetic center absorbs the radiation and flips its magnetic field to the opposite direction. The amount of radiation that is absorbed is proportional to the number of paramagnetic centers, which is proportional to the amount of radiation absorbed in the past. In the 1980s and 1990s, the ESR method was revamped to measure uranium (U) uptake.

Conclusion

The development of accurate dating methods is critical to understanding the evolution of humans, both biologically and culturally. Over the past century, newer and more accurate chronometric methods have been developed—radiocarbon dating, potassium-argon dating, obsidian hydration, and so on. Ideally, multiple dating techniques, including both relative and chronometric, would be employed for any one site, thereby cross-checking dates for accuracy. While many of the chronometric techniques are costly, continued improvements of the methods may help to make dating sites more cost-effective. New methods are also developed and employed in the effort to reconstruct our past.

INTERPRETING EVIDENCE

DONALD R. PERRY

Branchport, New York

The Copernican revolution, which had its beginning in 1543, represents a case study of how intuitive knowledge is ultimately replaced by scientific empiricism to produce a new theory of nature. From the time of Ptolemy, observations that planets, stars, sun, and moon traverse the day and night skies led to the misconception that these heavenly bodies circled a stationary earth. However, planetary orbits tabulated by Copernicus indicated that in actuality planets revolved around the sun. Known as the *solar system*, this understanding of nature was resisted for over a century as astronomers grappled with a succession of empirical observations by Tycho Brahe (1577), Galileo (1610), Newton (1687), and others who ultimately established the solar system as scientific fact.

The curious match between North and South America's continental outline and that of Europe and Africa caused comparable conflicting conclusions. A 1915 textbook written by Alfred Wegener examined fossil strata and living species on both sides of the Atlantic. Noting the strong similarities between them, he proposed a compelling view of geology called *continental drift* suggesting that these continents were adjoined in the distant past. Prominent geologists of the time argued that a geologic force capable of heaving about huge land masses did not exist. They brushed off the outlines' similarities as mere coincidence. These scientists hypothesized that in the past continents were linked

together by long land bridges that allowed species to march across oceans and populate distant shores.

A half-century later, global seafloor maps revealed a striking pattern. New crust was forming and causing the seafloor to spread; the continents were in motion. In the mid-Atlantic, for example, the continental plates that once joined North and South America to Europe and Africa were being pushed apart. When these moving plates collided with other plates, at subduction zones, one slid under the other to form high-mountain ridges like the Andes and the Himalayas. Patterns frozen in the earth's crust established the science of *plate tectonics*.

Why would the Copernican revolution and plate tectonics be relevant to the field of anthropology? These scientific advances are a result of empirical data that challenged and replaced the intuitive views of nature espoused by older theories. Paleoanthropology, the field devoted to understanding the process of human evolution, is based on the intuitive assumption that human intelligence and the relatively large human brain are the result of evolutionary activities that took place at the ground. This article compares the terrestrial view with a new empirical interpretation of fossil, behavioral, anatomical, and archaeological evidence that indicates climbing activities must have had a profound influence on the evolutionary increase in human-brain size.

Terrestrial Theory

A century and a half ago, Charles Darwin (1871) developed the terrestrial theory of human evolution in his book, *The Descent of Man and Selection in Relation to Sex*. He summarized his theory as follows:

The ancestors of man were no doubt, inferior in intellect, and probably in social disposition, to the lowest existing savages; but it is quite conceivable that they might have existed, or even flourished, if they had advanced in intellect, whilst gradually losing their brute-like powers, such as that of climbing trees. (p. 151)

Darwin noted that individuals from regions where tree climbing was practiced had a smaller brain size than Europeans who did not often climb in trees. Darwin postulated that it was our unique way of life at the ground rather than activities in trees that stimulated the evolutionary increase in our brain size.

This terrestrial theory about the origin of human intelligence has great intuitive appeal. After all, apes climb trees, have a smaller brain, and do not make sophisticated tools or speak. Stephen J. Gould (1981) examined 19th- and early 20th-century brain-size data in his book, *The Mismeasure of Man*, and showed that Darwin's conception of brain-size differences between forest and urban people was racially biased. Small forest people that regularly climb will naturally have a smaller average-brain size than large-bodied northern Europeans. Small-body size, not an ability to climb, explains the brain size of climbing cultures. Yet Darwin's observation was the primary support for the idea that climbing hindered human-brain evolution. Even though no new data has filled this void, the intuitive appeal of linking human-brain size and intelligence to evolution at the ground remains.

