The microscope at that time was a crude instrument, and there was no satisfactory means of illuminating the specimens being observed. In fact, what is remarkable is that the disease was recognized at all, when one considers its rarity, on the one hand, and the continual epidemics of infectious diseases as well as chronic ailments of the last century which occupied the medical profession, on the other. But after recognition, reports of suspected or actual cases of leukemia began to appear in the literature, slowly revealing its worldwide distribution. Case reports from Europe and America also indicated the ineffectual nature of any known therapy.

Two breakthroughs occurred in the last half of the nineteenth century. The first was the discovery by Ernst Neumann in 1868 of the importance of the bone marrow in the formation of blood; a year later, he published his report on the changes in the bone marrow in leukemia, which introduced the term *myelogenous leukemia.* The second came in 1877, when Paul Ehrlich, a medical student at the time, developed a stain that permitted the cells to be clearly defined. By then, the microscope had been improved, and the new technique of staining enabled features of the blood to be studied that had hitherto been unseen or unsuspected.

Thus began a new era in hematology, but it was to be nearly 70 years before any progress was to be made in the treatment of leukemia. This began with the realization that folic acid was important to blood cell formation, and that its lack caused anemia and, significantly, a decrease in the white cells. Ensuing experiments showed that some preparations containing folic acid inhibited growth of experimental tumors, whereas other observations indicated that it might stimulate the growth of leukemic cells. This

led a group of researchers in the United States to develop a series of new drugs that were designed as antagonists of folic acid for trial in the treatment of human cancers. Aminopterin was one of these new drugs and was used with much success in the treatment of acute leukemia by Sidney Farber and his group at Boston Children's Hospital in the late 1940s. Much research followed in a quest for new and more successful drugs to combat leukemia, with the result that by the late 1980s there was an established armamentarium of drugs used mostly in combination to achieve a remission and to maintain it.

Leukemia is a disease of major interest in both hematology and cancer research where much progress has been and is still being made, measured in terms of patient survival. Moreover, the outstanding "problem areas" of research are now more clearly defined and recognized, and current research efforts (in both pure and applied settings) within the fields of cell and molecular biology, immunology, cytogenetics, and virology are directed toward investigating such problems as the following:

1. Application of molecular mechanisms in therapy to destroy leukemic cells
2. Role of viruses in influencing the development of the disease
3. Nature of environmental triggers of leukemia
4. How to achieve earlier recognition of leukemia
5. How to understand the scientific basis for remission and thus how it can be maintained
6. How to eliminate residual disease

It is hoped that improved therapy for both adult and childhood cases will result from these complex and concentrated research efforts and that survival rates will be increased even more. Virchow wrote the following in 1858: "I do not wish by any means to infer that the disease in question [leukemia] is absolutely incurable; I hope on the contrary that for it too remedies will at length be discovered." Today there is optimism that Virchow's hope will be realized.

Lupus Erythematosus

Lupus erythematosus (LE) is a clinical syndrome that has multiple, but largely unknown causes. It exhibits an extremely broad spectrum of symptoms, and it can range in severity from being potentially fatal within a few weeks to eliciting minor indolent symptoms which, prior to immunologic testing, are virtually undiagnosable. When limited to the skin, it is called *discoid lupus erythematosus* (DLE); when the viscera are symptomatically affected, it is termed *systemic lupus erythematosus* (SLE). The inciting causes activate immunologic mechanisms that mediate the pathological, predominantly inflammatory, tissue responses.

History

Medical use of the term *lupus* has been traced to the fifteenth century, when it designated a variety of cancer. The term was reintroduced by London physician Robert Willan in 1808 to designate cutaneous tuberculosis, particularly when it affected the face. Cutaneous tuberculosis eventually received the synonym *lupus vulgaris.* In 1851 P. L. Alphée Cazenave of Paris used the term *lupus erythemateaux* to describe the condition that came to be called discoid lupus erythematosus (DLE) by Vienna's Moriz Kaposi in 1872 (Jarcho 1957). During 1866–70,

Kaposi diagnosed this disease in 22 patients and concluded that it was more common and more severe in women. All 3 deaths occurred among his 15 female patients. Although one of these had pulmonary tuberculosis, and cutaneous tuberculosis was common, Kaposi believed that DLE is not related to tuberculosis. Such a causal relationship, however, came to be advocated, particularly by French dermatologists, and remained under discussion until the 1930s. During the 5 years in which Kaposi saw 22 cases of DLE, 279 cases of lupus vulgaris were seen in the same department (Kaposi 1872). One generation later, among 30,000 dermatologic patients seen in Manchester, England, between 1893 and 1913, a diagnosis of DLE was made in 142 instances (0.47 percent), and lupus vulgaris in 1.5 percent. Of the DLE cases, 66 percent were female, ranging in age from 15 to 63 years, whereas males ranged in age from 8 to 66 years.

Kaposi (1872) used the term *disseminated lupus erythematosus,* but referred thereby to cases with widespread skin lesions rather than visceral involvement. Nevertheless, he described some cases having fever, pleuropneumonia, arthralgia, and arthritis. Recognition developed slowly that various visceral manifestations are attributes of the systemic disease rather than coincidences. From 1894 to 1903, William Osler saw 29 patients (17 aged 3–15 years; 12 aged 18–57 years), who had an "erythema with visceral lesions." He is credited with having provided the first clear descriptions of *systemic lupus erythematosus* (SLE) although, by modern criteria, the diagnosis that resulted from those descriptions does not fit all of the cases.

Osler (1904) added involvement of the kidneys and central nervous system to the description of Kaposi, whereas Alfred Kraus and Carl Bohac (1908–9) recognized that pneumonia belongs to the syndrome. Before the 1940s, most publications on lupus erythematosus were written by dermatologists, and consequently, skin lesions were considered essential to satisfy the diagnosis. Emanual Libman and Benjamin Sacks (1923) described four cases of noninfectious endocarditis (heart inflammation) of which three had the skin lesions of LE. A review of 11 cases of Libman–Sacks endocarditis in 1932 found that 5 lacked the skin eruption. George Belote and H. S. Ratner (1936) concluded that this form of heart disease nevertheless is a manifestation of SLE. Leukopenia and sensitivity to sunlight were convincingly related to SLE in 1939, but it was only in the 1940s that it became accepted that a skin eruption is not a necessary component of

SLE. Recent data indicate that even with the current longer life expectancy of SLE patients, only about 40 percent ever have the "butterfly" facial rash, and that an eruption occurs somewhere on the body in about 75 percent of the cases. The concept that DLE and SLE are manifestations of the same disease was first proposed by Harry Keil in 1937, but two decades passed before the concept became generally accepted.

SLE was perceived to be rare and uniformly fatal because only the most severe cases identified by their rash were being diagnosed. For example, at the University Hospital in Prague there were just eight cases from 1897 to 1908. At the Johns Hopkins Hospital, only three cases were diagnosed between 1919 and 1923. In fact among 7,500 autopsies of cases above 13 years of age reviewed at the same hospital in 1936, there were just five instances of SLE. Five cases were diagnosed at the Mayo Clinic between 1918 and 1921 (Goeckerman 1923), but, as the disease became more familiar, 132 cases were recognized during the decade 1938 to 1947 (Montgomery and McCreight 1949).

In 1948, Malcolm Hargraves, a hematologist at the Mayo Clinic, reported a discovery, which he said "has been called an L.E. cell in our laboratory because of its frequent appearance in the bone marrow in cases of acute disseminated L.E." (Hargraves 1969). In the next 4 years, numerous modifications of Hargrave's procedure were devised in various laboratories to make demonstration of the LE cell easier and more reliable.

In 1954 it was discovered that the formation of LE cells results from a reaction between a factor in the serum and leukocyte nuclei. This led in 1957 to the development of a quantifiable test of this antigen–antibody reaction. The determination of antinuclear antibodies (ANA) has gradually replaced the LE cell as the principal diagnostic test for SLE. These tests have greatly increased case finding and thereby have led to the recognition that SLE exhibits a broad range of severity. Nevertheless, the ANA test may cause confusion because many circumstances induce ANA reactions, at least in low titer. In North America and Europe, "false positive" reactions are most often due either to a drug or to another connective tissue disease, whereas in tropical Africa they have been related to endemic malaria.

The next advance was the standardization of criteria for the diagnosis of SLE. For this purpose, a committee of American rheumatologists in 1971 published a battery of clinical and laboratory findings of which a specified number had to be present for the

diagnosis to be probable. This schema was well received, and a modification prepared in 1982 has been adopted in many countries (Tan et al. 1982).

Drug-Induced SLE
A syndrome that was indistinguishable from SLE was recognized at the Cleveland Clinic in 1954 in patients who were taking the antihypertensive drug hydralazine. Since then, many drugs have been suspected or have been proven potentially to have such an effect. By far the most consistent SLE-inducing agent is procainamide; this drug, used to treat cardiac arrhythmias, was first reported to induce SLE in 1962. After 6 months of therapy, ANA develop in at least half of these cases; and after 1 year, a quarter of the cases may exhibit symptoms of SLE. In patient populations in which potentially lupus-inducing drugs, such as procainamide, hydralazine, phenytoin, and isoniazid are widely used, about 10 percent of the cases of SLE are drug-induced (Lee, Rivero, and Siegel 1966). Drug-induced SLE is relatively benign. The female preponderance is diminished and its most frequent symptoms are pleurisy and arthralgia. Fever, leukopenia, and skin lesions occur about half as frequently as in idiopathic SLE; renal involvement and pericarditis are rare, and central nervous system involvement does not occur. Only the development of ANA warrants close observation. If it is possible to discontinue the inciting drug after symptoms have developed, those symptoms will disappear within several weeks.

Treatment and Mortality
In the 1940s it was generally acknowledged that there was no effective treatment for either DLE or SLE. The initial breakthrough occurred in 1949, with the discovery that the *corticosteroids* cortisone and corticotropin can exert a dramatic suppression of most symptoms of SLE. Prednisone, a synthetic derivative of cortisone, was introduced in 1955 and has become the most commonly used orally administered corticosteroid (Urman and Rothfield 1977). Only the cutaneous and renal manifestations are frequently refractory. In 1951, quinacrine, an antimalarial drug, was found to be effective against DLE. Soon thereafter, the *antimalarials* chloroquine and hydroxychloroquine were found similarly useful, and the latter is now principally employed. In SLE the antimalarials are also most effective against the rash, but they may also ameliorate some visceral symptoms. The third major therapeutic category is the *immunosuppressive drugs*. The first to be tried was nitrogen mustard, in 1950. Now the most

commonly used drugs in this category are azathioprine and cyclophosphamide (Wagner 1976). This type of treatment is reserved for severe renal involvement and refractoriness to corticosteroid therapy.

Modern therapy has not only improved the quality of life of the SLE patient but has also greatly prolonged his or her survival. Before the advent of corticosteroids, one-half of these patients died within 2 to 3 years of being diagnosed. Now the mean survival of 15 years after diagnosis has reached 75 percent. Two factors in addition to the therapeutic agents cited above help to account for this improvement: (1) better antibiotic therapy for potentially fatal bacterial infections; and (2) recognition of much milder cases for which a more benign course is likely even with minimal therapy.

Mortality is influenced by race and sex. According to U.S. data for 1968 to 1976, the annual mortality rate, relative to 1.0 for white males, was 1.6 for black males; 3.7 for white females; and 10.5 for black females (Gordon, Stolley, and Schinar 1981).

Epidemiology, Distribution, and Incidence
Reviews of the proportion of cases of DLE in the clientele of dermatology clinics began to be reported at the beginning of this century. An incidence of between 0.25 percent and 0.75 percent has been consistently found in various parts of the world (Gahan 1942). The early belief that the disease is rare in the tropics and among black populations has been disproved in Africa and in the United States (Rothfield et al. 1963; Findlay and Lups 1967).

The only epidemiological conclusion about SLE reached until the 1950s was that the disease occurs predominantly in young women. In 1952 an ethnic predisposition was postulated, based on the observation of the often deleterious effect of sun exposure: Redheaded, freckled persons with an inability to tan were deemed most susceptible (Brunsting 1952). This conclusion was contradicted, however, by M. Siegel and his colleagues (1964), whose epidemiological data indicated that SLE is actually more common among blacks. Studies in San Francisco (Fessel 1974) and Baltimore (Hochberg 1987) substantiated this increased susceptibility of blacks, particularly among black women. National data from Veterans Administration hospitals have confirmed the racial difference among men as well (Siegel and Lee 1973). Unlike infectious diseases such as rheumatic fever or tuberculosis, the occurrence of SLE appears not to be related to socioeconomic factors. In terms of total population, the annual incidence of SLE in the United States has been estimated at

about 5 per 100,000, with black females about three times more susceptible and black males two times more susceptible than their white counterparts. The mean age of onset is 28 to 30 years, but the preponderance of female patients varies with age. *About twice as many females as males suffer from the disease during the first decade of life and from the seventh decade on.* But between ages 20 and 40, there are 8 female patients for every male.

The prevalence, sex ratio, and mortality rates for SLE in northern Europe resemble those of U.S. white populations (Helve 1985; Hochberg 1987). In other parts of the world, as recognition of the disease has increased, more cases are being diagnosed. For example, SLE was rarely diagnosed in India before 1970, but from 1974 to 1985, 181 cases were seen in one hospital in New Delhi (Malaviya et al. 1987). Studies in Hawaii (Serdula and Rhoads 1979) and Malaysia (Frank 1980) indicate greater susceptibility of Chinese than other ethnic groups, and the death rate due to SLE for Oriental women in the United States (nearly three times that of white women) is similar to that of black women (Kaslow 1982). The prevalence of SLE among Polynesians also exceeds that of Caucasians (Serdula and Rhoads 1979; Hart, Grigor, and Caughey 1983).

In the predominantly black population of Jamaica, SLE constitutes a remarkably large proportion of treated rheumatic diseases. Indeed, 22 percent of all outpatients and 37 percent of inpatients with rheumatic disease suffer from SLE (Wilson and Hughes 1979). In view of the prevalence of SLE among nonwhite populations elsewhere, the apparent rarity of the disease among African blacks has been perplexing. The first case was reported from Senegal in 1960. Between 1967 and 1978, only 21 cases were recorded in Kampala, Uganda. A 5-year prospective analysis of cases of polyarthritis in Zimbabwe reported in 1969 found no case of SLE, whereas another study during 1979–84 discovered 31 cases (30 female, ages 13 to 46 years) (Taylor and Stein 1986). The possibility of differences in susceptibility of various African ethnic groups must be considered. During 1960–72, for example, 130 cases of SLE were admitted to two hospitals in Cape Town, South Africa. These included 86 "coloureds" (mainly Indian), 36 whites, and only 8 "Bantu." In terms of each 1,000 female admissions, this meant a rate of 4.9 "coloured," 3.8 "Bantu," and 2.3 white (Jessop and Meyers 1973). The data from much of the world remain inadequate to draw firm conclusions about ethnic and other possible variables related to SLE.

Lyme Borreliosis (Lyme Disease)

Lyme borreliosis is a tick-borne spirochetal bacterial disease caused by *Borrelia burgdorferi*. Lyme borreliosis is a systemic illness with potential involvement of the skin, neurological, cardiac, and articular systems. It can mimic a variety of other diseases such as juvenile rheumatoid arthritis, multiple sclerosis, and syphilis.

Epidemiology

The disease is the most frequently diagnosed tick-transmitted illness in the United States. The three major geographic loci of Lyme disease in the United States are the Northeast and middle Atlantic coastal regions, the upper Midwest, and the Pacific Northwest. The disease is found in Europe, Australia, the former U.S.S.R., China, Japan, and several African countries. The vector of Lyme disease is the tick, *Ixodes dammini*, or related *Ixodes* ticks such as *pacificus, scapularis,* or *ricinus. B. burgdorferi* has been found in other ticks such as the *Dermacentor variabilis, Amblyomma americanum,* and *Haemaphysalis leporispalustris;* however, transmission has not been proved.

B. burgdorferi has been found in horseflies, deerflies, and mosquitoes, but proof that these insects are possible secondary vectors has not been established. The reservoirs of *B. burgdorferi* occur in animals parasitized by infected ticks. The *Ixodes* tick is a three-host tick with a life cycle of 2 years. Adult ticks mate and feed primarily on deer in late fall; the female deposits eggs on the ground, which produce larvae that are active late the following summer. The tiny larvae obtain a blood meal from infected rodents such as white-footed mice, shrews, chipmunks, and squirrels, which are primary reservoirs for *B. burgdorferi*. Ground foraging birds are also important hosts for the larvae and nymphs. After a blood meal, the larvae molt to a nymphal form, which is active the following spring and early to

midsummer. It seeks an animal host, obtains a blood meal, and molts to an adult stage to complete the 2-year life cycle. The animal hosts can include humans, dogs, deer, cows, horses, raccoons, cats, skunks, black bears, and Virginia opossums.

Each developmental stage of the tick requires feeding once and may take several days. *B. burgdorferi* is transmitted to the host during the blood meal. The longer the time of attachment of the infected tick to the host, the greater probability of transmission.

Etiology

The detection of *B. burgdorferi* in human tissue or body fluids is the most reliable technique to prove the cause of an infectious disease. In Lyme borreliosis, cultivation of the organism has been difficult, probably because of slow growth of *B. burgdorferi* and its low density in body tissues.

An alternative method to establish proof of infection by *B. burgdorferi* relies on the detection of its antibody. In early Lyme borreliosis, the immunoglobulin (Ig) M form of the antibody response appears first, peaks 3 to 6 weeks after exposure, and then declines. The IgG then becomes detectable and is present in late-stage disease states. However, antibodies are frequently not detectable in the early stages of the disease by current techniques. In the late stages of the disease, they are almost always positive. Other spirochetal diseases, such as yaws, pinta, or syphilis, may give false-positive results, but can be excluded by clinical evaluation.

Clinical Manifestations

Lyme borreliosis is a multisystem disease. Its primary target organs include the skin initially and later, potentially, the neurological, cardiac, and articular systems. Lyme borreliosis is categorized in three phases. Arbitrarily:

Stage I involves the dermatologic system and is diagnosed by the classic rash, erythema chronicum migrans (ECM).

Stage II involves the neurological or cardiac system months to years after exposure to the organism.

Stage III, involving the joints, also can occur months to years after the initial exposure.

These three stages may overlap and occasionally can present simultaneously. Moreover, any of these stages may occur in the absence of the others.

Erythema chronicum migrans (ECM) is pathognomonic for Stage I Lyme borreliosis. The average incubation period is 1 to 3 weeks (range: 3 days to 16 weeks). This rash is a diagnostic marker of the dis-ease and begins as a small flat (macule) or swollen (papule) spot at the site of the tick bite and then expands to a very large (10 to 20 centimeters) oval or round lesion with a red to pink outer border and a very clear central area. Viable *B. burgdorferi* occasionally can be cultured in the advancing margins. Blood-borne spread of the spirochete may produce multiple, secondary lesions days to weeks later. The rash persists for a few days to weeks, and is usually unaccompanied by systemic symptoms, although occasionally fever, chills, and fatigue may occur. Because the rash can be asymptomatic or on areas of the body that may not be observed, many people may go undiagnosed. More than 20 percent of adults who have Lyme borreliosis will not remember having the rash, and the percentage is much higher in children.

Stage II of Lyme borreliosis may involve the neurological system. Of patients, 10 to 15 percent may have this involvement and present with a meningitis-type picture or have cranial nerve palsies. The most commonly involved cranial nerve is the seventh (facial) nerve, which results in an inability to control properly the facial musculature. In individuals with meningeal irritation, episodic headaches, neck pain, and stiffness may occur. Cerebrospinal fluid analysis frequently shows a predominance of mononuclear white blood cells. Occasional patients with stroke syndromes including hemiparesis as well as cases mimicking multiple sclerosis or encephalitis have been reported. Individuals may have associated confusion, agitation and disorientation, and memory loss. The symptoms and signs may wax and wane over weeks and months.

Heart involvement is rare as part of Stage II manifestations of Lyme borreliosis. Cardiac manifestations are commonly detected only as first-degree heart block on electrocardiographic tracings, although some patients can have a more serious second- or third-degree heart block and present with episodic fainting spells. Both the neurological and cardiac manifestations may occur within weeks to months or even longer after infection with the *B. burgdorferi* organism, and they can occur without any antecedent rash.

The most common late manifestation of Lyme borreliosis is arthritis. It usually occurs several months after the tick bite, but the range is 1 week to over 10 years after exposure. It is usually an oligoarticular form of arthritis (fewer than four joints) involving the large joints such as the knee or ankle. The attacks may last from a few days to several months. Some individuals will have recurrence with variable periods of remission between

attacks. The intensity of articular involvement is variable, because some patients complain only of aches (*arthralgias*), whereas others demonstrate joint swelling (*arthritis*). In children the symptoms and signs of Stage III Lyme borreliosis can mimic juvenile rheumatoid arthritis. Antibody testing to *B. burgdorferi* can provide valuable clues to diagnosis of Lyme borreliosis in those individuals who present with Stage II or III without antecedent history of ECM or tick bite exposure.

B. burgdorferi infection can be spread transplacentally in humans. Infections during pregnancy can result in spontaneous abortion, premature delivery, low birth weight, and congenital malformation. These complications are similar to those caused by the spirochete *Treponema pallidum,* the causative agent of syphilis.

Lyme borreliosis is treated with antibiotics. The best results are achieved with prompt administration of oral antibiotics at the time of initial infection (Stage I). The duration of the rash and associated symptoms is abbreviated by a 3-week course of oral tetracycline, penicillin, or erythromycin therapy. In Stage III Lyme borreliosis, 3 weeks of parenteral penicillin or ceftriaxone are the drugs of choice. The earlier antibiotics are instituted, the more likely a cure may be achieved. A delay in starting antibiotics may result in lifelong, intermittent or even chronic, residual symptoms from the disease.

History

In 1909, in Stockholm, Swedish dermatologist Arvid Afzelius (1910) described a rash (which he labeled *erythema migrans*) on a female patient following a bite from an *Ixodes* tick. In 1913 an Austrian physician described a similar lesion on a patient and labeled it *erythema chronicum migrans* (ECM). Recognition that ECM was associated with systemic symptoms occurred in France in 1922. Investigators described patients with tick bites who developed subsequent erythema migrans and lymphocytic meningoradiculitis (nervous system involvement). In 1934 a German dentist described six patients with erythema migrans and associated joint symptoms. And in 1951 beneficial effects of penicillin in the treatment of a patient with ECM and meningitis suggested a bacterial etiology.

In the United States the first documented case of ECM occurred in a grouse hunter in Wisconsin in 1969. In 1975, two homemakers reported to the Connecticut State Health Department that several children living close together in Lyme, Connecticut, had developed arthritis. A following investigation by Al-

len C. Steere revealed an associated rash (ECM) in 25 percent of patients. He named the syndrome Lyme disease in honor of the town in which it was first observed.

In 1977 it was observed that an *I. dammini* tick bite preceded the ECM rash on a human subject. Willy Burgdorfer and his colleagues (1982) isolated a spirochete from the midgut of the *I. dammini* tick; this spirochete was subsequently named *Borrelia burgdorferi.* The following year, Steere isolated the spirochete from blood, skin, and spinal fluid from patients with the Lyme disease syndrome and concluded that it was the causative agent. Also, in 1983 in West Germany, H. W. Pfister and his colleagues (1984) concluded that *B. burgdorferi* isolated in spinal fluid from a patient with lymphocytic meningoradiculitis (Bannwarth's syndrome) was causative, and they implied that the original description of 13 patients provided by A. Bannwarth (1941) may have been due to the same organism. Dermatologist Klaus Weber and his colleagues (1984), working in West Germany, noted an elevation of IgG antibodies in the blood of patients with the skin lesion *acrodermatitis chronica atrophicans* (ACA). ACA is an uncommon late dermatologic manifestation of Lyme borreliosis. The first description of ACA was given by the German physician Alfred Buchwald (1883), and may have been the first reported case of Lyme borreliosis.

Malaria

Malaria is the disease resulting from infection by one or more of four species of protozoan parasites of the genus *Plasmodium*. These parasites are normally transmitted from one human host to the next by the bite of an infected female mosquito of the genus *Anopheles*. Although malaria has receded from many temperate regions in this century, the disease continues to be a major cause of morbidity and mortality in many tropical and subtropical countries. Three of the species – *Plasmodium vivax, Plasmodium falciparum,* and *Plasmodium malariae* – are widely distributed; the fourth, *Plasmodium ovale,* is principally a parasite of tropical Africa. *P. vivax* (the agent of benign tertian malaria) and *P. falciparum* (causing malignant tertian malaria) are responsible for the great majority of cases and deaths attributed to malaria throughout the world.

Malaria is characteristically paroxysmal, and often periodic. The classical clinical episode begins with chills, extends through a bout of fever, and ends with sweating, subsiding fever, a sense of relief, and, often, sleep. Between the early paroxysms the infected person may feel quite well; as the disease progresses, however, the patient may be increasingly burdened by symptoms, even in the periods between febrile paroxysms. Although infection by any species may have serious, even fatal, consequences, *P. falciparum* infection is particularly dangerous because of complications associated with this parasite.

The term *malaria,* from the Italian *mala* and *aria* ("bad air"), was certainly in use in Italy by the seventeenth century to refer to the cause of intermittent fevers thought to result from exposure to marsh air or miasma. Horace Walpole wrote home from Italy in 1740 about "[a] horrid thing called mal'aria, that comes to Rome every summer and kills one." This is said to be the first use of the term in English, and it may well have been the first appearance of the word in print (Russell et al. 1963). However, Walpole and other writers of the eighteenth century, and later, used the term to refer to the presumed cause rather than the disease. It was only after the pathogenic agents were identified at the end of the nineteenth century that usage shifted so that the term "malaria" came to refer to the disease rather than the agent.

Etiology

Protozoa assigned to the genus *Plasmodium* are parasitic in many species of vertebrate animals including birds, reptiles, amphibians, and mammals. Most Old and New World primate species serve as hosts for plasmodia, and some of these parasites are closely related to the species established in human populations. It is generally accepted that the human malaria parasites evolved in association with early human beings, perhaps differentiating into the four species recognized today in the mid-Pleistocene (Garnham 1966; Bruce-Chwatt and Zulueta 1980).

All of the mammalian plasmodia have similar two-phase life cycles: an asexual (*schizogonic*) phase in the vertebrate host and a sexual (*sporogonic*) phase in female *Anopheles* mosquitoes. These cycles reflect ancient anopheline and vertebrate host–parasite relationships that seem to date from at least the Oligocene.

The sexual phase in the mosquito is initiated as the female anopheline takes a blood meal from a human or other vertebrate host. Parasites in ingested red blood cells are released as male and female gametes in the stomach of the mosquito. Fusion of the gametes produces a *zygote,* which, after

rapid development, migrates and encysts in the stomach wall. At maturity, after some 10 to 20 days, this oocyst releases thousands of *sporozoites,* motile forms that migrate to the salivary glands. When the now infective mosquito bites and probes for vertebrate blood, many of these sporozoites are likely to be injected into the new host in released saliva. The duration of the sexual or sporogonic phase of the cycle is controlled principally by environmental temperature and humidity. *P. vivax* requires a minimum temperature of 16°C; *P. falciparum,* at least 18°C. The duration of *P. vivax* sporogony is 9 to 16 days and that of *P. falciparum,* 12 to 24 days, when environmental temperatures range between 20° and 25°C (Bruce-Chwatt 1987).

Most of the sporozoites injected by the biting mosquito are phagocytosed, but some, traveling in the bloodstream, reach the liver, enter parenchymal cells, and (as tissue *schizonts*) proceed by nuclear division to form large numbers (10,000 to 20,000) of merozoites. Eventually, about 6 to 16 days after initial infection, the preerythrocytic schizont ruptures, releasing its *merozoites* into the bloodstream. Those merozoites that escape phagocytosis invade red blood cells and, as *trophozoites,* initiate the erythrocytic portion of the asexual phase. The trophozoite form breaks down the hemoglobin of the host erythrocyte, leaving hematin pigment as a digestive product. As it grows, the parasite (now called an erythrocytic schizont) divides, producing 8 to 24 merozoites, depending on the species. For the human malaria parasites, schizogony in the red cell lasts about 48 hours or, for *P. malariae,* about 72 hours. When the schizont reaches maturity, the erythrocyte bursts and the merozoites are released. Again some will be phagocytosed whereas others will invade uninfected red cells. Erythrocytic schizogony may then continue through repeated cycles with increasing synchronism, manifest as clinical periodicity. As a consequence, more and more red cells are parasitized and destroyed. Immune responses or therapeutic intervention can check the process short of profound anemia, complications, and death.

Following clinical recovery, *P. vivax* and its close relative *P. ovale* are capable of causing relapse, even after several years. Recrudescence of quartan malaria (*P. malariae* infection) may occur after many years, even 30 or more years after initial infection. *P. vivax* and *P. ovale* infections can persist because of the survival in the host liver of dormant stages capable of reinitiating erythrocytic schizogony. Recrudescent *P. malariae* infection appears to be due to long-term survival of erythrocytic-stage parasites.

P. falciparum parasites, on the other hand, are much more limited in time of survival; if the disease is left untreated and is not fatal, *P. falciparum* infection will terminate spontaneously without relapse, usually in less than a year. Instead of developing as trophozoites, small numbers of red cell merozoites differentiate as male and female forms (*gametocytes*). These circulate in erythrocytes and may eventually be ingested by a female *Anopheles* mosquito – to begin a new sexual phase of the life cycle.

Although malaria transmission normally follows the bite of the infected mosquito, several other routes have been recorded, including congenital transmission and direct transfer of parasites by blood transfusion or by contaminated needles shared by drug abusers. Before the advent of antibiotic therapy, malaria infections were also sometimes induced by injection for therapeutic purposes – for example, to produce high fevers in the treatment of late-stage syphilis.

Distribution and Incidence

Although the eradication campaigns of the 1950s and 1960s contributed to substantial declines in the incidence of malaria in many countries, and to the elimination of transmission in some, malaria persists as a major contributor to ill health in vast areas of the tropical and subtropical world. Reported cases of malaria are increasing from year to year, especially in areas of Asia and the Americas undergoing agricultural colonization with forest clearing and pioneering of unexploited lands. Eradication campaigns have given way to long-term control programs in most areas where the disease remains endemic, and in some countries control is now being linked to or integrated with systems of primary health care (Bruce-Chwatt 1987; Hilton 1987).

The present global situation has been categorized by David Clyde (1987) as follows:

1. Areas where malaria never existed or disappeared spontaneously (with a current population totaling some 1.3 billion)
2. Areas where control and eradication campaigns, in combination with other factors, have eliminated endemic malaria in recent years (population about 800 million)
3. Areas under continuing control, including most endemic countries of Asia and the Americas (population about 2.2 billion)
4. Areas with little or no organized control, mainly in Africa south of the Sahara (population about 400 million)

Table VIII.85.1. *Malaria in 1984*

Geographic areas	No. of cases reported to the World Health Organization	Population at risk (millions)	Estimated incidence per 1,000 population at risk
The Americas	914,000	179	11.8
Europe, including Turkey and former Soviet Union	60,000	47	2.1
Africa south of the Sahara	5,000,000[a]	385	202.6
North Africa and western Asia	305,000	166	5.4
Central and South Asia	2,711,000	844	10.5
Eastern Asia and Oceania	1,300,000	1,069	7.5
Total	10,290,000		

[a]Estimated; mainly clinical diagnoses.

Source: Adapted from World Health Organization data and Clyde (1987, tables 1 and 2).

Reported cases, and estimates for Africa south of the Sahara, are summarized in Table VIII.85.1 for 1984, together with incidence estimates. The total of some 10 million cases probably represents less than 10 percent of actual cases for that year because of reporting and surveillance deficiencies. Clyde (1987) believes that the infected population in 1984 may actually have exceeded 100 million in a population at risk of 2.6 billion. Malaria-related deaths are also poorly reported; David Hilton (1987) notes that worldwide estimates of deaths are still in the range of hundreds of thousands every year.

The Americas. The United States, Canada, and most countries of the Caribbean are essentially free of malaria transmission and report only small numbers of imported cases. Costa Rica, Panama, and several southern South American countries are also nearly free of local transmission. Haiti and the Dominican Republic report only *P. falciparum* cases, although in substantial numbers. *P. vivax* is the prevailing species in Mexico, Central America, and northern South America, although many *P. falciparum* cases are also reported, especially from Brazil, Colombia, and Ecuador.

Europe, Turkey, and the former Soviet Union. Malaria is no longer endemic in Europe and the Soviet Union, but Turkey still reports some autochthonous cases.

Africa south of the Sahara. About 90 percent of the population in this region is still at risk, and transmission is high in many areas, especially in rural West Africa (Spencer 1986). *P. falciparum* is the predominant species.

North Africa and western Asia. Only a few small foci of autochthonous transmission persist in this region.

Central and South Asia. Malaria remains endemic in most countries of the region. *P. vivax* is predominant, but *P. falciparum* is also important, and this species appears to be increasing in relative prevalence (Spencer 1986).

Eastern Asia and Oceania. The northeastern area of Asia, including Japan, is free of transmission, as are many of the smaller islands and island groups in Oceania. Endemic foci persist in some of the larger island areas (e.g., the Philippines, the Solomon Islands, Papua New Guinea, and Indonesia) and in most of mainland Southeast Asia and China. *P. vivax* prevails in China, where the incidence is steadily declining. In Thailand, which is also experiencing a decline in incidence, *P. falciparum* is somewhat more prevalent than *P. vivax*.

Epidemiology and Control

Malaria transmission in any locale depends upon the complex interactions of parasites; vector mosquitoes; physical, socioeconomic, and environmental factors; and human biology, demography, and behavior.

The four species of plasmodia differ in many biological characteristics. Each species, for example, has somewhat different environmental temperature requirements for sporogony; each is different in many features of its schizogonia cycle, and as a consequence, each has distinctive clinical manifestations. *P. falciparum* differs so much from the other three species (of the subgenus *Plasmodium*) that it has been assigned to its own subgenus, *Laverania* (Garnham 1966). Within each species, variation in

strains is also important. Differences in strains influence sporogonic development in mosquitoes, virulence and thus the clinical course, and the development of resistance to antimalarial drugs.

The presence of anopheline mosquitoes capable of supporting sporogony is fundamental for natural malaria transmission. Although more than 400 species of *Anopheles* have been described, natural sporozoite infections have been found in only about 67 species, and only some 30 species are recognized as important vectors (Spencer 1986). Usually, in any endemic area, only one, two, or three vector species are responsible for most of the malaria transmission. Parasite species and strain differences affect anopheline receptivity to infection. Vector competence for transmission is also influenced by mosquito population densities, flight ranges, feeding and resting habits, blood meal preferences (anthropophilic for human blood; zoophilic for animal blood), blood meal frequencies, and the lifespan of the female anopheline. In recent decades, resistance to insecticides has also become a major vector-related determinant of transmission.

Vector, parasite, and host interactions are profoundly affected by factors in the environment. Physical factors, such as temperature, rainfall, and humidity, control mosquito survival and the duration of sporogony. Other factors such as latitude, altitude, and landscape characteristics (natural or human-modified) influence mosquito breeding, vector densities, and vector survival, as well as many kinds of human behavior. In addition, features of the social and economic environment contribute in many ways to patterns of transmission.

Age, gender, and a variety of human demographic variables, together with genetic factors, immune mechanisms, and health conditions (e.g., nutritional status, pregnancy, and concurrent infections), constitute the final host-related set of determinants in the malaria epidemiological complex that must be well understood before fully effective control can be instituted in any setting.

The incidence and prevalence of clinical cases may be useful measures for describing the status of malaria in an area, but parasite and spleen rates are even more helpful for determining the level of endemicity – spleen rates particularly, because enlarged spleens are indicative of past or recent active erythrocytic schizogony. The *spleen rate* is the proportion of persons, usually children 2 to 9 years old, with enlarged spleens at a particular time, whereas the *parasite rate* is the proportion of persons in a population with microscopically confirmed parasitemia at a particular time.

Malaria endemicity is classified on the basis of spleen or parasite rates:

1. *Hypoendemic malaria:* spleen or parasite rates up to 10 percent in 2- to 9-year-old children
2. *Mesoendemic malaria:* spleen or parasite rates of 11 to 50 percent in 2- to 9-year-olds
3. *Hyperendemic malaria:* spleen or parasite rates over 50 percent in 2- to 9-year-olds together with a high adult spleen rate
4. *Holoendemic malaria:* spleen or parasite rates over 75 percent in 2- to 9-year-olds with low adult spleen rates and high infant parasite rates

In a pioneering work, George Macdonald (1957) attempted to fit many of the variables noted above into an epidemiological model. His ideas continue to be influential in contemporary malariology despite many advances in epidemiological and mathematical modeling sophistication. Macdonald's principles in defining stable and unstable malaria, for example, continue to be helpful in studies of epidemiological patterns. Stable malaria is characteristically endemic, often hyper- or holoendemic. There is little seasonal change; transmission continues through most or all of the year; epidemics of malaria are very unlikely to occur; and most of the population, except infants, has some immunity as a result of experience with the disease. Control under these circumstances is likely to be very difficult. Malaria in much of tropical Africa south of the Sahara corresponds to Macdonald's stable extreme.

Unstable malaria may be endemic, but transmission varies from year to year and may be strictly seasonal, reflecting the strong seasonal change typical in unstable areas. Seasonal epidemics may occur, collective immunity varies and may be low, and children as well as infants may be nonimmune. Control is relatively easy, and indeed, many of the countries only recently freed from endemic malaria were in the unstable category.

Immunity

Acquired and innate immunity are important factors in the epidemiology of malaria. Innate resistance has been recognized in some human populations. In parts of Central and West Africa, many individuals lack the Duffy blood group antigens Fy^a and Fy^b and are thus resistant to *P. vivax* infection. Generally, in these areas, *P. ovale* replaces *P. vivax* as the prevailing cause of benign tertian malaria. In endemic *P. falciparum* areas of Africa, those individuals heterozygous for hemoglobin AS or sickle trait are more likely to survive malignant tertian ma-

laria than are hemoglobin A homozygotes. The persistence of sickle-cell disease (in hemoglobin SS homozygotes), with its unfortunate consequences, is balanced by the substantial advantage conferred by the AS condition, but only as long as *P. falciparum* remains endemic in the area. Several other hemoglobin variants have been thought to provide some protection against *P. falciparum* infection; it is known that persistent hemoglobin F (fetal Hb) delays development of falciparum parasites (Bruce-Chwatt 1987). Another genetic condition, deficiency of the red blood cell enzyme glucose 6-phosphate dehydrogenase (G6PD), also provides a degree of protection against falciparum infection.

Acquired immunity in malaria is species-specific and also specific to stage, that is, to the sporozoite, to the asexual forms in the blood, or to the sexual stages (Clyde 1987). In endemic areas, newborns may be protected for a few months by maternal antibodies that have crossed the placenta. After this phase of protection, however, infants and toddlers are especially vulnerable; most of the severe illnesses and deaths due to malaria in endemic regions occur in these early years. Older children and adults gradually acquire immunity with repeated exposure to infection. This partial immunity (*premunition*) is sustained in the presence of low densities of parasites in the blood. In premune individuals the spleen may remain enlarged; hence the spleen rate may be relatively high in an adult population despite a low parasite rate. With prolonged exposure and infection, however, as in a holoendemic area, eventual spleen scarring and shrinkage leads to a low adult spleen rate. Attenuated malaria certainly contributes to impaired resistance to other diseases; thus improved malaria control in endemic areas generally results in declines in morbidity and mortality from all causes (Bruce-Chwatt 1987).

Clinical Manifestations and Pathology

The classical malaria paroxysm is initiated by a chill, lasting up to an hour and often accompanied by headache, nausea, and vomiting. The chill is followed by a period of spiking fever lasting several hours. The subsiding fever is accompanied by sweating, often profuse. The relieved patient may drift off to sleep, to awaken feeling relatively well. The early paroxysms may be asynchronous. As the clinical episode progresses, *P. malariae* paroxysms occur about every 72 hours (*quartan* periodicity), whereas those of the other three species occur with *tertian* (48-hour) periodicity. *P. falciparum* infection is less likely to become clearly synchronous, and the classic

clinical picture may never develop. Mixed infections of two or even three species may produce atypical and confusing clinical manifestations.

These clinical events are related to the behavior of the parasites in the bloodstream. The onset of chill reflects the escape of parasites and metabolic products from great numbers of ruptured red cells. By the end of the paroxysm, the parasites will have invaded new red cells to initiate another generation of erythrocytic schizogony. With each cycle of invasion, multiplication, and rupture, more red cells are destroyed. In the absence of treatment and immune defenses, severe anemia may develop, particularly in falciparum malaria. The spleen enlarges during the acute episode, in part because of its function in filtering out of the bloodstream the detritus resulting from red cell destruction. The liver may also increase in size.

Although malaria caused by the other three species may be fatal, most of the serious complications and deaths are caused by *P. falciparum*. This species can invade a high proportion of the total red cell mass, and the parasitized cells tend to agglutinate, occluding capillaries in almost any organ. These occlusions are considered to underlie cerebral, gastrointestinal, adrenal, and other complications in falciparum malaria. Cerebral malaria begins with headache and may progress to convulsions, delirium, and coma. Gastrointestinal complications resemble bacillary dysentery or cholera.

The initial uncomplicated and untreated episode of malaria usually lasts 2 to 4 weeks (about twice as long for *P. malariae*). Relapses commonly occur in untreated malaria. Drug-resistant strains of *P. falciparum* may also cause relapses after inadequate treatment.

Blackwater fever is a distinctive intravascular hemolytic disorder associated with longstanding and repeated falciparum malaria infection, especially in hyper- and holoendemic areas. The incidence of blackwater fever has fallen considerably in the second half of this century as malaria control has improved and as drug prophylaxis and treatment has expanded from an earlier dependence on quinine. Quinine is not an essential etiologic factor, but the onset of blackwater fever has often been noted to follow the administration of therapeutic doses of the drug. It is also known that the disorder rarely occurs in persons who have taken quinine regularly as a prophylactic. Blackwater fever is characterized by abrupt onset, chill, fever, jaundice, nausea, vomiting, and red or dark-brown urine containing hemoglobin. The case mortality rate, resulting principally

from anuria and uremia, usually falls between 10 and 30 percent.

History and Geography

Since at least the mid-Pleistocene, many thousands of generations of humans have been parasitized by the plasmodia (Garnham 1966). Species very similar to the human plasmodia have also been described from gorillas and chimpanzees; indeed the relationships of the malaria parasites of humankind and the African apes are extremely close (Dunn 1966; Garnham 1966). It is therefore certain that human malaria is an Old World disease in its origins. There has, however, been some debate about the timing of malaria's appearance in the Western Hemisphere (McNeill 1976). Some have suggested that malaria was present in the New World long before the time of European contact, but a strong case can be made that the hemisphere was malaria-free until the end of the fifteenth century (Dunn 1965; McNeill 1976).

Malaria could have reached the New World before 1492 only as an infection of migrants from northeast Asia or by pre-Columbian sea-borne introductions. The possibility that humans brought malaria overland into North America from Siberia can almost certainly be discounted; conditions for malaria transmission were unsuitable in the far north during and after the Pleistocene, as they are today. It is equally unlikely that the Vikings could have introduced malaria in the centuries before Columbus. These voyagers came from regions of Europe and the North Atlantic (Greenland, Iceland) presumably free of malaria at that time, and they seem to have visited northeastern North American coasts that were north of any possible receptive anopheline mosquito populations. Similarly, any voyagers landing on American shores from the central or eastern Pacific could not have carried the parasites with them because islands in that region are free of anopheline vectors and thus of locally transmitted malaria. Voyagers reaching American coasts from eastern Asia (e.g., fishermen adrift from Japan) could conceivably have introduced malaria, but this possibility too is remote.

Moreover, and more to the point, colonial records indicate that malaria was almost certainly unknown to the indigenous peoples of the Americas. It is also evident that some areas that supported large pre-Columbian populations soon became dangerously malarious after European contact (McNeill 1976). The absence in aboriginal American populations of any of the blood genetic polymorphisms associated with malaria elsewhere in the world is another kind of evidence consistent with the conclusion that the Western Hemisphere remained free of the disease until contact (Dunn 1965).

In the first two centuries after 1492, malaria parasites must have been introduced many times from Europe and Africa. Anopheline vectors were at hand, species native to the Americas. Together with smallpox, measles, and other infectious diseases brought across the Atlantic from the Old World, malaria soon began to contribute to the depopulation of the indigenous peoples, especially those of the lowland American tropics (Borah and Cook 1963; Crosby 1973; McNeill 1976).

From its early, usually coastal, sites of introduction, malaria spread widely in North, Central, and South America, limited principally by altitude and latitude – that is, by factors controlling the distribution of vector mosquitoes. By the nineteenth century in North America, the disease was prevalent in much of the Mississippi Valley; seasonal transmission occurred even in the northernmost areas of the Mississippi basin (Ackerknecht 1945). Malaria transmission, unstable and seasonal, also extended into the northeastern United States, well north in California, and far to the south in South America. By the eighteenth and nineteenth centuries, malaria had also become established as a stable endemic disease in the American subtropics and tropics, including most of the islands of the Caribbean.

The Old World gave malaria to the New; the New World, however, provided the first effective remedy for the disease. It is recorded that a sample of cinchona bark, taken from a Peruvian tree as a medicinal, was carried to Europe in 1632 by a Spanish priest (Russell et al. 1963). The bark was soon discovered to provide relief from certain intermittent fevers. This therapeutic action allowed Richard Morton and Thomas Sydenham in England in 1666, and Francesco Torti in Italy in 1712, to begin the process of defining malaria as a clinical entity separable from other fevers, which failed to respond to cinchona (Russell et al. 1963). By the end of the seventeenth century, cinchona bark was an important export product from Peru, well established in the treatment of intermittent fevers.

The human malaria parasites have evolved in association with their evolving hosts and have followed the human species through most, but not all, of its dispersal in Africa, Asia, and Europe. Transmission, dependent on suitable anopheline mosquitoes, has always been limited by all those environmental conditions, influenced by latitude and altitude, that control vector breeding and survival.

The antiquity of the human–*Plasmodium* associa-

tion in the Old World is symbolized, biologically, by the existence in modern populations of some of the blood genetic polymorphisms. Early texts – Chinese, Hindu, Chaldean, Greek – give us other evidence of this ancient association (Russell et al. 1963; McNeill 1976; Bruce-Chwatt and Zulueta 1980). Malaria was probably endemic in Greece by the fourth century, B.C.; Hippocrates described the types of periodicity of intermittent fevers – quotidian, tertian, quartan – and took note of the enlargement of spleens in those who lived in low, marshy districts. In Italy, too, the intermittent fevers were well known, for example, to Cicero, and well described by Celsus, Pliny the Elder, and Galen (Russell et al. 1963).

Malaria was certainly a disease of some importance in the centuries of Roman domination of Europe and the Mediterranean basin. However, in their review of malaria in early classical times, especially in relation to military operations, L. J. Bruce-Chwatt and J. de Zulueta (1980) reached the conclusion that malaria was much less destructive than it has been in recent centuries, primarily because *P. falciparum* was absent or rare and the other species were less intensely transmitted. The conclude that *P. falciparum* failed to spread in those centuries because *Anopheles atroparvus* was refractory as a vector for the falciparum strains then introduced from time to time by travelers. *A. atroparvus*, basically a zoophilic species, was also a poor vector for *P. malariae* and *P. vivax*. By late classical times, however, it appears that two other anopheline species, *Anopheles labranchiae* and *Anopheles sacharovi*, had been introduced and dispersed along the coasts of southern Europe from their North African and Asian origins. These anthropophilic species were much more effective as vectors for all three of the species of plasmodia. By the final centuries of the Roman Empire, malaria was a more lethal force and may have contributed to the social, political, and cultural decline that had set in.