Given the importance of understanding the origin of intelligence, why is the intuitive terrestrial theory still embraced? As Thomas Kuhn (1962) pointed out in his book, *The Structure of Scientific Revolutions*, an accepted view is tenacious. Theories are erected to fill vacuums in our worldviews. If the terrestrial theory were abandoned, what would replace it? No other theory has come close to accounting adequately for the biological, fossil, behavioral, and archaeological evidence.

Canopy Signposts

Our general body plan, bipedal walking, long arms and fingers, and our reduced dependence on olfaction are a few of the numerous arboreal aspects of human nature. These attributes are well-known, accepted evidence of our arboreal-primate roots. But it is generally believed that we abandoned our canopy home deep in the distant past, so long ago that our arboreal life could not have had any influence on the brain's evolution.

However, an aspect of human physiology is incongruous with the idea that archaic humans were strictly terrestrial. Menstruation is a good example. No terrestrial species has a monthly period. A variety of grizzly predators, such as large felines, cave bears, and hyenas, roamed the ancient landscape, and they easily detected and tracked blood. This is why women who are menstruating are routinely taken on bear-hunting expeditions in Alaska. A species with females that lacked claws, fangs, speed, and strength while experiencing a heavy blood flow for up to 7 days every month is a truly unique terrestrial adaptation.

Infants, too, appear ill adapted to life at the ground. Terrestrial young steadfastly adhere to a tenet of behavior that can be called "silence is golden." After dropping from the womb, they often remain quietly huddled under shrubs or in clumps of grass. Only in dire circumstances would an unguarded juvenile attempt to summon a parent, for the cry of defenseless young is sweet music to predators' ears. Human infants, however, boldly shriek for absentee parents. They have not been encoded with this terrestrial rule of life.

One reflex might be considered an anomaly if it were not viewed in light of our treetop origins. The *parachuting reflex* takes control when a young child falls forward from a standing position. The arms are flung instantly out to the sides. If this reflex had been selected for as the result of terrestrial falls, the child's arms would move straightforward to protect the head from striking the ground. This reflex is perfectly suited for catching a vine or branch at the beginning of a fall from a high position.

The parachuting reflex is complemented by several other behaviors that appear to have originated with an arboreal way of life: Children learn to climb and walk simultaneously, a newborn infant can hold its entire body weight while hanging onto a bar, children love tree climbing and tree houses, and they prefer playgrounds that mimic the structure and motions of an arboreal world.

Perhaps the most enigmatic infant behavior is the *Moro reflex*. Physicians activate the reflex by placing a baby on a table covered with soft, spongy material, supporting its head in cupped hands, then allowing the head to drop slightly but suddenly while still being held. (Do not attempt this.) The baby's arms are flung out sideways, its whole body stiffens, and a few seconds later, the baby relaxes and begins to cry loudly. This reflex disappears after a few months. The Moro reflex can also be triggered by sudden, nearby movements or a loud noise, both of which would indicate potential, impending doom to a canopy resident. In the forest, booming thunder and limbs crashing down would have been familiar loud sounds that caused concern. If a platform was struck by a falling limb, a resting infant could easily bounce off the platform's edge. Heavy selection would account for the sideways arm extension of the Moro reflex, along with a stiff body to minimize rolling and stabilize an infant. The startle reflex, as it is also called, makes little sense as an adaptation for terrestrial young.

Although the retention of active arboreal reflexes in infants strongly suggests that our ancestor's full-time terrestrial status must be a recent event, these behaviors and adaptations are sometimes dismissed as "evolutionary baggage" left over from an ancient era when protohuman ancestors were active tree climbers. But the evolutionary-baggage explanation does not square with the biological purpose of innate infant reflexes. These are potent genetic programs that ensure survival in the specific habitat where a newborn will grow and develop.

Scansorial Humans

The *Cambridge Encyclopedia of Human Evolution* (Jones, Martin, & Pilbeam, 1992) states that humans no longer use their arms for locomotion. It describes our upright posture and states that we are bipedal, walking and running on two legs. This definition claims that, unlike apes, we are 100% terrestrial.

In contrast, the zoological definition of human locomotion takes into account our full locomotor capabilities. Species that travel at the ground and climb in trees are known zoologically as *scansorial*. This form of locomotion is shared by bears, squirrels, raccoons, and humans. The word *scansorial* does not appear in the index of the *Cambridge Encyclopedia of Human Evolution*. Expunging the role of our arms in locomotion nullifies the entire spectrum of our scansorial nature, reflexes, behavior, and body form. For paleoanthropologists, the only habitat remaining where our relatively large brain could have originated is the ground. Likewise the structure of our foot is seen as 100% terrestrial, a view that even Charles Darwin would probably have found odd. Darwin (1871) was an astute observer and well aware that the human foot and hand are scansorial. He stated, "With some savages, however, the foot has not altogether lost its prehensile [grasping] power, as shewn (sic) by their manner of climbing trees" (p. 136). The human foot's prehensile ability is inborn. This ability is prominently displayed by people who have lost the use of their arms as children. They can use their feet like hands to open jars, write, and drive. Functionally, the human foot is still a scansorial appendage.

What would a fully terrestrial foot look like? Nonclimbing, terrestrial feet are often rigid, raised up on the tips of elongated toes and capped by a hoof, as in horses and deer, or the last digit of each toe is bent and padded, like those of dogs and cats. Our feet lack this rigidity. With their ability to help secure us to a tree trunk and grip branches, our feet retain the arboreal competency that allowed our evolving ancestors to harvest canopy foods and climb to safety efficiently.

One arena in particular highlights human-scansorial status. We are unique in our ability to climb a 1,000-foot-high rock face without the safety of direct aid or ropes. No ape can climb this way. They lack both the balance and the

purpose. We are one of the most advanced climbing machines in evolutionary history. There is a fundamental difference between apes and humans in our body design and climbing technique—human hands, fingers, toes, and body shape have been integrated over evolutionary time with highly advanced cognitive abilities. Humans and apes stand on equal but different evolutionary-climbing peaks in that we think our way up vertical surfaces, a form of locomotion called by some "cerebral-climbing." Since this is perhaps the newest primate-climbing method, it cannot be brushed off as evolutionary baggage.

Encephalization in the Canopy

Which was most important in the evolutionary expansion of the human brain, the treetops or the ground? An evolutionary biologist explores this quandary by examining the fossil and living record of other tetrapods (four-legged vertebrates). Over a 200-million-year span of evolution from the diminutive brain cavity of bulky dinosaurs to the optical bulges of bird skulls and pteranodons to the elaborate olfactory apparatus of mammals to the highbrowed primate foreheads, the largest relative brain sizes occurred only in species that once climbed trees.

The canopy habitat has been recognized as the premiere factory of brain evolution for well over a century. Harry Jerison (1973), of the department of Psychiatry and Biobehavioral Sciences at UCLA, formalized this broad understanding of brain evolution with equations (subsequently refined by others) that quantified the canopy's influence on the ballooning brain. There are many exceptions such as the opossum, which is an animal that has climbed for tens of millions of years without ever experiencing significant brain expansion. Nonetheless, relatively large-brained species have never sprung from the terrestrial habitat. The scientific implication of this remarkable observation is not found in theories of human-brain evolution.

One reason for this is that for over a century the evolution of human intelligence has been inseparably linked to bipedal posture. Darwin's claim that walking upright on the ground freed our hands and allowed for the subsequent manipulation and invention of tools was accepted for a long time. But there was evidence to the contrary. Kangaroos, kangaroo rats, bipedal dinosaurs, and prosimians stood up and walked or hopped on two feet. But rather than master the art of toolmaking, the hands and arms of these animals shrank in size while relative brain size remained the same. So evidence derived from nonhuman species does not support the view that walking upright and having free hands leads to encephalization.

Unlike the above groups, humans are unique in standing fully erect. Perhaps posture was the main ingredient in stimulating our brain expansion. Millions of years ago there existed at least two human genera, *Australopithecus* and *Paranthropus*, that also stood perfectly upright on

two legs with free hands. Based on measured genetic distances between apes and humans, these early ancestors were at least 99% identical to living humans. Yet the fossil record shows that after millions of years of trudging around on the ground, their relative brain size stagnated, and they did not leave behind evidence of significant tool use. Neither standing perfectly upright nor a virtually identical genome promoted brain evolution. A critical evolutionary ingredient was still missing.

That ingredient was met by a species that followed australopithecines in the fossil record. *Homo habilis*, or handy man (a taxon that may represent several similar species), stood perfectly upright. It was during his tenure that the evolving human brain underwent its most rapid expansion. Something freed him from the stagnant mental plane of our ape forebears to embark on a revolutionary, intellectual path.

Initially *H. habilis* was considered 100% terrestrial, which conformed to the view that human-brain evolution took place at the ground. But this view flipped when it was discovered that *H. habilis* had long arms relative to modern humans as well as long, curved fingers. Most paleoanthropologists now accept that *H. habilis* regularly climbed trees, yet they have ignored the tight zoological link between climbing and encephalization.