After the fall of the Roman Empire, the history of malaria in Europe and the Mediterranean region is obscure for many centuries (Bruce-Chwatt and Zulueta 1980). With few exceptions medieval medical writers provide only sketchy and confusing accounts of cases and outbreaks that may have been due to malaria. During the Renaissance, the historical record is clearer and richer, but malaria appears not to have represented a major problem to society in those centuries. It is not until the seventeenth and eighteenth centuries that malaria became resurgent in Europe, not only in the south but, in periodic outbreaks, as far north as the Netherlands, Ger-

many, southern Scandinavia, Poland, and Russia (Bruce-Chwatt and Zulueta 1980).

Through all of these centuries the record of malaria's human impact in Asia and Africa is fragmentary. With the onset of European colonization, however, it soon became obvious that endemic malaria was a threat almost everywhere in the Old World tropics, especially to the colonizers (who were, of course, generally nonimmune upon arrival in the tropics). The beginnings of tropical medicine and modern malariology are entangled in this recognition (Dunn 1984).

The modern era in malariology began in the last two decades of the nineteenth century with the identification of the causal parasites and the recognition of the role of anopheline mosquitoes as vectors. These discoveries provided the rationale for new strategies in malaria control, developed during the first third of the twentieth century. Malaria control itself was not a new concept; nor was the control of mosquitoes a new idea at this time. Humankind had sought from ancient times to control biting mosquitoes as pests (Russell et al. 1963). The new rationale, however, provided for much more specific vector control, directed principally at those anophelines that proved to be important in transmission. Malaria control was further strengthened in the 1930s with the introduction of synthetic antimalarials, useful not only in treatment but also in prophylaxis. The 1940s brought further advances in chemotherapy together with the first of the residual insecticides, DDT.

By the late 1940s and early 1950s, the resources for treatment and control of malaria appeared to be sufficiently formidable to justify attempts at national eradication in a few countries (e.g., Venezuela, Italy, the United States). Early success in local or aerial eradication, based on residual spraying, together with concerns about the emergence of anopheline resistance to DDT and other insecticides, led to a decision in 1955 to commit the World Health Organization to malaria eradication. This commitment pushed many countries into supposedly time-limited eradication campaigns, often with considerable WHO financial and adivsory support. Some of these campaigns were successful, especially in countries with unstable malaria, but others faltered after dramatic initial reductions in incidence. By the end of the eradication era, in the early 1970s, some hundreds of millions of people were living in areas where campaigns had eliminated endemic malaria (Clyde 1987), but in many other areas malaria continued to prevail, forcing a return to long-term control strategies.

In 1980 the World Health Organization began to recommend that malaria control be coordinated with primary health care. The experiences, especially the difficulties, of the eradication years also made it imperative that modern malaria control be strongly supported by epidemiological field work with recognition of local variability in transmission patterns and of sociocultural, economic, and human behavioral influences on transmission and control (Bruce-Chwatt 1987). Malaria control and therapy continues to be complicated by mosquito resistance to insecticides and by parasite resistance to drugs. Vaccine development proceeds, although slowly. The problems posed by malaria persist, but they are not insoluble. Malaria will remain endemic in many countries in the twenty-first century, but the prospects are good for steady improvement in control.

VIII.86
Marburg Virus Disease

History

In 1967, a disease outbreak occurred in a laboratory in Marburg, Germany, where the kidneys of cercopithecoid (Green African; vervet) monkeys were being taken out for preparation of cell cultures. Twenty-seven laboratory workers (including a worker in Yugoslavia) fell ill with a grave illness, and seven died. There were four secondary cases in total (including the wife of an infected laboratory worker in Yugoslavia secondarily infected by sexual intercourse), but none fatal. Early suspicions focused on yellow fever, but this was soon ruled out (Casals 1971). In due course, a virus was isolated and found to be quite distinct from any other known viruses. Electron micrographs revealed a virus with bizarre morphology of a type never seen before (Peters, Muller, and Slenckza 1971). Pictures taken resembled photographs of a bowl of spaghetti. The agent was named Marburg virus and the disease Marburg disease. Strict monkey quarantines were initiated. No further cases were seen in laboratory workers.

An intensive and extensive series of field studies were initiated in East Africa, which had been the monkeys' homeland (Henderson et al. 1971; Hennessen 1971; Kalter 1971). No virus recoveries were made from any of the monkeys examined. In later years, serologic studies involving humans and primates, and also rodents, have been carried out in many regions, as can be seen in Table VIII.86.1.

The first Marburg cases seen in Africa occurred in February of 1975. A young Australian couple touring in Rhodesia (Zimbabwe) became ill by the time they got to South Africa. They were admitted to a major hospital in Johannesburg where the young man died and the young lady recovered. A nurse tending them also sickened and recovered. After the disease was determined to be Marburg, a thorough epidemiological inquest was carried out all along the

route of passage of the victims, concentrating particular attention on every locale where they spent a night. Animal, insect, and human populations were sampled. No evidence of endemic disease was found (Gear et al. 1975).

On January 14, 1980, a 58-year-old man from western Kenya was seen in a Nairobi hospital. He died 6 hours after admission, and a physician who attended him also became ill but recovered. A Marburg virus was isolated from his blood (Centers for Disease Control 1980). Subsequent epidemiological investigations carried on in western Kenya produced a positive finding: Antibodies against the Marburg virus were found in two vervet monkeys from among many primates examined.

The latest episode involved a boy in Kenya in 1987 who became infected in a visit to a park in the western part of Kenya. The boy died. There were no secondary cases reported.

Etiology

Electron microscopic examination of blood, liver, and spleen of guinea pigs infected with materials from patients show a long, viruslike agent, quite unlike any virus particle ever before visualized. The particles vary in length, up to several microns. The width of the particles is also variable, with limits of 720 to 1100 Å (7,200 to 11,000 nanometers). There is an outer shell, an intermediate clear zone, and a nucleo-

capsid core of approximately 280 Å width (Peters et al. 1971). Marburg virus was shown (Casals 1971) to be unrelated to the many arboviruses against which it was tested, and most closely resembles the Ebola virus agent discovered in 1976. In fact, both Marburg and Ebola viruses have since been placed in a new family, Filoviridae (Kiley et al. 1982), which includes but the two members thus far.

It was discovered that the Marburg virus could be inactivated by gamma irradiation (Elliot, McCormick, and Johnson 1982); this finding made the preparation of inactivated diagnostic reagents possible. Cultivation of Marburg in cell culture has allowed observation of growth and multiplication taking place in a number of mammalian and avian cell types. A cytopathic effect on cells was observed in *Cercopithecus* kidney cell lines, and human amnion cell lines (Hoffmann and Kunz 1971).

Immunoglobulin responses have been studied (Wulff and Johnson 1979), measured by immunofluorescence. Immunoglobulin M antibodies appear in sera of patients infected with Marburg virus 4 to 7 days after onset of illness. Titers peak 1 to 2 weeks later, and by 1 to 2 months have decreased considerably. Antiviral IgG antibodies appear at the same time as or a little later than IgM antibodies and persist much longer (Wulff and Johnson 1979). In autopsy material, antigenic material is present in large amounts, and can be demonstrated as late as 3

hours after death by use of immunofluorescent techniques (Wulff, Slenczka, and Gear 1978).

Clinical Manifestations and Diagnosis

The incubation period following exposure varied from 5 to 7 days. In six cases for which data are available, death occurred between days 7 and 16. The onset was indicated by malaise, myalgia, and often prostration (Martini 1971). Vomiting frequently occurred by the third day, and conjunctivitis by the fourth, by which time the temperature had reached 40°C. A rash occurred on the fifth day, was macular in type, and progressed usually to a maculopapular rash that later coalesced into a more diffuse rash. In severe cases, a diffuse dark livid erythema developed on face, trunk, and extremities. An enanthem of the soft palate developed at the same time as the rash. Spleen and liver were not palpable. Lymph node enlargement was noted in the nuchal region and the axillae. A diarrhea appeared, often with blood in the stools. The South African cases differed only in that there were no enanthem and no lymph node enlargement.

The above description was declared by several clinicians to make diagnosis easy. This may be true when there is a clustering of cases, and epidemiologists are on the alert; however, in much of Africa, the occurrence of single cases, however severe, would not be likely to arouse suspicion. Moreover, during the first 5 to 6 days, the symptoms could be mistaken for those of many other diseases. Laboratory diagnosis is accomplished by means of immunofluorescence techniques, by electron microscopic examination of a serum sample from a patient, which has been centrifuged and placed on a grid (Wulff et al. 1978), and by inoculation of laboratory animals. None of these methods is readily accessible in the usual field situation; yet early diagnosis is imperative in order to abort a possible developing epidemic.

Mortality

Because descriptions of Marburg virus pathology are equally applicable to Ebola virus, some pathologists feel that the findings are not distinctive enough to permit a positive diagnosis of either on the basis of pathology alone, especially in regions where there are many causes of fever and death.

Guinea pigs and rhesus and vervet monkeys are susceptible to the virus. The infection is fatal for the monkeys and, often but not always, fatal for the guinea pigs. Guinea pigs that recover may have persistent virus in serum and urine for several weeks. The same has been observed for human beings.

Ebola virus infection is considerably more fatal in humans than is the Marburg virus. In the four secondary Marburg cases studied, it was clear that their clinical course was less severe than that seen in primary cases, and there was no mortality.

Treatment and Prophylaxis

No effective therapy has been found. In one case in a London treatment center, therapy was instituted using interferon in conjunction with immune plasma. The patient, a secondary exposure case, recovered. Further clinical trials on human beings await further cases.

Basic methods for the management of patients with suspected viral hemorrhagic fever include strict isolation and precaution in examination and in taking specimens from patients, as well as in handling material from suspect cases in the laboratory. Such procedures are not readily applicable in bush clinics in many parts of Africa. Further precautions are necessary in the movement of suspected cases internationally and in the shipment of specimens internationally (Simpson 1977; Centers for Disease Control 1988).

Prophylaxis and control await further epidemiological information on animal reservoirs of disease, modes of transmission from animal reservoirs (if indeed there are animal reservoirs) to humans, and modes of persistence of the virus in nature.

VIII.87
Mastoiditis

Infections of the middle ear and mastoid encompass a spectrum of potentially serious medical conditions and sequelae. Decreased hearing from ear infections may have a lifelong impact on speech, learning, and social and vocational development, causing these conditions to remain a major health concern. Because of the anatomic relationship of the middle ear and mastoid to the middle and posterior cranial compartments, life-threatening complications may occur.

Classification

Inflammatory diseases of the middle ear and mastoid are categorized according to the underlying disease process and location:

1. *Acute suppurative otitis media* (AOM) is characterized by obstruction of the eustachian tube, allowing the retention and suppuration of retained secretions. AOM is the medical term associated with, most commonly, the acute ear infection of childhood. Generally the course of this infection is self-limited, with or without medical treatment, and the retained infected secretions are discharged through either the eustachian tube or a ruptured tympanic membrane.

Acute coalescent mastoiditis can result from failure of these processes to evacuate the abscess. Coalescence of disease within the mastoid leads to pus under pressure and ultimately dissolution of surrounding bone. This condition may require urgent surgical evacuation because the infection is capable of spreading to local and regional structures.

3. *Otitis media with effusion* (OME) is an inflammatory condition of the middle ear in which serous or mucoid fluid accumulates. Both AOM and OME are precursor conditions to tympanic membrane retractions and perforations. Ongoing eustachian tube dysfunction predisposes to persistent retained secretions in the ear and recurrent acute attacks of otitis media. A small percentage of these patients develop a chronic tympanic membrane perforation which, in most cases, allows eventual aeration of the middle ear and mastoid air-cell spaces and resolution of the underlying disease process.

4. *Chronic suppurative otitis media* (CSOM) is defined as an ear with a tympanic membrane perforation. Benign CSOM is characterized by a dry tympanic membrane perforation, unassociated with

active infection. Active CSOM is the result of intermittent bacterial infection often in the presence of ingrown skin in the middle ear and mastoid cavities. This skin ingrowth is known as *cholesteatoma formation*. *Primary acquired cholesteatoma* occurs through a tympanic membrane retraction into the attic of the middle-ear space, with a subsequent potential for extension into the middle ear and mastoid air-cell systems. *Secondary acquired cholesteatoma* is defined as skin growth through a tympanic membrane perforation into the ear.

Distribution and Incidence

Surveys of large pediatric populations demonstrate that 80 percent of all children will experience one or more episodes of AOM by the age of 6. Together AOM, OME, and CSOM comprise one of the most common disease entities affecting human populations. Indeed, AOM is thought to be the most common disease treated with antibiotics.

Prevalence studies have demonstrated an extraordinarily high incidence of complicated infections of the middle ear in African, American Indian, Alaskan and Canadian Eskimo, Australian aboriginal, and New Zealand Maori pediatric populations, suggesting that disease-manifesting tissue destruction of the middle-ear and mastoid structures is much more prevalent in these areas. By contrast, studies of children in different geographic areas indicate that the incidence of uncomplicated disease in the middle ear is similar in all areas.

The incidence of complicated infections producing mastoiditis has dramatically declined since the advent of antibiotics in the 1930s and 1940s. Prior to that time, acute coalescent mastoiditis complicated AOM in approximately 20 percent of the cases. Initially, antibiotics cut into mortality rates from mastoiditis, but overall moribidity remained unchanged. By the 1950s, however, the incidence of acute mastoiditis resulting from AOM had declined to 3 percent. Current reports indicate that mastoiditis and other infectious complications will develop in less than 0.5 percent of cases of AOM.

Epidemiology

A variety of host and environmental factors, as well as infectious etiologic agents, have been linked to infection of the middle ear and mastoid. AOM occurs most commonly between 6 and 24 months of age. Subsequently, the incidence of AOM declines with age except for a limited reversal of the downward trend between 5 and 6 years of age, the time of entrance into school. The incidence of uncomplicated AOM is not significantly different in boys from that in girls. Mastoiditis, however, would appear to be more common among males.

Studies of eastern coast American children have demonstrated a higher incidence of middle ear infections in Hispanic and Caucasian children than in black children. The higher incidence of middle ear and mastoid infections in certain peoples is not readily explained. Variability in eustachian tube size, orientation, and function among racial groups has been suggested as being responsible for differences in disease incidence. Genetic predisposition to middle ear infection and associated complications has also been demonstrated. Down syndrome, cleft palate, and other craniofacial anomalies are also associated with a high risk of developing AOM, OME, and CSOM.

The severity of otitic infections is related to factors such as extremes of climate (temperature, humidity, and altitude) and poverty with attendant crowded living conditions, inadequate hygiene, and poor sanitation. There is a well-recognized seasonal variance in the incidence of AOM. During the winter months, outpatient visits for AOM are approximately 4-fold higher than in the summer months. Although intake of mother's milk and avoidance of cigarette smoke appear to confer some protection against OME, no effect on the incidence of suppurative complications has been shown.

Etiology

Eustachian tube dysfunction is the most important factor in the pathogenesis of middle ear infections. The most commonly cited problem is an abnormal palatal-muscle, eustachian-tube vector, which commonly occurs in young children. With adolescent growth, descent of the soft-palate-muscle sling relative to the eustachian tube orifice improves the eustachian tube opening. However, poor tubal function may persist with mucosal disease (allergic, inflammatory, immunologic impairment, or immotile cilia), extrinsic compression (enlarged adenoid or nasopharyngeal tumor), or palatal muscle dysfunction (cleft palate and other craniofacial anomalies). Persistent eustachian-tube dysfunction induces a relative negative pressure in the middle-ear space. The lack of aeration and the accumulation of effusions provide an environment conducive to the development of OME or AOM.

Bacteriologic studies identify *Streptococcus pneumoniae* and *Hemophilus influenzae* most frequently as the pathogenic organisms in AOM. Group A beta-

hemolytic streptococcus, *Staphylococcus aureus,* and *Branhamella catarrhalis* are less frequent causes of AOM. Gram-negative enteric bacilli are isolated on occasion in infants up to 6 weeks of age with AOM.

When AOM continues beyond 2 weeks as a result of inadequate antimicrobial therapy, progressive thickening of the mucosa lining the middle ear obstructs free drainage of purulent secretions, thereby permitting bone destruction and extension of infection. This process may eventuate in mastoiditis and possibly other local or intracranial extensions of suppuration.

Immunology

The respiratory mucosal membrane that lines the middle-ear space and mastoid air cells is an immunologic defense consisting of constantly renewed mucus that contains lysozyme, a potent, bacteria-dissolving enzyme. In response to an invading organism, production of mucus is increased. Inflammatory dilation of vessels, white blood cell migration, and proteolytic enzyme and antibody deposition contribute to the formation of mucopurulent (containing both mucus and pus) secretions. All of the major classes of immunoglobulins have been identified in middle-ear effusions of patients with AOM. A significant type-specific antibody response in the serum to the bacteria responsible for AOM has been demonstrated. The presence of this type-specific antibody in middle-ear effusions is associated with clearance of mucopurulent secretions and an early return to normal middle-ear function.

The incidence of otitis media and attendant complications is higher in individuals with congenital or acquired immunologic deficiencies. The presence of a concomitant malignancy, the use of immunosuppressive drugs, uncontrolled diabetes, and previous irradiation are also associated with a higher risk of developing AOM and related complications.

Clinical Manifestations

The onset of AOM in childhood is often associated with fever, lethargy, and irritability. Older children may experience earaches and decreased hearing. Examination with a hand-held otoscope demonstrates tympanic membrane redness, opacity, bulging, and poor mobility when pneumatic pressure is applied. However, there is considerable variability in the symptoms and signs of acute otitis media.

OME is often characterized by hearing loss and a history of recurrent episodes of AOM. Otoscopic findings usually consist of fluid visible behind a retracted tympanic membrane.

CSOM in its active form often presents with foul-smelling drainage and longstanding hearing loss. Otoscopy reveals tympanic membrane retraction, perforation or hyalinization, and often, evidence of bony erosion, with the development of a cystlike mass called *cholesteatoma.* Development of pain in such an ear is a foreboding sign, as it often represents the obstruction of drainage of the infection, and pus under pressure. Local complications of CSOM include bone erosion producing hearing loss, facial nerve dysfunction, sensorineural hearing loss, ringing sounds in the ear, and vestibular disturbances. On occasion, infection will extend into the bony skull or into the soft tissues of the neck and scalp, either through normal preformed pathways such as vascular channels, or through progressive bone destruction. Catastrophic intracranial complications include abscesses, abnormal fluid accumulation, lateral sinus thrombosis, meningitis, and brain herniation.

Pathology

Pathological findings associated with AOM demonstrate inflammatory changes in the lining of the middle ear as well as suppurative exudates in the middle-ear cleft. The quantity of the exudate increases with time and exerts pressure on the tympanic membrane. The bulging tympanic membrane may rupture spontaneously in the central or marginal portions. Marginal perforations are more likely to lead to ingrowth of skin and the formation of a secondary acquired cholesteatoma. Primary acquired cholesteatomas arise in retraction pockets of the tympanic membrane that are induced by eustachian tube dysfunction. Cholesteatoma can also arise from congenital or traumatic implantation of skin into the middle ear as well as from abnormal changes in the middle-ear mucosal lining in response to inflammation.

Suppurative AOM persisting beyond 2 weeks can initiate the development of acute coalescent mastoiditis. The progressive thickening of the mucosa of the middle ear begins to obstruct the drainage of mucopus through the eustachian tube. Stoppage of blood in the veins and the high acidity of that blood promote demineralization and the loss of bony partitions. As a consequence, separate air cells of the mastoid coalesce into large cavities filled with mucopurulent secretions and thickened mucosal granulations. The erosion of bone, however, may not be confined to the air cell partitions within the mastoid bone. Other portions of the temporal bone including the posterior wall of the external canal, the mastoid cortex, and the

thin, bony plates separating air cells from the sigmoid sinus and dura may likewise be eroded. Extension of the infection beyond the mucosal lining of the middle ear and mastoid air cells may produce an intracranial complication, generally by passage of the infection along preformed bony pathways or through inflamed veins in intact bone.

History and Geography

Antiquity Through the Sixteenth Century

It is likely that humanity has always suffered from acute infections of the middle ear and attendant suppurative complications such as mastoiditis. Studies of 2,600-year-old Egyptian mummies reveal perforations of the tympanic membrane and destruction of the mastoid air-cell system. Evidence of suppurative destruction of the mastoid is also apparent in skeletal specimens from early Persian populations (1900 B.C. to 800 B.C.).

Hippocrates appreciated the potential seriousness of otitic complications and noted that "acute pain of the ear with continued high fever is to be dreaded for the patient may become delirious and die." Early in the Roman era, the Roman physician Aulus Cornelius Celsus observed that "inflammation and pain to the ear lead sometimes to insanity and death." The Arabian physician Avicenna related suppuration of the ear and mastoid with the brain, reasoning incorrectly that the ear discharge was caused by the brain disease. For centuries, middle-ear and mastoid infections producing discharges from the ear were considered virtually normal conditions because they occurred so frequently.

Although the seriousness of ear suppuration was appreciated much earlier, the concept of opening the mastoid to relieve infection did not occur until the sixteenth century. The great medieval surgeon Ambroise Paré was called to the bed of Francis II of France. Paré found the young king febrile and delirious with a discharging ear. He proposed to drain the pus through an opening in the lateral skull. The boy-king's bride, Mary, Queen of Scots, consented. However, the king's mother, Catherine de Médici, refused to let the surgery take place, causing Mary to lose her first husband and throne while she was only 18 years old.

Seventeenth Through Eighteenth Century

Notable advances in understanding the pathophysiology of aural suppuration were made in the late seventeenth century. Joseph DuVerney wrote *Traité de l'Organe de l'Ouie* (1683), which is generally regarded to be the first monograph published on the subject of otology. It was the first book to contain an account of the structure, function, and diseases of the ear, whereas earlier works were devoted to purely normal otologic anatomy. In this work, DuVerney described infectious aural pathology and the mechanisms producing earache, otorrhea, and hearing loss. He was the first to describe extension of tympanic cavity infection posteriorly to the mastoid air cells to produce the characteristic symptoms and findings of mastoiditis.

Noteworthy contributions were made by Antonio Valsalva (1704), who still believed that aural suppuration was secondary to cerebral abscess formation and was not the primary lesion. He did, however, suggest a method for removing purulence from the ear. This procedure consisted of blowing out strongly while holding the mouth and nose firmly closed, thus forcing air to pass into the middle ear by way of the eustachian tube. He suggested this maneuver as a means of expelling pus in cases of otitis. Valsalva's student Giovanni Morgagni, in his great work *On the Sites and Causes of Disease* (1761), revealed postmortem evidence that demonstrated that aural suppuration was the primary source of lethal, intracranial abscesses.

In the early eighteenth century, Jean Petit of Paris performed what is generally believed to have been the first successful operation on the mastoid for the evacuation of pus. He demonstrated recovery "after the compact layer had been taken away with gouge and mallet." He stressed the need for early drainage of mastoid abscesses because of the potential for "accidents which may supervene and render the disease infinitely complicated and fatal."

S. Stevenson and D. Guthrie, in their *History of Otolaryngology* (1949), describe how, in 1776, a Prussian military surgeon apparently treated a painful, swollen, draining mastoid by removing a portion of the overlying mastoid cortex. The surgeon was probably unaware of Petit's work, and the authors quote him saying, "Perhaps this is no new discovery, but for me it is quite new."

Performance of the mastoidectomy operation suffered a setback when the procedure was performed on Baron von Berger, personal physician to the King of Denmark. The baron, hearing of the success of Petit and others, persuaded a surgeon to operate upon his mastoid to relieve tinnitus and hearing loss. The operation was performed before the importance of surgical asepsis was realized, and resulted in a wound infection. The baron died of meningitis 12 days later, and the mastoidectomy operation fell into disrepute until the middle of the nineteenth century.

France was one of the first countries to remove otology from the sphere of the general surgeon and to give it a place of its own. One of the first to specialize in this discipline was Jean Marie Gaspard Itard. Itard was a military surgeon in Paris who carried out extensive study of otologic physiology and pathology, and published a textbook on these subjects, *Traité des Maladies de l'Orielle et de l'Audition,* in 1821. He exposed many errors of his predecessors, particularly their opening of the mastoid cavity as a cure for deafness. Like Itard, Jean Antoine Saissy, a Parisian surgeon, was strongly opposed to puncturing the tympanic membrane for aural suppuration as recommended by his predecessors. Instead, he treated middle ear and mastoid suppuration by rinsing through a eustachian catheter. He described the technique in his *Essai sur les maladies de l'oreille interne* (1829).

In 1853, Sir William Wilde of Dublin – father of the poet Oscar Wilde – published the medical classic *Practical Observations on Aural Surgery and the Nature and Treatment of Diseases of the Ear.* In this publication he recommended incision of the mastoid through the skin and periosteum for fluctuant mastoiditis when symptoms and findings were life-threatening.

The nineteenth century saw the successful employment of ether in a surgical operation by William Thomas Green Morton in 1846 and the introduction of chloroform by James Young Simpson in 1847. These, coupled with bacteriologic discoveries made by Louis Pasteur and the work of Joseph Lister on antisepsis, the invention of the electric light by Thomas Edison, and the work of Rudolph Virchow in cellular pathology, had profound effects upon the development of otologic surgery for suppuration.

James Hinton, a London surgeon, and Hermann Hugo Rudolf Schwartze of Halle are credited with establishing the specific indications and method of simple mastoidectomy. This operation involved removal of the bony cortex overlying the mastoid air cells. The insight and work of Schwartze led to the first systematic account of the operation as a scientific procedure to be performed when specific indications were present and according to a definite plan. His rationale was so convincing that by the end of the nineteenth century, the operation had attained widespread acceptance and had overcome more than a century of prejudice against it.

In 1861 the German surgeon Anton von Troltsch had reported successful treatment of a case of apparent mastoiditis with a postauricular incision and wound exploration. He subsequently recognized that failure to address disease deeper within the middle ear recesses and mastoid invariably resulted in recurrence of otorrhea. In 1873 he proposed extensions of Schwartze's simple mastoidectomy to treat surgically these problematic areas.

Following a similar line of reasoning, Ernst von Küster and Ernst von Bergmann, in papers read before the German Surgical Society in 1889, recommended extending Schwartze's mastoidectomy procedures to include removal of the posterior wall of the external canal and middle ear structures "to clear away all disease and so fully to expose the source of the suppuration that the pus is nowhere checked at its outflow." This extended procedure became known as the *radical mastoidectomy.*

Prior to these remarkable advances in the surgical treatment of mastoiditis, the "mastoid operations" frequently failed because of delayed surgical intervention in cases in which infections had already extended beyond the mastoid process to involve intracranial structures. George Shambaugh, Jr., has noted that these patients died most likely despite, not because of, their mastoid operation (Shambaugh and Glasscock 1980). Many surgeons trained before 1870 were unable to absorb and practice Listerian doctrines, and this fact may have contributed to an overly conservative approach to surgical procedures. Properly indicated and performed, mastoidectomy for a well-localized coalescent infection proved to be extremely effective in removing the risk of serious complication from an abscess within the mastoid and in preventing continued aural suppuration. The addition of techniques for exteriorizing infectious processes in the less accessible apex of the temporal bone, as well as progress in making earlier diagnosis of mastoiditis, capped this important phase of otologic surgery for aural suppuration.

In many cases of chronic otorrhea treated with radical mastoidectomy, previous infection had destroyed the middle-ear sound-conducting system. Removal of the tympanic membrane and ossicular remnants was necessary in order to extirpate the infection completely. However, it soon became apparent that in a subset of cases of chronic otorrhea, the infectious process did not involve the inferior portions of the tympanic membrane or ossicular chain. In 1899, Otto Körner demonstrated that, in selected cases, the majority of the tympanic membrane and ossicular chain could be left intact during radical mastoidectomy, thus maintaining the preoperative hearing level.

In 1910 Gustav Bondy formally devised the modified radical mastoidectomy for cases in which the

inferior portion of the tympanic membrane (pars tensa) and the ossicular chain remained intact. He demonstrated that the removal of the superior bone overlying infected cholesteatoma adequately exteriorized and exposed disease while preserving hearing. Despite the successful demonstration of this less radical approach in selected patients, otologic surgeons were slow to accept Bondy's procedure. Most likely, the preoccupation with preventing intracranial suppurative complications forestalled acceptance of this less aggressive approach. Shambaugh and others in America and abroad recognized the utility of the Bondy procedure, and it finally gained widespread acceptance by the 1930s.

A marked decline in the need for mastoid operations developed with the use of sulfanilamide and penicillin. The favorable results that were achieved with the use of these antibiotics in many cases encouraged their application at earlier stages of severe infections including mastoiditis. At first, otologic surgeons were hesitant to abandon the established surgical drainage procedures for mastoiditis, fearing that antibiotics would mask the clinical picture and lead to late complications. It soon became evident, however, that if antibiotics could be given before localized collections of pus were established, fewer complications requiring surgical intervention would result. Nonetheless, modern-day physicians have recognized that too low a dose of an antibiotic given for too brief a time, or the use of a less effective antibiotic in the early stages of otitis media, may indeed mask a developing mastoiditis.

Interest in hearing-preservation in conjunction with surgical treatment of chronic ear infections continued to grow. The German surgeons F. Zöllner and H. Wullstein share credit for performing the first successful repairs of the tympanic membrane using free skin grafting techniques in 1951. The ability to repair perforations of the tympanic membrane and seal the middle ear reduced the likelihood of persistent aural suppuration and associated mastoid and intracranial complications.

The emphasis on preservation and restoration of hearing in conjunction with the management of chronic ear infections has fostered the development of methods of ossicular reconstruction since the 1950s. Techniques in ossicular reconstruction are designed to simulate the middle-ear sound-conducting mechanism. Alloplastic prostheses made of polyethylene and Teflon and bioceramic materials have produced mixed results with respect to long-term hearing and prosthesis stability and acceptance.

The incus interposition technique of ossicular re-

construction was introduced by William J. House in 1966. C. L. Pennington and R. E. Wehrs are credited with refinement of this technique for reestablishing ossicular continuity between the tympanic membrane and the cochlea.

In 1954 B. W. Armstrong reintroduced a procedure, first suggested by Adam Politzer in 1869, to reverse the effects of eustachian tube dysfunction. The procedure entails a limited incision of the tympanic membrane and insertion of a tympanostomy tube. Theoretically, a functioning tympanostomy tube exerts a prophylactic effect by maintaining ambient pressure within the middle ear and mastoid and providing aeration and drainage of retained middle-ear secretions. Tympanostomy tubes appear to be beneficial in restoring hearing and preventing middle-ear infections and structural deterioration while in place.

This review of the historical development of otology reports an evolution in the understanding and management of aural infections. Interestingly, current principles of the surgical treatment of chronic ear infections recapitulate this evolution. The essential principles and objectives upon which modern surgical procedures are based are (1) removal of irreversibly infected tissue and restoration of middle-ear and mastoid aeration; (2) preservation of normal anatomic contours, and avoidance of an open cavity, when possible, by maintaining the external ear canal wall; and (3) restoration of the middle-ear sound-transformer mechanism in order to produce usable postoperative hearing.

The historical lessons learned by otologists underscore the importance of adequate surgical exposure and removal of irreversibly infected tissue followed by regular, indefinite postoperative follow-up in order to maintain a safe, dry ear.

VIII.88
Measles

Measles (rubeola; hard measles; red measles; 9-day measles; morbilli) is a common, acute, viral infectious disease, principally of children, with worldwide distribution, that is clinically characterized by fever and a typical red, blotchy rash combined with cough, coryza, or conjunctivitis. It is a vaccine-preventable disease, and its vaccine is one of the vaccines included in the Expanded Programme on Immunization (EPI) of the World Health Organization (WHO). The disease is known by many local names throughout the world.

Etiology and Epidemiology

Measles is caused by a virus, which is in the genus *Morbillivirus* of the family Paramyxoviridae. Although the virus does not survive drying on a surface, it can survive drying in microdroplets in the air.

Measles is one of the most highly communicable diseases, transmitted by contact of susceptible individuals with the nose and throat secretions of infected persons, primarily by droplet spread. Infection also occurs by direct contact, and by indirect contact through freshly soiled articles and airborne transmission. There is no reservoir for measles other than human beings, which means that a continuous chain of susceptible contacts is necessary to sustain transmission. The period of communicability is from slightly before the beginning of the prodromal phase of the disease to 4 days after the start of the rash. There is no carrier state. Measles has an incubation period from time of exposure to onset of fever of about 10 days with a range from 8 to 13 days. The incubation period from time of exposure to rash onset is about 14 days.

In populated areas with no or low vaccination cov-

erage, measles is primarily an endemic disease of children, with epidemics occurring every 2 to 5 years. In such areas, the greatest incidence is in children under 2 years of age. Epidemic measles has a winter–spring seasonality in temperate climates and a less marked hot–dry seasonality in equatorial regions. This seasonality may be primarily the result of the indirect effect of climate on socioeconomic conditions and population movements. In more remote isolated populations, measles is not endemic and disease is dependent upon introduction of the virus from the outside, at which time an epidemic may occur, affecting all age groups born since the last epidemic. There is no evidence for a gender difference with respect to incidence or severity of measles, or a racial difference with respect to incidence. Differences in severity among certain populations are most likely the result of nutritional and environmental factors.

Measles mortality is highest in the very young and the very old. In malnourished children in the developing world, the case fatality rate may be as high as 5 to 10 percent or more. Some studies have indicated that multiple cases within a family group may lead to higher mortality rates.

Distribution and Incidence

Measles has a worldwide distribution, and the Expanded Programme on Immunization of the World Health Organization maintains an information system on reported cases and vaccination coverage in member countries. Because of underreporting, worldwide reported measles incidence represents only a small fraction of an estimated 50 million cases and 1.5 million deaths caused annually by measles in developing countries. It should be emphasized that reported incidence is subject to completeness of reporting and also to a general trend of improving disease surveillance. Measles vaccination as part of the Expanded Programme on Immunization, with global coverage estimated at 55 percent for children under 1 year of age (52 percent in developing countries), is currently averting over 40 million cases and over 1 million deaths resulting from the disease each year in Third World countries.

In populated areas where measles is both endemic and epidemic, over 90 percent of the adult population will show serologic evidence of prior infection. In remote or island populations where measles is not endemic, a significant proportion of the population can be susceptible, which may produce large outbreaks when the measles virus is introduced from the outside. In some countries, such as the United States, a national goal of measles elimination has been adopted, and impressive progress toward its control has been achieved.

Immunology

Infants usually have a passive immunity to measles as a result of maternal antibodies acquired transplacentally from immune mothers. This passive immunity protects the infant from measles infection for 6 to 9 months, depending on the amount of maternal antibody acquired.

Measles infection induces a lifelong immunity. Several methods for confirming infection and immunity have been developed, including the following: serologic tests, fluorescent antibody techniques, and isolation of the virus from patients during the acute phase of the disease.

A single dose of live attenuated measles virus vaccine confers long-term, probably lifelong, immunity in over 95 percent of susceptible individuals. The optimal age for vaccination is related to the persistence of passive immunity from maternal antibodies and patterns of disease transmission. For developed countries with low incidence, such as the United States, vaccination at 15 months of age is recommended, whereas in developing countries the Expanded Programme on Immunization recommends vaccination at 9 months of age.

Measles vaccine may confer immunity if given within 72 hours of exposure; and immune globulin (IG), if given within 6 days of exposure, may provide a limited-duration protection from measles, owing to passively acquired antibodies from the immune globulin.

Clinical Manifestations and Pathology

The prodromal phase of measles disease typically includes symptoms and signs of fever, cough, coryza, and conjunctivitis. During this stage, small whitish specks on reddened areas of the mucosal lining of the mouth called *Koplik's spots* are diagnostic of measles. The prodromal period continues for 3 to 7 days until the characteristic blotchy reddish rash appears. This rash usually appears first on the head and then spreads down the body and outward to the limbs, lasting about 4 to 7 days. After its peak, in uncomplicated cases, all the symptoms and signs begin to recede and the rash fades in the same order it appeared.

Complications due to viral replication or secondary bacterial infection may occur, however, and

result in middle-ear infections and pneumonia. Diarrhea may also complicate measles and, in the developing world, is one of the most important causes of measles-associated mortality. Neurological involvement may also occur, resulting in encephalitis during or soon after the acute illness or in the rare subacute sclerosing panencephalitis (SSPE) after a lengthy incubation period. Measles is uncommon during pregnancy, and the limited data available do not appear to demonstrate clearly any increased risk of fetal mortality or congenital malformations.

History and Geography

Ancient Times Through the Eighteenth Century

The origin of measles is unknown. Francis Black (1976) has noted that populations of a sufficient size to allow for a continuous chain of susceptibles required to sustain measles transmission would not have developed until sometime after 2500 B.C. He has suggested that measles may have arisen as an adaptation of one of the other viruses of the same genus (which includes rinderpest and canine distemper). It is interesting to note that Hippocrates, writing in the fourth century B.C., did not describe a rash illness that would be consistent with measles, even though his recorded case histories document the existence of many other infections in ancient Greece.

The history of measles is confused with that of smallpox in much of the early literature. Although records are scanty, major unidentified epidemics with high mortality rates spread through the Roman Empire in A.D. 165–80 and again in 251–66. William McNeill (1976) has noted that there are some suggestive circumstances that make it tempting to believe that these two "demographic disasters" signaled the arrival of measles and smallpox. In China, two major epidemics with high mortality were recorded in A.D. 161–2 and 310–12, but again there is uncertainty of the diseases, and McNeill states that, given the fragmentary and imperfect data, it is possible to conclude only that "some time between A.D. 37 and A.D. 653 diseases like smallpox and measles arrived in China." The Persian physician known as Rhazes is generally credited with the first authentic written record of measles by differentiating the two diseases in approximately A.D. 910 in his *Treatise on the Small-Pox and Measles*. Rhazes, however, quoted previous writers, including the famous Hebrew physician El Yahudi, who lived 300 years earlier. Rhazes used the word *hasbah* for measles and believed that "the measles arise from very bad blood." He considered the disease "more to be dreaded than smallpox." Around the year 1000, Avicenna of Baghdad also wrote about measles, and translators of his writings are said to have introduced the term *rubeola* for the disease.

During medieval times, measles was referred to by the Latin term *morbilli*, the diminutive of *morbus*, meaning the "little disease." August Hirsch (1883–6) notes that measles was also called *rubeola*, *rossalia*, *rosagia*, as well as the colloquial names *fersa* or *sofersa* (Milanese), *mesles* and later *measles* (English), *maal* and *masern* (German), and the *masura* or *spots* (Sanskrit). The derivation of the English name "measles" is in some doubt. One suggestion is that it may have come from the Latin term *miscellus* or *misella*, a diminutive of the Latin *miser*, meaning "miserable" – a term given to those suffering from leprosy. The sores on the legs of leprosy patients were known as *mesles*, and John of Gaddesden in the early fourteenth century unjustifiably coupled these *mesles* with the disease *morbilli* of medical authors. Eventually the term "measles" lost its connection with leprosy.

Measles, smallpox, and other rash illnesses continued to be confused in Europe during the Middle Ages. The seventeenth-century physician and epidemiologist Thomas Sydenham studied measles epidemics in 1670 and 1674 and made observations on the clinical features of the illness and its complications. He is generally credited with differentiating and describing measles in northern Europe, and his famous descriptions of the disease in "Of Measles in the Year 1670" and "On the Measles" were published in *Process Integri* in 1692. The first clear demonstration that measles was an infectious disease is attributed to Francis Home who, in 1758, attempted to prevent the illness and provide immunity by placing blood from measles patients beneath the skin or into the nose of susceptible persons. Numerous measles epidemics were reported in the seventeenth and eighteenth centuries in the English medical literature.

Nineteenth Century

The most famous epidemiological study of measles was conducted by Peter Panum and reported in his classic *Observations Made During the Epidemic of Measles on the Faroe Islands in the Year 1846* (1940). Measles attacked about 6,100 islanders during 1846 and was associated with the deaths of 102 of the 7,864 inhabitants, who had been completely free of

the disease for 65 years. Panum confirmed the respiratory route of transmission, the incubation period, and the lifelong immunity acquired from previous infection. Hirsch (1883–6) built on Panum's work and recorded the universal geographic distribution of measles by noting accounts of epidemics that had occurred in most parts of the world. He noted that measles reached the Western Hemisphere soon after the arrival of the first European colonists and followed the westward movement of the settlers. He suggested that introduction of the disease into the Australian continent occurred in 1854 after first appearing in the Hawaiian Islands in 1848.

A particularly vivid account of the dramatic 1876 measles epidemic in Fiji quoted by Hirsch illustrates the conditions that accounted for the relatively high mortality:

Later in the epidemic, when it is said to be like plague, . . . the people, seized with fear, had abandoned their sick. . . . The people chose swampy sites for their dwellings, and whether they kept close shut up in huts without ventilation, or rushed into the streams and remained in the water during the height of the illness, the consequences were equally fatal. The excessive mortality resulted from terror at the mysterious seizure, and [from] the want of the commonest aids during illness. . . . Thousands were carried off by want of nourishment and care, as well as by dysentery and congestion of the lungs. . . .

It was especially dramatic when measles struck a "virgin soil" population that had no prior or recent exposure to measles disease or measles vaccine, and thus the outbreak affected most persons. With regard to the introduction of measles by the Spaniards from the Old World into the Amerindian populations of the New World, McNeill (1976) noted that "measles followed hard upon the heels of smallpox, spreading through Mexico and Peru in 1530–1. Deaths were frequent, as is to be expected when such a disease encounters a virgin population dense enough to keep the chain of infection going." High mortality was also reported in measles epidemics that occurred in virgin soil island populations in the Pacific Ocean in the nineteenth century: 40,000 deaths out of a population of 150,000 in Hawaii in 1848, 20,000 deaths comprising 20 to 25 percent of the population of Fiji in 1874, and 645 deaths out of 8,845 cases in Samoa in 1911. High mortality in these settings was likely due to some of the same factors that result in high mortality rates among unvaccinated individuals in many areas of the developing world today, including lack of supportive care, lack of treatment for complications, and malnutrition. In virgin soil settings where populations were well nourished and where better medical care was available, the mortality rate was much lower, as noted in the outbreak of measles in southern Greenland in 1951 where, in one district, 4,257 persons out of a population of about 4,400 contracted measles and 77 deaths occurred (Christensen et al. 1953).

Not until 1896 did Henry Koplik publish a description of Koplik's spots, although apparently their significance was independently recognized about a century earlier by John Quier in Jamaica and Richard Hazeltine in Maine.

Prevention and Control

Research leading to the development of current measles vaccines began around the beginning of this century. John Anderson and Joseph Goldberger (1911) demonstrated that the illness was caused by a virus, by injecting filtered material from patients with acute diseases into monkeys. Harry Plotz (1938) and Geoffrey Rake and Morris Shaffer (1940) reported the cultivation of measles virus in tissue culture. In 1954, with the advent of reliable tissue culture techniques, J. F. Enders and T. C. Peebles were able to isolate the measles virus. Subsequent research by S. L. Katz, M. J. Milanovic, and J. F. Enders (1958) resulted in the development of an attenuated strain of measles vaccine which was produced in 1958. In 1963, after field trials, the attenuated ("live") measles vaccine was licensed for general use in the United States. An inactivated ("killed") measles vaccine was also developed, but was shown to be inferior and is no longer available.

With the establishment of the World Health Organization Expanded Programme on Immunization in 1974, measles vaccine has been introduced into the national immunization programs of most countries. The current levels of immunization coverage for measles vaccine show wide geographic variation. Except for more remote isolated populations where the occurrence of measles disease is not endemic and is subject to infrequent introduction of virus, the geographic occurrence in the world today is related to the immunization coverage with measles vaccine. In countries with sustained, large-scale immunization programs and reliable disease surveillance, the impact of control efforts has been documented through decreasing numbers of reported cases. Global measles eradication is considered to be technically possible, but it is increasingly recognized that extremely high immunization coverage levels will be necessary to achieve such a goal.

Meningitis

Meningitis is an acute inflammation of the meninges, the membranes covering the brain and spinal cord. The disease is usually the result of bacterial infection, but a number of viruses, fungi, and other microbial agents can also cause it. Meningitis can develop as well from noninfectious conditions such as tumors, lead poisoning, and reactions to vaccines. Meningococcal meningitis, caused by a bacterium, *Neisseria meningitidis,* is the only form that occurs in major epidemics. Also called *cerebrospinal meningitis* (CSM), it has been known in the past as "spotted fever," cerebrospinal fever, typhus cerebralis, and meningitis epidemica. Aseptic meningitis refers to inflammations of the meninges without detectable bacterial involvement. The most common causes are any of a number of viruses.

Etiology and Epidemiology

Many species of bacteria can cause meningitis, but over 80 percent of all cases in developed countries in recent years have been due to only three: *N. meningitidis, Hemophilus influenzae,* and *Streptococcus (Diplococcus) pneumoniae.* Other common members of the human bacterial flora such as *Escherichia coli* and various streptococci and staphylococci can also produce meningitis under special circumstances, as can members of the genera *Listeria, Pseudomonas,* and *Proteus.* Meningitis sometimes develops as a complication of tuberculosis.

Aseptic meningitis is usually the result of viral infection. Among the many types of viruses that can be involved are mumps, echovirus, poliovirus, coxsackievirus, herpes simplex, herpes zoster, hepatitis, measles, rubella, and several mosquito-borne agents of encephalitis. Fungi, most commonly *Cryptococcus,* are other possible agents.

Laboratory study is necessary to determine the cause of any particular case of meningitis, so it is generally difficult to be certain of the exact etiology of past meningitis cases or epidemics. However, despite the current relative significance of *Hemophilus* and *Streptococcus, Neisseria* is the most important pathogen for meningococcal meningitis; it is the only type that commonly occurs in major epidemics, and is the most likely to attack adults.

N. meningitidis is a nonmotile, gram-negative coccus closely related to the organism that causes gonorrhea. Its protective capsule is composed of one of several possible large sugar polymers (polysaccharides), which provide the basis for assigning a given specimen into 1 of about 13 currently recognized serogroups. Serogroups B, C, W-135, and Y have been especially active in the Americas in recent years; group A organisms are the most likely to cause large-scale epidemics and have historically been very prevalent in Africa. Serogroups can be divided into serotypes; these finer distinctions are often crucial in tracing connected cases or determining if a given outbreak has a common origin. Humans are the only natural host.

N. meningitidis is a common inhabitant of the mucosal membranes of the nose and throat, where it normally causes no harm. As many as 5 to 50 percent of a population may be asymptomatic carriers without any cases of meningitis developing, but such carriers are crucial to the spread of the disease. The organism is transmitted by droplets sneezed or coughed from the noses and throats of carriers or, less commonly, meningitis patients. It is very susceptible to desiccation and to sunlight, so close and prolonged contact is favorable to propagation.

The majority of victims, especially in sporadic cases and small outbreaks, are children under age 5. Among adults, new military recruits crowded into barracks have traditionally been prime targets. Throughout the nineteenth and twentieth centuries, wartime mobilization in Europe and America was always accompanied by sharp increases in meningitis case rates.

Meningitis is a highly seasonal disease. In temperate regions, a large preponderance of cases develop in the winter and early spring. The reasons for this are not clear, but indoor living, crowding, and the effects of cold temperature and low humidity on potential hosts' mucous membranes may all play a role. Epidemics in sub-Saharan Africa develop during the cool, dry season, when people travel more and sleep indoors to keep warm. African outbreaks tend to end abruptly when the rains come.

Immunology

N. meningitidis stimulates the production of serotype-specific antibodies in persons who have experienced infection. The antibodies in most serogroups develop against the polysaccharides of the bacterial capsule, but the basis for antigenicity in serogroup B is unclear. Infants can acquire passive immunity from their mothers and be protected for a few months. Vaccines are available for protection against several serogroups, including A, C, Y, and W-135.

Clinical Manifestations and Pathology

Infection with *N. meningitidis* can result in one of three conditions. In the large majority of cases, bacteria are carried in the nose and pharynx without any symptoms or with just a sore throat. Serious disease develops only if the bacteria reach the bloodstream. This can produce fulminating blood infection or meningococcemia, which is characterized by sudden prostration, high fever, skin blotches (*ecchymoses*), and collapse. Most of these cases are fatal unless promptly treated, and death may ensue in a matter of hours, before the meninges become involved.

Meningitis, however, is the more common result, occurring when bacteria travel through the blood to infect the membranes of the brain and spinal cord. Fever, violent headache, stiff neck, and vomiting are typical symptoms, and, as in meningococcemia, many victims show a petechial rash due to blockage of small blood vessels. A thick, purulent exudate covers the brain, and arthritis, cardiac damage, and shock may develop. Coma, convulsions, and delirium are frequent, and death rates for untreated cases range from 50 to 90 percent. Even in epidemic conditions, however, only a small minority of persons harboring the organism develop clinical disease. It is not known why most people remain healthy carriers whereas others become desperately ill. Individual susceptibility, damage to mucous membranes, and concomitant infections with other bacteria may all play a role.

Diagnosis is based on clinical signs and the recovery of pathogens from the cerebrospinal fluid or, in meningococcemia, from the blood. Culture of organisms from throat swabs is used to monitor carrier rates and circulating strains.

Therapy was revolutionized with the introduction of sulfa drugs in the late 1930s, and sulfonamides were widely used as a prophylaxis for exposed populations. The appearance and spread of sulfonamide-resistant bacteria after 1963 has forced a shift in preventive tactics, but the pathogen is still very sensitive to treatment with penicillin. Military re-

cruits are routinely vaccinated in most countries, and extensive inoculation campaigns have helped control epidemics in Africa. Better ventilation and reductions in crowding in living and sleeping areas are useful in barracks and other institutional settings. Prophylaxis with rifampin is helpful in reducing carrier rates and preventing outbreaks after cases have occurred in specific populations, as, for example, children in day-care centers.

History and Geography

Meningococcal and other forms of meningitis occur throughout the world. Meningitis is endemic in tropical and temperate regions and in both urban and rural settings, and sporadic cases and small epidemics can develop anywhere. In this century, epidemic cerebrospinal meningitis (CSM) has repeatedly cut a wide swath throughout African savanna country in a belt south of the Sahara; these unusual epidemics are caused by serotype A of *N. meningitidis*.

Antiquity Through the Nineteenth Century

Meningitis was not described in a form recognized as definitive until after 1800, so the antiquity of the disease is unknown. Mention of "epidemic convulsion" in tenth-century China and a possible description by T. Willis in England in 1684 could indicate earlier recognition of meningococcal meningitis. There are many other possible references to meningitis outbreaks in European medical literature of the sixteenth, seventeenth, and eighteenth centuries. An episode described in Munster in 1788 could well have been meningococcal meningitis. Indeed, although the first clear clinical description was of cases in Geneva in 1805, it seems highly unlikely that meningitis of meningococcal or other etiology is really such a new infection in humans.

In the early months of 1805, a small epidemic of CSM was described in Geneva by Gaspard Vieusseux. Most victims were infants and children. Clinical accounts, complemented by autopsy studies by A. Matthey, establish the identity of the disease. In March 1806, a cluster of 13 or 14 cases were described in Medfield, Massachusetts. As in Switzerland, the victims were infants and children. Nine patients died, despite frantic application of an array of depletive and stimulating therapies. The case descriptions and five autopsies confirmed a diagnosis of CSM. An epidemic of apparent meningitis afflicted British troops in Sicily in 1808, and French garrisons in Grenoble and Paris were struck in early 1814. In North America, meningitis epidemics were reported in Canada in 1807, in Virginia, Kentucky, and Ohio in 1808, in New York State and Pennsylvania in 1809, among American troops during the War of 1812, and were described as "sinking typhus" or "spotted fever" in New England from 1814 to 1816.

Relatively little more was heard about this deadly and apparently quite new disease until the years 1837 through 1842, when a series of outbreaks occurred in French garrisons, and civilians also came under attack in some nearby towns. Thus epidemics in Algeria from 1840 to 1847 began among French troops, but caused many deaths among the indigenous Moslem population as well, especially in the Algiers and Constantine areas during 1846 and 1847. Meningitis was also widespread in southern Italy from 1839 to 1845, and there were scattered reports from Corfu, Ireland, and especially Denmark in the period 1845 to 1848. There was also a series of small epidemics in the United States in the 1840s, primarily in the South.

The first recorded major epidemic of CSM began in Sweden in 1854, starting in Göteborg in the late winter and slowly spreading to the north and east during the next five winters. It died out in the summers and resumed a slow, irregular progress during winters, reaching 61° north in 1857 and 63° north in 1858. The epidemic declined in 1859, with scattered cases reported in the next several years and a small flare-up in the years 1865 to 1867. Government returns showed a total of 4,158 meningitis deaths from 1854 to 1860 and 419 in 1865–7.

During the 1860s, numerous small but deadly epidemics occurred in Germany, the Netherlands, England, France, Italy, Portugal, Austria, Hungary, Greece, Turkey, Poland, and Russia. There were numerous outbreaks in the United States during the same decade, with both Union and Confederate troops suffering during the Civil War. In the United States and elsewhere, recruits and small children continued to be the most common victims. Scattered cases and sporadic outbreaks continued for the rest of the century, with flurries of activity in the mid-1880s and at the end of the century.

Twentieth Century

There was a new burst of meningitis activity in the first decade of the twentieth century. The first cases from Australia were recorded in 1900–1. Portugal had more than 5,000 cases from 1901 to 1905; a series of North American epidemics from 1904 to 1907 involved much of the United States and Canada, with 2,755 patients in New York alone in 1905. A severe epidemic in Silesia caused almost 10,000 cases from 1905 to 1908.

For most of the twentieth century, meningitis in the developed countries has followed a pattern of small, local epidemics and scattered cases, mostly among children. The two world wars caused major spurts as military authorities crammed large numbers of recruits into crowded barracks. In England and Wales, for example, cases rose from a few hundred a year prior to World War I to a peak of more than 3,500 by 1915. Similarly, annual cases and deaths rose more than fivefold in the early 1940s, with over 23,000 cases in 1940 and 1941. But except for a peak of almost 1,300 cases in 1974, there have been fewer than 1,000 cases a year reported since the early 1950s.

For the United States, there were 5,839 cases and 2,279 deaths among soldiers during World War I. In 1942 and 1943, however, although there were 13,922 military cases, thanks to new therapy there were only 559 deaths. Moreover, except for a spurt to about 14 cases per 100,000 people in 1942, civilian case rates in the United States have remained under 4 per 100,000 since the late 1930s. Total meningococcal infections have rarely exceeded 3,000 a year, but reported cases of aseptic meningitis have risen steadily and have totaled two to four times the meningococcal figure during the 1980s.

The situation in non-Western countries is quite different. Incidence rates tend to be much higher, and there are still major epidemics like those that afflicted Sweden and Silesia in the past. For example, China has experienced three major epidemics of serogroup A meningococcal meningitis since 1949, with peak incidence rates of 50 to 400 per 100,000 in 1959, 1967, and 1977. During the 1963–9 epidemic, which coincided with the upheavals of the Cultural Revolution, there were more than 3 million cases and 166,000 deaths.

Africa has had two kinds of experience with the disease. In most of the continent, meningitis is a sporadic disease that behaves much as it does in the West, although often with higher incidence and fatality rates. Much of north, central, east and southern Africa falls into this pattern. In South Africa, scattered cases were reported in the 1880s. Mining compounds have had favorable conditions for meningitis, with newly hired African workers forced to live in conditions similar to those of military recruits. CSM is endemic in east Africa, producing a few hundred cases in most countries in recent years.

On the other hand, there has been at least one terrible epidemic. In 1913 CSM swept Kenya and Tanganyika, killing over 20,000 people in Kenya alone and, partly as a result of military activity,

lingering in Tanganyika until 1919. Both territories, as well as neighboring Uganda, had dramatic surges during World War II. In North Africa, Algeria and Egypt experienced meningitis epidemics in the nineteenth century, and the disease has been reported throughout the region in recent decades. Morocco had over 6,000 cases in 1967.

The classic area for epidemic CSM, however, has been the savanna zone south of the Sahara Desert from Sudan to Senegal. This "CSM belt" has been swept by a series of great epidemics during the twentieth century. Indeed, there the disease has behaved in a very different fashion, advancing on a regular front and killing tens of thousands of people in a season. Only the Swedish epidemic of the 1850s seems to have displayed a similar broad geographic pattern. In both places, macroscopic examination indicated that the disease advanced in a regular manner from season to season, but also that actual cases were scattered widely within the afflicted zone in a totally unpredictable manner. The epidemic hopped about, skipping many large communities and sometimes striking hard at small, relatively isolated places. Areas struck in one CSM season were usually spared in the next.

The reasons for the unusual behavior of CSM in the African "CSM belt" are unclear. Open grassland country facilitates mobility, and much of the region has a fairly dense population. A long, cool dry season creates dusty conditions and may dry out mucous membranes of the nose and throat while it also allows people to travel easily and encourages them to sleep indoors. Housing is often crowded and poorly ventilated. Perhaps the savanna dry season is analogous to the Swedish winter; people are forced to congregate indoors, and the seasonal low humidity in Africa was replicated in Sweden by home heating. The Swedish outbreaks ceased every year with the arrival of spring, whereas the sub-Saharan zone experiences relief with the first rains.

Although there has been a tendency, exemplified in the studies of the British colonial physician B. B. Waddy, to view the entire savanna belt as a single epidemiological unit, there have been distinct geographic zones of CSM. Thus the disease did not spread in great waves from southern Sudan across the grasslands to West Africa. Epidemics in southern Sudan and northern Uganda, especially destructive in the late 1920s, have been independent of developments in central and northern Sudan. And, with an exception in 1934 and 1935, central Sudanese epidemics have not been linked to those in Chad and westward.

The antiquity of meningitis in the savanna zone is not known, but some evidence exists that the disease had occurred in central Sudan and the densely populated Hausa country of northern Nigeria by the 1880s. Small outbreaks in troops in Senegal in the 1890s and in the Gold Coast (Ghana) in 1900 did not afflict wide regions. The first of the great West African epidemics began in northern Nigeria in early 1905. It spread westward as far as French Sudan (Mali) and northwest Ghana in 1906, lingering in these places until the rains of 1908. British authorities guessed the 3-year death toll in Ghana at some 34,000; case mortality was estimated at 80 percent. Total deaths in the 1905–8 epidemic are not known, but there clearly was a major disaster.

The second CSM cycle in the western savanna began in northwest Ghana in 1919, spread to Upper Volta (Burkina Faso) in 1920, and swept northern Nigeria and Niger from 1921 to 1924. Weak political and medical infrastructures precluded accurate estimates of cases or deaths, but the death toll in one northern Nigerian province, Sokoto, was put at over 45,000 in 1921 alone, and French officials assumed that at least 15,000 persons died in Niger over the 4-year period.

The third great cycle of CSM activity in West Africa began in 1935, when Chad was attacked by an epidemic that had raged during the previous year in the Kordofan and Darfur provinces of central Sudan. This was the first and only time that a clear pattern of east–west spread from Sudan has been demonstrated. Carriers brought infection westward during the rainy seasons to Chad, to northern Nigeria, and thence to Niger, with disastrous epidemics developing in early 1937. CSM hit Upper Volta in 1938 and Mali and northern Ghana in 1939, and local outbreaks continued through 1941. Mortality statistics are very unreliable, but even with the advent of sulfa drugs, several tens of thousands died. CSM was again epidemic in the years 1943–7, with major outbreaks reported from Chad to Senegal. Upper Volta, western Niger, and northwest Ghana were especially seriously afflicted.

Another cycle of epidemics developed in 1949 from foci in northern Ghana, northern Nigeria, and Upper Volta, spreading eastward as far as Sudan by 1952. By this time, meningococcal meningitis had become well established throughout the region, and geographic patterns of spread were much less distinct. At least 250,000 and perhaps a million or more people died of CSM in West Africa between 1905 and the end of the colonial period in 1960. The disease remains a very serious public health problem in the entire CSM belt, despite the advent of sulfa and penicillin therapy and vaccines against serogroup A pathogens.

The puzzlingly late discovery of meningitis as a clinical entity did not retard development of knowledge of its etiology. The sporadic nature of outbreaks and the apparent lack of transmissibility of infection by victims led many nineteenth-century writers to believe that the disease was not contagious and was somehow linked to climate or environmental conditions such as crowding. By about 1860, however, it was widely assumed that there was some sort of specific poison or agent involved. In 1887 an Austrian pathologist, Anton Weichselbaum, described the meningococcus under the name *Diplococcus intracellularis meningitidis*. This organism was suspected of being the primary pathogen for many years, but its role was not proven until studies done in 1904 and 1905 in connection with the great Silesian epidemic. By 1910 it was recognized that the meningococcus was responsible for epidemics and that other bacteria could cause sporadic cases. Lumbar puncture, introduced in 1891 by Heinrich Quincke, provided an easy method to get cerebrospinal fluid for study, and was sometimes used to provide relief from the terrible headaches caused by the disease. The crucial epidemiological role of asymptomatic carriers was appreciated by the turn of the century.

After 1905, inspired by success against diphtheria, there were many attempts to develop a therapeutic serum. Some early successes were reported, especially in France, but by 1909 it was clear that there were important serologic differences among strains. Workers in Britain, the United States, and France had established four major serogroups by the end of World War I. Vaccine therapy remained of limited value, but in the absence of anything else, it was frequently tried. In the 1930s, French efforts to protect Africans against serogroup A by vaccination had inconclusive results, and similar British trials in Sudan were unsuccessful.

The development of sulfa drugs in the 1930s revolutionized meningitis therapy. Gerhardt Domagk published on one such drug in 1935; French workers at the Institut Pasteur introduced a more effective active form, sulfanilamide, later in the same year. Clinical trials showed the almost miraculous impact of sulfanilamide on meningococcal infections in 1937. This drug, one of a group of chemicals called *sulfonamides,* reduced case-fatality rates from between 50 and 80 percent to 20 percent and less, and saved many thousands of lives during the meningi-

tis epidemics of World War II. Sulfa drugs were successfully used for prophylaxis and to reduce carrier rates by the U.S. Army beginning in 1943; the technique was widely adopted for troops and during outbreaks.

The advent of this class of "wonder drugs" had an especially dramatic impact in the CSM belt of Africa, where they were introduced in early 1938 in the midst of major epidemics in Sudan and West Africa. Prior to this date, Africans had been well aware that European therapy was useless. Preventive measures seemed equally futile and were often arbitrary and very harsh. Victims were usually quarantined, and cordons were sometimes thrown around whole villages and districts. Such efforts disrupted trade and care of the sick, but, given the key role of asymptomatic carriers and the use of bush paths to avoid police checkpoints, they did nothing to impede the spread of the disease. Annoying procedures like "nasopharyngeal disinfection" of travelers in Chad or destroying houses or removing their roofs in Sudan did not encourage African cooperation with colonial medical authorities. Indeed, Africans very sensibly tried to hide cases, preferring not to add government public health measures to the burdens of an epidemic. Sulfa drugs were, however, extremely effective. Africans responded pragmatically to this new treatment and, seeing death rates plummet, eagerly began to report cases and seek treatment for themselves and their children. In many areas, a shortage of medical workers forced authorities to give supplies of drugs to chiefs to pass along to the sick. This and the introduction of drug prophylaxis meant that CSM, in sharp contrast to earlier decades, was overreported during the 1940s and 1950s.

In 1963 sulfa-resistant strains of *N. meningitis* were detected by U.S. military doctors and the spread of such strains has forced an end to sulfa prophylaxis. Penicillin therapy is still very effective, but this antibiotic has no preventive value. Vaccines against serogroup C and A organisms were introduced in 1971 and 1973, respectively. Improved vaccines for these and other serogroups have been developed in recent years, although there is still no protection against serogroup B bacteria. Meningitis will probably remain a public health problem, especially in underdeveloped countries. Death occurs in about 5 percent of all cases, even with prompt treatment. Poverty, logistical problems, and financial difficulties make meningitis a continuing threat in the traditional CSM belt of Africa.

Milk Sickness (Tremetol Poisoning)

Milk sickness, usually called *milksick* by early nineteenth-century American pioneers, denotes what we now know to be poisoning by milk from cows that have eaten either the white snakeroot or the rayless goldenrod plants. The white snakeroot, common in the Midwest and upper South, is a member of the Compositae called *Eupatorium urticaefolium*. It is also known as white sanicle, squaw weed, snake weed, pool wort, and deer wort. A shade-loving plant, it is frequently seen growing on roadsides, in damp open areas of the woods, or on the shaded north side of ridges. The rayless goldenrod, *Haplopappus heterophyllus,* is the cause of the disease in southwestern states, such as Arizona and New Mexico.

Milk sickness has been called variously alkali poisoning, puking disease, sick stomach, the slows or sloes, stiff joints, swamp sickness, tires, and trembles (when it occurs in animals). It is now known as

tremetol poisoning after an identified toxic ingredient of the white snakeroot and rayless goldenrod. Tremetol, obtained from the leaves and stems of these plants by extraction with ether, is an unsaturated alcohol with the empirical formula $C_{16}H_{22}O_3$. In consistency and odor, it resembles turpentine.

Distribution and Incidence

Milk sickness was unknown in Europe or in any other region of the world except North America. It appeared in North Carolina as early as the American Revolution near a mountain ridge named Milk Sick. Its highest incidence was in dry years when cows wandered from their brown pastures into the woods in search of forage. As more forests were cleared so that cattle had more adequate pasture, and as fences were built, the incidence of milk sickness decreased rapidly.

The disease wrought havoc in the Midwest, especially in Illinois, Indiana, and Ohio, and in the upper southern states of Kentucky, North Carolina, Tennessee, and Virginia. Milk sickness was, in some years and some localities, the most important obstacle to settlement by the pioneers. Beginning about 1815, a flood of pioneers moved west. As they penetrated the forest wilderness of the Midwest they all too frequently came upon evidence of epidemics of the disease as several villages were abandoned. Physicians in Kentucky and Tennessee described milk sickness as being so widespread that the Kentucky legislature appointed a committee in 1827 to investigate its cause. A few years later, the state medical society of Indiana also attempted a similar investigation. Interestingly, in that state it has been noted that "Evansville, Indiana, owes its prominent position . . . today, in part at least, [to] the fact that its early competitor, Darlington, was abandoned" because of milk sickness (Snively 1967).

Epidemiology and Etiology

In 1811, an anonymous author wrote that milk sickness was a true poisoning because it involved no fever. He also believed that it was caused by poisonous milk that had a peculiar taste and smell. The source of the poison, he wrote, was vegetation eaten by the cows. He further advised that finding the offending plant would remove a major stumbling block to emigration westward.

In the years that followed, the theories as to the cause of milk sickness were numerous. One suggested that the cause was arsenic; another claimed it was a mysterious soil organism, whereas another attributed the disease to a mysterious exhalation from the soil. Still others incriminated various poisonous minerals and springs. Nonetheless there was no definite identification of one specific toxic plant during the nineteenth century. In the 1880s, the medical revolution following the discoveries of Louis Pasteur in France and Robert Koch in Germany led to the expectation that many obscure diseases such as milk sickness would prove to be of bacterial etiology. This expectation appeared to have been realized when Edwin Jordan and Norman Harris (1909) reported that *Bacillus lactimorbi* was the cause of milk sickness in humans and trembles in cattle. Needless to say, they were wrong.

Beginning in 1905, however, Edwin Moseley of what is now Bowling Green State University in Ohio began a scientific study of the white snakeroot that lasted for over three decades. In careful animal-feeding trials, he established the toxic dose of snakeroot for animals at 6 to 10 percent body weight. He also found that the stems were less poisonous than the leaves and that neither freezing nor drying destroyed the poison. His book, published in 1941, is the definitive work on milk sickness.

Finally James Couch (1928) reported that he had isolated three poisonous substances from the white snakeroot: a volatile oil and a resin acid that did not produce trembles, and an oily liquid with the characteristics of a secondary alcohol that did. The last he identified as $C_{16}H_{22}O_3$ and, drawing on the Latin *tremērē* meaning "tremble," named it *tremetol*.

Heating reduces somewhat the toxicity of poisoned milk, and oxidation readily destroys the toxic properties of tremetol. Because only a small number of cows are likely to be secreting toxic milk at one time, human illness is seen chiefly when milk from a single animal or herd is consumed. It is now thought that the dilution that occurs in the usual dairy collection and distribution of milk from a large milk source, rather than pasteurization, is the reason for the failure of milk sickness to develop in urban areas. For that reason, milk sickness has become extremely rare. Moreover, in rural areas, farmers are now well aware that to avoid trembles or milk sickness, one need only abandon woodland grazing, for the white snakeroot is a woodland plant and almost never found in bright and open pastures.

Clinical Manifestations

When milk sickness occurs in animals, chiefly cattle, it is called trembles. The animals suffer from anorexia, weakness, falling, stiffness, and trembling.

In humans the symptoms of milk sickness include anorexia, listlessness, severe constipation, and –

most important of all, and underlying most of the symptoms – profound acidosis; the latter, if untreated, leads to coma and death. Because of the acidosis, the breath smells of acetone, described in the past as an overpowering "fetor." The weakness is thought to be due chiefly to hypoglycemia, and death, to ketoacidosis and marked fatty degeneration of the liver, kidney, and muscles. The disease can be chronic or latent, and is likely to recur if the patient is subjected to fatigue, starvation, intercurrent infection, or vigorous exercise.

The lethargy that characterizes the patient who has not completely recovered from an attack of milk sickness helped give it the name of slows (or sloes). Abraham Lincoln knew it by that name, and, annoyed by the desultory progress of the Army of the Potomac in the early months of the Civil War, he once tartly remarked that General McClellan "seemed to have the slows."

History and Geography

Milk sickness has vanished from the list of major concerns of modern Americans. Although endemic in the Midwest and upper South, it had never been seen elsewhere in the United States, in Europe, or in any other continent. The settlers along the Atlantic seaboard knew nothing of it, and if the Indians or their cattle suffered from the disease, they did not inform the early settlers. Not until the pioneers began to push westward beyond the Alleghenies did the disease attract attention.

The first sporadic cases to be recognized occurred in North Carolina in the years preceding the Revolution. It was generally known that on the western side of the Allegheny Mountains from Georgia to the Great Lakes a disorder called trembles prevailed among cattle, and that wherever it appeared, the settlers were likely to get a disease, which from its most prominent symptom received at first the name "sick stomach" and from a theory concerning its cause that of "milk sickness."

In 1811, the *Medical Repository* of New York contained an anonymous report entitled "Disease in Ohio, Ascribed to Some Deleterious Quality in the Milk of Cows." This appears to be the earliest surviving reference to a disease that was to become a frequent cause of death and a major source of misery and mystification in the rural South and Midwest through a large part of the nineteenth century.

William Snively and Louanna Furbee (1956) described a discovery made in 1834 by Anna Pierce Hobbs, a pioneer doctor, in southeastern Illinois. Having learned from a Shawnee medicine woman

that white snakeroot caused trembles and milk sickness, she had a calf fed several bunches of the root. The calf developed typical trembles, enforcing her conviction that she had found the cause of milk sickness. John Rowe, a farmer of Fayette County, Ohio, wrote in 1838 that he had discovered through similar experimentation that trembles was caused by ingestion of white snakeroot.

During the second half of the nineteenth century, milk sickness occurred sporadically, which made sequential observations difficult to make, and the reason for its cause was lost in the widely held medical belief in miasmas and exhalations from the ground. Moreover, because milk sickness was limited to the Midwest, upper South, and Southwest, influential eastern physicians tended to ignore it or even discount the possibility that it really existed as a disease *sui generis*.

Nonetheless, the solution was eventually found when attention was turned back to the poisonous plant theory advanced during the first half of the century. Although many plants were suspected, such as poison ivy, water hemlock, Virginia creeper, coralberry, spurge, mushrooms, and march marigold, scrutiny finally centered once again on white snakeroot. Yet it was not until 1928 that the white snakeroot was established with certainty as the cause of milk sickness – over a century after the anonymous 1811 article appeared.

The question that Snively has asked remains: "How could a disease, perhaps the leading cause of death and disability in the Midwest and Upper South for over two centuries, go unrecognized by the medical profession at large until 1928?"

VIII.91
Multiple Sclerosis

Multiple sclerosis is a disease of the central nervous system characterized clinically by recurring episodes of neurological disturbance which, especially early in the course of the disease, tend to remit spontaneously, although as time goes by there is often a gradual accumulation of disability. The course of the disease is quite variable, at one extreme lasting for 50 years without the development of significant disability, and at the other terminating fatally in a matter of months. Overall, about one quarter of patients remain able to work for up to 15 years after the first recognized clinical manifestation, and the mean duration of life is approximately 25 years from that time. Nevertheless, because the disease commonly affects young adults and produces disability in the prime of life, the economic burden is heavy, in the United States averaging $15,000 per annum per family with a member afflicted (Inman 1983 data, cited in McDonald and Silberberg, eds. 1986, 180).

Overview

Multiple sclerosis is a remarkable disease. It was first clearly described more than 120 years ago in a way which we would recognize as a modern, pathologically based account that discusses the clinical features of the illness and their possible pathophysiology (Charcot 1868). It is only since the early 1970s, however, that real progress has been made in understanding its nature, course, and pathogenesis. It was discussed in treatises on pathology by R. Carswell (1838) and J. Cruveilhier (1835–42), and more knowledge was added by E. Rindfleisch (1873), but the French school did most to delineate the disease. Good descriptions were appearing in standard textbooks of neurology before the end of the nineteenth

century, and in 1916 J. W. Dawson gave an exhaustive account of the pathology of the disease which has remained a standard reference.

Three personal accounts of multiple sclerosis by sufferers are worth reading for the insights that they give into its course and its consequences. The first two take the form of diaries, one written in the nineteenth century by Augustus d'Esté, one of King George III's illegitimate grandsons, and the other early in the twentieth century by a young naturalist who used the pseudonym W. N. P. Barbellion (Barbellion 1919; Firth 1948). The third, a well-illustrated account of the visual experience of optic neuritis (one of the common manifestations of multiple sclerosis the main symptoms of which are well described by d'Esté), was recently provided by Peter MacKarell (1986), a professional painter who was afflicted by it.

The geography of multiple sclerosis is interesting because it is strange and because understanding it may provide a crucial clue to the nature of the disease (see Matthews et al. 1985; McDonald 1986). Geographic peculiarities were first noted 85 years ago when Byron Bramwell argued that the higher incidence of multiple sclerosis in his practice in Edinburgh than that of neurologists in New York reflected a real difference in frequency between the two cities.

Forty years ago, the notion of the relevance of genetic background as well as latitude was pointed out by Geoffrey Dean on the basis of the lower prevalence of multiple sclerosis among Boers than among British descendants in South Africa; in both groups the prevalence of the disease in Africa was the same as in their countries of origin. The idea that genetic background was important also received support from the discovery of the rarity of multiple sclerosis among the Japanese. In the past 20 years, strenuous efforts have been made to determine the consequences of migration at different ages from areas of high to low prevalence, and vice versa. These studies support the general idea of an interaction between latitude and genetic factors determining the geographic distribution of the disease.

Pathology

The characteristic lesion of multiple sclerosis is the *plaque of demyelination* – a patch varying from a few cubic millimeters to many cubic centimeters in which the myelin sheath of nerve fibers is destroyed, leaving the axons relatively intact. Small plaques are oriented around small veins (the venules), though this orientation is often obscured in large

lesions. The venules in areas of active demyelina-
tion, as judged by the presence of inflammatory cells
and myelin breakdown products, are surrounded by
cells derived from the immune system. Such cells
are also present in the substance of the brain itself –
in the lesions, especially at the edges, where it has
been suggested that they may play a role in limiting
the spread of damage.

The outstanding feature of the chronic lesion is
the formation of a fibrous scar as a result of prolifera-
tion of the astrocytes, one of the supporting cells of
the central nervous system. Remyelination, at least
in most cases coming to post mortem, is scanty, al-
though it is an open question whether it may be
more extensive early in the course of the disease.

The plaques are distributed asymmetrically
throughout the brain and spinal cord, but there are
certain sites of predilection which determine the char-
acteristic clinical pattern of the disease. The impor-
tant functional consequence of demyelination is
block of electrical conduction in the nerve fibers
which leads to many of the clinical features of the
disease.

Clinical Manifestations

In at least 80 percent of patients, the disease follows
a relapsing and remitting course, often in the later
stages entering a steadily progressive phase. Fully
5 to 10 percent of patients experience a steadily
progressive course from onset. The typical episode of
neurological disturbance develops over a matter of
days or a week or two, persists for a few weeks, then
resolves over a month or two. Common manifesta-
tions include reversible episodes of visual loss (optic
neuritis), sensory disturbance or weakness in the
trunk or limbs, vertigo, and bladder disturbance.
Obvious disturbance of intellectual function is un-
common, except in severe cases. Recently, however,
subtle defects have been demonstrated early in the
course of the disease.

Certain special clinical patterns are of interest.
Steadily progressive spastic weakness is more com-
mon in late-onset cases (older than 40 years). In
Orientals generally, severe and persistent visual
loss and limb weakness are particularly common. In
the same group, a curious form of spasmodic disorder
of the limbs is also frequent. The reasons for these
well-documented ethnic differences in the pattern of
clinical involvement are unknown.

Distribution and Incidence

Multiple sclerosis affects principally individuals of
northern European Caucasoid origin living in temper-

ate zones, though it does occur infrequently in the
tropics and in other racial groups. Because the course
of the disease is so prolonged and the manifestations
are so variable, it is difficult to determine its true
incidence, and prevalence rates are generally used to
compare the frequency of the disease in different
populations. Females are affected about twice as com-
monly as men. The average age of onset is 30 years
old, and it rarely starts over the age of 60 or before
puberty. In Caucasoid populations, approximately 10
percent of patients have an affected relative. The
concordance rate in twins (i.e., the frequency with
which both members of a twin pair have the disease)
is about 30 percent for identical twins and 2 percent
for nonidentical twins, the latter being similar to the
frequency in siblings. The difference in concordance
rate between identical and nonidentical twins pro-
vides strong evidence for the implication of a genetic
factor in the etiology of the disease, but the rather low
concordance rate in identical twins suggests that an
environmental factor is also involved. Further evi-
dence implicating both environmental and genetic
factors comes from a consideration of the geography
and epidemiology of the disease.

Geography and Epidemiology

There are two relevant geographic aspects: the distri-
bution of the disease and the distribution of its ge-
netic associations. Among Caucasoids the preva-
lence of multiple sclerosis is generally higher in
higher latitudes. In the United Kingdom, for exam-
ple, the prevalence in the Orkney and Shetland Is-
lands is 309 per 100,000, in northern Scotland 178
per 100,000, and in the south of England 100 per
100,000. It must be pointed out, however, that these
prevalence studies have been conducted at different
times, and the reliability of ascertainment varies.
Nevertheless, data from other regions suggest that
the trends are real: Multiple sclerosis is more com-
mon in the northern United States and Canada than
in the southern United States, and in the more tem-
perate south of New Zealand and Australia than in
their northern portions.

The influence of migration on risk has been stud-
ied in several populations. Migration from high
prevalence (e.g., northern Europe and the northern
United States) to low prevalence areas (e.g., Israel,
South Africa, or the southern United States) before
puberty appears to decrease the risk of developing
the disease, while migration after puberty does not.
The total number of patients involved in these stud-
ies is small, but the consistency of the results sug-
gests that the observation is significant. Studies of

migration from low-risk to high-risk zones (Vietnam to Paris, New British Commonwealth to the Old) are based on even smaller numbers, though they have yielded concordant results. These observations provide further, albeit rather weak, evidence for the operation of an environmental factor in the etiology of multiple sclerosis, although this would seem to be the case if the risk of developing the disease is influenced by where individuals spend their first 15 years.

On the face of it, stronger evidence comes from the study of apparent clusters of cases in the Faroe Islands in the North Sea. No cases had been identified in the Faroe Islands prior to World War II. But between 1943 and 1973, there were 32 cases; there have been no new cases since. Although it cannot be certain that cases prior to 1943 were not missed, the balance of evidence is in favor of there being an unusual run of them in the 30 years after that date. J. F. Kurtzke and K. Hyllested (1986) have analyzed the data minutely and have suggested that there were two mini-epidemics within the main one. In addition, they have pointed out that the pattern of presentation of the cases suggests a point source epidemic and, noting that the places of residence of the patients were close to the location of army camps during World War II, have proposed that an infection was introduced by the British troops occupying the islands during that period. C. M. Poser and P. L. Hibberd (1988) have challenged these conclusions. Nonetheless, the overall clustering of cases is striking and probably a phenomenon of biological significance, indicating exposure to a newly introduced environmental agent in the early 1940s. Other examples of clustering have been reported but are less convincing.

Multiple sclerosis is much less frequent in non-Caucasoid populations. No postmortem-proved case has yet been described in African blacks, and prevalence of the disease is lower in American blacks than in whites living in the same areas. The disease is similarly rare among American Indians, the Maoris in New Zealand, the gypsies in Hungary, and Orientals living in California and Washington State but not in the larger populations they live among. Multiple sclerosis is also rare among the Japanese in Japan; among the Chinese in Taiwan, China, and Hong Kong; and among Indians living in India. It is so far unreported in the Eskimo. In many of these groups (but not Orientals in the United States and Japan), problems of ascertainment may have led to a significant underestimate of the true frequency of the disease. Nevertheless, it is clear that there are real differences in the frequency of the disease in different ethnic groups, again suggesting the operation of a genetic factor in determining susceptibility.

Genetics

The most intensively studied genetic associations of multiple sclerosis are those within the human leukocyte antigen (HLA) region of the sixth chromosome. The most frequent association in Caucasoid populations is with HLA-DR2, though others, including DQwl, have been reported. The strength of the associations varies in different population groups. R. J. Swingler and D. A. S. Compston (1986), though cautious in interpreting their data, have reported that in the United Kingdom the north–south gradient of prevalence of multiple sclerosis is mirrored by a similar gradient in the frequency of DR2 in the *control* population. In the New World, G. C. Ebers and D. Bulman (1986) have shown that in the United States the areas of highest prevalence correspond with the areas of immigration from Finland and Scandinavia (where there is a high frequency of DR2), and D. C. G. Skegg and colleagues (1987) have shown that multiple sclerosis is three times less common in the north than in the south of New Zealand – the latter a site of preferential migration for the Scots, who have a particularly high frequency of DR2.

There are fewer data for non-Caucasoid populations. In a small study, multiple sclerosis was found to be associated with the Dw2 (related to DR2) in blacks in Philadelphia. Among the Arabs, multiple sclerosis is associated with DR2 in some groups, and DR4 in others. No HLA association has been found in the Japanese and Israelis.

It should be noted that multiple sclerosis is rare in two populations in which DR2 is common: the Hungarian Gypsies (of whom 56 percent of controls are DR2 positive) as well as the Maoris – raising the possibility of the existence of an overriding genetic protective effect. Protective genes have also been postulated in Mongoloid and Caucasoid populations. Moreover, current research suggests that multiple sclerosis may be associated with peculiarities in the structure of certain genes in the HLA region.

What is one to make of this mass of confusing and sometimes conflicting data? The frequency with which some association with the HLA system is found suggests that the observations are significant. Yet it is clear that none of the factors so far identified alone confer susceptibility to the disease. The simplest explanation would be that DR2 is acting as a marker for another gene (or genes) conferring susceptibility, and that other genetic factors are involved as well.

Other possible genetic associations have been little studied, although there is evidence for an association with genes concerned with the control of antibody structure located on the fourteenth chromosome. A consistent pattern has not yet emerged. What is common to all the genetic associations so far identified is that they are concerned in one way or another with the genetic control of the immune response.

Pathogenesis and Etiology

In considering how the geographic, epidemiological, genetic, and pathological data might fit together, it must be stressed that there is no wholly satisfactory framework within which to incorporate all the data.

Pathogenesis

Much evidence has accumulated suggesting an immunologic basis for the disorder in patients with multiple sclerosis. There is abnormal synthesis of antibodies, both inside and outside the brain; there are changes in the number and functional activity of peripheral blood lymphocyte subsets in active disease; and there are immune-competent cells around the venules in the lesions and in the brain itself. The occurrence of such changes in the retina (where there is no myelin) is evidence that the vascular events are not secondary to myelin breakdown produced in some other way. This, combined with the results of recent functional vascular studies and other evidence, suggests that a vascular change is a critical early event in development of the new lesion.

Etiology

These processes provide a plausible though incomplete explanation for the development of the lesions in established multiple sclerosis. What of its initiation? There is good evidence from family studies and epidemiology that an environmental trigger, probably infective, is required in the genetically susceptible individual. The most likely infective agent would be a virus, though interest in spirochetes has been revived recently on rather slender grounds.

Two possible mechanisms for demyelination following viral infection are now known that occur only in genetically susceptible hosts. With visna, a retrovirus infection of certain strains of sheep, there are recurring episodes of demyelination of the central nervous system dependent on a direct attack of the virus; the remissions are due to the formation of neutralizing antibodies, whereas the exacerbations are due to mutations that lead to the loss of antibody control and renewed multiplication of the virus

(Johnson 1982). There are, however, a number of important clinical and pathological differences between visna and multiple sclerosis, including the consistent failure to isolate, reproducibly from the latter, a virus or fragments of one.

The second plausible mechanism involves the development of an autoimmune form of demyelination (after complete elimination of the virus) in mice inoculated intracerebrally with corona virus (Watanabe, Wege, and Ter Meulen 1983). The limitations of this model are that it is not known whether the process occurs after a natural route of infection, and whether in appropriate strains of animals a spontaneously relapsing and remitting disease can develop.

In conclusion, a solution to the problem of the nature and cause of multiple sclerosis would seem to be within sight. When we understand the reasons for the peculiar distribution of the disease, we are also likely to understand its etiology and pathogenesis.

Mumps

Mumps (infectious parotitis; epidemic parotitis) is a common, acute, viral infectious disease, principally of children, with worldwide distribution. It is frequently clinically characterized by fever and painful enlargement of one or more salivary glands. Inapparent infection is common and occurs in about one-third of infections. Sometimes postpubertal males with mumps may develop painful swelling of the testicles, usually only on one side, with sterility an extremely rare complication. Mumps is a vaccine-preventable disease, but the vaccine is not yet widely used on a global basis.

Etiology and Epidemiology

Mumps is caused by the mumps virus, a member of the genus *Paramyxovirus* of the family Paramyxoviridae. Mumps virus has an irregular spherical shape averaging about 200 nanometers in diameter and contains a single-stranded RNA genome.

Mumps is a contagious disease, only slightly less contagious than rubella and measles, transmitted from infected persons to susceptible individuals by droplet spread and by direct contact with saliva. Mumps virus has also been shown to be transmitted across the placenta to the fetus. There is no natural reservoir for mumps other than human beings, which means that a continuous chain of susceptible contacts is necessary to sustain transmission. Although the period of communicability may be from 6 days before salivary gland symptoms to 9 days afterwards, the period of greatest infectivity is about 48 hours before salivary gland involvement. There is no carrier state. Mumps has an incubation period from time of exposure to onset of salivary gland swelling of about 18 days with a range of 2 to 3 weeks.

In populated areas with no or low vaccination coverage, mumps is primarily an endemic disease of children, with epidemics occurring in closely associated groups such as schools. Its peak incidence is found in the age group 6 to 10 years, and mumps is rare before 2 years of age. Outbreaks may occur at intervals ranging from 2 to 7 years. There is a concentration of cases in the cooler seasons in temperate climates, and there is no apparent seasonality in tropical areas. In more remote isolated populations, mumps is not endemic, and disease depends upon introduction of the virus from the outside, at which time an epidemic may occur, affecting all age groups born since the previous epidemic. There is no evidence for a sex or racial difference in incidence of mumps, although clinically apparent mumps may be more common in males than in females.

Distribution and Incidence

Serologic surveys as well as recorded outbreaks have demonstrated the existence of mumps throughout the world. Mumps is not a reportable disease in most countries, is underreported even in countries where it is a notifiable disease, and may be clinically inapparent in 30 to 40 percent of infections. In populated areas where mumps is both endemic and epidemic, over 80 percent of the adult population will show serologic evidence of prior infection. In remote or island populations where mumps is not endemic, a significant proportion of the population can be susceptible which may lead to large outbreaks when the mumps virus is introduced from the outside.

In some countries, such as the United States, where mumps is a reportable disease and mumps vaccine has been extensively used (often in combination with measles and rubella vaccine), there have been impressive declines in reported cases of mumps.

Immunology

Infants usually have a passive immunity to mumps because of maternal antibodies acquired transplacentally from their immune mothers. This passive immunity protects the infant from mumps infection for about 6 months, depending on the amount of maternal antibody acquired.

Mumps infection in both clinically apparent and inapparent cases induces a lifelong immunity. Because a significant percentage of mumps infections

are clinically inapparent, persons may develop im-
munity without recognizing they have been infected.
Several serologic tests for confirming infection or
immunity have been developed, and it is also possi-
ble to isolate the virus from patients during the
acute phase of the disease. Skin tests for immunity
are not considered reliable.

A single dose of live attenuated mumps virus vac-
cine confers long-term, probably lifelong, immunity
in over 90 percent of susceptible individuals.

Clinical Manifestations and Pathology

The prodromal phase of mumps disease may be ab-
sent or include symptoms of low-grade fever, loss of
appetite, malaise, and headache. Salivary gland
swelling will often follow the prodromal period
within a day, although it sometimes will not begin
for a week or more. The salivary gland swelling
progresses to maximum size in 1 to 3 days. The
gland is painful and tender to the touch. Typically
both the parotid salivary glands are affected, usu-
ally with one gland enlarging a few days after the
other; hence the name "infectious or epidemic paro-
titis." One-sided parotid gland involvement occurs
in approximately one-fourth of patients who have
salivary gland involvement. The fever may last for a
variable period (from 1 to 6 days), and the parotid
gland enlargement may be present for 6 to 10 days.
It should be emphasized that approximately one-
third of mumps cases may go unrecognized or be
completely asymptomatic.

A common manifestation of mumps in approxi-
mately 20 to 30 percent of postpubertal males is
painful testicular swelling (orchitis), usually one-
sided. Sterility is an extremely rare outcome of
testicular involvement on both sides, which occurs
in only approximately 2 percent of cases. The next
most common manifestation of mumps is central
nervous system involvement in the form of a usually
benign meningitis, which may occur in about 10
percent of all infections. Uncommon manifestations
of mumps include involvement and sometimes pain-
ful swelling of other glands such as the ovaries,
breasts, thyroid, and pancreas. Mumps-associated
complications are rare and may include encephali-
tis, neuritis, arthritis, nephritis, hepatitis, pericard-
itis, and hematologic complications. Deafness, usu-
ally one-sided and often permanent, is reported to
occur once per 20,000 cases of mumps. Although
increased fetal mortality has been reported in
women who contracted mumps during the first tri-
mester, there is no evidence that mumps in preg-
nancy increases the risk of fetal malformations.

History and Geography

In the fifth century B.C., Hippocrates is believed to
have first recognized mumps as a distinct clinical
entity in his work *Epidemics I*. He described an
outbreak of an illness on the island of Thasus, noting
that "swelling appeared about the ears, in many on
either side, and in the greatest number on both
sides ... in some instances earlier, and in others
later, inflammations with pain seized sometimes one
of the testicles, and sometimes both." Greek and
Roman medical writers of antiquity as well as medi-
eval practitioners at various times recorded cases of
mumps-like illnesses, but there was relatively little
study of the disease. Outbreaks of mumps in Paris in
the sixteenth century were recorded by Guillaume
de Baillou. In 1755 Richard Russell described
mumps and expressed his opinion that the disease
was communicable.

Mumps is called *Ziegenpeter* or *Bauerwetzel* in Ger-
man and *oreillons* in French. The origin of the term
"mumps" is unclear although it may come from the
English noun *mump,* meaning a "lump," or the En-
glish verb *mump,* meaning "to be sulky," or even
perhaps from the pattern of mumbling speech in
individuals with significant salivary gland swelling.

In 1790, Robert Hamilton presented a very full
description of mumps to the Royal Society of
Edinburgh. He emphasized that orchitis was a
manifestation of mumps and suggested that some
mumps patients had symptoms of central nervous
system involvement. In the beginning of the eigh-
teenth century, interest in the study of epidemics
helped to establish the communicability and wide
geographic distribution of the disease.

August Hirsch collected references to some 150
epidemics occurring between 1714 and 1859 in tem-
perate latitudes in both hemispheres as well as in
cold, subtropical, and equatorial regions. He specifi-
cally mentioned accounts of outbreaks that had oc-
curred in diverse countries and places: "Iceland, the
Faroe Islands, Lapland, Alaska, Egypt, Arabia, In-
dia, Malay Archipelago, Polynesia, the West Coast of
Africa, Mexico, the West Indies, Peru, Italy, Sweden,
Prussian Saxony, Schleswig and Holstein, the depart-
ments of Dusseldorf and Treves, the Cologne depart-
ment, Martinique, Canton Zurich, Denmark, Lower
Bavaria, Central Franconia, the quondam Duchy of
Nassau, New York, Halle, Moscow, Bombay, and Ber-
lin." He also stated that during the American Civil
War, 11,216 cases among Confederate troops were
reported during the first year of the war and 13,429
cases during the second year. He concluded that
mumps "occurs in widest diffusion over the globe, no

part of the world being exempt from this strange malady."

Data have also demonstrated the occurrence of epidemic mumps in the closely associated populations of prisons, orphanages, boarding schools, garrisons, and ships. Indeed, Haven Emerson noted that mumps was the most important disease in terms of days lost from active duty in the American Expeditionary Force in France during World War I; and Surgeon General T. Parran of the U.S. Public Health Service stated in 1940 that mumps was one of the most disabling of the acute infections among armed forces recruits, exceeded only by the venereal diseases.

Despite earlier animal experiments suggesting that the fluid of the salivary glands was infective, C. D. Johnson and E. W. Goodpasture were not able to prove conclusively the viral etiology of mumps until 1934. They demonstrated that mumps was caused by a filtrable virus in saliva by transmitting mumps from patients to rhesus monkeys. In 1945 K. Habel successfully cultivated mumps virus in chick embryos. In 1948 G. Henle and associates experimentally confirmed the significant percentage of clinically inapparent infections by deliberately exposing 15 susceptible subjects to mumps, then following their clinical condition, isolating the virus, and performing serologic studies. In 1951, an experimental killed-virus vaccine was used in humans. A live mumps virus vaccine has been used in the former U.S.S.R. since the early 1960s. In 1966 E. B. Buynak and M. R. Hilleman reported on the development of a live attenuated mumps virus vaccine, and they, R. E. Weibel, and others conducted a successful trial of the vaccine, which led to its licensure in 1967 in the United States.

The worldwide geographic distribution of mumps is well documented, even in Hirsch's collection of some 150 epidemics noted earlier. In populous countries without any sustained, large-scale immunization programs, mumps is widespread. In island or remote communities, large numbers of susceptible persons may exist. In countries with sustained, large-scale immunization programs, the impact of control efforts has been documented through decreasing numbers of cases of reported mumps.

VIII.93
Muscular Dystrophy

The muscular dystrophies are a group of genetically determined, almost exclusively pediatric diseases. Generally, the earlier the age at which symptoms begin, the poorer is the prognosis. Because of a considerable overlap of manifestations and rates of progression and, until recently, the lack of any biochemical test, their classification is still unsettled. As a group, the principal differential diagnosis of the muscular *dystrophies* is from the muscular *atrophies*. In the former, the primary defect is in the voluntary muscle fibers; in the latter, it is in the innervation of muscles.