Opposable Big Toe and Encephalization

It is a possibility that the rapid expansion of *H. habilis*'s brain was accompanied by a radical change in foot morphology. The australopithecines, considered to be *H. habilis*'s predecessors, had an opposable big toe. Even though they walked perfectly upright, their feet would have functioned like hands. The big toe was like a thumb that could grasp branches while climbing trees. They were climbing trees as apes would, and they had a relative brain size comparable to apes. Although they still climbed, limited evidence suggests that *H. habilis* may have been the first human taxon to lose an opposable big toe. This would mean they were the first primate to climb with opposable first digits limited exclusively to the hands. *H. habilis* had entered a much more stringent evolutionary-selective environment than all prior primates.

The loss of an opposable big toe as a potential stimulus for encephalization has not been considered adequately. Imagine how risk escalated when the number of appendages capable of grasping was reduced from four to two. This was a dramatic reduction in climbing equipment. To continue climbing with just two hands would require evolutionary compensation, and that compensation could not compromise safety. The enlarging brain, along with the loss of opposable big toes, functioned to integrate cognitive action with climbing. The combination initiated a unique intellectual safety net. From an evolutionary perspective, this was the dawn of cerebral climbing.

There is a lengthy list of selective forces that may have existed within evolving climbing culture that links neurological evolution with the origins of speech, advanced toolmaking, knot tying, social structure, advanced rock throwing, stone-tipped spear making, wooden-shelter construction, and rafting to name a few. Many of these speculative scansorial explanations for human-mental origins are found in the online book, *The Descent: The Untold Story of Human Origins* (Perry & Halsey, 2008).

Archaic Climbers

In numerous journal articles, paleoanthropologists judge the potential tree-climbing capability of possible human ancestors based on a dichotomy similar to those used in plant and animal keys. The reasoning goes something like this:

- If the fossil suggests modern-human skeletal anatomy, then the ancestor was not a climber.
- If the fossil suggests ape skeletal anatomy, such as long arms and curved fingers and toes, then it was a climber.

The long, apelike arms and curved fingers of *H. habilis* led anthropologists to conclude that these ancestors spent considerable time in trees. But as the successor to *H. habilis* in the paleontological record, *Homo erectus* (another taxon that may represent several species) was different. Its more humanlike body proportions inspired paleoanthropologists to christen this taxon as the first 100% terrestrial human. One glitch remains: *H. erectus*'s hands and feet have not yet been found. Alan Walker and Richard Leakey (1993) presumed that these will prove to be humanlike, but as the fossil history of *H. habilis* amply demonstrates, surprises lurk in the fossil record. Apelike hands cannot be ruled out. So it is merely assumed that *H. erectus* did not frequently climb trees.

Even if *H. erectus* had shorter, humanlike fingers, would this indicate it was not an active climber? Baboons have humanlike fingers and hands, and they are active climbers. Dyak tribesmen climb barehanded over 100 feet above ground to collect honey and other products from the canopy. Strength is the essential ingredient that determines climbing prowess. Since archaic humans were much stronger than Dyaks, they would have had virtually unlimited access to the canopy. Ian Tattersall of the American Museum of Natural History, as well as other experts, conclude that before about 40,000 years ago, most of our potential predecessors had what are called *robust* skeletons. This has been interpreted to mean that they were as much as 2 to 3 times stronger than modern humans. There is no doubt that our archaic ancestors had the strength to be astounding climbers.

Understanding the climbing potential of robust human skeletons throws a different light on *H. erectus*'s probable

way of life. Although it is claimed that *H. erectus* was 100% terrestrial, investigators report apelike strength in the shoulder girdle and arms. M. F. Gengo (2009) of the University at Buffalo stated in a recent article that “[the] shape of the chest put the shoulders of *H. erectus* in a position adapted more for tree-dwelling than balanced bipedal walking” (p. 451). Also, its spine was weak, more like that of an ape. The spine may have been too weak for certain human activities that put tremendous pressure on the spine, such as fast running and jumping. Therefore, the evidence indicates that *H. erectus* may have been as proficient at climbing as walking.

Water Holes?

There has been endless speculation concerning the function of one of the most common artifacts of the Paleolithic period, the *hand axe*. The most widely accepted idea is that it was a multipurpose tool, but the hand axe lacks any obvious multipurpose use. Earlier varieties were too heavy to be thrown effectively, and hand-holding the stone to strike prey or aggressors or to dig roots would have produced lacerated hands. The tool has even been classified as an ancient religious object.

Several sites contain a preponderance of these tools such as Olorgesaillie, Africa, where hundreds of hand axes lie together at the bottom of a large mud hole in an ancient streambed. A prominent terrestrial assumption is that these human-made deposits represent caches in what are thought to have been dry watercourses. But a more likely assumption is that those streambeds were flowing with water during the hand-axe era. In that case, rather than a tool-storage site, the mud hole would have served the same function as today. Mud holes are often excellent fishing/hunting locations.

This would explain the peculiar design of the hand axe. Early hand axes that weighed several pounds and possessed a sharp-edged perimeter were perfect weapons that could be dropped on prey from a high perch. The hand axe’s fusiform profile (in contrast to rounded stones) may well represent the first high-powered projectile that could enter the water with the killing force of a rifle bullet. The perimeter’s cutting edge maximized the possibility of killing or maiming surface-feeding fish and other prey. Even large prey that visited water holes to drink could have been overcome by the massive hand axes that have occasionally been discovered. No other plausible explanation has accounted for the purpose of these large stones. After the tools were dropped, some inevitably became lost in the mud, or if large reptiles were lurking about, it may have been too dangerous to retrieve them.

The terrestrial theorist, Milford Wolpoff, a professor of anthropology at the University of Michigan, believes this function is implausible since he has had personal and unsuccessful experience in throwing stones at fish. He feels that a hand axe used as a dropstone would be ineffective as

an arboreal-hunting weapon. But further consideration reveals that high-velocity rock throwing involves rapid movements of the body and arms that are guaranteed to frighten fish. In comparison, the use of dropstones is somewhat like hunting with a bow and arrow. The hunter would have been silent, hidden, and motionless up to and including the moment of the stone’s impact. Since streams were usually embedded in forest in ancient times, trees would have been present to support this form of canopy fishing/hunting.

The dropstone’s ability to kill or maim prey combined with the robust bodies of our ancestors (presumably *H. erectus*) represent an exciting new interpretation of life during the Paleolithic period. The perception of an early human-canopy hunter contrasts vividly with the popular notion of an ancestor who scavenged food from predator kill sites due to a lack of effective weaponry.

Tree Houses

Many researchers have noted that predation was a frequent and serious threat in ancient times, which brings up the question of where our ancestors slept. Before around 40,000 years ago there is little evidence of fire use and virtually no evidence of fortified terrestrial shelters that would have provided protection from large predators.

Heading back in time, it turns out that caves were used less and less frequently. Several categories of evidence are found in cave deposits. Prior to 40,000 years ago, evidence of cave use by human ancestors is minimal. Some evidence indicates ritual burial rather than occupation. Other evidence reveals that early humans were dragged into caves and eaten by predators. Stratigraphic analysis of the infrequent cave that indicates genuine occupation, such as Combe-Grenal in Europe, suggests that caves were occupied only a few days per year. Some caves hold only animal remains; others are empty. Overall, this apparent lack of evidence has led many, including Ian Tattersall as well as Jeffrey Schwartz, of the University of Pennsylvania at Pittsburgh, to conclude that Neanderthals were not cavemen.

If these archaic humans were not living in caves, then they were living either in terrestrial shelters or tree houses. Although the archaeological record has been extensively examined for evidence of human-made terrestrial shelters for over a century, few have been found that are older than 40,000 years. Paleoanthropologists have never examined the archaeological record for tree-house remains. Of course one wouldn’t expect to find evidence of a prehistoric, wooden tree house, while the crumbled walls of stout, terrestrial rock shelters should be ubiquitous. Serious consideration should be given to canopy sleeping shelters.

Claims that early humans preferred sleeping on the ground or in caves assume they had given up their great-ape heritage of building tree platforms, often called *nests*.

Platforms are built by all great apes, with the exception of gorilla males, which become too large to sleep in trees. Yet gorilla females and young still sleep on tree platforms to escape predation. Early humans were small and never approached gorilla size, so comparative evidence leans toward the enhanced safety of sleeping above ground.

Actually, ancient tree-house locations may have already been discovered. There are several sites where tools and debris from human activities have been found in streambeds. While a dry, sandy streambed would be a comfortable location to work and camp, it would not be as safe as a tree platform. When one assumes that streams were flowing with water, the debris is best explained as having fallen off an aerial platform or dropped from a limb.

Cracking the Human Evolutionary Code

If *Homo sapiens* recently began to build shelters at the ground rather than in trees, the archaeological and fossil record should reveal the timing of this event. An increase in terrestrial shelters and sweeping skeletal changes in evolving humans would be two types of evidence to look for. The latter would be caused by a dramatic drop in mechanical loading as a result of less climbing. Both types of evidence are prominent features of a cultural event known as the *creative explosion* that began around 40,000 years ago.