Classification

The most common of the dystrophies and the first to be described was that delineated by Guillaume B. A. Duchenne, a French neurologist, in 1868. *Duchenne muscular dystrophy* (DMD) is a sex-linked recessive disorder. Consequently, it clinically affects only males and is inherited through female carriers of the gene. Although affected boys have abnormally elevated concentrations of muscle cell enzymes such as creatine phosphokinase in their blood, this abnormality is also found in about three-fourths of the asymptomatic female carriers. DMD appears to have a rather uniform incidence worldwide, with a mean incidence estimated to be about 1 case per 4,000 live male births, or 15 to 33 cases per 100,000. Most surveys have been of predominantly Caucasian populations, but the results of a study in Japan were consistent with the others. A family history of DMD can be obtained in only about one-third of cases. The others are attributed to either a previously unexpressed carrier state or to a new mutation.

Cases can be identified during the first week of life by an excessive concentration of creatine phosphokinase in the blood, although the infant appears to be normal. The boy learns to walk somewhat late, falls easily, and has difficulty in getting up again. The gait gradually becomes broad based and waddling. Nevertheless, the diagnosis usually is not made before the age of 5 years. Unless the boy has been identified by biochemical screening during infancy and the parents receive genetic counseling, their risk of producing additional dystrophic children remains high.

The appearance of the child may be perplexing because, although he is weak, his muscles may appear to be unusually well developed. This *pseudohypertrophy* is due to the infiltration of muscle and replacement of muscle fibers by fat and connective tissue. As the disease progresses, muscle fibers increasingly appear abnormal microscopically, and others disappear. The upper extremities are affected later but in the same fashion as the pelvic girdle and lower limbs. Smooth muscle (e.g., intestinal tract, bladder) is not affected. As a result of subnormal stress on the developing skeleton from the weak musculature, ossification of long bones is delayed, and the mineral content of bones is deficient. Once weakness has resulted in confinement to wheelchair or bed, contractures of extremity joints and *kyphoscoliosis* (deformity of the vertebral column) supervene. A moderate degree of mental retardation frequently is an associated problem. Death is generally due to respiratory failure before the age of 20.

The defective gene of DMD was identified in 1986. Soon thereafter it was discovered that this genetic abnormality causes a deficiency of a protein, now called *dystrophin,* in the membrane of muscle fibers. Although this substance normally constitutes only 0.002 percent of the total muscle protein, its deficiency can now be detected and can serve as a specific diagnostic test.

At the other extreme from DMD in the spectrum of severity, there is *facio-scapulo-humeral dystrophy* (FSHD), which was described by the French neurologists Louis T. Landouzy and Joseph J. Déjerine in 1884. Onset usually occurs during adolescence, but can be much later. Its incidence has been estimated to be from 5 percent to 50 percent of the incidence of DMD. Inheritance is autosomal dominant, and FSHD occurs equally in both sexes. As the name indicates, the muscles of the face and shoulder girdle are affected first. Sometimes only facial muscles are involved. An affected person may be unable to close the eyelids completely or to purse the lips. Muscular involvement progresses downward to the pelvic girdle and legs, but it may become arrested at any time. Reproduction is not impaired. Death from sudden heart failure occurs in some cases. So far there is no effective treatment for the underlying abnormality of any of the muscular dystrophies.

VIII.94
Myasthenia Gravis

Myasthenia gravis is a disorder of skeletal muscle characterized by weakness and easy fatigability due to autoimmune destruction of the acetylcholine receptor in the postsynaptic membrane of the neuromuscular junction.

Distribution and Incidence

The disease has a worldwide distribution and has been identified as the primary cause of death at the average annual rate of 1.5 per million in the United States. If cases coded as contributory or as a complication are included, then the total would be 2 to 2.5. This seems to be the safest method of reckoning the actual incidence of myasthenia gravis, and previous estimates of 1 in 1,600 of the population probably vastly overestimate the incidence of myasthenia. There is no difference between whites and non-whites, and there is no difference in nationality. The death rate is slightly higher for women than men. In age-adjusted death rates for all ages, there is no appreciable difference in nine geographic regions of the United States. Thus myasthenia gravis seems to

be uniformly distributed throughout the United States, and probably is uniformly distributed throughout the world. There is no difference between city and country in the incidence of myasthenia gravis, and the age-specific death rates for the United States, based on a survey of 675 death certificates listing myasthenia gravis as the primary cause of death, showed that 90 percent of the decedents were older than 15 years of age. For this population the age-specific death rate is less than 1 per million until age 35, when there is a steady increase in the incidence of death for myasthenia gravis up to age 75. There appears to be a twin-peaked incidence, with females peaking between the ages of 15 and 24, and men peaking between ages 40 and 60. But if all ages are considered together, the sex ratio is probably close to 1. Morbidity data in surveys of the United States, Canada, England, Norway, and Iceland over a 10-year period using retrospective analysis show that the incidence of myasthenia is probably 0.2 to 0.5 per 100,000, with the prevalence being 3 to 6 per 100,000. In other words, the prevalence is approximately 10 times the incidence.

Etiology and Immunology

The overwhelming evidence is that myasthenia gravis is due to an immune system dysfunction that produces an autodirected antibody against the acetylcholine receptor in the postsynaptic membrane of the neuromuscular junction. The evidence is clinical, laboratory, serologic, and therapeutic. The clinical evidence that myasthenia is an autoimmune disease is based on the association of myasthenia with vaccination, insect sting, infection, or trauma; and its association with autoimmune diseases such as hypothyroidism, systemic lupus, and polymyositis. Many laboratory abnormalities point to the immune system dysfunction in myasthenia gravis. These include serologic abnormalities, increased incidence of a specific human leukocyte antigen (HLA-B8) in certain types of disease, histologic abnormalities of thymus and skeletal muscle, and abnormal responsiveness of lymphocytes to mitogens. Antinuclear antibodies are positive in uncomplicated myasthenia in about 18 percent of cases and in 54 percent of myasthenic patients who have thymoma, a tumor derived from elements of the thymus. Antistriated muscle antibodies are present in about 11 percent of patients with uncomplicated myasthenia and in all patients who have myasthenia associated with thymoma. Perhaps the most important serologic test in myasthenia is the IgG antibody directed against the acetylcholine receptor.

This antibody is probably positive in 70 to 95 percent of clinically diagnosed myasthenic patients and is the cause of the weakness and easy fatigability in the disease. Myasthenia gravis can be readily produced in animals by immunizing them against their acetylcholine receptor. Experimental autoimmune myasthenia gravis usually develops 2 to 3 weeks after immunization with the receptor and has all the features of human myasthenia gravis. Myasthenia gravis responds to all of the manipulations against the immune system that one would expect to see if the disease were of autoimmune origin. Thymectomy is effective, as are prednisone, Cytoxan, plasma exchange, and any other treatment that neutralizes the effect of excessive autoimmunity.

Clinical Manifestations

The single most important clinical feature of myasthenia gravis is weakness of skeletal muscle worsened by exercise and relieved by rest. Without this feature there can be no diagnosis. Weakness with easy fatigability is the only constant in this disease; all other features are variable. For instance, the weakness is usually worse in the afternoon and evening, although some patients are weaker in the morning when they first awaken. Usually the muscles supplied by the cranial nerves are the first and most severely affected, with resultant diplopia, ophthalmoplegia, dysphagia, dysphonia, dyspnea, and dysmimia. The disease may involve proximal lower- and upper-extremity muscles. In rare instances, however, proximal muscles weaken first. Involvement of individual muscles may be symmetrical, but is often asymmetrical with a dominant leg and arm usually weaker than a nondominant counterpart. Myasthenia gravis can also present as weakness of a single muscle – for example, the external rectus or superior oblique in one eye – or as a single complaint – for instance, jaw ptosis from inability to close the mouth. It can also present as a symptom seemingly unrelated to the neuromuscular system – for instance, burning eyes from exposure to keratitis, from incomplete eye closure during sleep, or a sore throat on awakening from mouth breathing during sleep. The disease may affect people at any age or of either sex and varies in severity from mild nonprogressive disease involving the eyes only (ocular form) to severe cases that may be rapidly fatal such as acute myasthenia gravis afflicting older men.

Diagnosis and Pathology

No two myasthenic patients look alike or have the same signs and symptoms. The classical appearance is unmistakable and is usually associated with bilateral ptosis, weakness of the face, and difficulty in smiling, chewing, and talking. The clinical diagnosis is confirmed by demonstrating electrical defects in transmission at the neuromuscular junction, responsiveness to anticholinesterase drugs, or the presence of the anti-acetylcholine receptor antibody circulating in the patient's blood. The consistent pathology found in every patient is autoimmune destruction of the postsynaptic receptor, simplification of the postsynaptic membrane, widening of the synaptic gap, and reduction in the acetylcholine receptor numbers and efficiency. Thymic pathology is also present in myasthenia gravis. Approximately 80 percent of patients have germinal centers and enlarged thymus, and about 10 percent of patients have a thymic tumor, a thymoma.

History

Seventeenth Century

Although myasthenia gravis was not described with any pretense of completeness as a clinical entity until the last quarter of the nineteenth century, a reference by Thomas Willis, an astute seventeenth-century English clinician, indicates that Willis probably knew of the disease and recognized the chief symptom of asthenia of the voluntary muscles with recovery after rest. The description of weakness in his patients occurs in his book on the physiology and pathology of disease with illustrated cases, *De anima brutorum* (1672), published in two separate editions the same year in Oxford and in London. The book was translated into English by S. Pordage in 1683 and published as "Two Discourses Concerning the Souls of Brutes" in Willis's *Practice of Physick* (London 1684). The significant part is as follows:

There follows another kind of this disease i.e., the palsy, depending on the want and fewness of spirits in which although motion be not deficient in any part or member wholly, yet it is not performed in any but the weakly and depravedly only. For though the distempered are free from want of motion they are not able however to move their member strongly or to bear any weight. Moreover, in every motor endeavor, they labor with a trembling of their limbs which is only a defect of debility and of a broken strength in the mode of power.

He then goes on to say that the patients with this affliction, although languishing in their limbs, are well in their stomachs and have a good and laudable pulse and urine. "Yet, they are as if they were innervated and cannot stand upright and dare scarce enter upon local motions, or if they do cannot perform

them long. Yea, some without any notable sickness are for a long time fixed in their bed as if they were everyday about to die" Willis then goes on to state what has been often quoted:

At this time I have under my charge a prudent and honest woman who for many years have been obnoxious to this sort of spurious palsy, not only in her members, but also in her tongue. She for sometimes can speak freely and readily enough, but after she has spoke long or hastily or eagerly, she is not able to speak a word but becomes mute as a fish, nor can she recover the use of her voice under an hour or two.

Thus did Willis note that his patients developed general, "although partial paralysis," and that they were not able to move their members strongly or bear any weight. This seems to be a description of myasthenia gravis, although, of course, we will never really know.

Nineteenth Century

Nearly 200 years were to pass from the time of Willis before myasthenia gravis was again mentioned in the medical literature. The next recorded observation appears to have been made by an English physician, Samuel Wilks in 1877, one of the physicians to Guy's Hospital, London, who, when describing some cases of bulbar paralysis, described a patient with symptoms slightly similar to myasthenia gravis. He talked about a woman who could scarcely walk and had defective extraocular movement. Her speech was slow and deliberate, and she fatigued easily. Subsequently, she developed trouble swallowing and was unable to cough and died of respiratory paralysis. This is an incomplete discussion, but is the first fatal case of myasthenia gravis ever described in the medical literature. This report by Wilks was of some importance because the patient was autopsied and no abnormality could be found in the nervous system, indicating that the patient's trouble was due to some kind of functional defect.

The first really complete report of myasthenia gravis was given by Wilhelm W. Erb in 1879; he described a patient, age 55, who was seen in 1868, 11 years prior to the publication of the case record. The patient's illness had developed over a period of four months, and the first principal symptoms, which were clearly described, included ptosis, neck weakness, and dysphagia. Some atrophy was noticed in the neck muscles, and the patient seemed to respond to faradism (induced current). The patient was probably one of the first to be treated by Erb with electricity. The patient, George Fuss, a day laborer, went

into remission, and it was natural for Erb to attribute the improvement to his electrical treatment. Erb's second case was Magdalene Meisel, a peasant 30 years of age, first seen in 1870. Her symptoms were double vision, ptosis, dysphagia, and weakness. She died suddenly at night, and no autopsy was done. She had clear-cut exacerbations and remissions. The third patient reported by Erb, August Thal, a merchant, age 47 years, had difficulty holding his head up, and showed bilateral ptosis and facial weakness.

Subsequently, a score more cases were reported by 1893, when Samuel V. Goldflam reported a detailed study of myasthenia gravis. Goldflam mentions all of the currently accepted clinical signs and symptoms of the disease, which he summarized as follows:

1. The disease occurs in early life.
2. Both sexes are equally affected.
3. It is a disease of the motor system.
4. Chewing, swallowing, and eye movements are most affected at first, followed by involvement of trunk extremity.
5. Trunk involvement is usually but not necessarily always symmetrical.
6. Most patients are worse in the afternoon and evening and are improved by rest.

Goldflam also mentioned that daily exacerbations and remissions may occur, and that death may be due to respiratory impairment, and may occur suddenly. His article in many ways is the most important ever written in the history of myasthenia gravis.

The next major advance occurred a year later, in an 1894 paper by F. Galle. He was the first to analyze the reaction of muscles in myasthenia gravis to electrical stimulation and to name the disease. He also suggested physostigmine as a form of drug treatment, but he does not seem to have followed up on this important point; it was left to Mary Walker, 40 years later, to demonstrate the therapeutic value of physostigmine.

Twentieth Century

Modern studies of the pathological physiology of myasthenia gravis started with the work of A. M. Harvey (1948), and a series of illustrious colleagues, including Richard Masland, D. Grob, and T. R. Johns. These men recognized the characteristic response of the evoked muscle action potential to repetitive stimulation of nerve, thereby localizing the defect of myasthenia gravis to the neuromuscular junction.

In 1964, E. Elmquist and colleagues, using microelectrode techniques on human intercostal muscle, seemed to show that there was too little acetylcholine in each quantum released from the nerve terminal, an abnormality that could be explained by the presence of a false transmitter or by an abnormal binding or packaging of acetylcholine quanta. This particular finding, as it subsequently turned out, was in error, and we now know that the postsynaptic membrane is poorly sensitive to infused acetylcholine and that the defect in myasthenia gravis has nothing to do with any presynaptic defect. In fact, presynaptic release of acetylcholine in myasthenia gravis is normal.

In the meanwhile, evidence was accumulating that there was an immunologic disorder in myasthenia. This was first suggested by D. W. Smithers in 1959, who recognized the histological parallel between the thymus in myasthenia and the thyroid gland in thyroiditis. The following year, J. A. Simpson drew attention to the increased frequency, in myasthenia gravis, of other diseases regarded as autoimmune, especially rheumatoid arthritis. But the major advance occurred in 1973, when J. Patrick and J. M. Lindstrom injected rabbits with acetylcholine receptors purified from electric eel, intending to make antibodies to the acetylcholine receptor. In the process, they induced and recognized experimental autoimmune myasthenia gravis. This led to experiments indicating the nature of the human disease. We now know that the disease is caused by a circulating antibody directed against the acetylcholine receptor and that treatments directed against the abnormal antibody are effective in modifying the clinical signs and symptoms of myasthenia gravis.

VIII.95
Nematode Infections

The roughly 500,00 species in the phylum Nemathelminthes, the nematodes or roundworms, include both free-living forms and important parasites of plants and animals. Many species of nematodes parasitize humans, and several of them are major public health problems in poor countries, especially in the tropics. Some species reside as adults in the intestine; others are found in the blood and tissues. See *Ascariasis, Dracunculiasis, Enterobiasis, Filariasis, Onchocerciasis, Strongyloidiasis, Trichinosis,* and *Trichuriasis.*

K. David Patterson

VIII.96
Onchocerciasis

Onchocerciasis is caused by a filarial nematode, the roundworm *Onchocerca volvulus.* Humans are infected by larval microfilariae transmitted by blood-feeding female flies of the genus *Simulium.* Symptoms include skin damage, extreme itching, and ocular lesions, which can lead to permanent blindness. Synonyms include river blindness in West Africa, *sowda* in Yemen, and *enfermedad de Robles* in Latin America.

Distribution and Incidence
Onchocerciasis is widely distributed in Africa south of the Sahara, especially in the savanna grasslands from Senegal to Sudan. Its range extends southward into Kenya, Zaire, and Malawi. The region encompassing the headwaters of the Volta River system in northern Ghana, northeastern Ivory Coast, southern Burkina Faso (Upper Volta), and adjacent territories has been a major center for the disease. Onchocerciasis was almost certainly indigenous to Africa, but it has been transmitted by the slave trade to the Arabian Peninsula (Saudi Arabia and Yemen) and to the Caribbean basin, where scattered foci exist in Mexico, Guatemala, Colombia, Venezuela, Ecuador, and Brazil. The disease has a patchy distribution within its range; infection rates in particular villages may range from zero to virtually 100 percent.

In the 700,000 square-kilometers of the Volta Basin region alone, the World Health Organization estimated that in the early 1970s, about 1 million of the 10 million inhabitants were infected, with about 70,000 classified as "economically blind." In northern Ghana alone, surveys in the early 1950s determined that about 30,000 people, roughly 3 percent of the population, were totally blind because of onchocerciasis. In some West African villages, adult blindness rates of from 10 to 30 percent have been observed. Conversely, dermatologic symptoms predominate in Arabia, and ocular involvement is rare.

Clinical Manifestations, Diagnosis, and Treatment
O. volvulus, one of several filarial worms that are important human parasites, lives in the cutaneous and subcutaneous tissues. Humans are the only definitive host; there is no animal reservoir. Numbers of adult worms, the females of which may reach a length of 50 centimeters, live in large coiled masses, which usually become surrounded by fibrotic tissue generated by the host. In these nodules, which may reach the size of a walnut and are often easily visible on the head, trunk, hips, or legs, the adults can live and breed for as long as 16 years. Thousands of larvae, the microfilariae, emerge from the nodules and migrate in the tissues of the skin. Host immune reactions to dead or dying microfilariae cause various forms of dermatologic destruction, including loss of elasticity, depigmentation, and thickening of the skin. These changes are complicated by the host's reaction to the extreme pruritis caused by the allergic reactions to the worm proteins; the victim may scratch him- or herself incessantly in a vain attempt to relieve the tormenting itch. This condition is sometimes called "craw-craw" in West Africa. Wandering microfilariae can also cause damage to the lymphatic system and inguinal swellings known as "hanging groin." Microfilariae that reach the eye cause the most damage. Larvae dying in various ocular tissues cause cumulative lesions that, over a period of one to several years, can lead to progressive loss of sight and total blindness. There appear to be distinct geographic strains, which help to explain different pathological pictures in parts of the parasite's range; for example, in forest regions of Cameroon a smaller percentage of infected persons experience ocular complications than do inhabitants of the savanna.

Diagnosis is by detection of nodules, by microscopic demonstration of microfilariae in skin snips,

and, in recent years, by a number of immunologic tests. Therapy includes surgical removal of nodules, which has been widely practiced in Latin America to combat eye damage, and various drugs to kill the wandering microfilariae. The first drug to be widely used was diethylcarbamiazine (DEC), but in heavily infected people it may cause serious side effects when the immune system reacts to the allergens released by large numbers of dying worms. Dermatologic complications of DEC can be severe, but these are treatable with antihistamines and corticosteroids; ophthalmologic complications are less common but more dangerous. Suramin, a drug used to combat trypanosomiasis, is effective against both microfilariae and adult worms, but it has serious side effects and, like DEC, is too dangerous to use in mass campaigns. Some success has been reported with antihelminthics like mebendazole, but only ivermectin, a microfilaricide introduced in the early 1980s, seems safe and effective enough for widespread use in rural areas of developing countries.

Etiology and Epidemiology

The vectors and intermediate hosts of the pathogen are blood-feeding flies of the genus *Simulium*, especially members of the species complex *Simulium damnosum*. These annoying and appropriately named insects, sometimes called buffalo gnats, are close relatives of the familiar "black flies" of the northern United States and southern Canada. The females bite people, cattle, goats, wild animals, or birds to obtain blood meals. Flies feeding on infected humans may ingest microfilariae. These migrate from the insect's stomach to the muscles of the thorax, where they undergo about a 1-week developmental process before migrating to the salivary glands. Here, as infective larvae, they await the opportunity to enter a new host when the fly feeds again. Once this happens, the larvae wander briefly in the skin before settling down in clumps to mature, breed, and produce microfilariae.

Simulium females lay eggs on rocks and vegetation in swiftly flowing, richly oxygenated water. Ripples around rocks, bridge abutments, and dam spillways provide favorable conditions for the larval development of the vector. There is no transovarial transmission, so newly emerged adults must acquire onchocerca in a blood meal. Adult flies have extensive flight ranges: Infected females aided by winds and weather fronts can move hundreds of kilometers to establish new foci of disease. However, because of the vector's breeding preferences, most flies and hence most onchocerciasis cases are found within a few kilo-

meters of a stream with suitable breeding sites. The term "river blindness" accurately reflects the geographic distribution of the disease.

Onchocerciasis often has dramatic effects on human activities and settlement patterns. In many heavily infested areas, notably in the headwaters of the Volta River, swarming flies, tormenting skin infestation, and progressive blindness among a significant proportion of the population have resulted in progressive abandonment of rich, well-watered farmlands near the rivers. Depopulation of river valleys due to onchocerciasis has been going on for decades in much of northern Ghana, with people being forced to cultivate crowded and eroding lands away from the streams. In many areas, land-hungry people were settling the river valleys in the early twentieth century, but, as John Hunter has shown in his classic study of Nangodi on the Red Volta, in recent decades the line of settlement has been retreating from the rivers. It is possible that a cycle of colonization and retreat, with farmers caught between malnutrition and land shortages on the one hand and the perils of onchocerciasis on the other, has been going on for centuries in parts of the Volta basin.

History

As stated above, onchocerciasis is almost certainly a disease that originated in Africa and has spread to Arabia and the New World as an unintended byproduct of the slave trade. Skin lesions caused by onchocerciasis were first described by J. O'Neill, who detected microfilariae from Africans in the Gold Coast (modern Ghana) suffering from the tormenting itch of "craw-craw." The organism was first described in 1893 by the eminent German parasitologist K. G. Friedrich Rudolf Leuckart, who studied adults in nodules extracted from Gold Coast Africans by a missionary. In 1916 the disease was first recognized in the Americas when the Guatemalan investigator Rodolfo Robles discovered onchocerciasis in the highlands of his country. Robles linked nodules to eye disease and suggested that the distribution of infection implicated two species of *Simulium* as vectors. D. B. Blacklock, working in Sierra Leone, showed in 1926 that *S. damnosum* was the vector. In 1931 J. Hissette, working in the Belgian Congo, linked onchocerciasis with blindness for the first time in Africa, but despite confirmation in the Sudan a year later, colonial doctors generally considered onchocerciasis only a skin disease. Just before World War II, French doctors in what is now Burkina Faso began to link the disease with mass blindness and river valley abandonment. Their colleagues across the frontier in the British

Gold Coast did not make a similar discovery until 1949. Although British physicians and administrators were aware of river valley depopulation, onchocerciasis, and substantial blindness in the northern part of the colony, they did not link these phenomena, partly because doctors who became interested in the problem in the 1930s were repeatedly distracted by other duties or transferred. After the war, the association was finally made, especially in a crucial 1949 report by B. B. Waddy. A series of investigations in the 1950s confirmed the widespread incidence and serious consequences of the disease in a number of African countries, and Latin American foci were delimited.

Control

In 1975 the World Health Organization, supported by a number of donor and afflicted countries, began the Onchocerciasis Control Programme, an ambitious and expensive 20-year effort to eliminate onchocerciasis in the entire Volta Basin. The basic strategy was to kill fly larvae by aerial spraying of an organophosphate called Abate (generic name: temephos) over breeding sites scattered over a huge and repeatedly extended portion of West Africa. The absence of an effective agent to kill adult flies has not prevented tremendous success in reducing and sometimes eliminating *Simulium* populations. Although treatment of victims was less successful until very recently because existing drugs were too dangerous for mass use, the vector control program, though costly and constantly faced with the problem of reintroduction of adult flies from places beyond the limits of the control program, has resulted in dramatic declines in biting rates, infection, and blindness in most of the region. Recently, treatment of thousands of victims with ivermectin, a safe and effective microfilaricide, has helped to reduce blindness among infected persons and has reduced the chances that a feeding fly would ingest infective microfilariae. The absence of an agent to kill adult worms and the logistical and financial difficulties of the massive larviciding campaign make total eradication unlikely, but vector control and microfilaricidal treatment can reduce the number of infected persons and lessen or eliminate severe clinical symptoms. Success at this level could help make thousands of square kilometers of valuable farmland safe for use in many regions of Africa. It is, however, clear that there must be a long-term commitment to the campaign for many years into the future, or river blindness will reconquer its old haunts.

Ophthalmia (Conjunctivitis and Trachoma)

In its broadest sense, ophthalmia is an inflammation of the eye, especially of the conjunctiva of the eye. The term derives from the Greek word *ophthalmos* (the eye). Hence, almost any disease that attacked the eye was called *ophthalmia* in many Greco-Roman and later European sources until the beginning of the twentieth century. As medical knowledge was refined, defining terms were attached, such as "purulent ophthalmia," "neonatorum ophthalmia," or "Egyptian ophthalmia." The problem for historians attempting to define eye diseases in the past is that the term "ophthalmia" meant many diseases that attack the eyes or that manifest symptoms in the eye, and that blindness due to "ophthalmia" had many causes. Two important causes of ophthalmia were trachoma and conjunctivitis; this essay is limited to these.

Trachoma (also called *granular conjunctivitis* and *Egyptian ophthalmia*) has been defined as a contagious keratonconjunctivitis caused by *Chlamydia trachomatis* (serotypes A, B, Ba, and C). It is characterized by the formation of inflammatory granulations on the inner eyelid, severe scarring of the eye

in the fourth stage, and blindness (but not in all cases). It was one of the leading causes of blindness in the past, and still blinds millions in Asia, the Middle East, and Africa (Bietti and Werner 1967; Rodger 1981; Insler 1987).

Conjunctivitis (purulent ophthalmia) may appear with trachoma and may complicate the progression of the disease so that blindness rather than healing occurs. Although conjunctivitis may denote any inflammation of the conjunctiva ("the mucous membrane lining the inner surface of the eyelids and covering the frontpart of the eyeball"), bacteria often infect the conjunctiva at the same time as does trachoma, thus causing an acute bacterial conjunctivitis. In the Middle East, for example, "spring and fall epidemics of gonococcal and Koch–Weeks conjunctivitis account for much of the corneal scarring seen in these populations" (Thygeson 1964). If trachoma attacks as well, the two in combination may blind many individuals. Viruses can also cause conjunctivitis, and historical descriptions that stress mild cases of ophthalmia often point to a viral or bacterial conjunctivitis. By contrast, the more severe ophthalmia that scarred the eye or permanently blinded individuals was often trachoma. It was almost impossible to identify the various forms of conjunctivitis before twentieth-century scientific methods of testing, but even at present, in desert and tropical areas, forms of bacterial and viral conjunctivitis are still confused with trachoma, with which they often occur.

Ophthalmia neonatorum is a term used for eye disease in newborns since the Greeks, but vague historical references make it difficult to identify the actual disease. Blindness in newborns may be due to various infections acquired in the birth canal. Before the twentieth century, ocular gonorrhea may have been the major cause of blindness in newborns, but in the twentieth century (at least in the industrialized nations) chlamydial infection is the most common type of ophthalmia neonatorum (Thygeson 1971; Rodger 1981; Insler 1987).

Distribution and Incidence

Trachoma remains widespread in the twentieth century. Two estimates place the number of victims worldwide at 400 million to 500 million, with millions suffering from sight defects and perhaps 2 million totally blinded (Bietti and Werner 1967; Rodger 1981).

In 1935 Adalbert Fuchs found that the greatest frequency of the disease was in Egypt, "where 98 percent of schoolchildren in the fourth grade are afflicted by trachoma" (Fuchs 1962). In the 1960s,

Egypt still led the list of areas where a majority of the population was affected. Because a dry climate seems to affect incidence, among the highest rates of infection are the countries of North Africa and the Muslim Middle East – that is, from Morocco to Egypt and the Sudan in North Africa, and from the Red Sea to Turkey and Iran in the Middle East. It is also widespread in Asia, with 20 to 50 percent of the population infected in Burma, Pakistan, India, China, Southwest Asia, Indonesia, and Borneo. These rates also occur in Africa south of the Sahara, except for West Africa, where the incidence falls below 20 percent. Similar trachoma rates continue along the Mediterranean coast of Europe, in Eastern Europe, parts of Russia, Korea, Japan, Australia, New Zealand (among the Maoris), and the Pacific Islands. In the Western Hemisphere, Brazil and Mexico have the highest incidences, but trachoma also infects Indians and Mexican-Americans in the southwestern United States. Sporadic cases appear in parts of Europe, the Philippines, and some Central and South American countries. The disease is practically extinct in Canada, Switzerland, Austria, and northern Europe – that is, in the countries with the highest standards of living and sanitary conditions and without pockets of extreme poverty. Where living conditions have improved, trachoma has declined or disappeared (Bietti and Werner, 1967). It is, however, a disease that still afflicts the impoverished who live in crowded conditions in the desert and tropical regions of Africa, the Middle East, Asia, and Latin America (Bietti and Werner 1967; Rodger 1981).

Etiology and Epidemiology

Trachoma generally requires prolonged contact among individuals in filthy and overcrowded living conditions for transmission. In endemic areas, infection first occurs in childhood as a result of close family contact. Transmission may be from mother to baby, from eye to eye, by fingers, and by eye-seeking flies. In urban slums or poor villages where people live crowded together under unsanitary conditions, garbage and raw sewage attract flies that breed copiously. As the insects swarm on the faces of infants and children, they feed on the infected eye discharges of those with trachoma and carry it to the eyes of other victims. Most children in endemic areas have trachoma at an early age, but hosting the disease in childhood does not provide a lifelong immunity.

Trachoma transmission may also occur by direct touch, by the contamination of clothing or bedding, possibly by bathing in pools in which people swim

and wash, and by sexual means. According to B. R. Jones:

[I]n the vast majority of cases infection (with the TRIC agent) is transmitted from person to person by intimate sexual contact involving at various times genital, rectal, oral or other mucosal surfaces. No doubt it can be directly transferred to the eye during such activities. However, in the vast majority of cases it appears to be transferred to a genital mucosal area, and then by means of transferring a genital discharge by hand, or other vectors, it reaches the eye. (Cited by Rodger 1981)

Factors that contribute to the severity of trachoma are ocular irritants and bacterial conjunctivitis. It is most prevalent where the climate is hot and dry, and low humidity leads to excessive drying of the conjunctiva. Winds and dust, along with smoke in unventilated huts, further irritate the eyes. Bacterial infections, particularly the seasonal outbreak of bacterial purulent conjunctivitis, often cause the worst cases. Frederick Rodger (1981) suspects that such infections are "related to the peak period of reproduction of the fly population."

Clinical Manifestations and Pathology

Trachoma

The clinical features of trachoma are usually divided into four stages, following the classification system of A. F. MacCallan published in 1931:

Stage 1 (incipient trachoma) is characterized by increasing redness of the conjunctiva lining the upper lids and covering the tarsal plate. Magnification reveals many small red dots in the congested conjunctiva. As the organism proliferates, larger pale follicles appear. Both features then spread across the upper conjunctival surface. A minimal exudate occurs, which may be more profuse if there is a secondary bacterial infection. This stage is difficult to distinguish from the similar follicles of folliculosis and follicular conjunctivitis. Another characteristic of this acute stage is that the upper part of the cornea becomes edematous and infiltrated with inflammatory cells that invade the upper part of the cornea from its edge. In the last phase of incipient trachoma, *pannus* ("an abnormal membranelike vascularization of the cornea, due to granulation of the eyelids") appears in the upper cornea. Rarely does pannus appear in the lower cornea, and then only with pannus in the upper cornea. The duration of Stage 1 is several weeks to several months.

Stage 2 (established trachoma) marks the increase of all the symptoms established in Stage 1 and is often termed the "florid stage" because of the "florid inflammation mainly of the upper tarsal conjunctiva with the formation of follicles" and then of papillae with the "follicles appearing like sago grains." The pannus increases toward the apex of the cornea. Because the red vessels in the cornea are dilated, they are visible to the naked eye. In severe cases, because a secondary bacterial infection may worsen the appearance of the eye, there will be purulent and copious secretions. In dark-skinned populations the conjunctiva may take on pigment, which remains after the healing stage. The duration is 6 months to several years.

Stage 3 (cicatrizing trachoma) is the scarring and healing stage. The follicles rupture, and scar tissue forms on the undersurface of the upper lids. Scar tissue also appears elsewhere on the conjunctiva. At first, the scars are pink but later turn white. It is not uncommon for a new infection of *C. trachomatis* to occur at this stage and to start the process all over again. Thus Stages 2 and 3 may coexist for many years and may be further complicated by repeated bacterial infections. With each new attack, more scar tissue appears, and an ever-increasing pannus covers the cornea. This phase may be several years in duration.

Stage 4 (healed trachoma) is the final stage of the disease in which healing has been completed without any signs of inflammation, and the disease is no longer infectious. Trachomatous scarring remains, however, and may deform the upper lid and cause opaqueness in the cornea. The thickening of the upper lids gives a "hooded appearance to the eyes." Because scarring of the upper lids involves the tarsal plate, which buckles, twists, and inturns, these features indicate a past trachoma. When the inturning occurs, the lashes often rub on the cornea (*trichiasis*), causing constant irritation and tearing until the corneal surface is scarred. Ulcers may develop, and bacterial infection of the ulcers can lead to blindness. Another complication may be drying of the conjunctiva and cornea. The combination of corneal scarring, opacification, and vascularization plus secondary bacterial infections all account for impaired vision and blindness (Thygeson 1964; Yanoff and Fine 1975; Grayson 1979; and Rodger 1981).

Conjunctivitis

Simple acute conjunctivitis is a common eye infection, caused by a variety of microorganisms. Its most characteristic sign is the red or bloodshot eye. In mild cases, there may be a "feeling of roughness or sand in the eyes," but in serious cases there is "great pain" and photophobia (dread of light). In its early

stages discharges from the eyes are thin and serous, but after a few days they may become so purulent that the secretions gum the lids together, and it becomes difficult to open the eyes, especially upon waking. The infection often begins in one eye before spreading to the other one. An acute conjunctivitis may last for 1 to 2 weeks (Thomson 1984).

Severe forms of conjunctivitis include *ophthalmia neonatorum,* due to infectious discharges in the birth canal; *follicular conjunctivitis,* which is often confused with the early stages of trachoma; *phlyctenular conjunctivitis,* which may lead to ulceration in the cornea; and a highly infectious *hemorrhagic conjunctivitis,* which affected 15 to 20 million in India in 1981 (Thomson 1984).

Gonococcal conjunctivitis, due to *Neisseria gonorrhea,* infects newborns as well as children and adults. Whereas newborns acquire the eye disease in the birth canal from their mother's vaginal secretions, others may contract the disease by direct or indirect contact. Although there may be nonvenereal transmission – especially in the tropics – the disease is now transmitted mainly by sexual intercourse. In infants the eyelids may be very swollen, and ulceration of the cornea often follows. Ocular gonorrhea infection used to be one of the principal causes of blindness in Europe until the 1880s, when a silver nitrate solution came into use in newborns. Since then, "the dramatic decrease in blindness that has resulted" is "one of great victories of scientific medicine" (Thygeson 1971; Insler 1987).

In contrast to gonococcal conjunctivitis, which has declined in the developed world, *chronic follicular conjunctivitis* and *acute conjunctivitis* in newborns have been on the increase along with other sexually transmitted diseases. "*Chlamydia trachomatis* [serotypes D through K] is now the most common sexually transmitted infection in the developed world" (Insler 1987). It causes not only conjunctivitis in newborns and adults but also genital tract infections. In adults symptoms of chronic follicular conjunctivitis include "foreign body sensation, tearing, redness, photophobia, and lid swelling." In newborns *inclusion conjunctivitis* or *blennorrhea* of the newborn usually appears 5 to 14 days after birth, since the baby acquires the chlamydial infection during its passage through the birth canal. Descriptions of infants with purulent ophthalmia – abnormal discharges of mucus some days after birth – may suggest this disease. Because purulent ophthalmia usually does not lead to severe visual loss, blindness in newborns is more likely due to gonococci and other bacteria that often complicate chlamydial infection.

The herpes simplex virus, other viral infections, or other bacterial infections (due to *Staphylococcus* or *Pseudomonas*) may also cause an ophthalmia neonatorum (Insler 1987).

History and Geography

Antiquity

Trachoma is an ancient disease. It was known in China in the twenty-seventh century B.C. (Bietti and Werner 1967) and ancient Egypt from the sixteenth century B.C. In 1872 George Ebers discovered a medical papyrus at Thebes that clearly described a chronic conjunctivitis (ophthalmia, lippitudo, chronic granular disease). The ancient Egyptians called the disease *Hetae,* and their symbol for it was the rain from heaven, which means a flowing downward of fluid. The papyrus also describes the white spot (*sehet*) or leukoma of the cornea, but still more clearly "the hairs in the eye" (*shene m mert*) or trichiasis (inwardgrowing eyelashes). All of this is very suggestive of trachoma (Worms and Marmoiton 1929; Hirschberg 1982; Meyerhof 1984).

Greek and Latin. By the time of the ancient Greeks, eye inflammations (ophthalmia) were frequently described and sometimes defined, and in about A.D. 60 the term *trachoma* ("roughness") first was used by Dioscorides (Worms and Marmoiton 1929; Chance 1939). Although the Hippocratic books do not define ophthalmia precisely for us, Galen defines it as "an inflammation of the conjunctiva." The Greeks also used the term *lippitudo* (exudation from an eye) for the secreting eye, which is a possible reference to trachoma. Later Greek authors distinguished among a severe irritation of the conjunctiva, the true conjunctivitis or secreting eye, and a simple conjunctivitis. The most important reference to trachoma comes from the book *On Vision,* in which the Hippocratic corpus describes not the disease but rather its treatment. It stresses the scraping of the lids of the eye along with the cutting away from their inner side of the fleshy granulations followed by cauterization of the lid with a hot iron. Another book in the Hippocratic corpus describes an early operation for trichiasis (Meyerhof 1984). Possibly one reason for the amount of attention given to trachoma in the Hippocratic corpus is that there appears to have been a major outbreak of the disease among the Athenians during the Peloponnesian War (431 to 404 B.C.) (Chance 1939; Cornand 1979).

For the treatment of trachoma, Greek physicians stressed scraping thickened lids with fig leaves or

the rough skins of sea animals, such as sharks. Writing in Latin in the first century A.D., Celsus describes trachoma, which was then called *aspiritudo.* "This [roughness] often follows inflammations of the eyes, sometimes more sometimes less violently. Sometimes this roughness is followed by a running eye." He also recommended treatment for trichiasis. About A.D. 45, a younger contemporary of Celsus wrote a book of remedies for many diseases, including several for trachoma. The Greek physician Dioscorides recommended fig leaves and the shell of octopus for scouring the "rough and fig-like granulations of the lids." Galen also refers to the octopus-shell as well as to the skin of sharks for scraping the lid in severe cases of trachoma (Meyerhof 1984).

The Romans were also well acquainted with trachoma. The movement of Roman troops throughout the empire must have dispersed trachoma from the Mediterranean region to wherever the Roman soldiers sought to extend the empire. Some evidence for trachoma on the frontiers of the Roman Empire (France, England, and Germany) comes from the stone-seals of Roman oculists, which record the names of remedies used for trachoma (James 1933; Chance 1939). Roman medical books also include typical remedies for the ailment. In the fourth century A.D., Theodorus Priscianus reported his personal experiences with patients who suffered from "the malady of roughness (*asperitatis vitium*)"; he used garlic juice to anoint the conjunctiva. In the sixth century A.D., Christian physicians from Asia Minor – Alexander of Tralles and Aetius of Amida – referred to trachoma and trichiasis. Aetius distinguished four stages of trachoma (*dasytes* = "density" = slight thickening of the conjunctiva; *trachytes* = "roughness"; *sykosis* = "figlike granulation"; and *tylosis* = "callousness" = cicatricial trachoma) (Chance 1939; Meyerhof 1984). To some extent this understanding of the disease is reflected in the trachoma descriptions in the seventh century A.D. of Paul of Aegina, an Alexandrian physician:

Trachoma is a roughness of the inner surface of the lids. When the disease is of greater intensity it is also called "fig disease." If the disease is chronic and cicatricial then it is called "scar." Topical medications are indicated. They consist of wine and two kinds of red iron ore. These are washed and then the inner surface of the lid is gently cauterized. (Hirschberg 1982)

Paul also provides descriptions of trachoma treatments. He refers to everting the lid and scraping it with pumice, octopus shell, fig leaves, or an instrument. Patients with trichiasis were operated on with a needle and thread, a procedure that was reinvented in 1844. To prevent inflammation of the eyes, he recommended the method of "cutting and of burning the forehead and temples" – a treatment that was used on St. Francis of Assisi in medieval Italy and that was still common among Egyptian peasants in the twentieth century (Meyerhof 1984; Green 1987). Paul and Aetius were also familiar with eye diseases in newborns. Paul, for example, referred to a "purulent exudation" in the eyes of newborns, while Aetius recommended the irrigation of the eyes of a newborn – "oil should be dropped into them" (Hirschberg 1982).

Arabic. After the important medical writings in Greek or Latin, the next significant surviving treatises on eye diseases are in Arabic, dating from the eighth and ninth centuries A.D. Unfortunately, earlier texts by Syriac-speaking Christians of Syria, Mesopotamia, and Persia have been lost except for one that follows Galen. The later Arabic authors, however, enable us to continue to track trachoma through accurate medical descriptions. In the ninth century, the first attempt, by Ibn Masawaih, does not provide a good description of trachoma but does refer to pannus and trichiasis. His successor and pupil, Hunain ibn Is-haq, distinguished the four forms of trachoma, using the Greek names but with Arabic explanations. He also called pannus "varicose ophthalmia" (Meyerhof 1984).

According to Max Meyerhof, the best Arabic sources on eye diseases including trachoma were composed after A.D. 1000. The first and best of these is *The Memorandum-Book of a Tenth-Century Oculist* (*Tadhkirat al-Kahhalin*), composed in the early eleventh century A.D. by a Christian oculist living in Baghdad, Ali ibn Isa. As well as distinguishing 13 diseases of the conjunctiva and 13 of the cornea (Hirschberg 1985), he clearly describes trachoma:

Trachoma is of four kinds: the *first* exhibits redness at the surface of the inner side of the lid. Its symptom is that you see, when you evert the lid, something like grains resembling those of dry mange (*hasaf*). It is less severe and painful than the three other kinds. It is accompanied by lachrymation: it mostly follows an acute ophthalmia (*ramad* = acute conjunctivitis). In general, the causes of all the kinds of trachoma are saline humours, long exposure to the sun, dust and smoke and improper treatment of ophthalmia. . . .

The *second kind* of trachoma exhibits more roughness that [*sic*] the first; it is associated with pain and heaviness, and both kinds produce in the eye moisture and lachrymation. . . .

The *third kind* of trachoma: It is stronger and more severe than the second kind and has more roughness. Its symptom is that you see the surface of the inner side of the lid like a split-up fig; therefore this kind [is] called the "figlike" (*sycosis*). . . .

The *fourth kind* of trachoma is more grave than the three other kinds and exhibits still more roughness; it is more dangerous and chronic. It is associated with severe pain and callosity, and it is impossible to root it out in a short space of time, on account of the thickening of the lid, especially when it is old. Sometimes it causes the growth of superfluous lashes. Its symptom is that you see on the everted lid a dark-red blackish colour and on it a kind of prominent crust (cicatricial tissue). (Meyerhof 1984; Hirschberg 1985)

This is the first time that the connection between trichiasis and trachoma was made in the literature (Meyerhof 1984). It is also the best description of trachoma and its treatment written in antiquity and probably the best until the work of J. N. Fischer of Prague in 1832. Certainly subsequent works in Arabic do not improve on Ali ibn Isa's, because most copied his chapters on trachoma. One exception is *The Luminous Support on Eye-Diseases* by the Cairo oculist Sadaqa ibn Ibrahim al-Sadhili, who used his personal experience in ophthalmic operations to write his textbook in the second half of the fourteenth century. For the first time, as Meyerhof (1984) notes, we have a reference to the "frequency of certain eye-diseases in Egypt. . . . The inhabitants of Egypt suffer mostly from ophthalmia, on account of the abundance of dust and sand in their land." He goes on to describe the four kinds of trachoma, but what is new, he notes, is that "one of the forms developes [*sic*] from the preceding form by inappropriate treatment. He insists on the frequency of trichiasis with the fourth and most severe form of trachoma" and states that "pannus is often a sequela of ingrown lashes." Furthermore, he reported that "pannus is often observed after a neglected acute ophthalmia or a very chronic trachoma."

The Greeks and the Arabs thus knew far more about trachoma than did their counterparts in Europe until the nineteenth century. They recognized different forms of trachoma (MacCallan's four stages in contemporary language); the follicles and papillae, which they compared to the appearance of a halved fig; the scars; the contagiousness (sometimes referred to as "heredity," meaning "in the family"); and the danger of old trachoma, or reinfection. The Arabs were also able to recognize the connection of trichiasis and pannus with trachoma, and their operative and topical treatments of tra-

choma were superior to those in the West (Meyerhof 1984). From the accuracy of their descriptions, it is clear that they had had a long acquaintance with the disease.

Europe from Medieval Times Through the Eighteenth Century

In contrast, Medieval Europe was poorly prepared to confront trachoma when it appeared in epidemic forms, often accompanying returning Crusader armies from North Africa or the Middle East (Cornand 1979). Because Arab authors used the term *jarab* (scabies), medieval Latin translators from the Arabic called trachoma "scabies." As late as 1561, Pierre Franco would term the disease *scabie et prurit en oeil* (Hirschberg 1985). That trachoma existed in Jerusalem is attested by the writings of Benvenutus of Jerusalem (thirteenth century), whose description of his surgical treatment of trachoma survives (Chance 1939; Hirschberg 1985). Because of the frequent movement of Italian merchants and crusading armies between Italy and the Middle East, it is not surprising that Italy and especially Salerno became a center of knowledge about eye diseases (Chance 1939). Arabic and Greek writers were translated into Latin and influenced Italian concepts of trachoma and its treatment. At the end of the thirteenth century, Lanfranchi of Milan referred to a trachoma treatment (Worms and Marmoiton 1929). One possible description of trachoma from medieval Italy appears in a biography of St. Francis of Assisi, which traces the progression of his ophthalmia, acquired on a trip to Egypt and the Middle East. "Wiping the tears from his sore eyes," he returned to Italy, in the early stages of the disease. As his sight deteriorated, he sought treatment at an ophthalmia center in Rieti and later underwent cauterization on both temples with a hot iron, an ancient treatment for trachoma. He was finally blinded shortly before his death (Green 1987).

In the fourteenth century, French surgeon Guy de Chauliac provided a "recognisable description" of trachoma (Boldt 1904; Chance 1939), whereas in England one medical tract on eye diseases survives from the same century. Written by John of Arderne in 1377, it concentrates on treatments that seem characteristic of folk medicine, but some references suggest trachoma, although a form of conjunctivitis is more likely. Crocus, for example, "relieves the redness of the eyes and stays the flux of humours to the eye, it deletes pannus, which is macula of the eye, for it becomes dissolved and wasted away." His cure for *lippitudo* (the Greek term for "secreting

eye") and watery eye included fresh butter and a man's urine (James 1933).

Although trachoma was poorly identified, one suspects that it remained established in medieval and early modern Europe and did not die out between the period of the Crusades and the sixteenth century, when notable epidemics of "ophthalmia" occurred in connection with the movement of armies. A well-known epidemic occurred in 1556, and was described by Forestus. English doctors characterized the disease by the term *paupières mûrales,* because the conjunctiva seemed to them to be like a wall (Worms and Marmoiton 1929). A little later, Jean Costoeus referred to the treatment of trachoma by cautery. Other epidemics similar to the 1556 epidemic occurred at Breslau in 1699 and 1700, and again among the English troops at Westphalia in 1762. In the second half of the eighteenth century, trachoma epidemics swept through Sweden and Finland (Worms and Marmoiton 1929).

Napoleonic Period

Although trachoma was a problem in Europe long before 1800, it could also be imported, as it was after Napoleon Bonaparte's campaign in Egypt (1798–1801), when an ophthalmia epidemic swept Europe. Many of the returning French troops had lost their sight as a result of "ophthalmia." Trachoma and forms of conjunctivitis were still endemic in Egypt. Indeed European travelers to Egypt, especially those of the eighteenth century, referred to Egypt as "the land of the blind." A Bohemian visitor even described the "masses of flies on the eyes of the natives, especially children," and he attributed the prevalence of eye disease to the "general filthiness" of the poor. Meyerhof (1932) suggests that the incidence of trachoma and blindness had increased in Egypt under the rule of the Mamelukes and Turks, when 2 million peasants were living in misery. Perhaps it was that combination of poverty and the arrival of a foreign army that set the stage for the terrible epidemic or epidemics of "ophthalmia" that would torment Europe for half a century.

In any event, when Napoleon's 40,000 troops invaded Egypt in the summer of 1798, they first suffered from a contagious ophthalmia, which was probably the conjunctivitis caused by the Koch–Weeks bacillus, prevalent in Egypt during the summer months. By September, "few soldiers had escaped ophthalmia," and cases had become acute. Some were suffering from gonorrheal conjunctivitis and trachoma, and soldiers had "eyes completely blinded by the swelling of the lids." Of one group of

3,000 soldiers, 1,400 were unable to fight because of "ophthalmia." Thousands of others suffered from eye diseases, and the blinded were either hospitalized, sent home, or, in their helpless condition, massacred by local people or armies. Many veterans of the Egyptian campaigns continued to suffer from eye problems for years after their return to Europe (Meyerhof 1932).

The Turkish and British armies in Egypt also contracted ophthalmia. It was the British who first characterized it as contagious, a theory not always accepted in the nineteenth century. A British surgeon, George Power, described the disease as a "purulent conjunctivitis," which had been prevalent among the Irish peasantry about 1790. Actually, epidemics of ophthalmia had been common among the peasants of Ireland in the eighteenth century, and Power regarded it as infectious and of "a species of the same disease" as Egyptian ophthalmia (Collins 1904; Meyerhof 1932). The French military surgeon Dominique Jean Larrey referred to the contagious disease of "granular conjunctivitis" in 1802 (Chance 1939).

"Egyptian ophthalmia" accompanied the British troops on their return to England and Ireland, where it became known to "almost every medical practitioner" by 1806 (Meyerhof 1932). As early as 1802, Patrick MacGregor described granulations that he observed on the conjunctivae of 56 veterans who had returned from Egypt. "In all of them the eye-lids were more or less affected; and when the inner surface of the eye-lids was examined with a magnifying glass, the small sebaceous glands situated there were found increased in size, and of a redder colour than natural" (Meyerhof 1932). Most writers on that epidemic, according to E. Treacher Collins (1904), stress "the purulent character of the discharge, the acuteness of the symptoms, and the rapid and destructive ulceration of the cornea which was liable to ensue – characteristics which we associate today with gonorrhoeal ophthalmia rather than Trachoma."

When the British tried to capture Egypt in 1807, the troops again came down with acute ophthalmia; and when they moved on to Sicily, they spread the disease there. Ophthalmia continued to ravage the British army for about 10 more years. By 1818, over 5,000 men had been invalided from the British army for blindness. The epidemics, of course, had spread to the other armies who fought during the Napoleonic period. The Italian troops were infected in 1801 at Elba and Leghorn by the French. This epidemic lasted until 1826. The Italians carried the disease to

the Hungarian (1809) and Austrian (1814) armies. One of the most severe epidemics was in the Prussian army from 1813 to 1817, when 20,000 to 25,000 men were affected. From there it passed to the Swedish troops in 1814, and to the Dutch in 1815. More than 17,000 troops were attacked in the Russian army during the years 1816 to 1839, and by 1834, 4,000 Belgian soldiers had become completely blind. In fact, in 1840 one in five in the Belgian army still suffered from ophthalmia. When the epidemic hit Portugal in 1849, it affected 10,000 soldiers over an 8-year period. It even reached Cuba in the New World in 1813, where it devastated 7,000 soldiers, "most" of whom "became blind." Because of its association with soldiers in the nineteenth century, the disease had become known as "military ophthalmia," with some even believing that it was an "eye affection exclusively found among soldiers" (Boldt 1904; Worms and Marmoiton 1929; Meyerhof 1932; Hirschberg 1986).

The interesting question, of course, concerns the identity of the ophthalmia contracted in Egypt and disseminated in Europe. According to Meyerhof (1932), the diseases that afflicted the French, Turkish, and British forces were the same eye diseases that prevail in Egypt: two forms of conjunctivitis – (1) acute catarrhal conjunctivitis caused by the Koch–Weeks bacillus and (2) acute purulent conjunctivitis caused by the gonococcus, sometimes blended with streptococcus or pneumococcus, which is often followed by postgonorrheal conjunctivitis – and genuine trachoma in its various stages. When trachoma occurs along with an acute form of conjunctivitis, such as the Koch–Weeks, and when it attacks adults, it tends to be more severe and contagious. Lack of sanitation in the armies and among the local population facilitated the rapid spread of the ophthalmias. Meyerhof also contrasts the high incidence of ophthalmia among the British troops in the early nineteenth century with only scattered cases among them in the twentieth century. This he attributes to the vastly improved hygienic conditions among the troops.

Not all the eye ailments that afflicted nineteenth-century European armies, however, came from Egypt. As we saw, trachoma had existed in Europe before Napoleon's time and, in fact, according to J. Boldt (1904), had long been endemic in Central Europe – from the Gulf of Finland to the Carpathian Mountains. Thus, when the Prussian army of the Napoleonic period became infected with trachoma, it was not due to the Egyptian epidemic, he believes, but rather to massive troop mobilizations that en-

listed trachomatous recruits from endemic areas in Central Europe. It may have been the case, then, that the war of the Napoleonic period facilitated the dissemination of trachoma and other eye diseases throughout Europe, only some of which owed their origin to the Egyptian campaigns.

Nineteenth Century

With the disbanding of armies and the return of peace in the first half of the nineteenth century, trachoma virulence declined in Europe; but as European nations turned their attention to imperial wars in Asia and Africa, the disease was on hand to attack the armies stationed abroad. Indeed, Collins (1904) notes that wherever British troops were quartered in the nineteenth century, ophthalmia "flourished." Soldiers came down with the disease in Africa, India, Ceylon, the West Indies, the Mediterranean, and Canada. In the German protectorate of the South Sea Islands, the Germans encountered a high incidence of ocular disease, including trachoma (1910–12). Military records thus permit historians to trace trachoma incidence throughout the world in the nineteenth century (Boldt 1904; Collins 1904; Cornand 1979; Kluxen and Bernsmeier 1980).

But the civilians carried the disease as well. Both voluntary and forced immigrants brought ophthalmia with them to the Americas. The British recorded cases of trachoma among immigrants from Poland, Finland, Russia, and Armenia, who were in transit to the United States or Canada. The problem of contagious eye diseases was so serious that the United States and Canada declared trachoma to be a "dangerous" disease and prohibited the entry of those infected with it. Nonetheless, many immigrants escaped detection. Among the immigrants with a high incidence of the disease were the Irish, for ophthalmia epidemics had been severe in the famine-plagued Ireland of the 1840s (Boldt 1904; Collins 1904).

Ophthalmia also attacked the "involuntary immigrants" of the nineteenth century. What was called "Egyptian ophthalmia" or just "ophthalmia" was one of the most feared diseases of the slave trade, as it could sweep through slave ships, blinding the entire cargo and crew of a slaver. If fortunate, a few of the crew would regain their sight and bring the ship into port. Ships where this was not the case were on occasion discovered drifting helplessly on the open seas. In 1819, the French slave ship *Le Rôdeur* experienced one of the best-documented cases of ophthalmia. The ship had traded at Bonny in West Africa. About 2 weeks into the voyage, the first symptoms of the

disease appeared among the slaves in the intermediate deck, and soon after this, the crew was infected:

In the morning when the patient wakes up he notices a slight irritation and itching at the lid margins which appear red and swollen. On the next day the lids are more swollen and the patient experiences severe pain.... On the third day there is a secretion which appears yellow and thick, but later turns green and stringy; the secretion is so ample that every 15 minutes when the patients open their lids a few drops escape. There is from the beginning considerable photophobia and epiphora ... the pain increases from day to day, similarly, the number of blinded patients; ... Some of the sailors were three times affected by the disease. When the lid swelling decreased one could see a few vesicles on the bulbar conjunctiva. (Hirschberg 1986)

When the ship arrived in Guadeloupe, those afflicted found their condition quickly improved by eating fresh fruit and by washing their eyes with fresh water and a lemon extract, which a black woman had recommended; but the epidemic had blinded 39 blacks and 12 crew members. The others lost vision only in one eye or had severe corneal scars (Hirschberg 1986).

Descriptions of ophthalmia also came from British reports on the conditions aboard slave ships that the Royal Navy detained in the nineteenth century. Thomas Nelson, a British surgeon, recorded two shipboard epidemics of blinding ophthalmia on slave ships off the coast of Brazil (1846). He reported on "swollen eyelids," a "discharge which keeps constantly trickling down their cheeks," and "ulcers on the cornea." Of particular interest is his description of the treatment of infected slaves with silver nitrate, which is now used in newborns to prevent blindness due to ocular gonorrhea.

When slave dealers unloaded the infected slaves in the markets of Brazil, epidemics of ophthalmia broke out in the port cities. In the 1830s and 1840s, slave ships from Angola and Benguela repeatedly introduced the disease into the slave market of Rio de Janeiro, and from there it spread into the city and to surrounding plantations. The exact cause of the ophthalmias in slaves is, however, difficult to determine.

On the other hand, ophthalmia was not the only cause of eye disease among slaves. Although descriptions of the blind (Luccock 1820) and the medical study of J. F. X. Sigaud (1844) suggest that trachoma was responsible for some blindness in Rio, Julius Hirschberg (1982–6) blames the epidemic aboard the Le Rôdeur on an acute or contagious form of blennorhea. Blinding ophthalmias also seemed to

have appeared frequently in the same slaves suffering from measles or smallpox; one of the slave ships Nelson examined, for example, that had been struck with ophthalmia had also experienced an epidemic of smallpox. Interestingly, during the North American Civil War, many soldiers had ophthalmia after virulent smallpox and measles epidemics (Cunningham 1958). Furthermore, blacks in the eastern United States seemed to escape trachoma. Swan Burnett of Washington observed only six "suspicious cases" of trachoma among 10,000 blacks (Boldt 1904). In Cuba, blacks had a lower incidence of the disease than whites – 1.1 per 100, with a slightly higher rate of 2.3 for mulattoes. In sharp contrast, the incidence for whites was 42 per 100 (Santos Fernández 1901). Although Africans and their descendants clearly contracted trachoma in Brazil, Cuba, and Africa (Rodger 1959, 1981; Fuchs 1962), such descriptions suggest that historians cannot attribute all ophthalmias in black slaves to trachoma. Along with acute conjunctivitis, other diseases that affect the eye, such as smallpox, measles, leprosy, tuberculosis, syphilis, and onchocerciasis (river blindness), doubtless also blinded slaves.

By the nineteenth century, the term ophthalmia had come to cover an extraordinary variety of identifiable and imaginary eye diseases in medical textbooks. Hence, such terms as cachectic, senile, menopausal, abdominal, and scrofulous were attached to the word ophthalmia (Furnari 1845; Hirschberg 1986). Only in the twentieth century were the actual causes of eye diseases isolated, and more accurate scientific descriptions of trachoma and conjunctivitis made possible.

VIII.98 Osteoarthritis

Osteoarthritis (OA) is the most common rheumatic disorder afflicting humankind and vertebrates in general. The most common alternative terms, *osteoarthrosis* and *degenerative joint disease,* are used because of divergent concepts of the nature and cause of the disorder. One school maintains that OA is a family of systemic inflammatory disorders with similar clinical and pathological end results. Another supports the use of the term "osteoarthrosis" because inflammation is not present. Still another uses the term "degenerative joint disease" because it is held that aging and "wear and tear" are responsible for its occurrence.

William Heberden, an eighteenth-century English physician, gained immortality by describing what we now term *Heberden's nodes,* a common heritable form of osteoarthritis, especially common in women. In his *Commentaries,* he writes:

What are those little hard knots, about the size of a small pea, which are frequently seen upon the fingers, particularly a little below the top, near the joint? They have no connection with the gout, being found in persons who never had it: They continue for life; and being hardly ever attended with pain, or disposed to become sores, are rather unsightly, than inconvenient, though they must be some little hindrance to the free use of the fingers (Heberden 1802)

Modern research provides new data for a comprehensive definition encompassing clinical, biochemical, and anatomic features (Denko 1989). OA is a multifactorial systemic inflammatory disorder with clinical symptoms of pain and stiffness in movable joints, showing radiographic evidence of cartilage loss and bony overgrowth. The anatomic changes – cartilage loss and a kind of bony overgrowth and spurs – may occur physiologically without clinical symptoms. Osteoarthritis is classified as *primary* (*idiopathic*) when there is no known predisposing factor; or *secondary,* when there is a clearly defined, underlying condition contributing to its etiology, such as trauma, metabolic diseases, or gout. Several symptom complexes are grouped as variant subsets such as generalized osteoarthritis or erosive inflammatory osteoarthritis.

Distribution and Incidence

Osteoarthritis spares no race or geographic area. In the majority of patients, especially the younger

group, the disease is mild and does not cause significant disability. However, in patients in the older age group it is more severe and often produces disability with loss of time from work and thus economic loss. The disease occurs with increased severity and frequency in older populations as a result of prolonged exposure to pathophysiological processes responsible for its development.

OA occurs with more frequency and more severity in women than in men. There is a sex difference in distribution of the joints involved. Lower spine and hip disease are more common in men, whereas cervical spine and finger arthritis are more common in women. The most commonly affected joints are the distal interphalangeal joints (*Heberden's nodes*); the proximal interphalangeal joints of the fingers (*Bouchard's nodes*); the first metatarsophalangeal (*bunion*) joints of the feet; and the spine, the hips, and the knees (Peyron 1984).

Studies of the incidence of osteoarthritis produce divergent data because of differences in definition and diagnostic techniques. For example, when the definition includes only pathological anatomic changes (cartilage loss and bony growth), investigators find evidence for the disorder in 90 percent of persons over age 40. Only about 30 percent of persons with radiographic changes of degenerative joint disease complain of pain in relevant joints (Moskowitz 1984). The frequency and severity of symptoms of the illness increase with age so that osteoarthritis is a major cause of symptomatic arthritis in the middle-aged and elderly population.

Epidemiology

The first epidemiological studies on osteoarthritis were reported about 60 years ago in England, using only questionnaires and clinical examination to evaluate incapacity and invalidism due to the disease. These methods, however, lacked diagnostic reliability, and classification of the disease was difficult. Later, use of roentgenograms to detect changes allowed for the classification of OA ranging from mild to severe, depending on the loss of cartilage and the presence of bony overgrowth. The cartilage loss is seen as joint space narrowing, whereas bony overgrowth can be one or more of the following: osteophytes, bony eburnation, or increased bone density. Early physical findings such as Heberden's nodes may precede radiographic changes.

Various surveys have explored demographic factors associated with osteoarthritis. A study of skeletal remains of contemporary white and black Americans, twelfth-century Native Americans, and protohistoric Alaskan Eskimos showed that those who underwent the heaviest mechanical stresses suffered the most severe joint involvement (Denko 1989). Climate does not influence the prevalence of OA. In two groups of Native Americans of the same ethnic descent but with one living in a cold mountain region and the other in a hot desert, no differences were found in radiographs of the hands and feet. Hereditary predisposition to Heberden's nodes have been found in half of the observed cases. The remaining cases are thought to be traumatic.

Differences in patterns of affected joints occur in different ethnic groups. Heberden's nodes are rare in blacks, as is nonnodal generalized osteoarthritis. Occupational factors may play a role in the incidence, especially in males. Studies from Great Britain, United States, and France show osteoarthritis to be a major cause of incapacity, economic loss, and social disadvantage in persons over the age of 50. Hip disease is more common in white populations than in blacks and Native Americans. Asian populations have a low incidence of hip disease, but incidence of OA of the fingers in Asia is high, as is the incidence in Europeans. Knee disease shows less difference among ethnic groups, being similarly prevalent in whites and blacks in South Africa and Jamaica (Peyron 1984).

Protective factors are few, including mainly the absence of mechanical stress such as that resulting from motor impairment, hemiplegia, or poliomyelitis. Predisposition to osteoarthritis occurs in individuals who have pseudogout (calcium pyrophosphate deposition disease). Deposits of urate crystals such as that occurring in gout also predispose the individual to osteoarthritis.

Etiology

The popular concept that osteoarthritis is a single disease resulting from attrition of cartilage due to age and wear-and-tear is not tenable in light of modern experimental studies. Osteoarthritis can be regarded as the result of aberrations in a complex pattern of biological reactions whose failure leads to anatomic changes in joint structure and function. One or more biological feedback loops may lead to malfunction of the complex system. Biological modifiers induce variable effects, depending on the target mechanism. A recent hypothesis proposes that OA is a multifactorial metabolic inflammatory disorder in which too little cartilage and too much bone are synthesized because of impaired liver function in processing growth hormone and insulin. Hepatic dysfunction results in altered neuropeptide levels: too

little insulin-like growth factor-1, which is required for cartilage growth, and too much insulin, which accelerates bony growth and osteophyte formation (Denko, Boja, and Moskowitz 1987).

Clinical Manifestations

Osteoarthritis usually has an insidious onset depending on the specific joints afflicted and the patient's tolerance to pain. The characteristic symptoms are pain and stiffness localized to the involved joints. In early disease the pain occurs with use of the joint; later pain occurs during rest. Morning stiffness is usually of short duration, less than 30 minutes. Frequently it is related to changes in the weather. The affected joint creaks on movement, and its motion is reduced.

The affected joint is enlarged, owing to bony overgrowth and to synovitis with accumulation of fluid. It is tender and painful. Late in the disease, subluxation and muscle atrophy occur. Rarely is there ankylosis or fusion with complete loss of motion.

Radiographic examination shows cartilage loss, causing joint-space narrowing with bony overgrowth. The bony changes include eburnation in the subchondral region as well as spur development around the margin of the joint. Subchondral erosions are common, as are subchondral cysts. Osteophytes usually form as these changes occur.

In a related disorder, excessive osteophytes occur along the anterior and anterolateral surfaces of the vertebrae and bridge the disk spaces. These patients are diagnosed as having diffuse idiopathic skeletal hyperostosis (DISH), a disorder different from osteoarthritis in its biochemical changes.

History and Geography

Since prehistory, vertebrates have presumably suffered from osteoarthritis. Bones of dinosaurs show bony spurs and ankylosed spinal segments that are markers of the disease. The same changes occurred in prehistoric humankind as well as in animals, modern and ancient, such as horses and dogs (Rothschild 1989). Clinical descriptions of arthritis date back to the fifth century B.C., to Hippocrates, who described the Scythians as having markedly lax or hypermobile joints:

I will give you strong proof of the hypermobility (laxity) of their constitutions. You will find the greater part of the Scythians, and all the Nomades, with marks of the cautery on their shoulders, arms, wrists, breasts, hip-joints, and loins, and that for no other reason but the hypermobility and flabbiness of their constitution, for they can neither strain with their bows, nor launch the javelin from their

shoulder owing to their laxity and atony: but when they are burnt, much of the laxity in their joints is dried up, and they become braced, better fed, and their joints get into a more suitable condition. . . . They afterwards became lame and stiff at the hip joint, such of them, at least, as are severely attacked with it. (Adams 1891)

The disorder was attributed to divine retribution for the destruction of the Temple of Ashkelon which the Scythians wrought during an invasion of Palestine. D. G. Rokhlin (1965) has illustrated severe shoulder OA, deforming arthrosis, in a Scythian skeleton derived from this Hippocratic period (fifth to third century B.C.). Evidently, shoulder OA was common among the Scythians despite their treatment.

Over the centuries, the names of disorders encompassing OA have changed and have included terms such as "rheumatism" and "lumbago," which are no longer scientifically used. Today we can recognize dozens of forms and subsets of OA.

The prevalence of OA and the pattern of joint involvement show wide geographic differences. Factors influencing the prevalence of osteoarthritis are very complex. Climate is often blamed for rheumatic troubles. Sixteen worldwide population samples – 13,200 Caucasians, blacks, and Native Americans aged 35 and over – were examined with X-rays, all of which were read by one observer. The following observations resulted, in part. OA was most prevalent in the north of England, where 67 percent of men and 73 percent of women had OA. The lowest incidence was in Nigeria and Liberia. Prevalence of OA was also low in Soweto, South Africa, and in Piestany, Czechoslovakia.

The incidence of OA also varied with the specific joint being studied. For exmple, OA of the hips was common in males over 55 in the north of England; 22 to 25 percent were affected. These men were mainly coal miners and shepherds. In contrast, only 1 to 3 percent of black men, and only 2 to 4 percent of the black women, were affected in Jamaica, Liberia, Nigeria, and South Africa. Data on Heberden's nodes in 10 of the population samples revealed the highest frequency – 32 percent – in the population of Watford, England; 30 percent in the Blackfeet Indians of Montana; and 26 percent in the people of Azmoos, Switzerland. All the black populations had low prevalence, as did inhabitants of Oberholen, Germany. The Pima Indians of Arizona had an 11 percent incidence in the women, whereas in the men 20 percent were affected, a reversal of the normal sex distribution. (For more examples see Lawrence and Sebo 1980.)

Factors influencing the prevalence of osteoarthritis in populations include heredity, occupation, and

possibly diet and resultant body build. Comparison of figures for populations living in very different parts of the world indicates no correlation with latitude, longitude, or any type of climate. Comparison was made of radiographs of hands and feet for 17 different European, African, and American groups of individuals living from 54° north to 26° south. Nine were white, four black, and four Native American. Eleven of the population groups lived in rural areas, six in urban areas. No significant differences were found among the different groups in the prevalence of osteoarthritis. A survey in Sweden showed that the highest incidence of OA was in the southeast and central northern regions of the country and seemed to correlate more closely with the occupations of the patients than with climatic conditions. More workers in farming and forestry had the disease than did workers in other occupations (Peyron 1984).

VIII.99
Osteoporosis

</div>

Osteoporosis is defined as a proportional decrease of both bone mineral and bone matrix, leading to fracture after minimal trauma. It differs from osteomalacia in which there is a normal amount of bone matrix (osteoid) but decreased mineralization. There are two clinical syndromes of osteoporosis. Type I, or postmenopausal osteoporosis, occurs in women aged 51 to 75; it involves primarily trabecular bone loss, and presents as vertebral crush fractures or fracture of the distal radius. Type II, or senile osteoporosis, occurs in both men and women, particularly after the age of 60; it involves trabecular and cortical bone loss, and more commonly presents with hip and vertebral wedge fractures. Postmenopausal osteoporosis is associated with decreased serum levels of parathyroid hormone and a secondary decrease in activation of vitamin D, whereas senile osteoporosis is associated with a primary decrease in activation of vitamin D and increased parathyroid hormone.

Osteoporosis is an enormous public health problem, responsible for at least 1.2 million fractures in the United States each year. Fractures of the vertebral bodies and hip comprise the majority, and the complications of hip fracture are fatal in 12 to 20 percent of cases. Nearly 30 percent require long-term nursing home care. The direct and indirect costs of osteoporosis in the United States are estimated at over 8 billion in 1989 dollars annually.

Age-related bone loss or involutional osteoporosis begins about age 40 in both sexes at an initial rate of about 0.5 percent per year. The bone loss increases with age until slowing very late in life. In women, an accelerated postmenopausal loss of bone occurs at a rate of 2 to 3 percent per year for about 10 years. Over their lifetime, women lose about 35 percent of their cortical bone and 50 percent of their trabecular bone, whereas men lose about two-thirds of these amounts (Riggs and Melton 1986). The skeletal bone mass is comprised of 80 percent cortical and 20 percent trabecular bone. Trabecular or spongy bone has a much higher turnover rate, nearly eight times that of cortical or compact bone.

Etiology

The process of age-related osteoporosis is universal, although certain populations are affected to a

greater degree or at an earlier age. Osteoporosis in
the elderly is exceedingly common and involves mul-
tiple factors of age, sex, endocrine system, genetics,
environment, nutrition, and physical activity. Age-
related factors include decreased osteoblast func-
tion, decreased intestinal calcium absorption, de-
creased renal activation of vitamin D, and increased
parathyroid hormone secretion combined with de-
creased clearance of the hormone by the kidney.

In women, decreased estrogen production in meno-
pause accounts for 10 to 20 percent loss of total bone
mass. Although men do not undergo the equivalent
of menopause, gonadal function declines in many
elderly men and contributes to osteoporosis. Multi-
ple pregnancies and extended breastfeeding in pre-
monopausal females may also produce negative cal-
cium balance and subsequent bone loss. Underlying
medical conditions or medications can contribute to
osteoporosis, particularly hyperthryoidism, hemi-
plegia or paralysis, alcoholism, use of glucocorticoid
steroids, and smoking.

Population and familial studies implicate both ge-
netic and environmental factors in causing or inhib-
iting osteoporosis. Blacks, for example, tend to have
greater initial bone mass or bone density than do
Caucasian populations. Even with similar rates of
bone loss, their osteoporosis begins at a later age
than that of their white counterparts. Black females
living in Michigan had similar relative vertebral
density by age to blacks living in Puerto Rico. Both
black groups had significantly less osteoporosis by
age group than did Caucasian females living in
Michigan. Within the Caucasian group, women of
British Isles' ancestry had a higher incidence of
osteoporosis than did whites of other national ori-
gins (Smith and Rizek 1966).

Nutrition, particularly calcium intake, plays a
role in the inhibition of osteoporosis. Long-term tri-
als of calcium supplementation, however, have had
mixed results in postmenopausal women. Such sup-
plementation may be more effective if initiated in
women years before onset of menopause. A high-
protein diet increases urinary excretion of calcium
and may therefore induce a negative calcium bal-
ance. The decreased renal activation of vitamin D
with age may also be a contributing factor in popula-
tions without vitamin D supplementation or with
the elderly confined indoors.

Physical activity decreases the rate of bone loss in
the elderly. The skeletal stresses from weight bear-
ing and muscle contraction stimulate osteoblast func-
tion, and muscle mass and bone mass are directly
related.

Epidemiology, Distribution, and Incidence

Osteoporosis was defined as a clinical entity by
Fuller Albright and colleagues in 1941. Since that
time a large number of epidemiological studies have
been performed to evaluate the varying rates of
osteoporosis and osteoporosis-related fractures in dif-
ferent populations. The process of age-related and
postmenopausal bone loss occurs in all populations.
It appears to start earlier for women in Japan and
India as compared to women in Britain and the
United States. It occurs later in Finnish women, and
age-related rates of bone loss of women between 35
and 64 years of age are lower in Jamaica and the
four African countries studied than in the other coun-
tries examined (Nordin 1966).

Relating the differing rates to calcium intake cor-
relates well with the populations in Japan, India,
and Finland but not Jamaica or the African coun-
tries. Other factors such as genetically determined
initial bone density or increased physical activity
may also be involved. The rate of hip fracture varies
according to the age distribution of osteoporosis in
all countries. This distribution involves a much
broader age group in India secondary to the preva-
lence of rickets and osteomalacia.

Black females in both Puerto Rico and Michigan
have less osteoporosis than do white females in
Michigan. However, both groups demonstrate a very
high prevalence with advanced age: 60 percent of
those over 65 years in Puerto Rico and 80 percent
over 65 years in Michigan (Smith and Rizek 1966).
The incidence rates of hip fracture are higher in
white populations in all geographic areas including
Israel and Singapore, compared to the indigenous
populations. A very low incidence rate is also noted
among the Maoris of New Zealand and Bantu of
South Africa compared to white populations in both
areas. The age-adjusted incidence rate of hip frac-
ture for females and males per 100,000 is 5.3 and 5.6
among the Bantu compared to 101.6 and 50.5 among
blacks in the United States (Cummings et al. 1985).

In the United States, over 90 percent of all hip
fractures occur in individuals over age 70 years. By
age 90, a third of all women will have sustained a
hip fracture. Vertebral fractures are present in 25
percent of women over age 70.

History

Age-related bone loss has also been examined in
prehistoric skeletal populations. Archaic Indians dat-
ing back to 2500 B.C. and subsisting as hunter-
gatherers showed differential rates between females
and males as well as overall rates of osteoporosis

quite similar to those of a modern hospital population. A more recent Hopewell Indian population showed greater age-related bone loss, probably resulting from genetic or nutritional factors (Perzigian 1973). A study of three ancient Nubian skeletal populations found that osteoporosis occurred earlier in life among these women as compared to modern Western samples, perhaps secondary to inadequate calcium intake or extended lactation (Dewey et al. 1969).

Paget's Disease of Bone

Paget's disease of bone was described as "osteitis deformans," a "chronic inflammation of bone" by Sir James Paget in an address to the Royal Medical Chirurgical Society of London in 1876.

His original description was masterful and thus has withstood the test of time. Paget's disease of bone describes an abnormal osseous (bony) structure whereby isolated and sometimes contiguous areas of the skeleton undergo changes leading to clinical deformity for some of those affected. Clinically affected people may have the appearance of enlarged bone, bowed extremities, shortened stature, and simian posturing because the body's usual system for maintaining strong and healthy bone malfunctions. Normal bone turnover is altered in the affected areas. The resorption process accelerates, and the repair process responds by building a heavy, thickened, and enlarged bone. Although the new bone contains normal or increased amounts of calcium, the material of the bone is disorganized, and the bone is structurally weak. The result may be pain, deformity, fracture, and arthritis.

Distribution and Incidence

The disease appears to have its greatest prevalence in Europe and in regions inhabited by European emigrants such as Australia, New Zealand, and areas of South America. For no apparent reason, the disease is distinctly uncommon in African blacks, Orientals, and inhabitants of India and Scandinavia. Where studied, the incidence ranges between 3.5 and 4.5 percent of the population in high prevalence regions of the world, with a high of 8.3 percent in a part of Lancashire, England, to a low of 0.4 percent in Sweden. In a U.S. survey of Paget's disease based on pelvic X-rays, the incidence was 3.9 percent in Caucasians residing in Brooklyn and 0.9 percent in Caucasians residing in Atlanta. Similarly, 1,000 pelvic X-rays revealed no Paget's disease in Lexington, Kentucky, and 1.1 percent pelvic Paget's disease in Providence, Rhode Island.

Epidemiology and Etiology

Males are more at risk from Paget's disease than are females by a 3:2 ratio. There is evidence of heritability: A survey, for example, revealed that 13.8 percent of patients with Paget's disease had relatives

with Paget's disease. Approximately half were from successive generations and half from siblings. Familial cases had an earlier onset than did isolated cases. An autosomal dominant pattern was suggested.

The etiology remains unknown. Paget named this disease "osteitis deformans" in the belief that the basic process was inflammatory and had an infectious origin. Recent ultrastructural studies of involved bone have revealed nuclear and cytoplasmic inclusions. They have not been found in bone cells of patients with other skeletal disorders, with the exception of giant cell tumors of bone. Morphologically the nuclei resemble those of cells infected with paramyxoviruses such as parainfluenza, mumps, and measles, and the cells resemble cultured cells infected with respiratory syncytial virus (RSV).

This tubular morphological finding has raised the question as to whether Paget's disease is a slow virus infection of bone. Other slow virus infections of human beings have similarly demonstrated a long clinical latent period, absence of an acute inflammatory response, a slowly progressive course, restriction of disease to a single organ system, patchy distribution in the body, and genetic predisposition.

Immunohistological studies of bone biopsy specimens have demonstrated antigen from RSV and measles. An indirect immunofluorescence antibody assay has demonstrated evidence for both measles and RSV antigens in Pagetic bone grown in culture from 30 patients. The suggestion of different RNA viruses (measles is a member of the genus *Morbillivirus,* whereas RSV is a member of the genus *Pneumovirus*) seems incompatible. It has been proposed that Paget's disease stems from a previously uncharacterized virus, perhaps of the *Pneumovirus* group. According to this hypothesis, Paget's disease patients are infected with a slow virus at an early age, probably under the age of 30. The slow virus isolates to particular areas of the skeleton by growth pattern and/or blood supply. As the metabolic activity of the skeleton decreases with age, the infested osteoclasts increase their metabolic activity, eventually producing diseased bone some 20 to 40 years following the initial infestation.

Clinical Manifestations

It is estimated that 80 percent of people with Paget's disease are asymptomatic and have no clinical findings suggestive of the disease. When symptomatic, the clinical manifestations are often defined by the complications of the disease. Clinical findings may include some or all of the following: frontal bossing, scalp vein dilatation, angioid streaks, simian pos-

Figure VIII.100.1. Severe Paget's disease of the bone in a 66-year-old male. Note the anthropoid appearance and simian posturing, with the anterior and lateral bow to the arms, thighs, and legs. There are functional flexion contractures of the hips and knees.

ture, short stature, flexion contractures at hips and knees, anterior and lateral bowing of long bones, warmth of involved extremity, periosteal tenderness, and compressive neuropathy. Figure VIII.100.1 shows a man with severe Paget's disease of bone.

Pagetic bone pain is uncommon, but when present it is aching, deep, poorly described, and occasionally continuous at night. It is often aggravated by pressure or weight bearing.

The following deformities may develop: (1) The involved skull may become soft, thickened, and enlarged; (2) the femora tend to migrate medially and superiorly deforming the softened pelvis; (3) enlargement of vertebrae alters the spine, resulting in an anthropoid appearance; (4) the affected long bones soften and bow from weight-bearing or from the force of the surrounding muscles.

Pathological fractures can also occur in the form of compression fractures of vertebrae, incomplete or stress fractures of the long bones, or completed fractures of long bones.

The relation of secondary osteoarthritis to Paget's disease has recently been emphasized. Low back pain is the most common clinical presentation of Paget's disease and is often related to secondary osteoarthritis.

Sarcomatous degeneration, although uncommon, does occur in approximately 1 percent of patients with Paget's disease, representing a 40-fold increase

over that of the general adult population. It is most often heralded by increasing pain.

Skull symptoms may include headaches, vertigo, rushing sensations, and noise in the head. Maxillary exceeds mandibular involvement by a 2:1 ratio, and both may disrupt the lamina dura or cause unsightly deformity. Hearing loss may be severe but is most often moderate.

Neural compression may occur from spinal stenosis or a spinal lateral recess syndrome. Paraparesis – paraplegia in Paget's disease – is most often related to Paget's disease of dorsal or cervical vertebrae.

History and Geography

Paget's disease is not a new disease, having been suspected in a Neanderthal skull. Although isolated case reports in the mid-nineteenth century describe what is now called Paget's disease, the classical clinical description by Paget and a pathological description by Henry Butlin clarified this entity in 1876. Paget was a major figure in the medical community, having been knighted at the age of 43, at which time he began his observations of the first patient with the bone disease that would bear his name. He is also credited with having defined such diseases as Paget's disease of the breast, rectum, and skin; carpal tunnel syndrome; and trichinosis. Paget's disease of bone is unique in that it affects only adult humans; reports of Paget's disease in animals are not convincing. A childhood osseous condition called *juvenile Paget's disease* appears to be a separate entity.

At present, it is difficult to reconcile the geographic isolation of this disease to Europeans (exclusive of Scandinavians) and their descendants. Theories of a slow virus infection in susceptible individuals seem dubious, for if this were the case, then theoretically the disease would have a more worldwide distribution. Isolated case reports of Paget's disease in South African blacks, Japanese, and Indians (from India) only serve to confuse the issue of transmission.

Temperature cannot be implicated, as high prevalence areas include disparate climatic regions of Italy, Spain, Germany, and eastern Russia. Similarly, occupation and degree of physical activity do not appear related to the cause of Paget's disease as the blend of geographic areas involves all types of lifestyles. Interestingly, the black population of the United States appears to sustain a higher frequency of Paget's disease than might be expected, given the rarity of the disease in Africa. An explanation in part involves intermarriage with those of European ancestry.

VIII.101
Paragonimiasis

Several species of the genus *Paragonimus,* the lung flukes, can parasitize human beings. The most important, *Paragonimus westermani,* is found in China, Japan, Korea, Southeast Asia, Papua New Guinea, and parts of India and Central Africa. It was first discovered in the lungs of tigers in European zoos in 1878. Other species occur in Asia, in Africa, and in Central America and parts of South America. Wild and domestic members of the cat and dog families and other carnivorous animals are also hosts, and in many places humans are accidental hosts for worms that normally reside in other mammals. Adult worms produce eggs in the lungs, which reach fresh water either in the sputum or by being coughed up, swallowed, and passed in the feces.

Motile larvae hatch, penetrate an appropriate type of snail, undergo two reproductive cycles, and emerge to seek the second intermediate host, a crab or crayfish. Here they penetrate between the joints of the crustacean's exoskeleton, and encyst there to await ingestion by humans or other definitive host. They then burrow through the intestinal wall and the diaphragm and enter the lungs, where they may survive for many years. Slow, chronic lung damage may become very serious in heavy infestations. Migrating flukes sometimes wander widely lost and reach atypical (ectopic) sites like the brain, where they cause a variety of neurological symptoms and may prove fatal.

Diagnosis of paragonimiasis depends on detection of the eggs in sputum or feces. Treatment of the lung form of the disease is usually effective, but may be prolonged. Prevention is achieved by avoidance of raw, poorly cooked, pickled, or marinated freshwater crabs and crayfish.

Parkinson's Disease

Parkinson's disease, or parkinsonism, is a syndrome (i.e., a constellation of clinical signs and symptoms) consisting of four cardinal features: resting tremor, bradykinesia (physical and mental sluggishness), rigidity, and impaired postural reflexes. The diagnosis is made on the basis of finding any three of the four cardinal features.

Distribution and Incidence

This disease occurs throughout the world, with no population protected against the condition. Most surveys have investigated Caucasian populations of northern European or of Anglo-Saxon descent, and few studies have been done on the occurrence of Parkinson's disease in other populations. In Caucasians the prevalence is 84 to 187 per 100,000 of population, with no geographic patterns and no clusters of increased incidence. Two studies seem to indicate a lower prevalence in blacks; this has been the clinical experience as well, probably indicating a decreased risk of Parkinson's disease for blacks. The annual incidence varies from 5 to 24 per 100,000 of the white population. These figures, of course, depend on the methods of ascertainment, the population studied, the length of time that data have been collected, and many other factors. If the prevalence is divided by the annual incidence, the average duration of the illness is approximately 10 years.

Epidemiology

Parkinson's disease usually occurs in late middle life or beyond. The mean age of onset is 58 to 62. Onset before age 30 is rare but is not unknown, and there is a juvenile form of Parkinson's disease. The greatest incidence is in the decade age 70 to 79 years, with an incidence of 1 to 2 per 1,000 population per year. Later the incidence of parkinsonism seems to decline, a finding which, if true, would have important implications about pathogenesis, indicating that the disease is not simply a result of the operation of the aging process on the nervous system. There appears to be no difference between the sexes in regard to the risk of being affected by Parkinson's disease; early studies in this respect were in error because of decreased ascertainment in females. It is now generally accepted that the ratio is almost or exactly the same for both sexes. Parkinson's disease was known before 1817, the year of publication of the famous

manuscript by James Parkinson, but prevalence studies have been possible only since the 1960s, and they indicate no substantial change in incidence.

In 1917 an epidemic of encephalitis lethargica started in Vienna and spread throughout the world. Following this illness, about half of the victims developed Parkinson's disease with tremor, bradykinesia, and rigidity often associated with oculogyric crises, parkinsonian crises (sudden episodic worsening of signs and symptoms), behavioral abnormalities, cranial nerve palsies, and a host of other central nervous system abnormalities. The age of onset of the postencephalitic Parkinson's disease is early compared to other types of Parkinson's disease. A popular and now discarded theory, the *Cohort theory*, hypothesized that all Parkinson's disease was caused by the encephalitis lethargica agent and that Parkinson's disease would therefore disappear in the 1980s. Since 1961 when the Cohort theory was promulgated, evidence against it has been overwhelming, and we now know that there is no decrease in the prevalence of Parkinson's disease, but of course, the postencephalitic Parkinson's disease has almost disappeared.

Mortality

The mortality rate from parkinsonism varies from 0.5 to 3.8 per 100,000 of population, and the duration averages about 10 years, with a large range of 1 to 33 years, depending on the age of onset, the rate of progression, the patient's general health, and the treatments received. M. M. Hoehn and M. D. Yahr found that victims of Parkinson's disease have a range of mortality 2.9 times greater than the norm, but treatment with levodopa increases the quality of life, decreases the symptoms of the disease, and also reduces this excess mortality. Genetic studies failed to show significant risks of parkinsonism in families, and careful analysis of monozygotic twins indicates a lack of concordance for this disease. The twin studies clearly show that the major factor in the cause of parkinsonism is not hereditary.

Etiology

The signs and symptoms of parkinsonism are caused by a decrease in striatal dopamine due to the loss of dopaminergic neurons in the substantia nigra of the midbrain. At the present time, environmental agents are the primary known cause of parkinsonism; exposure to manganese, carbon disulfide, and carbon monoxide are recognized environmental toxins that can produce the disorder. It is also known that drugs that interfere with dopaminergic pathways or receptors – such as phenothiazines, reserpine, and alpha-methyldopa – can produce the Parkinson's syndrome, and multiple head traumas, probably causing atrophy of the substantia nigra, also may do the same. The recent discovery that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a commercially available chemical intermediate used in the synthesis of organic compounds, induces parkinsonism, has again supported the concept that environmental chemicals play a major role in the pathogenesis of this disorder. Varying amounts of MPTP may be formed as a byproduct in the synthesis of potent analgesic drugs, one of which is MPPP (1-methyl-4-phenyl-4-proprionoxypiperidine), the reverse ester of meperidine, a strong analgesic drug similar to heroin and morphine. The self-administration of small amounts of MPTP by young drug abusers who were using MPPP as an alternative to heroin has resulted in a severe and permanent Parkinson's syndrome that resembles Parkinson's disease in its clinical, pathological, and biochemical features as well as its responsiveness to the drugs usually used in the treatment of Parkinson's patients. Primate models of parkinsonism using MPTP demonstrate that a Parkinson-like syndrome can be produced in the monkey, and it is now known that metabolic conversion by monoamine oxidase B of MPTP to MPP+ (1-methyl-4-phenyl-pyridinium) is the reaction that results in the ultimate toxin MPP+. It therefore follows that blocking monoamine oxidase B with a selective inhibitor such as L-deprenyl completely prevents the toxicity of MPTP, but administration of a selective monoamine oxidase A inhibitor such as clorgylin does not. Thus, MPTP turns out to be the first toxin positively known to cause Parkinson's disease whose neuropharmacology is known and whose toxicity can be prevented by preventing its metabolic conversion to the ultimate toxin, which is MPP+ (see Figure VIII.102.1).

Pathology

Nigrostriatal dopaminergic system failure is the important pathological feature of parkinsonism. Loss of pigment cells in the substantia nigra and the dopaminergic neurons associated with them results in a deficiency of dopa in the striatum and produces the clinical signs and symptoms of the disease.

Clinical Manifestations

The cardinal features of Parkinson's disease are resting tremor, bradykinesia, rigidity, and postural instability. The resting tremor usually is 4 to 6 cycles per second and is present at rest and decreases with
Figure VIII.102.1. Scheme illustrating the mechanism of MPTP toxicity at nigral dopamine neurons in primates. MPTP, which is lipophilic, enters the brain where it is transformed into MPP$^+$ by monoamine oxidase B located in glial cells or in serotonergic neurons. MPP$^+$ is taken up into the dopaminergic (DA) neurons, where it accumulates, by dopamine reuptake mechanisms. The binding of MPP$^+$ to neuromelanin might assist in the accumulation of MPP$^+$, or might contribute to its toxicity. MPP$^+$ within the neurons is assumed not to undergo redox cycling to reproduce free radical species but, rather, to be actively accumulated by mitochondria, where it inerferes with mitochondrial energy metabolism, leading to cell death. The precise mechanism of MPP$^+$ toxicity remains unknown. The sequence of events leading to MPTP toxicity can, in theory, be inhibited at a number of points: (1) Selective monoamine oxidase B inhibitors (MAOI B) such as deprenyl inhibit the conversion of MPTP to MPP$^+$; (2) dopamine reuptake blockers such as nomifensine inhibit the entry and accumulation of MPP$^+$ into dopaminergic neurons; (3) chloroquine might inhibit the binding of MPP$^+$ to neuromelanin and thus limit its toxicity for protective substances such as antioxidants (e.g., alpha-tocopherol); or substances such as acetyl-L-carnitine that protect mitochondria from toxic insults might inhibit the toxic mechanism of MPP$^+$; (4,5) other substances as yet unknown might inhibit the production of free radicals or boost energy metabolism. (From Joseph Jankovic and Eduardo Tolosa, eds. 1988. *Parkinson's disease and movement disorders.* Baltimore, Maryland: Urban and Schwarzenberg, by permission of the publisher.)

action. The tremor usually starts in the upper extremity on one side and then spreads to the lower extremity on the same side. Upper and lower extremities are usually time-locked, with the lower extremity a half cycle behind the upper extremity. Once the tremor has spread to one side of the body, the opposite upper extremity is usually involved, and then the opposite lower extremity. Postural tremor is also present in the majority of Parkinson's patients, and postural tremor is usually slightly faster than the resting tremor. *Bradykinesia,* which literally means "slow movement," is not the same as *hypokinesia,* meaning "decreased movement," or

akinesia, "no movement." All of these movement disorders can be part of Parkinson's disease. The bradykinesia shows up as a delay in the execution and initiation of voluntary movement, and also there is difficulty arresting the movement once it has been started. Akinesia is simply an extreme state of immobility, and some Parkinson's patients, particularly before treatment with levodopa became available, eventually ended their days totally rigid and immobilized. *Rigidity* is resistance to passive stretch of muscle, and the patients with parkinsonism have a characteristic stiffness of the muscles of the body. This stiffness can be brought out by passive rotation of the wrist or flexion–extension at the forearm. It is also present in the truncal muscles and can be examined by placing one's hands on the dorsal aspect of the patient's back muscles and having the patient flex and extend the body at the waist. The rigidity that is characteristic of parkinsonism is the rigidity that usually gives way in little catches and, hence, has been called *cogwheel rigidity.* The most disabling of the cardinal features of parkinsonism is the postural instability. This one symptom alone accounts for most of the falls that occur in this disease. The instability results in loss of balance with propulsion and retropulsion, and such patients are unable to anticipate a change in their posture and thereby correct for the change, and thus they often follow their center of gravity as they fall to the ground. Little postural corrections that are normally made automatically cannot be done, and this is the major motor defect in the disease. Other clinical features of parkinsonism include masked facies and decreased blinking, increased saliva production called *sialorrhea, hyperhidrosis* (profuse sweating) or oily skin, a low-pitched monotonous voice, stooped posture, scoliosis, decreased upward gaze, a tendency toward low blood pressure, micrographia, and a shuffling and small-stepped gait.