The present interpretation of this evidence is that the increase in terrestrial shelters was due to a population increase and/or migration into Europe, while the dramatic decrease in body strength of the evolving human skeleton is seen as evidence of a “less arduous” life. But these explanations are illogical. A move from southern, more hospitable climates into colder, northern zones (the generally accepted direction of this migration) would undoubtedly have led to a greater workload and a more arduous way of life. Preparations for winter would have required months of strenuous effort. Materials would have to be gathered to reinforce terrestrial shelters, animal carcasses would have to be dragged in and stowed, and greater amounts of firewood would have to be gathered. Except for the paradoxical weakening of the skeleton, there is no evidence to suggest that our ancestors’ lifestyle had become less arduous. So why would the evolving human skeleton become dramatically weaker as terrestrial shelters were increasing in number and daily life was becoming increasingly arduous?

J. Lee Kavanau, of the University of California, Los Angeles, thinks much more attention needs to be given to zoological factors that cause changes in body form of evolving species. A good primer is Gregory Paul’s (2002) book, *Dinosaurs of the Air: The Evolution and Loss of Flight in Dinosaurs and Birds*, which helps resolve this paradox. Paul painstakingly describes the skeletal changes expected when dinosaur species gave up using their arms for climbing and spent more time walking upright at the

ground. In such an event, mechanical loading shifts away from the upper torso, hands, arms, and shoulders, weakening all of them. Legs and feet adapt in ways that facilitate travel on the ground. Paul’s observations may be generalized to include all species, including human, that have undergone a similar change in mechanical loading. This evolutionary change can be called an *arbo-terrestrial transformation*.

An examination of this transformation in our lineage begins with thighbone cross sections from Neanderthals. (There is ongoing debate about whether or not Neanderthals were direct ancestors of modern humans. However, most theorists believe that our direct archaic ancestors would have had Neanderthaloid skeletal structure.) Neanderthal leg bones have uniformly thick walls that have been compared to those of apes. Climbing produces this type of leg-bone architecture.

Terrestrial theorists struggle ineffectually to explain the apelike, leg-bone structure of Neanderthals. One attempt claims that Neanderthals ran up and down mountain slopes and jumped between large rocks. But this lifestyle is comparable to modern humans who live in mountainous regions, and no data demonstrates that they have Neanderthal-like, leg-bone structure.

Neanderthals had exceptional strength from head to toe, not just the legs. The fingertips had broad apical tufts, fingers and hands were very strong, and the arms and shoulder girdle possessed tremendous strength. Long spines on the vertebrae indicate a powerful neck and the specialized shoulder blade sports a unique bony ridge.

From a zoological perspective, it is unsound to attempt to explain the strength of the legs, or any other parts, in isolation from the rest of the body. The bony ridge found on the Neanderthal scapula, for example, is explained as an adaptation to allow for a forceful, downward spear thrust. But what form of hunting would require that behavior? The principal location where a strong, downward spear thrust might be advantageous would be hunting from on top of a tree limb. However, this entails climbing, which would make climbing the preferred evolutionary explanation for Neanderthal upper-body strength and shoulder blade structure.

A related anomaly of Neanderthal skeletons is that they have many broken bones. These are similar to fractures found in ape skeletons, which strongly suggests that Neanderthal bone fractures were caused by falls from trees. But because discussions of an apelike, climbing, human ancestor are taboo, more fanciful explanations that suit our postape status are proposed. Rodeo contestants suffer bone breaks that resemble those of Neanderthals, so one explanation claims that Neanderthal body and hand strength were adaptations for riding bareback on wild animals. It is extremely difficult to imagine that an early human would be able to mount a wild animal and harder still to imagine that the enraged animal could be killed.

The temptation to provide independent terrestrial explanations for evolving human features has been taken to an

extreme. It has been widely reported, for example, that the reduction in the strength of the smaller toes around 26,000 years ago was the evolutionary result of wearing shoes. Wearing shoes, however, would not result in weakened toes. This is a Lamarckian explanation, since it implies that acquired characteristics are inherited. A genetic change could result only if shoes had killed strong-toed people before they reproduced. In any case, archaeological evidence of shoes has not been found from that era. Footprints dated to that time have been found embedded in mud on cave floors. They are always barefooted. A more pervasive evolutionary-selective force than shoes was afoot.

Evolutionary change swept over the evolving human body to reduce its many climbing adaptations. The hip joint of archaic humans allowed the legs to spread laterally. They had a humanlike foot with strong, smaller toes for gripping tree bark and small branches; extremely strong legs with pivoting ankles that allowed the feet to clamp against vertical surfaces; a muscular upper torso with powerful arms; broad hands and strong fingers with large apical tufts for bearing climbing forces at the fingertips; a sturdy neck with enlarged vertebral spines; and a powerful shoulder blade. This suite of interdependent adaptations, along with overall greater strength and appendicular mobility, confirms that archaic humans were excellent climbers.

The shift to a nearly full-time life at the ground set in motion extensive change in the archaic body. The strength needed for the rigorous demands of rapid climbing was excessively overpowered for a terrestrial existence. It became reoptimized for much less arduous activities, including fast, terrestrial locomotion. During this optimization, as much as 60% of the strength for rapid climbing was shed in an overall weakening of the shoulders, arms, hands, fingers, neck, torso, and smaller toes. Yet the skeleton maintained strength in the big toes and legs as the modern-human skeleton became a leaner, faster terrestrial machine.

Cro-Magnons, the first postarchaic humans, were more terrestrial than Neanderthals. This is demonstrated by their thighbone cross sections, which resemble those of modern humans. They traveled farther than archaic humans, such as Neanderthals, because their increased leg length allowed a longer stride. This is demonstrated by the fact that Cro-Magnons traveled long distances to collect stone for tool manufacture, whereas the origin of raw stone for Neanderthal tools was local.

Because Cro-Magnon populations increased while those of Neanderthals decreased, it is sometimes suggested that Cro-Magnons exterminated Neanderthals. But extensive studies show that around the time Neanderthals disappeared, average annual European temperatures were dropping, and forests were receding dramatically in response to the latest Ice Age. By 14,000 years ago, forests had almost completely disappeared from Europe, and as would be expected, the forest-dependent, Neanderthal body form vanished as well.

Korowai

Many doubt the intelligence of Neanderthals, though their brains were larger than those of modern humans. This is due to the Neanderthal archaeological record, which shows little inventive headway for over 150,000 years. There are those who feel that a few types of stone points and scrapers expressing little variation in design indicate intellectual stagnation and stupidity.

The Korowai, a tribe of modern-day humans that live in Irian Jaya, Papua New Guinea, cast doubt on that view. These forest dwellers live in tree houses that are marvels of invention and engineering. Some are built as high as 150 feet above ground. But the bare-bones existence of the Korowai depends only on the bow and arrow, a few trinkets, and a couple of stone tools.

Einstein resorted to thought experiments because it is difficult to test ideas about time, the speed of light, and gravitational fields. Thought experiments can be used in anthropology as well. Imagine that an anthropologist who is an advocate of the terrestrial view has just been catapulted 10,000 years to the archaeological site of a Korowai tree house. Assume that this person knows nothing about the Korowai.

Because the marvelous tree house and even the tree itself would have long since decomposed, the investigator sifts through a scattering of refuse at the ground. This reveals a meager distribution of simple tools and bone. No defined sleeping or living areas can be found, and there is little indication of how the people lived. Due to the paucity of tool types and a lack of inventive design, the scientist assumes the people are of low intelligence, nearly on a par with Neanderthals. The scattering of tools and bones are considered proof that the Korowai lived in modest shelters at the ground or were nomadic. Nearby, a full skeleton is found. The anthropologist classifies the Korowai's modern-human skeleton as 100% terrestrial with complete confidence, adding that perhaps they may have climbed trees, but trees played little role in their culture.

The terrestrial view fails dismally at reconstructing the Korowai way of life; therefore, it cannot be used to reconstruct our ancestors' more scansorial way of life.

Conclusion

Just as geologic patterns in the seafloor established unequivocal evidence of continental drift, the pattern of change in the evolving human skeleton confirms that robust humans spent a considerable amount of time climbing trees. By around 40,000 years ago, our ancestors began to spend much more time at the ground. This altered the mechanical loading on the evolving human skeleton resulting in a specific pattern called an arbo-terrestrial transformation. The upper torso weakened by as much as 60% as a rigorous climbing lifestyle employing the arms, hands,

shoulders, legs, feet, and toes was nearly abandoned. Meanwhile, leg length increased in correlation with time spent walking on the ground. As a result, the evolution of *Homo sapiens* produced a much weaker species.

Canopy theory unites behavioral, fossil, and archaeological data into a coherent framework about human physical origins that identifies the habitat of human-brain evolution. The living and fossil records from dinosaurs to primates, including humans, indicate that only climbing species have attained a relatively large brain. Empirical evidence indicates that climbing in trees, not walking at the ground, set the stage for modern-human intelligence.

Future Directions

Tree House Locations

Existing data from certain *open air* sites might represent debris that fell off ancient aerial platforms. To determine the pattern of dispersion of fallen objects, platforms of various sizes placed at various heights could be built. Objects would be dropped or thrown from these platforms and the resulting dispersal patterns measured and then compared to that of open air sites. Existing Korowai tree houses could be studied for the patterns of dispersion of items lost and buried in the muddy earth below to see if the pattern of their fallout is similar to open-air sites.