History

Tremor was mentioned in the writings of Hippocrates, Celsus, and Galen, but the real history of Parkinson's disease does not start until 1817, the year Parkinson's essay on the shaking palsy was published – when he was 62 years old. Parkinson called the disease the "shaking palsy," but he also provided a Latin term: *paralysis agitans.* He reported on six patients. The first was personally observed, two others were noticed casually in the street; case 4 had an abscess on the chest wall but was lost to follow-up; case 5 was evidently seen at a distance, and there are no details of that patient

available; and case 6 was a 72-year-old man who was visually inspected but evidently not examined.

In other words, by modern standards Parkinson's great essay on Parkinson's disease would not have passed muster. It is clear that the information he conveys in his essay is basically from visual inspection: He did not examine the patients personally. Despite that his paper was well received by the medical community, and subsequently, clinicians added to his description.

Armand Trousseau, in 1859, included a lecture in clinical medicine on parkinsonism and discussed the rigidity and the bradykinesia. The great French neurologist Jean Martin Charcot considered Parkinson's disease a neurosis because there was no proper central nervous system lesion to explain it, and the condition was characteristically worsened by stress or emotion. Charcot frequently commented that everything possible had been used to treat parkinsonism but with very little effect. He recommended belladonna alkaloids, especially hyoscyamine, an etropine isomer, now known to us as scopolamine. According to our modern biochemical understanding of parkinsonism, this agent should have a partial effect in improving the signs and symptoms of Parkinson's disease. In an interesting paper in 1893, Paul Oscar Blocq reported the case of a patient with hemiparkinsonism, who at autopsy was found to have a lesion in the inferior peduncle with complete destruction of the substantia nigra. This, of course, suggested that the neuroanatomic substrate of Parkinson's disease was the substantia nigra and probably is the first description in the medical literature of a lesion that produces parkinsonism. Many other descriptions were made by William R. Gowers and other famous physicians, but these merely added to the fundamental and original observations of Parkinson.

The road to effective therapy was paved in the 1960s by A. Carlsson, who showed in animals that reserpine produces a bradykinesia that could be reversed by the administration of L-dopa, a dopamine precursor. Because it was known that reserpine administration to humans produces a condition that resembles parkinsonism, L-dopa was administered to reserpinized humans to ameliorate the signs and symptoms of the reserpine-induced parkinsonism. O. Hornykiewicz and colleagues then studied the concentration of dopamine in patients dying of parkinsonism, comparing the results to those in normal controls, and reported that there was a marked decrease in dopamine in the caudate nucleus. In 1962 André Barbeau tried the oral administration of L-dopa (100 to 200 mg), and in 1961 W. Birkmayer and

Hornykiewicz experimented with intravenous levodopa (50 to 150 mg), both reporting temporary benefits in parkinsonism. Others, however, were unable to confirm any major effect until George C. Cotzias and colleagues initiated the modern era of therapy in parkinsonism by showing that much larger oral doses of the L-dopa, 1.6 to 12.6 grams per day, resulted in dramatic improvement in many patients. The improvements were so dramatic that the efficacy of levodopa treatment was established beyond any doubt, and a new era in the management of Parkinson's disease began.

Geography

As was previously mentioned, an increased incidence of Parkinson's disease has not been shown anywhere in the world. However, there is an increased incidence of a complex of parkinsonism, dementia, and amyotrophic lateral sclerosis (ALS) in Guam, the Kii Peninsula of Japan, Rota, and the western highlands of New Guinea. This peculiar disease, in which patients manifest abnormalities referable to almost every level of the neuraxis, resembles a combination of parkinsonism, Alzheimer's disease, and ALS. Two major theories have emerged to explain the increased incidence of this condition in areas of the world bordered by the Mariana volcanic fault. The first theory implicates a secondary hyperparathyroidism, which increases the deposition of toxic environmental metals in the nervous system. This theory is supported by the finding of increased manganese and calcium levels in nervous tissue taken from patients dying of this condition. The secondary theory implicates the ingestion of two toxic amino acids – beta-oxaloamine-1-alanine (BOAA) and beta-methylamino-1-alanine (BMAA) – by people in this area of the world. This theory is supported by the finding that infusions of toxic amino acids can produce nervous system disease in primates that does seem to resemble some of the degenerative diseases including parkinsonism, ALS, and Alzheimer's disease. Further work needs to be done to clarify the role of these toxic amino acids, if any, in the pathogenesis of the Parkinson's disease–ALS–dementia complex on Guam. Both theories, implicating environmental factors as the cause, are supported by the fact that the incidence of this peculiar combination of disorders is steadily decreasing.

Pellagra

Pellagra is a recurring nutritional disease associated with a severe deficiency of niacin, a vitamin of the B-complex group that includes both nicotinic acid and nicotinamide. Because the body can convert the essential amino acid *tryptophan* into niacin, inclusion of enough tryptophan in the diet is as effective as niacin in preventing the disease. Pellagra is usually associated with signs of deficiencies of other B complex vitamins and nearly always is linked with poverty and a diet composed substantially of maize. In recent years, pellagra in India and Egypt has been tied to consumption of another grain, *jowar,* a type of millet or sorghum.

Pellagra is characterized by dermatitis, diarrhea, and dementia, and thus is known as the *disease of the "3 D's."* If untreated, a fourth "D," death, may ensue. Before the cause of the disease was known, mortality was as high as 70 percent. As knowledge about the disease increased, however, and many mild cases, previously undiagnosed, were recognized, the mortality rate was reduced substantially.

Dermatitis is the characteristic symptom of pellagra and the one on which diagnosis is based. Symmetrical lesions appear on the hands and arms, on the tops of the feet and around the ankles, on the back of the neck, and across the face in a butterfly-shaped design. Weakness, a sense of malaise, and a reddened skin, sometimes confused with sunburn,

are the first indications of the disease. Later the skin crusts and peels, revealing a smooth glossy skin underneath. In Spain, where the disease was first described in the eighteenth century, it was called *mal de la rosa;* in France, peasants named it *mal de la misère.* In Italy, it was called *mal del sole* because its peak came with the spring equinox. Late in the eighteenth century, the Italian physician Francesco Frapolli named the disease pellagra, which means "rough or dry skin."

Distribution and Incidence

In the two centuries between 1730 and 1930, pellagra caused much death and chronic misery, first in Europe, then in the Middle East, parts of Africa and Asia, and in North America. It was associated always with a maize diet. Since the 1930s the disease has virtually disappeared from the United States and southern Europe, and its incidence is decreasing in the Middle East. It continues to be a problem in Egypt, among the Bantu in parts of Africa, and in India, particularly in the Hyderabad region, where consumption of jowar, not maize, apparently is the precipitating factor. The disease may appear whenever famine exists.

The greatly reduced incidence of the disease in the United States may be attributed to a changed economic status in the South, where it was once prevalent; to the widespread distribution of brewer's yeast, which is a pellagra preventive; and to the enrichment of bread, flour, and cornmeal with vitamins. An occasional diagnosis of pellagra is still made in the United States, usually in association with alcoholism or a malabsorption malady.

Even in those countries where pellagra continues to be a public health problem, it no longer appears in epidemic form, but rather in endemic foci. It is most likely to occur among agricultural workers whose diets are unsatisfactory, in adults rather than children, and in men rather than women.

Epidemiology and Etiology

Observations about pellagra made in Spain in the early eighteenth century have stood the test of time: The disease is associated with a maize diet and occurs mainly among the poor. These observations were repeated over the years, and their scientific validity was confirmed more than 200 years later by work done in the United States during the second and third decades of the twentieth century.

The U.S. Public Health Service, working in the southern states, linked pellagra conclusively to the peculiar *"3 M" diet* of the region – meat, meal, and

molasses – and to the poverty of which this diet was a symbol. Bread made from cornmeal was the largest component of the pellagrin's daily fare. Meat was pork fat back, and molasses was syrup made from cane. Widespread pellagra was found among tenant farmers and mill workers, in orphanages and mental institutions. The diet of pellagrins was always both monotonous and cheap. In what would become one of the classic studies in epidemiology, pellagra was linked irrevocably to economics. A systematic analysis of diet in relation to the income of workers in South Carolina mill villages showed that pellagra appeared wherever income was marginal and variety in diet was limited.

The missing element in the pellagrin's diet at first was called the pellagra-preventing or *"P-P" factor*. Although its exact nature was unknown, it was proved to exist in a number of foods including meat, milk, eggs, and certain vegetables, particularly turnip greens. One of the richest and least expensive sources was found in yeast. In 1937, the P-P factor was identified specifically as nicotinic acid, or niacin, a B-complex vitamin. Adding niacin to the diet almost magically eliminates even the worst symptoms of pellagra.

The discovery of niacin as the pellagra-preventive factor, however, did not answer all the questions about the disease. It did not explain why milk, a poor source of niacin, would prevent pellagra, nor why a diet based mostly on corn, which possesses more niacin than milk, causes it. The answer to part of the riddle lay in the discovery that the liver can convert the amino acid tryptophan, of which milk is a rich source, into niacin. The mystery of corn's association with pellagra lies in the type of niacin it contains.

Niacin is distributed in a wide variety of foods including cereals, legumes, oilseeds, meat, tea, and coffee. Its presence in food, however, does not mean that it is always available to the body. Niacin may appear in a free form ready to be absorbed; or it may appear in a bound form called *niacytin* and be biologically unavailable, as is the case with maize. Niacytin is released only after the grain is treated with an alkali such as lime. In Mexico and Central America, where pellagra has seldom been a problem even though corn is the dietary staple, the grain is soaked in lime and heated before being baked as tortillas. Treatment with lime also lowers the content of the amino acid leucine in corn.

It is the high leucine content of millet jowar (*Sorghum vulgare*) that is thought to be responsible for the appearance of pellagra in Egypt and India where this grain constitutes a large part of the diet. Niacin is found in jowar in a free form and is therefore nutritionally available, but the grain's protein has an imbalance between leucine and the amino acid isoleucine. Like maize, jowar contains a relative excess of leucine, about 12 percent, as compared with a level of below 8 percent in most other cereals. This excess brings about a conditioned niacin deficiency, one in which pyridoxine, vitamin B_6, appears to play a role.

The amount of niacin required in the diet is affected by the quality of protein consumed because tryptophan is a precursor of niacin. The term *niacin equivalent* is used because 60 milligrams of tryptophan supply 1 milligram of niacin. An adequate diet contains 6 to 9 milligrams of niacin-equivalents per day for infants, 11 to 18 for children, and 13 to 19 for adults.

Thus the etiology of pellagra is incredibly complex. The disease may result from either a niacin deficiency or an amino acid imbalance. Three essential amino acids – tryptophan, leucine, and isoleucine – and two vitamins – niacin and vitamin B_6 – are involved. The interaction of these nutrients is not fully understood, and other nutrients as well as hormones may have a role. There is also an apparent association of pellagra with sunshine.

Regular consumption of alcohol is related to the development of pellagra, as are parasitic infections, particularly schistosomiasis. Pellagra also may be precipitated by treatment with certain drugs. Isoniazid, used to treat tuberculosis, and 3-mercaptopurine, used to treat leukemia, can lead to a niacin deficiency. In patients with malignant carcinoid, tryptophan is diverted mainly to serotonin rather than to niacin, and pellagra may follow. *Hartnup's disease,* a genetic disorder that causes errors in tryptophan metabolism, looks much like pellagra and is responsive to niacin therapy.

Clinical Manifestations and Pathology

Pellagra usually appears in the winter or spring and seems to disappear a few months later, only to recur the following year. Symptoms become progressively worse. In the early stages of the disease, patients feel weak, tire easily, lose their appetites, and cannot sleep. The first definite sign of the disease, however, is a reddening of the skin, frequently mistaken for sunburn. In severe cases, the skin manifestation progresses rapidly and makes the disease easy to distinguish. It may appear on the feet and ankles, hands and forearms ("pellagra gloves"), or around the neck, and across the face. Lesions on the neck are called *Casal's necklace,* after the Spanish physi-

cian Gaspar Casal, who first identified *mal de la rosa* in 1735. In all cases, the skin manifestations are symmetrical and bilateral.

The first published description of pellagra, written by the French physician François Thièry in 1755, was graphic. The skin, he wrote, is "a horrible crust, dry, scabby, blackish, crossed with cracks, which causes much pain to the sufferer and throws off a very foetid odor." Although lesions usually occur on those parts of the body exposed to the sun, the genitals and pressure points may be affected. There is a clear demarcation between the affected and normal skin. Pellagra lesions sometimes peel, beginning from the center and spreading to the edges. In acute cases blisters occur. These may rupture, leaving weeping areas that resemble third-degree burns.

Although dermatitis is the diagnostic feature, the disease also affects the gastrointestinal tract. Patients may be nauseated or suffer from excessive salivation, have a reddened tongue, or experience a burning sensation in the abdomen. These symptoms, although associated with pellagra, are usually due to deficiencies of B-complex vitamins other than niacin. Diarrhea, sometimes intense, is characteristic of the disease.

Particularly distressing are the neurological symptoms. Insomnia is an early complaint, and patients are often apprehensive. Peripheral neuritis makes the movements of pellagrins uncertain. Mental aberrations are varied. Some patients suffer only mild depression, confusion, or loss of memory. Others manifest psychotic changes severe enough for admission to a mental hospital. Some are suicidal. All these symptoms are caused by biochemical changes still imperfectly understood. The amino acid composition of the skin is altered, and the collagen markedly reduced. The low level of urocanic acid in the skin may be related to pellagra's characteristic photosensitive rash since urocanic acid acts as an ultraviolet ray trap. There are also changes in the electrical rhythms of the brain, even if mental symptoms are not present. The majority of pellagra victims show an absence of normal alpha rhythms, but theta wave activity and high-voltage delta wave activity are found. These changes are believed to be related to an altered metabolism, in the brain, of serotonin, which is synthesized from tryptophan. Serotonin is one of the biogenic amines that modulate behavior.

History and Geography

Europe

Pellagra has always been associated with maize or corn, a grain native to America and the staple food of the American Indians. Carried to Europe as early as the third voyage of Christopher Columbus, maize was at first of interest chiefly to herbalists investigating the medicinal properties of plants. By the middle of the seventeenth century, however, at least one herbalist observed that the grain might have a deleterious rather than a sanguine effect if consumed in large quantities. An herbal of Caspar Bauhinus, published posthumously in 1658 at Basel, described how boys of the Guineas roasted and burned the grains and ate them in place of bread: "[I]f they take it a little too often [they] cannot rid themselves of the itch, since the plant produces blood that is too hot and virtually burned."

Despite this caveat, the obvious advantages of maize ensured its spread beyond the botanical gardens of Europe and into the fields. Its ease of cultivation and prolific yields made it an attractive substitute for wheat, barley, or millet. By the end of the eighteenth century, maize was widely grown in Italy, and from there spread into what is now Yugoslavia and into France, Austria, and Hungary. The ruling Hapsburgs of Austria-Hungary actively fostered its production not only because maize provided a staple food for the peasants, but because its greater yields meant larger tithes for the royal coffers.

Pellagra was first identified by Casal, a physician at the royal court of Spain. In 1735 in the town of Oviedo in the Austrias, he first noticed a kind of leprosy the peasants called *mal de la rosa*. "Since I never saw a more disgusting indigenous disease," he wrote, "I thought I should explain its characteristics." There followed the description of the disease with its extreme weakness, sensations of burning, crusts on the skin, and melancholia. Casal noted that victims of the disease lived primarily on maize, and he emphasized that the "rose" could be treated by adding to the diet milk, cheese, and other foods seldom seen by the poor. Thièry, then a physician at the court of Spain, read Casal's manuscript and wrote a brief description of the disease for a French journal, published in 1755. Casal's own work, *História natural y médica de la principado de Austrias,* was not published until 1762, 3 years after his death. In it, the section on *mal de la rosa* is set apart from other diseases discussed. It contains the volume's only illustration and is written in Latin rather than Spanish. Within 10 years, the disease was noted in Italy and given the name pellagra by Frapolli.

Accounts of pellagra in Spain are scarce after Casal's report, but by the nineteenth century the disease was rampant in northern Italy and southwestern France. Estimates were that 5 percent of

the population of Lombardy was affected and that in the worst areas, the ratio was 1:5. In Milan in 1817, a visiting English physician found that about 66 percent of the inmates of a mental institution were pellagrins. The lack of reports of the disease from Spain during this period puzzled the French physician Théophile Roussel; visiting Spain in the 1840s, he determined that some diseases called by various other names were indeed pellagra, and thus published a report to this effect. Although Spanish physicians resented his interference in their medical affairs, Roussel's insistence that there was unity in endemic pellagra-like diseases was a step forward.

In retrospect, it is possible to see why pellagra spread as it did with the cultivation of maize. It was not the grain itself that was to blame for the malady, but the social and economic conditions that forced the poorest segment of the populace to eat an increasingly monotonous diet. In Spain, for example, the disease occurred in the region where the once powerful guild that controlled the raising of Merino sheep had lost its influence. There were 321 different sheep taxes in 1758, and the formerly prosperous sheep industry was badly crippled. Peasants were left to fend for themselves. In Italy, a system of land tenure called *mezzadria* kept peasants impoverished, half their crops going to the landowner to pay rent. In southern France, maize was not an important crop until the late eighteenth century, and its production in the environs of Paris was not encouraged until 1829, the year the first pellagra case was reported in the country. The peasants who fell victim to the disease were primarily sheep herders. Their land was poor, and money and food were so scarce that they ate an exclusively vegetable diet. The French, however, were luckier than their neighbors. They benefited from the work of Roussel, who believed so strongly that pellagra was caused by eating maize that he encouraged reforms to improve the food supply and the working and living conditions of the peasants. He wrote two books on pellagra, the second appearing in 1866. In this volume, he wrote that the problem of pellagra would be solved not by scientific discovery but through social progress. His arguments were persuasive enough for the French government to decrease maize cultivation for human food and encourage animal husbandry. By the turn of the century, pellagra had virtually disappeared from France.

Few people were willing to accept the idea that a disease as horrible as pellagra was caused by economic conditions. Many, however, were ready to associate it with maize. The proponents of this view were

called *Zeists,* from *zea mays,* the botanical name of maize. They were led by an Italian physician, Giovanni Battista Marzari, who suggested that there were two problems with the corn diet of pellagrins. The grain was picked before it was ripe and molded in storage. More important, he believed that corn was lacking in certain nutritive elements. His followers tended to accept the spoiled corn theory and for years searched diligently for a toxin. Lodovico Balardini thought he had found it in copper-green molds growing on corn. Cesare Lombroso of Turin, who was as much interested in criminology as medicine, spent a quarter of a century studying these molds. The spoiled corn theory was used to explain why pellagra broke out in Yucatan in 1882, when locusts destroyed the Indian corn crop and the grain had to be imported from New York. Brought in the holds of ships as ballast, the grain spoiled en route. The poorer classes ate it anyway, and pellagra followed. When corn crops failed again in the early years of the twentieth century, corn was again imported to Yucatan. Again it arrived spoiled, and there were outbreaks of pellagra.

Not everyone was convinced that corn was responsible for pellagra. The Anti-Zeists thought that heredity played a part, that bad air was responsible, or that the disease was caused by some unseen organism, which they termed a virus. In the nineteenth century, however, the Zeists were for the most part triumphant, and when they were able to persuade governments to act in curtailing the consumption of corn, as they were in France, they met with a measure of success.

America and the Third World

For a century and a half after pellagra was first described, the magnitude of the problem outside Europe was not appreciated. Not until the 1890s, when the British epidemiologist Fleming Sandwith went to Egypt to serve on the staff of a hospital in Cairo, was anything about pellagra written in English. Sandwith found that many of his hookworm patients had pellagra, and he later discovered that they suffered from malaria and syphilis as well as other ailments. Sandwith noted that the disease was principally "country-bred," and he associated it with a diet of corn. He believed, however, that diseased corn, not good corn, was responsible. During the Boer War, when he was surrounded by poor Bantu people living on maize, he expected to find pellagra among them and he did, although the medical men of South Africa assured him that no such disease existed there.

When pellagra was identified in the southern United States, Sandwith was not surprised. Because this was an area where much corn was eaten, he had long suspected that the disease must be present. He expressed the "confident hope" that long unsolved pellagra problems would be mastered in the United States. The chief threat he saw to eventual success was that "enterprising" people in the South would diagnose everything as "doubtful pellagra." If that happened, he thought, the whole question of pellagra's etiology would fall into disrepute. Both his hopes and his fears were realized.

Pellagra came to the attention of the American medical profession in the spring of 1907 with the diagnosis of an epidemic at a mental hospital in Alabama. The mortality rate was a shocking 64 percent. In the months that followed, hundreds and then thousands of cases were identified, and there was a frantic search for a cause and a cure. The Zeists had their advocates in America, as in Europe, but there was also much interest in looking for an insect vector. The *Simulium* fly appeared to be the most likely suspect. This theory, advanced by Louis Sambon of the London School of Tropical Medicine, was greeted with relief by agriculturists in the United States. Because of the discovery that malaria, yellow fever, and Rocky Mountain spotted fever had insect vectors, pellagra might well have one, too. Some American physicians blamed foodstuffs other than corn, notably cane sugar and cottonseed oil.

While the search for a cause was underway, so was one for a cure. More than 200 remedies are recorded in the literature. Those most frequently tried were various arsenic compounds, both inorganic and organic, the most popular being Salvarsan, used in the treatment of syphilis.

The U.S. Public Health Service began its work on pellagra soon after the first cases were diagnosed in Alabama, but it was not until 1914, when Joseph Goldberger was assigned to the problem, that real progress was made. In a matter of weeks, Goldberger identified the essential cause of the disease: Something was missing in the diet. In a logical systematic way, he did what no one before him had done. He proved his case and found the missing element, although he did not specifically identify it.

Only 3 weeks after Goldberger began his work, he completely revamped the pellagra investigations of the U.S. Public Health Service and set them on a course that yielded fruitful results. His most important innovation was to introduce a new diet into selected institutions where pellagra was prevalent to see if the disease would disappear. Succeeding in that experiment, he then induced pellagra with a poor diet in a population of volunteer prisoners. To boost acceptance of the then novel idea that a disease could be caused by a dietetic deficiency and to squelch his critics, Goldberger next attempted to transmit the disease to himself and several colleagues. In several experiments over a course of 2 months in 1916, he used all the time-honored ways of experimentally transmitting a disease: blood, nasal secretions, epidermal scales from skin lesions, urine, and feces. Neither he nor anyone else got pellagra.

While these "filth parties" were underway, Goldberger began a study of the relationship of pellagra to economics. He noted that rural victims of the disease were sharecroppers and tenant farmers caught in a cycle of poverty tied to a one-crop agriculture. They grew little but cotton and used their meager share of profits to buy the "3 M" dietary articles which were all they could afford. Few grew much in the way of foodstuffs or kept a cow. Most were chronically in debt. In the mill villages, wages were kept notoriously low so as to attract industry into the so-called New South arising out of the debacle of Civil War. It was in the company-owned South Carolina mill villages that Goldberger demonstrated that poverty begets disease. Conducted over a period of 2 or 3 years, this epidemiological study conclusively proved that pellagrins were sick because they were poor. The study itself became a model in epidemiology. Victims of pellagra in the mill villages were poorer than those who escaped the disease.

In the 1920s, Goldberger turned from epidemiological studies to a search for the specific cause of pellagra. Working at the Hygienic Laboratory in Washington, D.C., a forerunner of the National Institutes of Health, he began a systematic search for the specific element missing in the pellagrin's diet. He was aided in this work by two fortuitous events. He got an animal model for his studies when research workers at Yale University determined that black tongue in dogs is an analogue of human pellagra, and, almost accidentally, he and his associates found one of the richest sources of the missing pellagra-preventive factor. In an effort to improve the dogs' appetite for the monotonous pellagra-producing diet, they added a cake of commercial yeast to the daily ration. The results were magical. Within 4 days after a dog with pellagra was given yeast, its condition had markedly improved.

The efficacy of yeast in preventing and treating pellagra was dramatically proved during the flood of

the Mississippi River in the spring of 1927, when thousands of people were driven from their homes and forced to subsist on a diet even more restricted than usual. With Goldberger's help and encouragement, the American Red Cross distributed tons of yeast to flood victims. Distribution of yeast became a standard feature of aid to people during the depression of the 1930s. It was from yeast and liver extracts, also found to be an effective pellagra preventive, that the missing dietary element was finally isolated.

Goldberger was studying liver extracts at the time of his death in 1929. That year there were probably more than 200,000 cases of pellagra in the United States, and the mortality rate was 33 percent. Ironically, it was in the years of economic depression which followed that the incidence of pellagra began to decrease in the United States as both the economy and government programs forced Southerners to grow something other than cotton. With diversification of agriculture and government programs that provided jobs, distributed surplus commodities, and encouraged people to grow more foodstuffs and preserve them for winter use, the disease began to disappear.

After Goldberger's work, the next scientific breakthrough in conquering the disease came from laboratories at the University of Wisconsin, where in 1937 nicotinic acid, later named niacin, was found to be the pellagra-preventive factor. Conrad A. Elvehjem and his associates found that a deficiency of nicotinic acid caused black tongue in dogs. Subsequently, they learned that nicotinamide is as effective in treating black tongue as is nicotinic acid.

Numerous studies were made to transfer the results of this research on dogs afflicted with black tongue to humans with pellagra. Tom Spies used nicotinic acid to treat pellagra patients with considerable success at a hospital in Cincinnati and later extended and expanded his work to Alabama. Commenting on the work of Elvehjem and Spies and fellow workers, the *New York Times* noted that "an ailment which has baffled medicine for centuries has at last been relegated to the curable diseases and . . . American Medicine has to its credit a triumph comparable with the conquest of yellow fever."

The incredible complexity of pellagra has provided years of work for researchers. Grace A. Goldsmith and her co-workers at Tulane University proved that the amino acid tryptophan is a precursor of niacin, and she helped establish the recommended dietary allowances for that vitamin. Physicians in India have been responsible for the observation that pellagra is associated with the consumption of millet.

Coluthur Gopalan linked the high incidence of pellagra on the Deccan Plateau to consumption of millet and to the grain's high leucine content. Another Indian physician, P. S. Shankar, also noted the association of millet with the disease and found that the drug isoniazid, given for treatment of tuberculosis, may precipitate pellagra.

The disappearance of pellagra from so much of the world where it was once endemic is due as much to economic and social factors as to advances in medicine. In the southern United States, enrichment of bread and flour with vitamins, begun in World War II, has certainly played a part in eliminating the disease, but so has burgeoning prosperity. The example of France in the late nineteenth century showed that government policy that encouraged a varied agriculture could result in important health benefits. Pellagra was finally brought under control in Italy by the 1930s, probably because of a rising standard of living.

From the time when pellagra was first described in the eighteenth century, members of the upper classes have tended either to deny the existence of the disease or to blame its appearance on the inherent moral weaknesses of its victims. In the American South, pellagra became a political and social issue. Its presence bespoke a distinctiveness for the region that many Southerners did not welcome. In the late twentieth century, the disease appears in only isolated pockets in Egypt, Lesotho, and India. Its victims are poor, just as were the Spanish peasants who consulted Don Gaspar Casal in Asturias in 1735.

Periodontal Disease (Pyorrhea)

The word "pyorrhea" comes from the Greek *pyon* ("pus") and *rhoia* ("to flow"). Thus the definition is a graphic description of the disease in which there is an outflowing of pus from the gingival (gum) tissues of the oral cavity. The term "pyorrhea" has been used in Europe since the mid-1500s and in America since the late 1800s. However, it was not until 1937 that the American Academy of Periodontology abandoned the term in favor of "periodontal disease."

The term "periodontal disease" is used in reference to any disease of the supporting structures of the teeth. These structures include the gingiva, periodontal ligament, and alveolar bone. In simplest terms, periodontal disease can be divided into two distinct, but not mutually exclusive, disease processes. The first involves inflammation of the gingival tissues, called "gingivitis," and the second, a destructive loss of bone and connective tissue attachment termed "periodontitis."

Distribution, Incidence, and Epidemiology
Epidemiological research during the past 25 years indicates that periodontal disease is one of the most common diseases affecting humankind. There is a direct cause-and-effect relationship between the bac-

terial colonization on the surface of the tooth and the inflammation (and often consequential destruction) of the tooth's supporting structures. The rate of destruction varies, and is dependent on the individual's response to the bacterial irritation.

Periodontal disease is a widespread chronic disease and remains as the primary reason for the loss of teeth in the adult population throughout the world. In fact, virtually all individuals in any population exhibit manifestations of the disease. The prevalence and severity of periodontal disease increase with advancing age, tend to be greater in nonwhites than whites, and are greater for males in both races. There appears to be a trend toward an increase in the prevalence and severity of periodontal disease in the over-35 age group. This increase is most pronounced in the lower socioeconomic groups and is highly correlated with differing levels of personal and professional oral hygiene care.

Many individuals in the older population have had fewer teeth extracted as a consequence of a lower caries (cavities) incidence, which is a result of fluoride use, improvements in dental care, and better public health education. Paradoxically, this increase in the retention rate of teeth in the aging population provides an increase in the number of teeth at risk to the development of periodontitis. The only improvement that has been noted since the 1970s has been a slight reduction in the incidence and severity of gingivitis among the under-35 age group.

Etiology
Numerous studies have firmly established the primary etiologic agent in periodontal disease as "plaque." Plaque is a colorless, soft, sticky film of bacteria that constantly forms on the teeth. Plaque is composed primarily of different and numerous types of microorganisms as well as adherent mucin (a protein and polysaccharide combination), foodstuffs, and cellular debris. One gram of dental plaque contains more than 10^{11} bacteria. Plaque can calcify to form a local tissue irritant – *calculus* (tartar) – to which new colonies of plaque can readily adhere. The microbial population of plaque is variable, and is determined by its location on the tooth surface, the intraoral environment at the time of the plaque formation, and the length of time that the colony has been present in the mouth. When plaque is removed, a new plaque may form, having different characteristics in its quantity, quality, and spatial arrangement. The microorganisms in plaque

produce metabolic products and cellular constituents that affect the underlying periodontal tissues. These include exotoxins, endotoxins, antigens, and enzymes.

Any microbial plaque within the gingival crevice causes at least gingivitis. In some areas of the mouth, plaque and gingivitis lead to a destructive periodontitis. Periodontal disease is not caused by the intraoral invasion of foreign pathogens, but rather by colonization of microorganisms of the normal oral flora that exists even in the absence of disease. Certain species of this bacterial plaque play a more significant part in the development and progress of the disease because they increase in relative proportions as well as in absolute numbers. These species are also relevant in that their virulent mechanisms act to disrupt the host's defenses.

Inadequate or improper oral hygiene techniques must be considered one of the etiologic factors in the development of periodontal disease. Other causative influences include food impaction between teeth, defective dental restorations, malposed teeth, physiological gingival stress due to high frenum attachment, effects of dry mouth, and, to a minor extent, heredity. Of course, there is a strong relationship between all of the etiologic factors and the host's resistance. The capacity to resist or repair depends on many factors such as adequate nutrition and assimilation, antibody production, hormonal influences, white cell defenses, and formative cell capabilities.

Clinical Manifestations and Pathology

The pathogenesis of periodontal disease must be considered in four stages: colonization, invasion, destruction, and healing.

During colonization, plaque accumulates on the teeth and microbial growth ensues. If the plaque is not removed through adequate oral hygiene, the formation of calculus may begin, and the early stages of microbial invasion into the adjacent gingival tissues commence. Clinical signs may consist of gingival tissues that are tender, swollen, and red. This tissue may bleed upon probing or during brushing. However, periodontal disease usually progresses over the course of many years, and discomfort is a rarity. It is because of this asymptomatic evolution that persistent bacterial invasion and local irritation can progress into the destructive phase of the disease in which loss of connective tissue and loss of alveolar bone take place. Signs and symptoms of the destructive stage can include pocketing around the tooth within the gingival crevice, gingival recession, sup-

purative exudate (pus) from the gingiva, and looseness or separation of the permanent teeth.

An examination of the teeth may entail numerous tests and measurements for the evaluation of the presence and severity of periodontal disease. These may include visual signs of inflammation, probing pockets' depths around teeth, evaluation of bleeding on probing, assessment of plaque or calculus accumulation above and below the gingival margin, phase-contrast microscopic analysis of the bacteria recovered from the crevice, assaying the crevicular fluid flow, and interpretation of dental radiographs.

The healing phase is the least understood of the four stages of the disease. However, studies reveal that periodontal disease is episodic, and undergoes periods of remission and exacerbation. Although colonization, invasion, and destruction are interrelated and overlapping, this fourth stage, healing, is clearly distinct in that it is characterized by reduction of inflammation, the repair of gingival tissues, and the sclerosis and remodeling of the alveolar bone.

History and Geography

Antiquity Through the Seventeenth Century

Although periodontology has been practiced as a specialty only during this century, the recognition of periodontal disease in various forms has persisted for millennia. The condition of the dental structures of teeth and bone of our ancestors has been revealed through examination and radiographs of skulls discovered in archaeological excavations. There is evidence that periodontal disease existed in some of the earliest members of humankind.

Egyptian mummies show signs of dental caries and periodontal disease as well as primitive, yet valiant, attempts at repairing these dental pathoses. Indeed, it is believed that the Papyrus of Ebers, which was written around 1550 B.C. by Egyptians, and describes various conditions of the oral cavity, is the earliest written record of dentistry as a distinctive branch of the healing arts. The Greek historian Herodotus described Egypt as being the home of medical specialties, including dentistry.

About 1300 B.C., Aesculapius, the mythical physician, supposedly recognized the importance of dental hygiene by recommending cleaning of the mouth and teeth. The physician to the King of Babylon, Arad-Nana, in the sixth century B.C., suggested removing the "film" and "deposits" from the teeth with a cloth-covered index finger. More aggressive peri-

odontal therapy appears about 25 B.C., when Celsus, a Roman physician, treated gums and loose teeth with gold wire and seared the gingiva with red-hot iron. Oral hygiene techniques can also be traced to the Mayan culture and to those living around Central America between 200 B.C. and A.D. 800.

Pliny, a Roman, published his book *Natural History* in the first century A.D.; in it he describes the prevalence of periodontal disease among the Romans as well as various remedies for its prevention and care. The most notable prescriptions were the use of dentifrices, mouthwashes, and toothpicks; the first mention of "toothbrushing" seems to have been made by the Roman poet Ovid in his *Art of Lovemaking,* in the first century A.D. The siwak, a fibrous wood product which preceded the toothbrush, was used by the Arabians since the ninth century, and can still be found in use in some areas today. The modern-day toothbrush, however, was invented in China only in 1498.

In 1530, Zene Artzney wrote a book dealing with dental therapeutics in which he discusses the formation and modes of prevention of calculus. He also noted in his writing that loose teeth and their premature loss were a result of "carelessness, weakness, or . . . disease." In 1575 Ambroise Paré coined the term "pyorrhea alveolaris," and describes the teeth attaching to the jaw via "a ligament which goes from the root of the tooth."

Eighteenth Century to the Present

Pierre Fauchard, the founder of modern dentistry, in his now famous 1728 publication *Le Chirurgien Dentiste,* or *Traité des Dents,* stated that the "relation between the gums and teeth is such that the diseases of one may easily extend to the other." In 1820, Eleazar Parmly recommended that for the "constant security of the teeth," all deposits on the teeth must be removed. He later became known as the "Apostle of Dental Hygiene." In the latter half of the nineteenth century, John Riggs, who was to become "the father of periodontology," described periodontal disease as a "progressive process from marginal gingivitis to the final exfoliation of the teeth." He developed preventive as well as surgical treatments for what he called "scurvy of the gums." For decades, any such condition was called "Rigg's disease."

Our understanding of periodontal disease, including its etiology and pathogenesis, grew enormously during the 1900s. Periodontal disease is currently under attack on several fronts, through preventive care, improvements in oral hygiene techniques, mechanical and chemical plaque inhibitors, nutrition, surgical intervention, drugs, and immunology. Much work, however, remains ahead, especially in the relationship of the disease to the host's immune system.

VIII.105
Pica

Pica is usually described as a pathological craving for nonfoods, although it can mean a craving for substances generally accepted to be food as well. Medical science has long been interested in this disorder, for although it does not constitute a disease, it is often a symptom of disease and frequently is associated with nutritional deficiencies, especially those connected with minerals. In addition, psychiatry and psychology find that pica is often connected with mental problems, including those of retardation. Anthropologists study it as a cultural phenomenon, since it has been associated with some religions and also perhaps because the use of nonfoods is indicative of food shortages in the distant past.

The word "pica" comes from the Latin for "magpie," a bird that eats practically anything. The term was first used by Ambroise Paré in the 1500s, although references to pica consumption can be found in many ancient and medieval writings. M. H. Boezo, in his 1638 work *De Pica,* was the first to draw a distinction between "pica," which he believed was an appetite for "absurd things," and which was common in both men and women, and "malacia," which referred to a voracious desire for normal food substances. He observed that the latter occurred most often in pregnant women, and believed the cause was a mental alteration caused by the pregnancy.

Classification

Probably the type of pica that has received the most scientific and lay scrutiny is the consumption of earth, called *geophagy.* This word was first applied by Aristotle, and it means, literally, "dirt eating." Since that time, it has gone under many names, including *allotriophagia* (Sophocles), *erdessen* (medieval Germany), *mal d'estomac* (French), *citta,* and *cachexia Africana.* The last, from the Latin, meaning "the wasting away of Africans," was a condition first noted by slave owners in the West Indies. Unlike some of the other types of pica, geophagy is and has been a nearly universal phenomenon. There are records of earth consumption on all continents, and at nearly all times. Throughout history, it seems humankind has been consuming dirt, clay, mud, chalk, and various other types of earth for nutritional, cultural, and psychological reasons.

Still another type of pica is called *papophagia,* although some believe that it is not a disorder at all. The word is from the Greek and means "the eating of frost or ice," and was coined by a U.S. Air Force doctor, Charles Coltman. Some modern weight loss plans recommend the chewing or sucking of ice as a method of appetite control, and those who work with people trying to quit smoking often suggest that smokers chew ice as a substitute.

Amylophagia refers to the consumption of laundry starch, which is almost exclusively associated with women. It was first noticed in the rural American South, and is believed to have begun with women who originally consumed clay, but switched to laundry starch. Hilda Hertz, in a 1947 article, observed that although the tastes of clay and starch are quite different, the texture is similar. Later research indicated that pregnant women ate starch because it relieved nausea, vomiting, and morning sickness. Local black culture held that if a woman consumed laundry starch while pregnant, her baby would "slide out" more easily during delivery.

Trichophagia is the ingestion of hair. Those suffering from trichophagia and its associated problems are almost always young, English-speaking females with long hair who exhibit the nervous habit of chewing strands of it. It is usually related closely to "mouthing" behaviors (chewing on pencils, fingernails, and so on but not swallowing them); if hair is accidentally ingested over a long period of time, "hairballs" can form in the stomach, causing serious gastrointestinal problems.

There are many other types of picas, including *lithophagia,* the eating of rocks or pebbles. Sometimes the danger arises not from the items consumed but from their effect on the digestive system or the body in general. One of the most dangerous, the consumption of paint chips by small children, can result in lead poisoning.

Incidence

The reasons for the practice of pica are almost as numerous as its types. The interpretation of data on the disorder is complicated because definitions of pica are unreliable and because there is a natural reluctance on the part of practitioners to admit to the ingestion of nonfoods. This is especially true of geophagy, since "dirt-eating" is generally considered to be degenerate behavior.

Pica has been closely associated with women and pregnancy since classical times, and until recently it was believed that pregnancy caused mental instability in a woman, and thus provoked her cravings for

both food and nonfood substances. Recent studies, however, have indicated that changes in sense of taste are not a constant in pregnancy, despite the desire for sharp-tasting foods. There have been many studies of the incidence of pica among pregnant women in the United States since World War II, most carried out in rural areas. One of the most prominent of the few urban studies was done by Harry Roselle (1970), a New York medical doctor. He discovered that some of his nonpregnant patients consumed laundry starch or clay, and thought that this practice might be associated with iron-deficiency anemia. He prescribed iron for these patients, but their lack of cooperation did not allow him to form a firm generalization about the link between iron deficiency and pica. He did observe that hemoglobin values were unchanged while they were consuming clay and starch, which led him to believe that pica was a symptom, rather than a cause, of the anemia.

Most medical investigations of pica tend to be most concerned with children. The practice is usually associated with those in poverty, especially black children in rural areas or urban slums. Reports conflict as to whether pica in this group is nutritionally motivated. There seems to be no difference in prevalence between male and female children. However, during adolescence, girls are more likely than boys to take up or continue the practice.

As babies explore their environment, they put a variety of things in their mouths. The actual ingestion of nonfood substances seems to start as early as 6 months of age, but tends to decline with a developmental increase in hand–mouth activity and to drop sharply after the child reaches 3 years of age. Often, when pica is encountered after that age, the possibility of mental disturbance is explored.

Pica is usually described as rare among adult males, although some claim that it is merely underreported and the most common picalike practice among men – chewing tobacco – is not generally viewed to be pica. A study, carried out in Columbus, Ohio, in 1968 by J. A. Halsted found that 25 percent of 302 general patients admitted to eating clay, starch, or dirt at one time or another. Of these, only 24 percent (18 patients) were male.

Etiology

The causes of pica are not clear, and the search for them has been the subject of medical speculation since antiquity. Pica has been seen by most modern doctors and nutritionists chiefly as a means of alleviating nutritional deficiency. Similarly, most ancient and medieval scholars concerned with the subject stressed the importance of good nutrition and recommended fresh fruit and vegetables as a remedy. Despite innumerable recent studies, however, no definite connection has been established between pica and dietary imbalance. Nutrients in which pica practitioners are thought to be deficient include vitamins C and D, phosphorus, calcium, zinc, and especially iron. As early as A.D. 1000, Avicenna was treating pica with iron, and the search for the relationship between iron deficiency and pica continues today.

Psychiatrists and psychologists often feel that both nutritional deficiencies and psychological disorders are linked in pica patients. Some believe it is merely a continuation of infantile hand–mouth behavior patterns. Paulette Robischon (1971) conducted a study of 90 children between the ages of 19 to 24 months, and demonstrated that children who practice pica after infancy generally are slower to develop than those who do not. Other studies have found that black children are more likely than white children to exhibit pica, which has been linked to the overall lower income levels of their parents rather than to any racial cause. Reginald S. Lourie and his associates (1957, 1963), in their numerous studies, discovered that the pattern of pica in youngsters is very close to that of addiction. They termed it "a distorted form of the instinctual seeking of satisfaction." Often pica seems a defense against loss of security, such as that occasioned by separation from one or both parents, or emotional difficulties of the parents. Most young children who practice pica exhibit other oral activities, including thumbsucking, nailbiting, and so on.

There is also a "cultural" etiology for pica. Anthropologists have long been searching the past for practical reasons to explain why certain cultures and religions require the consumption of nonfood items. Symbolic geophagy was practiced in ancient times in Europe (so-called terra sigilata, or "sealed earth"), in the Middle East (consumption of a bit of dust from Mohammed's tomb), and even among early Christians. In parts of Africa it is thought that clay eating promotes fertility in women and lactation during pregnancy. John M. Hunter (1973) has postulated a culture–nutrition hypothesis, which attempts to demonstrate how geophagy, a type of pica, evolved from a nutritional activity and physiological imperative into a cultural institution in some societies. Pregnant women in Nigeria consumed clay in a culturally acceptable way, purchased loaves in the marketplace, and gained needed calcium and magnesium as a result.

A last reason for pica is for pharmacological purposes. It has been suggested that individuals engaged in pica practice may be attempting to medicate themselves for real or imagined illnesses. Physiological problems that have been thought to cause pica include gastrointestinal malaise, stress, hunger, parasitic infestations (such as worms), and toxicosis.

History and Geography

Antiquity

Pica was well known to the ancients: Aristotle and Socrates both wrote of the practice of earth eating, and it is known that in Greece, as early as 40 B.C., the sacred "sealed earth" was used as a sort of magical "cure-all." The clays of the islands of Samos, Chios, and Selinos in the Aegean Sea were said to be especially effective. Galen took 20,000 lozenges of the clay from Lemnos back to Rome, and used them to treat poison victims.

Pliny the Elder noted that some residents of the province of Campania mixed white chalk with their porridge, to give it some color and texture. The chalk came from a hill called *Leucogauem,* which in Greek means "white earth." Supposedly, Caesar Augustus ordered 20,000 sesterces to be paid yearly to the Neapolitans on behalf of the Campanians for the lease of the hill, without which, the Campanians claimed, they could not make their porridge. Pliny also noted a region in northern Africa where a similar porridge was made with gypsum mixed in.

Many of the earliest medical writers tended to concentrate on the pica habits of pregnant women. In the sixth century, Aetius of Amida claimed that the urge to consume nonfoods was caused by a suppression of the menstrual flow, which in turn was caused by pressure from the fetus. He recommended exercise and fresh fruits and vegetables.

The Middle Ages

Avicenna described pica (although not by that name) and employed various iron preparations, among them iron dross steeped in fine wine and strained through a plant known as "Hippocrates' sleeve." Avicenna felt that an excessive appetite for sour and sharp-tasting foods was more easily remedied than one for dry things such as clay and charcoal. He further believed that pica in pregnant women was treatable by this method, but if the children of that pregnancy began practicing pica, they could not be cured of it. This disorder must have been fairly widespread, because Avicenna wrote of the need to control it in young boys, and recommended imprisonment if necessary, although pregnant women were to be treated more gently, for fear of damaging the infant.

Medical writers of the Middle Ages tended to view mental instability and food as important causes of pica. J. Ledelius, for example, stated that bits of leftover food in the stomach rotted and gave off four humors that ruined an individual's sense of taste and caused the craving of all sorts of odd substances. H. Betten, by contrast, argued that the cause of pica was not foul humors in the stomach but weakness of the mind. An individual whose mind was controlled by emotion was far more likely to consume nonfoods than one whose mind was controlled by discipline. He concluded that this was the reason women exhibited pica symptoms more often than men. However, he did not advocate denying women the substances they craved, for to do so, he thought, would damage the fetus. He recommended that nonpregnant women be given stern lectures to strengthen their wills, and various prescriptions to strengthen their stomachs.

Famine was often the cause of pica use. During periods of famine in China, individuals would consume clays of various colors and types in place of rice. Usually grass, foliage, weeds, and tree bark were used as famine food, but in truly desperate times, such as the famine of 1640 in what is now Hunan Province, the people ate not only clay but also boiled shoes, leather, and wood.

Similarly, in Europe, during the Thirty Years' War, while armies were ravaging the countryside and taking food from every village they encountered, the peasants of Pomerania turned to baking bread with dough mixed with powdered earth. The practice of baking earth into bread was also observed in Germany during the War of the Austrian Succession, not only in peasant villages but even in the castle of Wittenberg.

Nineteenth Century: Pica, Exploration, and Empire

As Europeans began to explore Africa, Asia, and the Western Hemisphere, they discovered that pica seemed to exist, or to have existed, on almost every continent of the globe. Alexander von Humboldt and A. Bonpland (1804) found that some of the natives of South America engaged in pica. The Otomac Indian tribe, who lived along the Orinoco River, were particularly fond of consuming an iron-rich clay during the lean months when the river overflowed its banks. Pica was also discovered among the natives of some mountainous regions of Peru, where powdered lime mixed with coca leaves was sold in the marketplaces.

The Indians of the Rio de la Hacha, however, preferred to consume the lime without additives, and usually carried it about with them in small boxes.

In central Africa, David Livingstone (1870) reported that some of the tribes were clay eaters. The Africans referred to the practice as *safura;* it was most notable among pregnant women of the area, but it was also practiced by males of all classes. The availability of food seemed to have no bearing on whether an individual chose to consume clay or not.

The literature of India indicates that geophagy was practiced on the subcontinent in ancient times; yet none of the early Portuguese or English accounts of India in the seventeenth and eighteenth centuries makes any mention of pica. By the end of the nineteenth century, however, British colonial physicians began to write about the earth eaters of India, believing that it was universal there. Native-born physicians also wrote about the subject, and one, Sarat Chandra Mitra (1904–7), thought it was a racial characteristic. Although he acknowledged that clay eating was practiced in many areas of the world, he thought that the Aryan and Dravidian races were unique in that they tended to use it for food on a regular basis, whereas other races ate it for sustenance only occasionally, or for pharmaceutical reasons.

David Hooper and Harold Mann (1906) published a more extensive study of pica in India a year later, in which they took issue with Mitra's assertion that clay eating was a racial characteristic. They believed that the reason people in all cultures of India consumed clay was to alleviate the symptoms of disease: gastric or intestinal irritation, anemia, even as a remedy for cholera.

Pica and Slavery

Plantation owners and managers in all areas of the slaveholding New World were concerned with the practice of pica by their slaves, because those who consumed earth appeared to become addicted to it, and the addiction was thought to be fatal. Planters referred to pica as a disease, calling it *mal d'estomac, cachexia Africana,* stomach evil, or dirt eating. Contemporary authors described the practice as widespread in the British West Indies. The dirt eaters usually became sick, suffering from stomach pains and difficult breathing. This was often followed by nausea and diarrhea, depression, and listlessness. Death followed within 2 or 3 months. Plantation owners and managers tried every means at their disposal to break the habit in those slaves who acquired it, but were generally unsuccessful.

John Imray, an Edinburgh-trained physician who resided in Dominica, wrote in 1843 that pica in the West Indies had become much rarer after the slaves were emancipated. He was convinced that a change in life-style was sufficient to cure earth eating. Slaves, in many cases, had been expected to feed themselves with their provision grounds, but because they had been overworked by the sugar planters, they had little energy left for their own crops. In desperation, they turned to earth eating. Freedom gave the blacks more time to grow and prepare their food. On the other hand, the diet and system of feeding slaves on the North American continent were much different from and nutritionally better than the diet and feeding system in the West Indies. Yet pica was also reportedly a serious problem among slaves in the southern United States.

Twentieth Century

The association of iron deficiency with earth eating, which we have seen since earliest times, has continued into the twentieth century, as physicians came increasingly to believe that anemia was the cause of geophagy, and that iron preparations were the cure. At the same time, however, the dangers of the consumption of some kinds of pica materials were discovered.

In 1924 J. C. Ruddock suggested, in an article in the *Journal of the American Medical Association,* that lead poisoning was the result of some types of pica. As awareness of the dangers of the consumption by children of paint chips increased, the U.S. government moved to limit the lead content of commercially available paints and plasters in the early 1940s. Unfortunately, pica continued to be a major cause of lead poisoning in children. In New York City alone, there were about 52 reported cases of lead poisoning every year, with case-mortality rates ranging between 13 and 27 percent. The cause of the poisoning was almost always the ingestion of plaster and chips of lead-based paint in old, run-down tenements.

Geographic studies of pica, especially geophagy, began to appear in the late nineteenth and twentieth centuries. In Germany, R. Lasch (1898) wrote a preliminary study, which was the basis for Berthold Laufer's larger study of geophagy, published by the Field Museum of Natural History in 1930. Laufer's approach was different from previous works in that he surveyed every continent on the globe in which geophagy had been reported, and for the first time, information of the practice in ancient China was published in English.

Articles by physicians and nutritionists appeared

in the late 1940s and early 1950s, as the practice of clay eating in the southern and urban areas of the United States was given a clinical examination. In their 1942 survey of black children in rural Mississippi, Dorothy Dickens and R. N. Ford found that of the 209 children in the sample, 25 percent of the girls and 26 percent of the boys had eaten either dirt or clay in the previous 2 weeks. Hertz (1947) observed the practice among pregnant black women in North Carolina, and because there were no reports of clay eating among the male population, she concluded that the practice was related to gender. Albert Whiting (1947), following up Hertz's study in that same year, examined the types of clays used in pica, and reported on the consumption of soot from stove pipes. Pica users did not eat the soot directly, but placed it in bags and soaked them in water, making a sort of tea. In the 1950s, Cecile Hoover Edwards and her colleagues (1954, 1959) undertook a study of rural women in Alabama, examining why pregnant women craved certain nonfood items. They issued questionnaires to 47 health agencies and 91 individual health workers in the southeastern region of the United States, and found that superstition and oral tradition played a large role in the selection of pica materials. In a subsequent study, intending to determine the nutritive value of the clays consumed, they discovered that women who ate clay and cornstarch had diets that were otherwise low in calories, calcium, iron, thiamine, and niacin.

Two major studies of pica appeared in the late 1950s. In 1957 Marcia Cooper published a book-length study of pica, which included its history and association with mental and physical illness, physical defects, and nutrition. According to Cooper, pica becomes established in children because they lack an understanding of dietary taboos. Poor nutrition leads them to practice pica with any number of substances that might be mouthed or eaten. Cooper acknowledged that the exact causes of pica were not completely demonstrated by her work, but was certain that more clinical studies in the future would elucidate them.

The other major work on pica, published by Bengt Anell and Sture Lagercrantz in Sweden in 1958, was focused on the geography of the disorder, and scrutinized geophagy in Indonesia and Oceania, as well as among blacks in Africa and America.

Throughout the century, most studies have assumed that a nutritional deficiency leads to pica, and, although iron deficiency is assumed to be the major cause, other trace elements, especially zinc, have also been investigated. Yet, despite the fact that the connection between iron-deficiency anemia and pica has been recognized for centuries, the question of whether pica is a cause or an effect of the anemia is still sometimes debated. Moreover, although both children and pregnant women engage in pica, there is no clear understanding of the physiological mechanisms that drive them to it. Thus, although pica has been recognized by practitioners of medicine since the beginning of recorded history, medicine seems little closer today to understanding its causes.

VIII.106
Pinta

Pinta (meaning "spotted") is also called *mal de pinto* and *carate*. It is the least destructive of the treponematoses that are pathogenic for humans. Although the taxonomy of these treponemes is by no means resolved, pinta is sufficiently distinctive to argue for a separate causal species, *Treponema carateum*. As a specific treponemal variety, it was not described until 1938. The disease is chronic, predominantly affects the skin, and is now found only among isolated rural groups in Central and South America and Mexico, where it is endemic. Local names for the illness are *tiña, empeines,* and *vitiligo.*

Distribution and Incidence

According to one historian of treponemal diseases, pinta may have had a considerable world distribution at the end of the Paleolithic period, some 10,000 years ago. However, its past geographic distribution is in some doubt, and an alternative view suggests that it may have evolved purely in Amerindian communities of the New World, as a final level of micro-

evolutionary change in the treponematoses there. Because it is not a very destructive condition, and may remain untreated in many individuals of the Third World countries of Latin America, it has been estimated that as many as a million individuals may have the disease.

Epidemiology and Etiology

Pinta is caused by *T. carateum,* which cannot be distinguished from *Treponema pallidum* (the causative agent of endemic and venereal syphilis). These treponemes are found mainly in the lower Malpighian layers of the epidermis, and may be present for years before the skin lesions eventually become inactive and depigmented. Large areas may be infected, and the disease may remain infectious for a long period. It is unusual for other areas of the body, such as the genitals, to be involved. In contrast to the other human treponematoses, the skeleton is never affected.

This chronic clinical condition usually begins in childhood and lasts into adulthood, if not for most of the lifetime of an infected individual. Social and hygienic factors result in the differential incidence of the disease in varying components of Latin American societies, with native Indians, mestizos, and blacks being most affected. Infection seems most likely to be by skin contact. Insect vectors have also been suggested as a means of transmission, but this has not been substantiated.

Immunology

Serologic reactions are positive early, then increase in degree. Experiments show that there is cross-immunity to a varying extent in individuals infected with *T. carateum, T. pallidum,* and *Treponema pertenue.*

Clinical Manifestations and Pathology

There is no chancre, and the condition begins as an extragenital papule, usually situated in the lower extremity (and perhaps associated with damage to the skin surface). Within 3 weeks, the papule has expanded into a reactive patch of circinate form, termed a *pintid.* In the next few months, a more general rash occurs on the face and limbs, which can be similar in appearance to such diseases as psoriasis, ringworm, and eczema.

Histologically, hyperkeratosis and intercellular edema are evident, with an increase of lymphocytes and plasma cells. In adults, there are usually pigmentary changes in the later stages. Bluish patches

are perhaps most characteristic, but lesions may be white. Pigmentary function is clearly disturbed, and in the white patches pigment is absent. It should be emphasized that other treponematoses can start out to some extent like pinta, but that the others progress beyond purely skin changes. The disease is not transmitted to the fetus.

History and Geography

Pinta is believed to be most prevalent in Mexico, Venezuela, Colombia, Peru, and Ecuador. It is an "old" disease in the Americas, clearly present before the arrival of the Europeans. Although a relatively mild disease, it has tended historically to evoke a variety of social responses. In some instances the *pintados* or "spotted ones" have been shunned, much like lepers in the Old World. Yet in other circumstances their distinctive appearance has brought them high status. For example, Montezuma, the Aztec emperor, selected such individuals to bear his litter, and they were apparently frequently formed into special and elite battalions in Mexican history.

It appears, however, that the earliest recognizable description of pinta as a separate disease was not recorded until 1757 in Mexico. Because of the possible similarities to leprosy in regard to the skin changes, it is not so surprising that a medical commission in 1811 reported on it as leprosy. In 1889 pinta was viewed as perhaps linked to syphilis and was thought to be transmitted by venereal contact. Indeed, this hypothesis seemed to "square" with accounts that reported the efficacy of mercury in the treatment of pinta, and the fact that infected individuals who worked in mercury mines felt better. The positive Wassermann reaction was demonstrated in 1925, but the true nature of this distinctive treponemal condition was not recognized until 1938.

VIII.107
Plague of Athens

The Greek historian Thucydides interrupts his history of the Peloponnesian War between Athens and Sparta to describe the following epidemic in 430 B.C.:

It was generally agreed that in respect of other ailments no season had ever been so healthy. Previous diseases all turned off into the plague; and the rest of the people were attacked without exciting cause, and without warning, in perfect health. It began with violent sensations of heat in the head, and redness and burning in the eyes; internally, the throat and tongue were blood-red from the start, emitting an abnormal and malodorous breath. These symptoms developed into sneezing and hoarseness, and before long the trouble descended into the chest, attended by violent coughing. Whenever it settled in the heart, it upset that organ, and evacuations of bile ensued, of every kind for which the doctors have a name; these also together with great distress. Most patients suffered an attack of empty retching, inducing violent convulsions, in some cases soon after the abatement of the previous symptoms, in others much later. The body was neither unduly hot externally to the touch, nor yellowish in color, but flushed and livid, with an efflorescence of small blisters and sores. Internally, the heat was so intense that the victims could not endure the laying-on of even the lightest wraps and linens; indeed nothing would suffice but they must go naked, and a plunge into cold water would give the greatest relief. Many who were left unattended actually did this, jumping into wells, so unquenchable was the thirst which possessed them; but it was all the same, whether they drank much or little. The victims were attacked throughout by inability to rest and by sleeplessness. Throughout the height of the disease the body would not waste away but would hold out against the distress beyond all expectation. The majority succumbed to the internal heat before their strength was entirely exhausted, on the seventh or ninth day. Or else, if they survived, the plague would descend to the bowels, where severe lesions would form, together with an attack of uniformly fluid diarrhea which in most cases ended in death through exhaustion. Thus the malady that first settled in the head passed through the whole body, starting at the top. And if the patient recovered from the worst effects, symptoms appeared in the form of a seizure of the extremities: the private parts and the tips of the fingers and toes were attacked, and many survived with the loss of these, others with the loss of their eyes. Some rose from their beds with a total and immediate loss of memory, unable to recall their own names or to recognize their next of kin. (Text of Thucydides [book 2, chap. 49], trans. W. L. Page, 1953)

Expanding rapidly in the early summer, the epidemic was far more lethal than others Thucydides had known, and he claimed that the novelty of this disease left Greek physicians powerless to deal with it. The epidemic was said to have begun in Africa, south of Ethiopia, spreading first to Egypt and Libya, then to Persia, then to Greece.

The stricken initially complained of "violent heat in the head," coryza, swollen and inflamed eyes, throat, and tongue, proceeding to violent coughing. Then the victims usually began to vomit, the disease bringing on "all the vomits of bile to which physicians have ever given names." Death claimed many of the sufferers in 7 to 9 days, a merciful end to wrenching convulsions, intense internal heat, and extreme thirst. Thucydides described an exanthem characterizing many cases: The skin, not hot to the touch, took on a livid color, inclining to red, and breaking out in pustules and ulcers. However, he did not offer clear comment about the distribution of the rash, thus permitting much disagreement in the literature.

Causing almost equal difficulty for medical observers today is Thucydides' description of the behavior of sufferers, hurling themselves into wells and cisterns in order to assuage the "inner heat" and satisfy their thirst. Thucydides does not identify any age group, sex, or socioeconomic category among those most at risk, rather emphasizing that the previously healthy were as likely to suffer and die as those previously debilitated by illness. He claims that 1,050 out of 4,000 adult male soldiers perished of the Plague – a high mortality rate even if all were afflicted. Pericles, the great orator and leader of Athens, apparently perished from the sickness, but Thucydides and Socrates did not. Thucydides assumes that the disease was contagious, and no one has questioned that assumption.

The epidemic lingered for 4 years in southern Greece, killing up to 25 percent of the population (if one accepts the highest mortality estimates). No subsequent epidemics in the Hellenic and Hellenistic Greek hegemony are comparable to this epidemic in magnitude. Because the epidemic, according to Thucydides and to many later historians of ancient Greece, was responsible for Athenian mili-

tary losses to Sparta, many have judged the Plague of Athens to be a "turning point" in the history of Western civilization.

Epidemiology and Etiology

Although many have speculated on causal questions surrounding the Plague of Athens and are convinced of their retrospective diagnoses, no consensus is likely to emerge. Fairly well supported arguments have advanced epidemic typhus, measles, and smallpox as candidates because all produce some of the dominant clinical and epidemiological features of Thucydides' description. Less frequently, bubonic plague, ergotism, streptococcal diseases, and, most recently, tularemia have found scholarly proponents.

Epidemic Typhus (Rickettsial Infection)

The facts that (1) the Plague of Athens occurred during wartime, (2) the severe clinical course lasted 7 to 10 days, (3) the fever was accompanied by first respiratory, then gastrointestinal, complaints and finally delirium associated with a rash – all have led several physician–historians to a diagnosis of epidemic typhus. Typhus is a louse-borne disease and severe cases could lead to circulatory collapse, accounting for the loss of distal extremities (fingers and toes) as well as damage to the optic nerve.

Insofar as Thucydides mentions vision loss as well as loss of the use of the extremities among some survivors, William MacArthur (1954) and Harry Keil (1951) find more support for this diagnosis of the clinical symptoms than for that of smallpox. By contrast, Hans Zinsser, in his 1935 classic *Rats, Lice, and History,* was not persuaded that the description Thucydides offered bore any resemblance to the typhus that cost so many lives in the two world wars. Yet other clinicians, citing their clinical experiences in wartime, have been equally persuaded that the description of Thucydides does suggest typhus. J. C. F. Poole and A. J. Holladay (1982) have most recently summarized this older literature.

J. F. D. Shrewsbury (1950) argues against a diagnosis of typhus, pointing out that Thucydides made no mention of either cloudy mental state or depression, both among the symptoms most frequently reported to accompany typhus infection over the last 500 years. Shrewsbury emphasizes the generally good personal and domestic cleanliness of the ancient Greeks, in order to argue that they were not lousy and thus could not have transmitted typhus with such ease. Yet Keil has provided an extensive survey of the words for lice found in Greek texts of the fifth century B.C., which indicates that they were hardly uncommon. Even so, Shrewsbury argues that typhus is too mild a disease to have killed a quarter of those who fell ill, and consequently, he holds that some "virgin soil" epidemic of a viral nature was the more probable cause of the Plague of Athens.

Measles Virus

Indeed, Shrewsbury favored a diagnosis of measles, as did classicist D. L. Page (1953). Shrewsbury points to similar levels of mortality in the severe, virgin soil epidemics of measles in the Fiji Islands in 1876, where more than 25 percent of the native population died. He considered the most significant passage in Thucydides to be the description of sufferers plunging themselves into cool water for relief. The Fiji Islanders displayed an identical behavior. Because even in the twentieth century, measles in adults could be malignant, causing severe diarrhea and pneumonia, he argued that the Plague of Athens may have been measles in its "pristine, virulent, early form," not the "emasculated" modern virus. Page agrees that the Plague of Athens was measles, feeling that the clarity of Thucydides' account was such that little support can be found in the text for other diagnoses; that is to say, Thucydides, although a layman, was not guilty of omitting crucial diagnostic details that medical contemporaries would have noted.

Smallpox Virus

Robert J. Littman and M. L. Littman (1969), however, argue for smallpox as the disease called the Plague of Athens, on the basis of the specific terms used by Thucydides to describe the exanthem or rash of the infection in question. Using Page's careful retranslation, the Littmans place emphasis on both the term φλύκταιναί ("small blister" or "pustule") and word ἕλκος ("ulcer" or "sore"), and contend that the description could refer only to a vesicle-forming eruption. In other words, Thucydides' description suggests a diagnosis of smallpox, because neither measles nor typhus typically forms vesicles in the exanthem. Moreover, the description hints strongly at the centrifugal spread of the rash, from face and trunk to extremities, again confirming a diagnosis of smallpox. The fact that Thucydides does not mention pockmarks among the survivors is found by the Littmans to be without import because they believed he was more concerned with the military impact of the disease than long-term effects on the survivors. In addition, the Littmans point to the absence of reference to pockmarking, even in some twentieth-century medical accounts of smallpox.

Other Explanations

Edna Hooker (1958) has been the last scholar to incline toward a diagnosis of bubonic plague, although many scholars found this a popular diagnosis during the first third of the twentieth century. Littman and Littman, however, argue against the bubonic plague, dismissing any possibility that the terms Thucydides chose could refer to buboes (lymphadenopathy associated with plague).

Another hypothesis, put forth by P. L. Salway and W. Dell (1955), suggests that ergotism, caused by fungal toxins in grain, explains the Plague of Athens even though Athenians rarely ate rye bread, the grain on which ergot usually grows. The occurrence of gangrene in extremities of victims who survived is, they maintain, an important symptom, which does not support the other diagnoses, but does support one of ergotism. John Wylie and Hugh Stubbs (1983) have provided a review of those infections with a wide host range that might have caused this level of human mortality 2,400 years ago, and thus they consider zoonoses other than plague and typhus. More recently, Alexander Langmuir and his colleagues (1985) have revived a pre-twentieth-century diagnosis of influenza virus, but emphasize that concurrent or subsequent staphylococcal infection could easily have created a "toxic shock" syndrome, with severe respiratory symptoms, bullous (or vesicular) skin infections, and violent gastrointestinal symptoms. As staphylococcal infection heightened the mortality from influenza in 1918, so a similar combination of viral and bacterial infection could explain the great Plague. On the other hand, Holladay (1986) takes issue with this latter explanation.

Methods of Historical Epidemiology

Study of the epidemic briefly described by Thucydides has inspired discussions of how diseases in the distant past can be identified, and thus discussions of the methods of historical epidemiology. There are three difficulties that emerge in the literature of the Plague of Athens that can and have presented themselves in other retrospective diagnostic efforts. First has to do with "virgin soil" epidemics. Although Thucydides only implies that all members of society were at risk of contracting the sickness, that no one was immune, and that immunity was conferred on the survivors of infection, he does specifically state that the disease was previously unknown to lay and medical Athenians. Some scholars hold that a new disease among a population immunologically virgin to the microorganism in question need display neither the expected seasonal onset characterizing the disease

nor the case-fatality rates usually seen. Those who oppose this methodological stance hold that this principle of retrospective analysis calls into question all diagnostic precepts. Many assume that supramortality would cause a breakdown in normal nursing care and hygienic services, leading to excess mortality; therefore, they stress the need for distinguishing the socioeconomic effects of a virgin soil epidemic from discussions of the virulence of the disease or the immunologic vulnerability of the population.

The second difficulty pertains to the changing epidemiology (or even clinical presentation) of diseases over time and thus is a variation of what is called "virgin soil epidemics argument": that infections of the past may have been caused by an organism known today but that the organism behaved quite differently in past individuals and populations. As Littman and Littman (1969) observed, "[A]s diseases adapt to new hosts under changing environments over the passage of years the symptomatology may change." From a historical standpoint, this can be a particularly pessimistic argument, and, in fact, James Longrigg (1980) has disallowed the possibility of ever discovering the cause of the Plague on much these grounds: "Epidemic diseases inevitably become modified in the course of centuries of alternating widespread prevalence and quiescence and . . . symptoms can, in any case, vary considerably in accordance with diet." Poole and Holladay (1979) go even further in denying any possible resemblance of the Plague of Athens to an infectious disease known in more recent times, whereas Langmuir and colleagues (1985) suggest that the discussion abandon altogether the hope for a one-to-one correspondence with a modern infectious disease and look instead to a physiological understanding of the processes involved.

The third difficulty focuses on the intent and fidelity of Thucydides' account to actual events. Of the authors discussed in this essay, only Watson Williams (1957) argues that Thucydides himself might not have been terribly well informed about the epidemic, because he did not write his history until after 404 B.C., approximately 25 years after the epidemic had taken place. Williams further suggests that even if Thucydides wrote from notes or consulted one of the few physicians who survived (the account claims that most died early in the epidemic), individuals tended to believe that their own experience with an infection was characteristic of all those who suffered from it.

Most assume, however, that Thucydides' account of the events lacks some crucial details from a modern point of view, but is otherwise accurate. Since

Page's review, which offers abundant detail that Thucydides was particularly well versed in medical terms and ideas, most have come to believe that the account was informed by contemporary medical knowledge. Longrigg (1980) argees, but skeptically considers the possibility that Thucydides "dramatically exploited [the Plague] for historiographical purposes." On the other hand, Jody Rubin Pinault (1986), tracing an ancient legend that Hippocrates himself devised the successful remedy of building fires to combat the epidemic at Athens, argues that Thucydides' "silence about this remarkable achievement of Hippocrates" is compelling evidence that he was not at all well versed about the Plague.

Clearly, discussions of the causes of the Plague of Athens form an important and instructive example of the study of the history of human infectious diseases. In addition, such a study reveals the many pitfalls connected with this type of integration and points to the need for still more sophisticated methods and techniques.

VIII.108
Pneumocystis Pneumonia (Interstitial Plasma Cell Pneumonia, Pneumocystosis)

This form of pneumonia is caused by *Pneumocystis carinii,* a protozoan of uncertain taxonomic status in the class Sporozoa. An extracellular parasite of the lungs of humans, dogs, rodents, and other mammals, the organism occurs worldwide. It appears to be of low virulence and almost never causes disease except in weak or immunosuppressed individuals. *P. carinii* was discovered in guinea pigs in 1909, but human disease was first recognized in the 1940s in malnourished and premature infants. Patients suffering from leukemia, Hodgkin's disease, and other immunosuppressive diseases, or organ transplant recipients and other patients whose treatment requires suppression of the immune system, are also vulnerable to infection. In the early 1980s, pneumocystis pneumonia achieved prominence as the most common opportunistic infection afflicting patients with acquired immune deficiency syndrome (AIDS). Over half of all AIDS victims suffer from this form of pneumonia, and it frequently is the proximate cause of death.

Transmission is usually by airborne droplets, although transplacental passage resulting in fetal death has been reported. Latent infection may be common, with clinical disease and droplet transmission developing only in weakened hosts. The parasite damages the alveolar walls and induces an abundant foamy exudate and fibrosis. Death results from asphyxiation due to the exudate. Although initial response to chemical therapy is common, treatment is difficult because of side effects of the drugs and the debilitated state of the patients.

Pneumonia

Pneumonia is an acute inflammatory condition of lung parenchyma (lung tissue excluding the airways) caused by a variety of infectious agents and toxins and favored by aspects of the environment and/or the general physical status of the patient. The term "pneumonia" is derived from the Greek word περιπλευμονιη meaning "condition about the lung"; the word refers to a clinicopathological state that arises in several different yet specific disease patterns. All of these are characterized by some degree of fever, cough, chest pain, and difficulty in breathing. Technically speaking, *pneumonitis,* which means "inflammation of the lung," is a synonym for pneumonia, but the former is usually reserved for benign, localized, and sometimes chronic inflammation without major toxemia (generalized effects). Many modifiers and eponyms are applied to the term pneumonia to reflect the cause (e.g., *embolic* pneumonia) or the localization (e.g., *pleuro-* or *broncho-* pneumonia). The classic form is *lobar* pneumonia, an infectious but not particularly contagious condition usually localized to part or all of one of the five lobes of the lungs, and caused by a pneumococcus, the gram-positive organism *Streptococcus pneumoniae* (formerly called *Diplococcus pneumoniae*). Untreated lobar pneumonia has a mortality of about 30 percent, but the advent of antibiotic treatment has improved survival rates.

Several other pathogens (bacterial, viral, fungal, and parasitic) are recognized causative agents. The extent of the pulmonary involvement; the onset, pattern, and duration of symptoms; as well as the mortality rate depend on both the causative organism and precipitating factors. Chemical irritation, environmental exposure to noxious substances, or hypersensitivity can occasionally cause pneumonia. *Aspiration pneumonia* is a chemical-related condition, arising when vomited gastric acid is taken into the lung (along with oropharyngeal bacteria) by a patient in a weakened or semicomatose state induced by drugs, alcohol, anesthesia, or other disease. This type of pneumonia is readily complicated by superinfection by one or more organisms.

In many cases, pneumonia is only one manifestation of another specific disease such as the acquired immune deficiency syndrome (AIDS), ascariasis, cytomegalovirus, influenza, Legionnaire's disease, plague, pneumocystis, Q fever, rickettsial diseases, tuberculosis, tularemia, and varicella.

Etiology and Epidemiology

Many pathogens have been associated with infectious pneumonia. Bacterial varieties include *Escherichia coli, Hemophilus influenzae, Klebsiella pneumoniae, Legionella pneumophila, Mycobacterium tuberculosis,* staphylococci, and streptococci. Common viral agents are arbovirus, cytomegalovirus, influenza, measles, respiratory syncytial virus, and varicella. Other pathogens include *Mycoplasma pneumoniae, Blastomyces, Nocardia, Pneumocystis carinii,* and the rickettsial pathogen *Coxiella burnetii.* This list is far from exhaustive.

Despite the large number of pneumonia pathogens, the disease develops only if other host or environmental conditions are met. Normally the airways and lung tissue distal to the throat (glottis) are sterile. Occasionally, organisms that are always present in the upper airway, in the digestive tract, or on the skin enter the lung. Ordinarily they are rapidly eliminated either by mechanical means, such as by coughing and the microscopic action of cilia, or by immune mechanisms. Infection and the resultant inflammation of pneumonia can occur in healthy individuals, but are often associated with a breakdown in one or more of the usual defense mechanisms or, more rarely, with exposure to a particularly virulent strain of pathogen or an unusually high aerosol dose of organism (as in Legionnaire's disease). Occasionally, *bacterial pneumonia* will occur as a result of septicemic spread from an infectious focus elsewhere in the body.

Immune defenses are altered by underlying debility, be it nutritional (starvation and alcoholism), infectious (tuberculosis and AIDS), neoplastic (cancer

or lymphoma), or iatrogenic. Iatrogenic causes of immune depression are becoming more important with the increasingly frequent use of immunosuppressive or cytotoxic drugs in the treatment of cancer, autoimmunity, and organ transplantation. One special form of immune deficiency resulting from absent splenic function leads to an exaggerated susceptibility to *S. pneumoniae* infection and lobar pneumonia. This condition, called *functional asplenia,* can arise following splenectomy or as a complication of sickle-cell anemia. Thus a relative predisposition to pneumococcal infection can be found in the geographic regions containing a high frequency of hemoglobin S.

Mechanical defenses are hampered by immobility due to altered consciousness, paralysis or pain, endotracheal intubation, and prior viral infection of the upper airway, such as bronchitis or a cold. Controversy surrounds the ancient etiologic theory about cold temperatures. August Hirsch (1886) found a high incidence of pneumonia in months having wide variability in temperature. Two factors do tend to support an indirect correlation between cold and pneumonia: Predisposing viral infections are more common in winter, and some evidence suggests that the mechanical action of cilia is slowed on prolonged exposure to cold.

Lobar pneumonia appears in all populations. Its incidence and mortality rate are higher in individuals or groups predisposed to one or more of the factors described above. Elderly patients frequently develop pneumonia as the terminal complication of other debilitating illness, hence the famous metaphor "friend of the aged" (Osler 1901).

Mortality rates for pneumonia are difficult to estimate because of its multifactorial nature and the fact that it can complicate other diseases. As mentioned previously, untreated lobar pneumonia can result in death in 30 percent of cases. With antibiotics, fatalities are reduced to a varying extent depending on the underlying condition of the patient, but in persons over the age of 12 years the mortality is at least 18 percent and in immunocompromised persons it is much higher. In the late nineteenth century, Hirsch suggested that the annual death rate averaged 1.5 per 1,000 in a survey of European and American municipal statistics (Hirsch 1886). Pollution of the atmosphere may have contributed to the apparent rise in pneumonia mortality in Britain during the last half of the nineteenth century (Howe 1972). William Osler saw pneumonia mortality as one of the most important problems of his era and applied to it John Bunyan's metaphor (originally

intended for tuberculosis), "Captain of all these men of death." Contemporary pneumonia mortality combined with influenza is still the sixth most common cause of death in the United States, where mortality is estimated to be approximately 0.3 per 1,000 (U.S. Public Health Service Centers for Disease Control 1989). Pneumococcal vaccination of high-risk groups with functional asplenia and other forms of debility has contributed to a decrease in incidence.

Other forms of pneumonia follow epidemiological patterns that reflect the frequency of the organism or causative toxins in the host's environment, as for example *Legionella,* which favors water in air-conditioning systems.

Clinical Manifestations

The incubation period for pneumonia is variable, depending on the causative organism, but pneumococcal pneumonia has a fairly uniform pattern. There may be a brief prodrome of coldlike symptoms, but usually the onset is sudden, with shaking chills and a rapid rise in temperature, followed by a rise in heart and respiratory rates. Cough productive of "rusty" blood-tinged sputum and dyspnea are usual. Most patients experience pleuritic chest pain. In severe cases, there can be inadequate oxygenation of blood, leading to cyanosis. If untreated, the fever and other symptoms persist for at least 7 to 10 days, when a "crisis" may occur consisting of sweating with defervescence and spontaneous resolution. With antibiotic treatment, the fever usually falls within 48 hours. Untreated, or inadequately treated, the disease may progress to dyspnea, shock, abscess formation, empyema, and disseminated infection. When empyema occurs, surgical drainage is essential.

Diagnosis is based on the classic history and physical findings. Dullness to percussion is detected over the involved lobe(s) of lung, and auscultation may reveal decreased air entry, crepitant rales, bronchophony, whispering pectoriloquy, and variable alteration in fremitus, which reflects the pathological state of the lung tissue as it progresses through edema to consolidation and resolution or suppuration. Confirmation of the diagnosis is made by chest X-ray, and the specific pathogen is identified in sputum stains and culture. Treatment consists of rest, hydration, oxygen if necessary, and antibiotics. The selection of the last is based on, or endorsed by, the culture results.

In the nonlobar forms of pneumonia with diffuse inflammation, the history may be atypical and physical examination unreliable. In these cases, chest X-ray and special cultures may be necessary. In some

cases, the precise identity of the pathogen is confirmed by serologic tests for specific and/or nonspecific antibodies (viral and mycoplasma pneumonia) or by immunofluorescence techniques (*Legionella*). When the patient is unable to cough or the inflammation is nonpyogenic, lung biopsy for microscopic inspection and culture is required (pneumocystis).

History

Antiquity Through the Eighteenth Century

Lobar pneumonia has probably always afflicted humans. Pneumococcal organisms have been found in prehistoric remains, and evidence of the disease itself has been observed in Egyptian mummies from 1200 B.C. (Ruffier 1921; Janssens 1970; Grmek 1983). Epidemics of this disease are probably less common than has previously been thought, however. In his pre-germ-theory observations, Hirsch cited sixteenth- to late-nineteenth-century reports of epidemic outbreaks of "pneumonia" in numerous places on six continents. He emphasized that nearly all these records drew attention to "the malignant type of disease" and the "typhoid symptoms" (Hirsch 1886). These qualifiers raise doubts about whether or not these outbreaks were truly pneumonia. It is probable that most, if not all, were caused by organisms other than pneumococcus. Conditions now called by another name and known to have pneumonic manifestations, like plague and influenza, are far more likely candidates for retrospective diagnosis (Stout 1980).

Pneumonia is not only an old disease, it is also one of the oldest *diagnosed* diseases. Hippocratic accounts of a highly lethal illness called *peripleumonin* give a readily identifiable description of the symptoms, progression, and suppurative complications of classic pneumonia and localize the disease to the lung. This disease was a paradigmatic example of the Greek theory that held that all illness progressed through *coction* (approximately, incubation and early illness) to crisis and lysis (breaking up), while certain days in this sequence were "critical" to the outcome (Sigerist 1951). These writers based the diagnosis on the symptoms, but the physical sign of "clubbing" or "Hippocratic nails" was associated with prolonged pneumonia. Auscultation was also recommended to confirm the presence of pus in the chest. Variant pneumonic conditions of the lung were also described, including lethargy, moist and dry pneumonia, also called *erysipelas* of the lung. Therapy included bleeding, fluids, expectorants, and, only if absolutely necessary, surgical

evacuation of empyemic pus (Hippocrates 1988; Potter 1988).

In the first century A.D., Aretaeus of Cappadocia distinguished this disease from pleurisy, and four centuries later Caelius Aurelianus recognized that it could be confined to only certain parts of the lung. Except for a few subtle modifications, little change occurred in the clinical diagnosis and treatment of pneumonia until the early nineteenth century.

Nineteenth Through Twentieth Century

It is true that eighteenth-century pathological anatomists drew attention to the microscopic appearance of the lung in fatal cases of lobar pneumonia. This work, however, had little impact on diagnosis until 1808, when Jean-Nicolas Corvisart translated and revised the 1761 treatise on percussion by Leopold Auenbrugger. This technique made it possible to detect and localize the presence of fluid or consolidation in the lung and to follow its evolution. Eight years later, Corvisart's student, René Laennec, carried this one step further when he invented the stethoscope. In calling his technique "*médiate auscultation,*" Laennec readily gave priority to Hippocrates for having practiced the "immediate" variety by direct application of the ear to the chest. Laennec recommended both percussion and auscultation of the breath sounds and voice to confirm the physical diagnosis of pneumonia. With this combination he was able to distinguish consolidated lung from pleural fluid or pus in the living patient. He introduced most of the technical terms for pathological lung sounds – including "rale," "rhoncus," "crepitation," "bronchophony," "egophony" – some of which became pathognomonic for disease states. In addition, he adopted Giovanni Morgagni's notion of "hepatisation of the lung," as a descriptive term for consolidation. Percussion and auscultation changed the concept of pneumonia from a definition based on classic symptoms to one based on classic physical findings. This conceptual shift was endorsed but not altered by the advent of the chest X-ray at the turn of this century.

The Italians Giovanni Rasori and Giacomo Thommasini had recommended high-dose antimony potassium tartrate (tartar emetic) as a treatment for pneumonia, and Laennec used the new method of statistical analysis with historical controls to suggest that this was an effective remedy. Yet in spite of its potential utility, the extreme toxicity of the drug guaranteed its unpopularity (Duffin 1985). Benjamin Rush, an American, and Laennec's contemporary, Jean Baptiste Bouillaud, were proponents of copious

"*coup sur coup*" phlebotomy. Until the late nineteenth century, when salicylates became available for fever, pneumonia therapy consisted of various combinations and quantities of the ancient remedies, emetics, mercury, and especially bleeding (Risse 1986; Warner 1986).

Germ theory had a major impact on the concept of pneumonia, but it was rapidly apparent that despite its fairly homogeneous clinical manifestations this disease was associated not with a single germ (like tuberculosis and cholera) but with a variety of pathogens. This situation cast some doubt on the imputed role of each new pathogen. In December 1880, Louis Pasteur isolated the organism that would later become the pneumococcus. Carl Friedlander discovered the first lung-derived pneumonia organism, *K. pneumoniae* (Friedlander's bacillus) in 1883. Albert Frankel identified the pneumococcus (*D. pneumoniae*) in 1884, and Anton Weichselbaum confirmed his findings in 1886. *Klebsiella* was found to be quite rare and seemed to favor the upper lobes, whereas the pneumococcus favored the lower lobes; however, there was some overlap between the pneumonic states induced by these organisms. Specific diagnoses could be made only by isolation of the pathogen in culture.

Gradually many other organisms and viruses came to be associated with pneumonia, usually in clinical settings that deviated more or less from classic lobar pneumonia. For example (and to name only a few), *H. influenzae* was isolated in 1918; *Mycoplasma pneumoniae* (the "Eaton agent" of "atypical pneumonia") in 1944; *L. pneumophila* in 1977 (Hudson 1979; Denny 1981; Stevens 1981; Levin 1984). It is likely that new pathogens will be recognized as antibiotics and vaccination alter the ecology of the lung.

Knowledge of the pneumococcus led to improvement in treatment and reduction in mortality from pneumonia, but it also had a major impact on the broad fields of immunology, bacteriology, and molecular genetics. Study of the capsule – its antigenic properties and capacity to transform – provided key information about drug resistance in bacteria: Acquired assistance of pneumococci was first recognized in 1912, long before the antibiotic era (Austrian 1981). Rufus Cole, Raymond Dochez, and Oswald Avery developed typologies for the pneumococci before and during World War I, and in 1929 René Dubos discovered a bacterial enzyme that decomposed the capsular polysaccharide of type III pneumococcus, a discovery that contributed to the later work of Jacques Monod (Benison 1976).

Treatment and prevention of pneumonia have been dramatically improved in the twentieth century. Oxygen therapy was introduced by William C. Stadie during the 1918 New York influenza epidemic (Harvey 1979). Typing of pneumococci led to the 1912 introduction of antisera by Rufus Cole, who claimed that, by 1929, this therapy reduced mortality in some populations to 10.5 percent (Dowling 1973). Antisera were effective only when the exact type of pneumococcus was known. Gerhard Domagk's Pronotosil (sulfanilamide) was not particularly effective against pneumococcus, but it did control other predisposing conditions. Its successor, sulfapyridine, was more effective. The advent of penicillin in the mid-1940s led to further reduction in mortality; however, it also led to the evolution of penicillin-resistant strains of pneumococci and the now seemingly endless chase after effective derivatives against so-called new organisms (Weinstein 1980).

Pneumonia control programs relied at first on antipneumococcal serum therapy, but as early as 1911, Almroth E. Wright conducted vaccination trials on thousands of black South African gold miners (Dowling 1973; Austrian 1981). These trials, conducted before the diversity of capsular types was fully appreciated, were inconclusive. It was not until 1945 that unequivocal demonstration of protection against type-specific pneumococcal infection in humans was demonstrated by Colin M. MacLeod and Michael Heidelberger using a tetravalent vaccine. Contemporary vaccines contain at least 23 capsular antigens and are 80 to 90 percent effective in immunocompetent persons, but may be useless in some forms of immunodeficiency.

VIII.110
Poliomyelitis

Poliomyelitis is an acute disease caused by inflammation and destruction of motor neurons after infection by a poliovirus. Sensory functions are not affected. Although frequently asymptomatic, the infection may cause fever and a number of other general symptoms, described as abortive polio or minor illness. Occasionally, however, these prodromal symptoms are followed a few days later by infection of the central nervous system (CNS) and fever, with meningitis, or paresis (weakness) or paralysis of one or more muscles. Many patients recover use of the muscle or some muscles affected in the following months, although some have permanent paralysis or paresis. When the muscles of respiration are affected, death may follow.

Other enteroviruses of the ECHO (Enteric Cytopathic Human Orphan virus) and Coxsackie groups may also cause meningitis and paresis, or temporary paralysis. In the past, cases of abortive polio and those with paralysis who later recovered were often included in statistics as polio cases. Today, only cases with paralysis or paresis after 3 months are recorded as paralytic polio.

Poliomyelitis was known by several names until the 1870s, when it became known as acute anterior poliomyelitis. Among them was Heine–Medin disease (after two early researchers, Jacob von Heine and Karl Oscar Medin) and infantile paralysis because it affected mainly young children. As more adults and older children were affected, poliomyelitis – inflammation of the gray marrow – became the name of choice and is often shortened to polio.

Etiology and Immunology

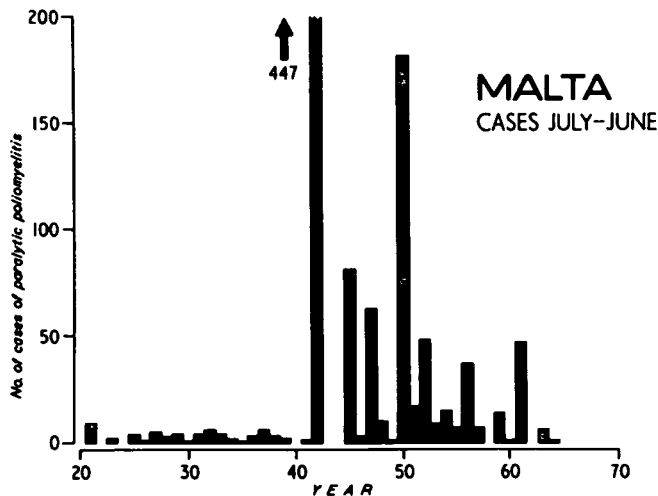
There are three immunologic types of poliovirus, with strain differences in each, and there may be minor cross-reactions between types 1 and 2. Within each type there is a wide range of ability to cause paralysis, from the highly virulent type 1 Mahoney strain to avirulent wild and vaccine strains. Wild


Figure VIII.110.1. Cases of paralytic poliomyelitis in Malta, 1920–64. Epidemics always occurred in the winter, with no cases in June to July even in other years; the cases are counted from July of one year to June of the next to emphasize the epidemics. Cases are those notified except for 1942, when late-diagnosed cases are included. In the late 1950s and early 1960s, inactivated poliovirus vaccine (IPV) was given to groups already mostly immune. In 1964 oral poliovirus vaccine (OPV) was given to all age groups and, from then on, to young babies and children.

strains may cause only a few cases of paralysis while immunizing other children. The introduction of a new virulent strain, however, may cause an epidemic, as in Malta in 1942 (Figure VIII.110.1). Strains differ widely in their transmissibility: In Malta, the pattern of cases among children in villages, among British servicemen, and in the next epidemic suggests that everyone in the island was rapidly infected. There are many other examples, however, of small epidemics without further cases in the region. The new technique of genomic sequencing has shown that small epidemics, many hundreds of miles apart, may be caused by viruses that are very similar.

The virus spreads from person to person via the fecal–oral route, although a few epidemics may have been caused by contaminated milk. Ingested virus replicates in the gut and associated lymphoid tissue. After 2 to 3 days, there is viremia lasting until about day nine, when the virus is neutralized by serum antibody. The level of viremia correlates with virulence; there is little or no viremia with avirulent strains. Animal experiments suggest that the level of antibody that protects is below the threshold of detection.

Exposure to virus leads to lifelong immunity to viruses of the same type. Although people who are

immune have some gut immunity, they may still be infected but they have no viremia and shed less virus for a shorter time. Humans are the only natural host and reservoir, although other primates may be infected experimentally or accidentally.

Since 1910 it seemed that immunization might be feasible. The first attempts in 1935 ended with cases and deaths attributed to the vaccines. Many vaccines were made for experimental use only, but a vaccine for humans was not possible until the virus could be grown in quantity outside the central nervous system of monkeys, the number of antigenic types could be established, and cheap methods of titrating virus and antibody could be developed. J. F. Enders, T. H. Weller, and F. C. Robbins grew poliovirus in human tissue culture in late 1948 and solved all three problems. In 1951 Hilary Koprowski fed an attenuated virus to 20 adults.

In 1953 Jonas Salk injected an inactivated vaccine (IPV) into over 100 children, and in the following year the vaccine was given to 400,000 children in an elaborate field trial involving 1.8 million children. The effort was successful, but a slightly different vaccine was finally licensed. Vaccine from at least one manufacturer – Cutter Laboratories – contained live virions, and there were about 250 resulting cases in what was called the "Cutter incident" of 1955. Manufacture and safety testing of the Salk vaccine were tightened but at the cost of reduced antigenicity. In the 1980s, a purified and more antigenic IPV was produced that required two doses instead of three to produce lasting immunity.

Two early attenuated oral poliovaccines (OPV), the Koprowski and Cox–Lederle vaccines, had been given trials in several countries but were abandoned. Use of the Cox–Lederle vaccine in West Berlin in the spring of 1960 was followed by a few cases that might have been vaccine-associated. On the other hand, inflammation in a muscle, caused by an injection, can greatly increase the chance of paralysis, and it may be that a drug such as thalidomide, which causes peripheral neuritis, might act in the same way, although without the localization that is the hallmark of provocation polio. Thalidomide, which was in use in 1960, caused peripheral neuritis, and analysis of the cases is consistent with the theory that thalidomide made those taking it more susceptible to CNS invasion by the vaccine virus.

In the 1950s A. B. Sabin produced an oral polio vaccine (OPV), which has been used extensively throughout the world. The advantages of the Sabin vaccine are many: (1) It can be given by nonmedical staff under supervision; (2) it induces gut immunity;

(3) it is inexpensive; and (4) immunity spreads to others not given the vaccine. Yet there are disadvantages: (1) Three separate doses are required; (2) it is quickly inactivated by heat; and (3) the virus reverts toward virulence and causes some vaccine-associated cases (VAC). Although there is no evidence that it can harm pregnant women, the Sabin vaccine is not given to them. About one child in a million given OPV develops paralysis. Early figures of risk were based on doses, not children, and included large numbers who were already immune and so not at risk. Hypogammaglobulinemic children are at risk from OPV, and a small number (about 2 percent) develop a chronic CNS infection with paralysis. A very small number of contact VAC occur, mainly among mothers of children given OPV. The number of such cases depends on the number of people who have not been immunized by vaccine or wild viruses.

Oral polio vaccine has been used very successfully in countries with temperate climates but less so in many warmer developing countries. The problems have been largely due to lack of cold-chain facilities (to prevent heat inactivation) and organization. The most effective method of immunization is the once or twice a year "polio day" pulse program. Distribution of the vaccine is made a few days before immunization to local immunization posts throughout the whole country, reducing the problems presented by the cold chain. On the day of immunization, which is heavily advertised in the media, all children 2 years and younger who are present are given OPV. The flood of virus shed by vaccinees then vaccinates any who did not receive OPV and displaces circulating wild virus.

Inactivated polio vaccine is more stable and may be combined with other vaccines such as that of diphtheria–pertussis–tetanus (DPT), thus simplifying immunization schedules and reducing cost. The latest IPV is very safe, highly purified, and antigenic. Although one dose may suffice, at least two doses are recommended.