Dropstones

Hand axes can be tested to see whether they function as dropstones. Early, large, hand-axe sizes and shapes would be the size of choice. Platforms can be built in trees over a productive water hole. Hand axe replicas can be dropped from these platforms to determine the killing or maiming potential of these weapons on surface-feeding fish. Models of mammals could be used to demonstrate impact, strength, and potential to kill prey. It is possible that hand axes were also slipped into the ends of shafts, using the heavy end of the stone as the weapon. Dropped from above, these would have been deadly weaponry that could penetrate the hide and crack the skulls of large game.

Bone Piles and Scatters

The function of cobbles, early hominid tools, can also be tested for effectiveness as dropstones. Platforms can be built at various heights. A pile of bones taken from predator kill sites can be put under a platform to attract game. One can then determine if rodents and larger mammals that arrive to scavenge at the bone pile can be killed by falling cobbles. Targets and models that measure force may be used. If one can successfully hunt in this manner, then some ancient-bone piles and scatters might represent bait sites where hunting from platforms

took place. If so, then early humans had a potentially effective means of hunting.

Existence of Cavemen

Whether or not a population of archaic humans lived in caves prior to around 40,000 years ago has not been statistically demonstrated. It is probable that existing data may confirm that these humans must have been living someplace else. Data on number of available caves could be cross-correlated at the same stratigraphic time horizon. Categories of interest would be number of occupied caves and duration of occupation, number occupied by predators, number used by predators as places to feed on hominids, and number that represent burial sites. A reasonable population size based on population biology can be estimated and then this number compared to the above information.

CROSS-CULTURAL STUDIES

CONSTANCE B. WILLIAMS

Queensborough Community College, City University of New York

The effect of people moving from one location to another or the realization that heritage is a major determinant in all that we do provides the background for the explanation of why we view and analyze cross-cultural studies. Looking back to the beginning, humans vary in numerous ways. Anthropology seeks to answer these questions about *Homo sapiens*. Scientists have sought to discover where and why humans appeared on earth, why the changes occurred, and why humans vary in physical features throughout the world.

Cross-cultural studies are significant because the relationship between different cultures has an effect on all cultures. The history of the area in which people live affects their lives, their families, and the communities they inhabit. Understanding heritage and understanding expectations in one's environment allows people to view themselves in a hierarchical structure. All cultures are organized, from the smallest tribe to the largest groups, and everyone must have knowledge of their community. This knowledge must include language, social structure, political insight, and religion. Even before these areas are identified and labeled, they have existed in both modern society and in the early gatherings of humans. Inherent in the differences is the fact that there are similarities in all cultures as each one strives to maintain its existence. This existence is vital even before the group assimilates with the larger environment.

It is reported that the first anthropologist to conduct cross-cultural studies was Abu Rayhan Biruni. He conducted

research in the Mediterranean area, the Middle East, and India long before any other scientists. European scientists also administered various interviews and recorded the results of their research. As American scientists continued this research process, the need for identical methods of gathering information became evident. Cross-cultural studies use scientific methods to analyze data. Samples of a larger proportion are used to better clarify behavior, traits, and beliefs of various cultures. With the larger samples, researchers are able to apply findings to statistical surveys. Each culture has some differences that apply to only that individual group, so compiling this information has to be accurate and consistent. As this information is recorded accurately, the data can be analyzed scientifically. With greater reliability, other disciplines can use data collected internationally and cross-culturally.

The importance of collecting field data will be discussed in this chapter, along with the statistical methods used. As more scientific methods are used, the connections with various disciplines is more easily recognized and assessed.

Overview

George Peter Murdock is noted among the earliest anthropologists. In the late 1940s, Murdock and colleagues organized the Human Relations Area Files (HRAF). He

recognized the need to set a standard to evaluate and list all cultural groups, and to put this in writing. HRAF now consists of years of committed research recorded by approximately 400 different ethnographers. Well before Murdock, Lewis Henry Morgan conducted research with the Seneca Indians, collecting data from more than 70 Native American Indian tribes in unilineal evolution. This comparison of cultures using evolution as a basis for organization was first undertaken by Morgan and is still considered advanced today. Some of the first British social evolutionists were Herbert Spencer, Sir Edward Burnett Tylor, Sir James George Frazer, and Edward Westermarck.

In 1949, a nonprofit organization based at Yale University further organized the HRAF ethnographic data and later preserved this information on microfilm. Now the files are accessible by electronic databases as well. As we view scientific data today, the availability of research to be shared and analyzed expediently is of great value to scientists and researchers. The proliferation of methods to study cultures and peoples is extensive. The refining of these methods scientifically spearheads the reliability of anthropological research. In this chapter, the major researchers are highlighted as well as the different theories they believe lead us to better means and methods of analyzing cultures.