Epidemiology

In most years it is very difficult to assess epidemics because there may be several polioviruses of different virulence and types circulating. Thus the extent of the circulation of the virulent viruses will not be known and the cases will not necessarily correspond to the geographic boundaries used for reporting. Moreover, because viruses change their virulence, the number of nonimmunes will be unknown. Surveys of immune status and examination of feces for virus are expensive and time-consuming, and sam-
Figure VIII.110.2. Case-fatality rates for poliomyelitis based on records from (X) England and Wales, 1947–50 (average of male and female rates; 28 notified cases); (O) Denmark, 1947–50 (28 paralytic cases); (●) France, 1952 (average of male and female rates; 28 notified cases); (■) Sweden, 1935–44 (28 confirmed paralytic cases); (+) Eskimos, Chesterfield Inlet (14 cases); (□) Cutter vaccinees (27 cases); (△) West Virginia (18 cases); (▲) Malta, 1942–3 (service cases, 20–30 years of age, no. of cases not specified); (▽) Sweden, 1911–13 (5 cases). [From Harold V. Wyatt. 1975. *Medical Hypotheses* 1 (1): 35–42, by permission of Churchill-Livingstone, publishers.]

ple only a tiny fraction of a given population. Thus our epidemiological knowledge of the disease is very dependent on virgin soil epidemics in islands and isolated communities with definite boundaries that contain many nonimmunes.

After an epidemic in 1919, polio was made a notifiable disease in Malta. About three cases were reported each year (Figure VIII.110.1) until 1942, when almost 3 percent of children under 3 years of age were stricken. Other epidemics followed at intervals of 2 or 3 years. Some of these epidemics were probably caused by the importation of virulent viruses from Egypt by returning Maltese in 1919, 1945, and 1947 and by the arrival by overnight flight of about 250 RAF men in 1942. Nearly all the Maltese cases were children under 5 years of age.

Prior to the 1930s, most polio cases occurred in young children, except in small isolated communities where older children, adolescents, and even adults were sometimes affected. Beginning in the 1930s, however, there was a shift to older children and adolescents, first in Scandinavia and the United States, and then in Europe. The older children suffered less paralysis, and, as Figure VIII.110.2 shows,

the case-fatality rate was low. By contrast, young adults had paralysis and case-fatality rates like those of small children. In many severe epidemics, the case-rate for 2-year-olds has been about 2 percent with increasing rates up to about 10 years of age, when the rate stabilizes at 25 percent. In a virgin soil epidemic among an Eskimo population in 1948, 2 out of 53 children and 25 percent of adolescents and adults were paralyzed.

Incidence in monozygotic and dizygotic twins suggests genetic susceptibility, and there are families who have had many cases over several generations. Yet, the overall level of familial incidence is low, and genetic susceptibility has been largely discounted. On the other hand, the changes in paralysis and case-fatality rates at about 3 years of age can be explained if two groups are genetically susceptible – the 2 percent of the population who are homozygotes and the 24 percent who are heterozygotes. This model suggests that genetic susceptibility is a maturation process, with about half the homozygotes becoming phenotypically susceptible at 1 year of age and all at 2 years. Heterozygotes would mature more slowly, reaching 24 percent at about 10 years.

Early epidemiological surveys often included all cases whether there was residual paralysis or not, and cases of abortive polio were also frequently included, although diagnosis in these cases is difficult and uncertain. From the late 1930s, it became increasingly common to restrict inclusion in the statistics to those with paralysis, and later only to those with residual paralysis. In countries where there is universal immunization and very few cases, each suspected case is investigated. A positive virus isolation or a rise in antibody titer between acute and convalescent sera is evidence of poliovirus involvement. Polioviruses are tested for affinity to vaccine and wild strains.

Distribution and Incidence

At all ages, there are more male than female cases. However, pregnant females have a higher incidence of poliomyelitis than nonpregnant females of the same age. Attempts to explain these differences have been unsuccessful. The case-fatality rates of males and females are similar. Studies of many hundred pregnant women with polio showed no increase in miscarriages, and there were no affected births. Moreover, 48 stillborn or aborted fetuses showed no signs of polio. A few fetuses have been examined for virus, which was isolated from many organs. The one stillborn fetus tested was positive for virus in the CNS (Wyatt 1979).

Yet when the mother had suffered paralysis between 7 days before and 10 days after birth, 40 percent of the babies suffered concurrent paralysis, with a 56 percent case-fatality rate. By contrast, babies born of mothers who had experienced paralysis earlier in the pregnancy (nonconcurrent) had a less than 0.01 percent chance of polio in the month after birth and only a 10 percent case-fatality rate. The few babies born by Caesarian section of mothers who contracted polio just before birth were not affected. Babies with paralysis 0 to 10 days after birth had a very short incubation time – 6 days – as compared with 12 days for concurrent cases in babies with paralysis 11 to 28 days after birth.

When a nonimmune person who is infected with a virulent poliovirus receives an injection of an inflammatory substance into a muscle, the chance of paralysis occurring 7 to 18 days later is much increased. In many cases, the muscle receiving the injection is the first paralyzed and the extent and severity of paralysis may also be increased. The phenomenon, called *provocation,* was recognized in 1950, when mass immunization with diphtheria–pertussis–tetanus vaccine (DPT) began. Risk of provocation was much reduced by giving DPT in winter when circulation of poliovirus was minimal. Sterile saline and human gammaglobulin did not provoke. Provocation had first been described, but not named, in 1914 when nearly a quarter of 22 babies with congenital syphilis were paralyzed with polio after treatment with multiple injections of Salvarsan. Further epidemics with 25 percent case-rates were noted in Rome between 1936 and 1947 among similar children given multiple injections of Salvarsan (arsphenamine) and, later, penicillin. Similarly, nonepidemic polio among children with congenital syphilis in Rome and London showed case-rates up to 25 times the rate in ordinary children, and simliar rates were seen in epidemics in the South Pacific in 1932 and 1951.

The degree of provocation increases with the ability to produce inflammation: Thus vaccines with adjuvants are more provocative than those without. Single injections may increase the risk up to 8 times, whereas multiple injections may increase the risk 25 times.

Injection of live poliovirus, as in the Cutter incident, may cause paralysis with features similar to provocation polio but with a shorter incubation. *Toxocara* infection increases the risk of polio: The dead larvae in the muscles may act as centers of provocation.

Tonsillectomy – but probably not tonsillotomy – increases the risk of paralysis and especially the risk

Table VIII.110.1. *Comparison of paralysis of lower limbs in temperate and developing countries*

| Regions | N | Percent of cases with involvement of: | | Coincident injections |
		Lower limbs only (mean %)	Lower limbs plus other paralysis (mean %)	
Tropical and sub-tropical, 1938–78[a]	6,278	85	89	very common
Temperate, 1905–50[b]	10,694	49	79	probably none
Singapore, 1946	116	48	72	few or none
Malta, 1942	420	51	–	very few

[a]Based on 12 papers: from Sri Lanka (1 paper), Madagascar (1), India (5), Nigeria (2), Congo (1), Cameroun (1), and Bahrain and Kuwait (1).

of bulbar polio. The increased risk not only is immediate but also persists for 5 or more years. The incubation time immediately after the operation is from 7 to 17 days – the same as for ordinary polio – which implies that entry of the virus does not occur directly in the oropharynx but only after viremia.

As immunity to polio is mediated by antibody, all hypogammaglobulinemics should be particularly susceptible. Before antibiotics, most of these children probably died of bacterial infections, but from 1950 to 1960, of 154 children and adults with inherited or acquired hypogammaglobulinemia, only 8 developed polio – about the number expected on the genetic model. Only about 2 percent of hypogammaglobulinemic children – about 10 percent of VAC children – develop polio after OPV has been given. The incubation is longer than 28 days; there is a high mortality after a long chronic illness, with abnormal lesions in the CNS and no reversion to virulence of the virus. Hypogammaglobulinemics are about 10,000 times more likely than other children to develop polio after the oral administration of polio vaccine.

Clinical Manifestations and Pathology

During the prodromal stage, there is viremia, and replication of virus occurs in the muscles. There may be muscle pains as well as fever. About 25 percent of those infected may show signs of abortive polio. There are two theories as to how virus reaches the CNS. The first suggests that virus crosses the blood–brain barrier (BBB) and travels along neuronal pathways in the CNS. However, David Bodian showed

that virus traveled up the sciatic nerve at 2.4 mm per hour. Postmortems reveal that lesions in the CNS can be discrete and separate, suggesting that virus enters at numerous endplate junctions of motor neurons in the muscles and reaches the CNS at many different places. The time taken to reach the CNS from any muscle depends on the length of the nerve to be traveled, during which time the virus would be shielded from antibody. Virus could enter a nerve at any time from about the second to the ninth day. Virus entering from a foot muscle on the ninth day in a tall adult would reach the CNS about 18 days later. This model would account for the incubation of about 3 to 28 days. As viremia ends about the ninth day, the BBB model requires the virus to be 18 days in the CNS before producing symptoms.

Leg muscles are more often affected than arms, as indicated in Table VIII.110.1. In general, the larger the muscle the greater the chance of paralysis, and the smaller the muscle the greater the chance of paresis. Muscles are not affected at random. The neurons serving them lie in adjacent and overlapping bundles in the CNS: Damage in one bundle will often spill over into an adjacent bundle, so there is a high probability that both muscles will be affected.

Up to 60 percent of the neurons serving a muscle may be destroyed before there is a loss of function, and thus patients who have had nonparalytic CNS infection may still have suffered considerable damage. In one such patient who was examined after death from an unrelated accident, there were a number of separate regions of damage. Many survivors
Figure VIII.110.3. Numbers of publications about polio by year, 1890 to 1986. The figures are not entirely comparable: The *Current Bibliography of Poliomyelitis* includes some papers about other viruses; *Index Medicus* puts the entry for a single paper in more than one section, so that the number of papers is overestimated by perhaps 5 percent. Entries in the *Bibliography of Infantile Paralysis* are listed by year of publication, whereas other bibliographies list entries by year of appearance in the secondary serial (e.g., 6 months later). The effects of world wars, slumps, large epidemics, and notable research findings are apparent (see J. R. Paul 1971). The peak of papers in 1984 is due to an international conference held in 1983.

are suffering late effects of polio (LEP) more than 30 years later. Previously unaffected muscles become weak; already affected muscles become weaker; and in addition, generalized weakness and fatigue occur. The muscles most commonly affected are those that recovered well from the initial attack and have been used strenuously ever since. There is continual loss of motor neurons with age, and LEP may be the effect of normal aging superimposed on previous loss through polio.

In the acute stage, there is massive proliferation of lymphocytes in lymph nodes, and the picture in the CNS resembles a host-versus-graft reaction. Infected neurons are destroyed, although the inflammation does not correspond with the location of virus. Delayed hypersensitivity to poliovirus does not occur, even after many injections of vaccine. Moreover, the short response time suggests that the lymphocyte proliferation is a secondary response. Sabin showed that some adults gave a skin response to primate gray matter. One explanation could be that infected neurons are damaged with loss of function, but that more damage is caused by lymphocytes sensitized to motor neuron antigen. The proportion of damage caused by virus and lymphocytes may depend on the presence of antibody. In animal experiments, Bodian observed that 75 percent of infected neurons recover.

Second attacks by a virus of a different type presumably should occur; yet only 44 have been reported – far less than one might expect. This and animal experiments, however, suggest that second attacks are not blocked by antibody against poliovirus. Some hypogammaglobulinemics suffer a chronic infection, and animal experiments show that coincident infections with other enteroviruses can be synergistic.

History and Geography

Polio may be as old as humankind, but there are very few early indicators of the disease. An Egyptian stele from about 1400 B.C., now in the Carlsberg Glyptothek, Copenhagen, shows a young priest with a shortened, deformed foot in the typical equinus position of polio. In the 1830s, three small epidemics of the disease were reported from England, the United States, and the island of Saint Helena. In the 1890s and early 1900s, there were more serious epidemics reported in Scandinavia, Massachusetts, and Vermont, and then the great New York epidemic of 1916 occurred with over 9,000 cases in the city itself. Almost all the patients in the New York epidemic were under 5 years of age, and 2 percent of the children aged 2 years were affected. After this, polio cases in the United States fell to a low level, then showed peaks and troughs, and rose again to an annual average of some 40,000 cases from 1951 to 1955. As Figure VIII.110.3 shows, polio research accompanied these peaks and troughs.

After 1955, with the widespread use of the IPV in the United States, Canada, South Africa, Australia, and some countries in Europe, the number of cases fell dramatically. As not all children were immunized, small epidemics still occurred among the poor living in substandard conditions. But soon almost all the countries in temperate climates were using polio vaccine, and the potency of the vaccine was improved. Nonetheless, by 1960 in the United States in particular, there were doubts that IPV would eliminate polio.

By the end of 1960, however, Sabin OPV, given to more than 115 million people in Russia and Eastern Europe, had almost completely eliminated polio there. Gradually, opinion swung toward the routine use of the OPV instead of IPV, although Scandinavia and Holland continued to use IPV.

With these exceptions, beginning in 1961, OPV was increasingly used in countries with the most temperate climate, and the number of polio cases fell to even lower levels, although there were still small epidemics where wild virus struck communities that refused immunization or were not receiving primary health care. In the United States there are now about 10 cases a year, roughly half of which are vaccine-associated in vaccines or their contacts, or in hypogammaglobulinemic children.

In Holland, by contrast, there is a large community that rejects immunizations on religious grounds, and thus these people have suffered eight epidemics since 1960. The disease has not, however, spread to the immunized population. The last epidemic, which occurred in 1978, produced 110 cases of which 79 were paralytic (one baby died) and as a result of which the virus was carried to Canada. There were cases in Alberta, British Columbia, and Ontario, from which it was carried to Pennsylvania, and then to Iowa, Wisconsin, and Missouri, and then back to Canada, causing 21 cases and three nonparalytic attacks in North America. Genomic sequencing of virus isolates from this epidemic confirms that the same virus was involved for over 15 months and on two continents and that it may well have come from Turkey originally.

Polio was previously thought to have been of very low incidence in developing countries, although the disease occurred in such diverse and remote places as Saint Helena, isolated Greenland villages, and Nauru in the southern Pacific, which suffered very severe epidemics. Individual cases in undeveloped countries were noted especially among older Europeans, but it was assumed that almost all infants were infected while still protected by maternal antibodies, and that very few developed paralysis. De-

spite an outbreak among New Zealand troops in Egypt in 1941 and, during the next few years, among British and U.S. servicemen in the Middle and Far East and India, little attention was paid to the disease, the epidemics in Singapore, the Andaman Islands, and Bombay not withstanding.

Early data from developing countries were based on acute admissions to hospitals and, consequently, seriously underestimate the true number of cases. Indeed, even in the mid-1980s, statistics sent to the World Health Organization (WHO) from individual countries may represent only 10 percent of the true number of the cases. In 1977, by way of illustration, in Nigeria more children attended one physiotherapy clinic than the officially notified number of polio cases for that year for the entire country. A truer estimate of cases can be made by lameness surveys of children in schools supplemented by searches of villages for children so disabled that they do not attend school. Unfortunately, such investigations are always out of date, and do not include those who died of polio. It seems likely that the deaths among girls with polio may be quite high in communities where girls are not as highly regarded as boys.

Moreover, case-fatality rates for polio in developing countries are usually based on admission to hospitals and may therefore grossly distort those rates, as only the more serious cases reach those hospitals. Reporting polio cases as an incidence per 100,000 population can also be misleading, as the proportion of children in the population can differ considerably from country to country. The prevalence, based on the total number of cases by the age of 5 years (Figure VIII.110.4), is a better statistic for developing countries.

Even when data on all hospital cases are collected in developing countries, only about half of the cases are found. Up to 10 percent of these cases occur in babies under 6 months, although few studies are this specific (Figure VIII.110.4). Because they will have already had many infections, adults can be expected to have a high level of protective antibodies which mothers should pass on to their babies. Nonetheless, despite repeated infections, pregnant women may still have very low levels of antibodies, and consequently, about 20 to 40 percent of all polio cases occur before the first birthday. For immunization to be effective, all children must be immune by 6 months of age. As Figure VIII.110.4 indicates, giving vaccine to individual children over 1 year is wasteful, and resources should be targeted for the youngest age possible.

Figure VIII.110.4. Age of onset of cases of poliomyelitis in developing countries, compared with Miami, Florida, United States, 1948–9 (lower points and line). Remaining symbols represent data from samples: Africa (11), India (4), Malta (1), and Singapore (1). (Author's compilation.)
OPV can be given at birth but is more usually given at intervals some time after. The WHO has set up the Expanded Programme on Immunization (EPI), and Rotary International, Save the Children, and UNICEF are also involved in immunization projects. Thus, by June 1987, WHO estimated that 45 percent of children under 1 year in developing countries (excluding China) had received three doses of vaccine.

Very promising programs are underway in South America; and Argentina, Brazil, Chile, Costa Rica, Cuba, Nicaragua, and Paraguay have programs that reach more than 80 percent of their children below 1 year of age.

In Central Africa, by contrast, few countries achieve a 50 percent immunization rate of children under 1 year of age. Similarly, India, with 22 million children born each year, immunizes less than half, and many lameness surveys show a rising prevalence among older children in the 5- to 10-year age group, despite increased use of vaccine during the period. Indeed, in India, surveys of all kinds since 1945 have revealed a steady increase in prevalence. This increase may reflect better reporting and investigation or could be due to the widespread use of unsterile syringes and injections causing provocation polio.

The pattern of muscle paralysis in children in Nigeria is consistent with provocation after injections in the two large muscles. Many children with polio have a history of injections in the paralyzed muscles.

Protein–Energy Malnutrition

Protein–energy malnutrition (PEM) or, as it is still sometimes called, *protein–calorie malnutrition* (PCM), is a term of convenience that refers to a range of syndromes among infants and children of preschool age in whom manifestations of growth failure occur because of protein and energy deficiencies. In most instances this condition besets those in the less developed world of Asia, Africa, and Latin America, where dietary factors are thought to be a crucial part of the etiology. PEM thereby tends to exclude what is conventionally known as "failure to thrive" in Europe and North America, in which the vast majority of cases result from organic disorders such as cystic fibrosis or congenital heart disease problems and are not so directly associated with diet as such.

PEM is best described in its two clinical versions of *kwashiorkor* and *marasmus*. In the former, edema is always present, whereas extreme wasting (commonly defined as below 60 percent that of normal weight for height) identifies the latter. Much of the research in the 1950s and 1960s focused on differentiating between the symptoms and etiologies of kwashiorkor and marasmus, but since then it has become evident that cases purely of one or the other are the exception rather than the rule. The majority display both edema and extreme wasting, plus a variable mix of other symptoms, that have earned them the rather inelegant designation of *marasmic kwashiorkor.* In addition, far more common than all of the three put together are numerous subclinical syndromes, usually referred to as mild-to-moderate PEM. A frequent analogy for PEM, therefore, is an iceberg; only a very small proportion of the total is clearly visible. Most cases remain below the surface and go undetected except under close analysis.

Numerous attempts have been made to develop a logically ordered, comprehensive classification of PEM, but several problems have prevented the achievement of one that satisfies the demands of both clinicians and field workers. A particular dilemma is that the various syndromes are not static. Mild-to-moderate cases fluctuate considerably and can move in the direction of kwashiorkor, marasmus, or marasmic kwashiorkor in ways that remain unclear. Also, once established, the clinical conditions do not always stay constant until they are resolved. Kwashiorkor can become marasmus, and vice versa.

Another problem is what to measure, especially in the subclinical stages. Biochemical tests are expensive to perform, and in any event, they have not proved to be very reliable discriminators. As a result, anthropometric characteristics are relied upon. The simplest such indicator, and longest in use, is that of *weight-for-age,* a measurement that gives a reasonably good picture of current nutritional status, assuming, of course, that age is known accurately, which all too often is not the case. More critically, weight-for-age fails to differentiate between chronic and acute malnutrition. Because of these liabilities, the tendency today is to try to combine *weight-for-height,* which measures the degree of wasting, and thus the presence of acute malnutrition, with *height-for-age,* an indicator of stunting or chronic malnutrition. Other measures that have frequently been used in the field such as head and upper arm circumference and skin fold thicknesses add nothing to clarify the picture. They simply indicate if malnutrition is present but do not help in specifying the type.

Overriding the issue of anthropometric classification are the growth standards employed. Those in longest use were derived from studies of middle-class white Americans and are known as either the Harvard or Boston standards. More recently these have been superseded in international comparisons by those developed at the U.S. National Center for Health Statistics (USNCHS) based on a larger sample that cuts across ethnic and socioeconomic groupings. Most authorities tend to accept the position that with proper nourishment and general good health there are no significant human differences in infant and child growth patterns. However, some, especially in India, argue that there are differences, and that by using growth standards based on children of predominantly European ethnic backgrounds, a serious overestimation of malnutrition in many other parts of the world results. In point of fact, the issue of differential growth is still unresolved. Until it is, the safest procedure is probably to accept the USNCHS standards, while remembering that these are designed for comparative purposes only and do not necessarily represent growth objectives that should be sought for each and every population.

Etiology

Traditional interpretations have stressed the predominant role of diet in the etiology of PEM, with protein singled out as the most important missing ingredient. Critical shortages of protein alone, it was believed, would lead to kwashiorkor, and when these were combined with severe energy deficits, created by famine or other food crises, either marasmus or marasmic kwashiorkor would result. Mild-to-moderate syndromes simply reflected lesser shortages of the two essential dietary requirements, protein and calories.

Beyond food supplies, the behavioral variables deemed most critical in the past appeared to be the duration of breastfeeding and subsequent food habits. Too early weaning onto poor-quality substitutes for mother's milk such as rice water, sugar water, diluted milk or formula, and corn starch mixtures, was associated with marasmus. These substances are often contaminated with bacteria because of polluted water supplies and unsanitary preparation and cooking utensils, and consequently, repeated bouts of diarrhea were seen to accentuate the nutritional shortages. In addition, many cultures use starvation to treat diarrhea, a therapy that has further negative repercussions for the victim. Later-aged weaning onto predominantly bulky carbohydrate–low amino acid foodstuffs, notably cassava and plantains, was seen as the pathway to kwashiorkor. Abrupt weaning was believed to be especially hazardous, particularly if the child had to compete for food from a "common pot" with older siblings and adult males who often monopolize the high-quality protein foods such as meat, fish, eggs, and milk. With kwashiorkor the problem was the balance of protein and energy, not the quantity of food consumed, which generally appeared ample.

This portrayal has proved to be not so much erroneous as somewhat oversimplified. Clinical research has verified that kwashiorkor is always associated with low serum proteins, but considerable variation has been found in energy intake. Some cases show deficits, whereas in others energy levels are adequate and occasionally even excessive. Protein deficiency is clearly quite secondary to energy deficiency in marasmus and, in all probability, marasmic kwashiorkor. Indeed, if energy was not so severely restricted, it is unlikely that signs of protein shortages would be observable.

An extremely important finding is that diet does not seem to play quite the overarching role in PEM that was initially believed. What is critical is the availability of nutrients to the cells, and thus infections can act as an equal if not more important limiting factor. Included in these infections are not only the various diarrhea-producing gastrointestinal disorders, but also such widespread childhood diseases as pneumonia, measles, tuberculosis, and malaria. All can initiate symptoms of PEM by induc-

ing anorexia and by lowering amino acid levels, and it is clear that malnourished children are more susceptible to serious episodes of infection. The various syndromes of PEM, therefore, are best construed as resulting from complex nutrition–infection interactions. Based on current knowledge, it would appear that how they develop depends on how the life history of a child unfolds within a particular environmental context.

Many cases undoubtedly begin in the uterus. Because of widespread maternal malnutrition, low birthweights are common throughout Asia, Africa, and Latin America. Breastfeeding on demand during the first 4 to 6 months of life tends to compensate for any fetal growth deficit, while at the same time providing important disease immunities, but those infants who are not so fortunate as to be breastfed are well along a pathway to some PEM syndrome. If a serious infection should ensue at this time, then symptoms of marasmus might very likely develop. If not, then at the least, growth failure will continue, and the child will remain at risk.

After about the first half year of life, breastfeeding alone no longer provides adequate nutrition, and it is now that many children often begin to show signs of mild-to-moderate PEM. Food supplies might be limited generally, or perhaps there is little knowledge of proper supplements. In any event, the course PEM takes will depend on the severity of the food shortage – a "hungry season" seems to be especially dangerous – and once again on the infections to which the child is exposed. When nutrition–infection stress is extreme, then overt clinical symptoms of PEM can be expected.

Weaning is frequently a time of stress, and, when it occurs after 18 to 24 months of age, symptoms of kwashiorkor tend to predominate over those of marasmus, assuming that there is not a gross deficiency of energy in the new diet. However, weaning by itself does not appear to produce kwashiorkor; this is true even if the staple foods are overwhelmingly of the starchy variety. The child must enter this stage of life already nutritionally disadvantaged or otherwise in poor health before discernible symptoms of kwashiorkor emerge. Some analysts refer to a "prekwashiorkor state," but how such a state differs from other mild-to-moderate syndromes has not been demonstrated.

The overriding etiologic issue, of course, is poverty, and PEM is a problem only where poverty is pervasive. Poverty means that local food shortages cannot be overcome by purchases, that living conditions will foster recurring infections, that education

for effective intervention will be inadequate, that proper parental supervision of the feeding of infants and young children is likely to be missing, and that preventive and curative health services will not be readily available. In a very real sense, then, PEM is the outcome of "total deprivation." An acceptance of this fact has led to recent shifts in policies designed to combat it. For many years emphasis was placed on providing protein-fortified and energy-rich food substitutes or developing meat and dairy industries, but these approaches have proven to be too costly for most people in need, and they address only a small part of the problem. PEM must be attacked on a broad front, including economic and political as well as nutritional intervention.

Clinical Manifestations and Pathology

In the earliest stages of PEM, the child simply appears smaller than he or she should be for that age. If the condition deteriorates further, however, clinical symptoms will begin to emerge. Although the mix is likely to be complex, for ease of description the symptoms are still best portrayed as those characterstics of either kwashiorkor or marasmus.

The edema that defines all cases of kwashiorkor varies. It can be mild and localized on the extremities and sacrum or more severe and general. Although muscle wasting is discernible, subcutaneous fat is usually retained, and consequently the child takes on a bloated appearance, known as the "sugar baby" look in the West Indies. There also tends to be some growth retardation in head length and circumference.

More often than not there are skin changes, including ulcerating areas, open and healed sores, scabies, and a condition known as "flaky-paint dermatosis," in which removal of the flakes reveals lighter patches of skin. When kwashiorkor persists, the hair begins to be affected; it loses its luster, and dark hair becomes lighter. Curly hair straightens, and eventually the hair becomes brittle and falls out, leaving bare areas of scalp clearly visible.

Upon examination, the liver and spleen frequently are found to be enlarged, and a range of other symptoms have been documented. Among the more common are anemia and vitamin A deficiency, with some vision impairment, a range of micronutrient deficiencies, plus tendencies to hypothermia, higher bilirubin, hyponatremia, hypoglycemia, and very low plasma albumin.

Behavioral changes are quite marked. Vomiting and diarrhea become persistent; without resolution, anorexia usually sets in. As the child's strength

wanes, motor skills regress, and eventually he or she becomes almost totally apathetic to external stimuli. It is as if the burden of life has become too great to bear. Because of this withdrawal, treatment is difficult outside of a clinical setting where the child can be fed intravenously.

The overt symptoms of classical marasmus are far fewer and less medically unusual. There is extreme wasting of both muscles and subcutaneous tissues, and stunting is quite marked. Because the victim is so emaciated, the head appears abnormally large, especially the eyes. The skin tends to be dry and patchy, but dermatosis is not seen, nor are there any significant hair changes. Anorexia is uncommon, and, in fact, the appetite is usually good, which helps to simplify therapy. As in kwashiorkor, there is likely to be hypothermia and a tendency to hypoglycemia. Dehydration is a problem as marasmus worsens, and behavior changes from being fretful and highly irritable to a semicomatose state that immediately precedes death.

With severe PEM, mortality is high – over 20 percent. It is seldom, however, that starvation is the final cause of death; rather it is one or more of the infections that brought on the condition, and these usually run their fatal course in just a few days. Although there is some debate among authorities, the onset of hypothermia and hypoglycemia probably signals the need for immediate treatment.

For those children who have suffered mild-to-moderate PEM or who have recovered from one of the clinical syndromes, the question of long-term effects remains. The available evidence does support a relationship between chronic PEM and some permanent stunting, but this by itself cannot be considered a serious impairment to performance later in life. Indeed, stunting can be viewed as an adaptation to food shortages that conserves energy supplies. Nevertheless, there is one possible impact on skeletal development that does have serious repercussions. In areas where chronic PEM is prevalent, there also appears to be a high incidence of cephalopelvic disproportion among women, a condition that leads to birth difficulties, notably miscarriages, stillbirths, and heightened maternal mortality. The theory is that PEM somehow interferes with calcium metabolism, thereby producing incomplete pelvic development, but this has yet to be proven conclusively. Although the data are even less adequate, there is also some suggestion that later-aged cardiovascular, liver, and pancreas diseases might somehow be connected with childhood PEM.

The issue that has stimulated the most interest and

controversy, however, is the effect of PEM on the brain. A considerable amount of research has shown that subnormal mental and psychomotor functioning tends to follow PEM, and during the 1960s and 1970s it was common for direct causal connections to be made. Some investigators even hypothesized that severe attacks of PEM resulted in permanent mental disabilities. But once again important reassessments have been forthcoming. The earlier tests generally failed to control for the learning environment of their subjects, and thus to sort out all the other factors that might be contributing to poor performance, such as reduced mother–child interaction and a lack of stimulating surroundings upon which the child could act in order to learn. This illustrates yet another dimension of the "total deprivation" that surrounds PEM. Currently, the prevailing view is that neither mild-to-moderate nor acute clinical PEM seems to be associated with long-term intellectual and psychological disabilities, assuming, of course, that the necessary social interventions are made. The matter of permanent injury caused by chronic PEM, notably of the marasmic variety during the first year of life, however, remains unresolved. There may very well be irreversible brain damage in the more serious of these cases, as is strongly suggested by research on laboratory animals.

History and Geography

In one form or another, PEM is undoubtedly as old as humankind, and, indeed, the term marasmus has been used to refer to starvation for centuries. However, other than implying its incidence on the basis of reported past famines and general living conditions, the medical literature fails to mention PEM specifically until about the middle of the nineteenth century. It was around this time that concepts of malnutrition were beginning to develop, most notably among the new pediatric specialists in France and Germany, who were treating the numerous serious health problems of childhood, especially illnesses seen among foundlings and infants sent out to wet-nurse. One disorder, in particular, began to receive considerable attention. Known as *mehlnährschaden,* it was attributed to diets that were based excessively on flour, usually breads or thin gruels, with little milk or meat included.

At the same time, in the wake of colonial expansion, doctors in the field began to send back reports of a similar disorder from many tropical areas. Although the disease was initially thought to be caused by parasites (as virtually all diseases of the tropics were thought to be in the early days of diagno-

sis), by the 1920s a dietary etiology began to gain some acceptance. A proliferation of terms ensued, the more common being infantile pellagra, nutritional edema, infantile edema, starchy dystrophy, and fatty-liver disease. These were all describing, of course, what is now known as kwashiorkor, a term that was first used by Cecily Williams in the 1931–2 *Annual Medical Report of the Gold Coast* (now Ghana). She took the term from the local Ga language, in which it designates an ill child who has been "deposed" from the breast because of a new pregnancy.

Although terminological and etiologic arguments continued, by the 1950s the concept of kwashiorkor had become firmly entrenched in the nutrition literature and accepted by the medical community as a certifiable human disease resulting from a deficiency of protein. Continuing research into its causes and consequences led to the discovery of other syndromes and to the formulation of the more general concept of protein–calorie malnutrition. The word "calorie," however, was subsequently replaced by "energy" in the early 1970s when the international system of unit measures was adopted by the United Nations.

Some analysts argue that too much attention has been paid to kwashiorkor. They feel that researchers' obsession with this condition has diverted attention away from more important PEM problems and, in the process, has led to many inappropriate policy decisions because of a mistaken emphasis placed on the limiting role of protein. But a more plausible argument can be made that far less would be known about PEM today had it not been for the efforts expended on kwashiorkor. It provided the important first entry into the maze that PEM is now understood to be. In time, we hope, the full maze will eventually be mapped.

Distribution

At one time the general geography of PEM seemed straightforward. Kwashiorkor existed in the year-round wet tropical forest zones of Asia, Africa, and Latin America, where root and tree crops make up the predominant food staples. By contrast, marasmus was found in wet/dry areas because of seasonal or longer shortages of the staple cereal grains. Marasmus also predominated in the cities as a result of the substitution of bottlefeeding for breastfeeding. Changing etiologic knowledge has put this neat generalization to rest, and, in point of fact, little can be said about the precise distribution of PEM. Field surveys are limited in number, and many of them are of small sample size. Additionally, studies are difficult

to compare because of temporal differences and differences in measurements. About the best that can be done with the data at hand is to portray a rough regional patterning, knowing that there will be many shortcomings and, in the process, hope to identify the main trouble spots. Two recent studies have attempted just such an exercise; one has used the more widely available weight-for-age information, whereas the other has relied upon weight-for-height (wasting) calculations, converting other measures where possible. Both have employed USNCHS growth standards and a variable sample of countries within the parameters of the World Health Organization's regionalization scheme.

What emerges from these two efforts is a focus of PEM in the Southeast Asia region. Some 52 percent of preschool children are estimated to fall below 80 percent of the weight-for-age standard, led by Bangladesh with 91 percent and India with 75 percent. No country in the region shows a prevalence of wasting (defined as greater than 2 standard deviations below the norm) among 12- to 23-month-olds under 10 percent. Once again, Bangladesh and India are at the upper extreme, with 53 percent and 43 percent, respectively.

Both the Africa and Eastern Mediterranean regions show 35 percent deficient by the weight-for-age criteria, and of the countries included in the surveys, only Yemen and Mali stand above 50 percent. Wasting totals are generally in the vicinity of 10 percent, but there are two countries that register exceptionally high totals: Malawi (36 percent) and Somalia (66 percent).

On both measurement scales, the less developed countries in the Americas fare much better. The regional below-weight-for-age average is 21 percent, and all countries except one show a less than 10 percent incidence of wasting. That lone exception is Haiti, where the figure is calculated at 18 percent, still far lower than figures for many places in Asia and Africa.

Limited trend data suggest some lessening of the incidence of PEM since the 1960s, an observation supported by declining infant and child mortality rates. This is true even in Africa, where scenes of famine have created the image of spreading malnutrition. Still, there is little room for complacency, given the magnitude of the problem that remains and the fact that poverty has proved to be intractable in many areas. Certain populations, notably landless rural laborers and the rapidly growing numbers of urban unemployed, seem to be sinking ever deeper into poverty and therefore could well be expe-

riencing an increase in PEM. Also, wars and civil strife provide ideal breeding grounds for PEM. The examples of Ethiopia and Kampuchea are vivid reminders of what can happen in the wake of political turmoil.

Protozoan Infections

Protozoa are one-celled animals or animal-like eukaryotic (having an organized nucleus) organisms. Older classifications treated the Protozoa as a phylum in the animal kingdom, but modern taxonomists generally consider them members of a distinct kingdom, the Protista, along with other simple eucaryotes. Three phyla (or classes) of Protozoa have species pathogenic for humankind: (1) The Sarcomastigophora – the flagellates and amebas – include trypanosomes, leishmanias, and parasitic amebas; (2) the Ciliophora – the ciliates – have only one human pathogen – *Balantidium coli*, an intestinal parasite with wide distribution but, usually, little clinical significance; (3) the Apicomplexa – the sporozoans – include many important pathogens, including the four species of *Plasmodium* that cause malaria.

VIII.113
Puerperal Fever

Historically the terms *puerperal fever* and *childbed fever* referred to any acute fever occurring in puerperae during the first few days after delivery. Less frequently, the terms were also applied to symptomatically similar diseases that occurred during pregnancy or even among the newborn. From a modern point of view, what was formerly called puerperal fever includes a range of disorders most of which would now be referred to as puerperal sepsis. Typically, puerperal sepsis involves postpartum infection in the pelvic region, but it can refer to disorders focused in other areas, such as mastitis. In modern usage, the term puerperal fever occurs mainly in discussions of the great fever epidemics that afflicted maternity clinics in earlier centuries.

Etiology and Epidemiology

A wide range of aerobic and anaerobic microorganisms have been associated with acute pelvic inflammation and with other postpartum inflammations that could be identified as puerperal fever. Group A streptococci (pyogenes) were probably the leading

causal agent in most puerperal fever epidemics in earlier centuries. However, since the 1970s, group B streptococci (agalactiae) have become the most prevalent causal agent.

Clinical Manifestations and Pathology

Among puerperae the clinical manifestations of puerperal sepsis include acute fever, profuse lochial flow, and an enlarged and tender uterus. Onset is generally between 2 and 5 days after delivery. Normally there is inflammation of the endometrium and surrounding structures as well as of the lymphatic and vascular systems. One also finds pelvic cellulitis, septic pelvic thrombophlebitis, peritonitis, and pelvic abscesses. Among neonates, infection usually becomes apparent in the first 5 days after birth, but onset is sometimes delayed by several weeks. Symptoms include lethargy, poor feeding, and abnormal temperature. Infection by group B streptococci is often clinically indistinguishable from other bacterial infections.

History and Geograpy

The Hippocratic corpus contains case histories of puerperal fever. Various epidemics were recorded in the sixteenth and seventeenth centuries. The disease was first characterized and named in the eighteenth century when serious epidemics began to appear with regularity in the large public maternity clinics of Europe. In the late eighteenth and early nineteenth centuries, various English and American obstetricians concluded that puerperal fever was sometimes contagious. Alexander Gordon and Oliver Wendell Holmes argued that physicians could transmit the disease from one patient to another, and they recommended various measures to reduce the frequency of such accidents. By the early nineteenth century, the disease was responsible for a mortality rate of between 5 and 20 percent of maternity patients in most major European hospitals. Smaller hospitals had outbreaks in which, through a period of several months, 70 to 100 percent of maternity patients died from puerperal fever. The etiology of the disease was unclear, although seasonal patterns and its high incidence in the maternity clinics seemed to suggest that it was usually due to a local poison conveyed through the atmosphere. By the middle of the nineteenth century, the disease was receiving a great deal of attention in the medical literature, and cases were being reported from around the world.

In 1847, Ignaz Semmelweis became assistant in the Vienna maternity clinic. The incidence of puer-

peral fever in the Vienna hospital was about 7 percent, which compared favorably with other hospitals around Europe. However, the Vienna clinic consisted of two divisions, one for obstetricians and the other for midwives; the first division consistently had a mortality rate three to five times greater than the second division. After several months of intensive investigation, Semmelweis concluded that the difference was due to decaying organic matter, usually from autopsied corpses, which was conveyed to patients on the hands of the medical personnel in the first clinic. He introduced washing in a chlorine solution for decontamination, with the result that the mortality rate in the first clinic dropped below that of the second. However, incidence of the disease had always been seasonal, and most obstetricians were unpersuaded.

By 1850 Semmelweis had become convinced that decaying organic matter was responsible for all cases of puerperal fever – even for the relatively few cases that occurred in the second clinic. Indeed, he provided an etiologic characterization of puerperal fever in which it became true by definition that all cases of the disease were due to contamination. Given Semmelweis's definition it also followed trivially that puerperal fever was not a unique disease but only a form of sepsis. Semmelweis had virtually no evidence for this strong position. His critics immediately cited cases in which women died from puerperal fever without ever having been exposed to decaying organic matter. Semmelweis responded that in such cases the decaying matter must have been produced internally, perhaps by the decomposition of blood or of placental fragments. Even the physicians who accepted his initial results rejected this bold and apparently unwarranted claim.

By the 1860s, Louis Pasteur's work on fermentation and putrefaction drew attention to the possible significance of microorganisms in some disease processes. Building on Pasteur's work, and certainly aware of Semmelweis's theories, Carl Mayrhofer examined the vaginal discharges of more than 100 healthy and diseased patients in the Vienna maternity clinic. In 1865 he identified and described various microorganisms that seemed to be present only in discharges from women suffering from puerperal fever.

Using the best techniques that he had available, Mayrhofer isolated these organisms, cultured them in solutions of sugar, ammonia, and water, and then reproduced the disease by introducing the organisms into healthy test animals.

Mayrhofer's work was unimpressive to his col-

leagues in Vienna, but it received considerable attention in Berlin. Within a few years a number of writers, many of whom explicitly based their work on the discoveries of Semmelweis and of Mayrhofer, were studying the microorganisms that were identified in puerperal fever and in other forms of sepsis. Through the middle decades of the nineteenth century, most of those who wrote on wound infections gave prominent attention to puerperal fever. These included Edwin Klebs, Robert Koch, and Pasteur. In 1879 Pasteur identified the streptococci that were the principal cause of the disease. By this time, it was apparent to most observers that puerperal fever was actually a form of sepsis. In this sense, therefore, puerperal fever ceased to exist as a unique diagnostic or theoretical entity.

Classical studies in the early decades of the twentieth century led to the serologic classification of streptococci and to the recognition that group A strains were the most prevalent agent in puerperal fever. Group B streptococci were first reported in puerperal sepsis in 1935 and recently have displaced the group A strains as the most prominent agents in puerperal sepsis in the United States and Great Britain. Infections of group A streptococci are generally exogenous and affect puerperae, whereas infections of group B pathogens are usually endogenous and, although the mother may be affected, generally strike the fetus or neonate. The change in relative frequency of causal agents, therefore, has had important ramifications in clinical manifestations, prophylaxis, and therapy. The development and use of various antibacterial agents have obviously revolutionized the management of puerperal sepsis. Improved care for delivering mothers has also had an important impact, and in recent years liberalization of abortion laws has reduced the incidence of puerperal sepsis associated with illegal abortions. However, control of sepsis is now recognized to be more difficult and complex than might once have been believed, and it remains a particularly difficult problem in Third World countries where medical care is not readily available. Therefore, although the incidence of puerperal sepsis has been drastically reduced, taken collectively the various forms of this disorder continue to be a leading cause of maternal and neonatal death throughout the world.

Q Fever

The "Q" in Q fever stands for "query," the designation applied by E. H. Derrick to an acute illness with fever and severe headache of unknown cause occurring in abattoir workers and dairy farmers in Queensland, Australia, in 1935. Despite the discovery of the causative agent, a rickettsia-like organism, this unenlightening name has remained current, although an alternative is abattoir fever. Q fever, occurring in epidemics in military personnel stationed in the Balkans and Italy during World War II, was known as *Balkan influenza* or *Balkan grippe*.

Q fever is caused by infection with *Coxiella burnetii*, previously known as *Rickettsia burnetii*, and is the sole member of the genus *Coxiella*, family Rickettsiaceae. It was initially confused with viruses, but though *C. burnetii* is an obligate intracellular parasite, it has a true bacterial cell wall.

Q fever is a zoonosis of worldwide distribution, and many species of animals, birds, ticks, and other biting insects are natural hosts. In animals, naturally acquired infection appears to be asymptomatic so that Q fever is not of any economic significance to farmers. Transmission to humans occurs via inhalation of con-

taminated dust while infected animals, carcasses, or animal products are being handled; via laboratory accidents; and sometimes via tick bite and the consumption of unpasteurized milk. Asymptomatic infection is common. Illness may take two forms. *Acute* Q fever is usually a self-limiting febrile flulike illness or atypical pneumonia lasting up to 4 weeks. Untreated, the fatality rate is less than 1 percent. *Chronic* Q fever may develop months to years later, presenting as endocarditis and/or hepatitis. Endocarditis usually occurs in those with preexisting heart valve disease; untreated, it is usually fatal.

Distribution and Incidence

The distribution of acute Q fever is worldwide, but chronic Q fever appears to be more limited, most cases being reported from the United Kingdom, Australia, and Ireland. In the United Kingdom, *Coxiella* infection accounted for 3 percent of all cases of endocarditis reported by laboratories during 1975–81. In other countries, it is still rare enough for individual cases to be reported in the medical literature. This anomaly may be due to underdiagnosis in most countries or perhaps to differences in the virulence of prevalent strains. Acute Q fever affects predominantly adult men, and there is a well-recognized association with certain occupational groups such as farmers, abattoir workers, and veterinarians. Q fever often occurs in seasonal spring and autumn peaks associated with lambing and calving.

It is certain that Q fever is very considerably underdiagnosed so that accurate national incidence figures are not available. In the United States by 1960, Q fever was recognized to be endemic in dairy herds throughout the country. Reports of human cases were uncommon but increased steadily from 1948 to 1977. Over this period, 1,164 cases were reported to the Centers for Disease Control. Although most states reported cases, fully 67 percent of them were from California, where there is a very high prevalence of infection in cattle and consequently a high proportion of cattle excreting organisms in milk. Reported infection in humans, however, is relatively rare, with only 148 being reported from 1970 to 1978. Seroprevalence surveys of cattle in the United Kingdom suggest that about 3 to 5 percent of dairy cattle and 2 to 6 percent of sheep have been infected. About 100 to 200 cases are reported by laboratories each year, and 10 percent of these are chronic infections.

Epidemiology and Etiology

Coxiellae differ from other rickettsiae in not needing an arthropod vector for transmission. Two cycles of

natural infection have been recognized. In the wildlife cycle, transmission between wild animals and birds occurs from tick bites, from inhalation of dust, and, possibly in carnivores, from ingestion of infected placentas and meat. Ticks are infected from the blood of an infected host, but transovarial spread has also been documented. Coxiellae multiply in the tick gut and salivary gland, and transmission occurs by biting or when tick feces contaminate broken skin. In the domestic animal cycle and in human infection, tickborne infection is considered less important, and transmission occurs usually from inhalation of contaminated dust and possibly from direct contact with infected animals. Cows, sheep, and goats are the main reservoirs for human infection. In these animals, coxiellae localize in the genital tract and udder and are excreted in vast numbers in milk, birth fluids, and placentas without usually causing disease or a drop in milk yield in cows, although abortion may occur in sheep and goats. Recent investigations have implicated rabbits and parturient cats as possible sources of human infection.

Coxiellae are very resistant to environmental conditions, surviving for months or years in dust or animal litter. Experiments have shown that these organisms can survive in 1 percent formalin for 24 hours, on wool for 7 to 9 months at 20°C, in dried blood for at least 6 months at room temperature, and in tick feces for at least 18 months at room temperature; they can also survive temperatures of 63°C for up to 30 minutes. The latter observation is important since it places coxiellae at the border of resistance to high-temperature, brief-interval milk pasteurization. However, there is still dispute about whether symptomatic Q fever can be acquired from drinking contaminated milk, although the prevalence of antibodies is raised in raw milk drinkers. Person-to-person spread has been documented but is very unusual. Laboratory accidents are a serious hazard when working with live organisms, and for this reason routine diagnostic laboratories seldom attempt isolation.

The vast number of organisms excreted by infected animals, the dissemination of the organisms in dust by wind, the hardy nature of the organism, and the low infective dose for humans (said to be one organism) explain a characteristic feature of Q fever – the occurrence of localized, explosive outbreaks often without an obvious source of infection. Moreover, even when the source of infection is identified, such as sheep used in medical research institutions, human cases occur in people only indirectly exposed by being in the vicinity of the animals.

Immunology

The serologic diagnosis of acute, as opposed to chronic, Q fever was considerably helped by the discovery of phase variation in the organism. Coxiellae isolated directly from animals or ticks are in phase 1; in this phase, specific antibodies are induced that are detectable by complement fixation and other serologic tests. When coxiellae are passed serially through chick embryo yolk sacs, phase 2 organisms become predominant. Passage of phase 2 organisms through animals causes the predominant phase to revert to phase 1. It has been found that phase 1 antigen reacts with late convalescent serums from inoculated guinea pigs; and phase 2, with early convalescent serums in guinea pigs.

Within 2 weeks of acute infection in humans, all or most patients will develop IgM, IgG, and IgA antibodies against phase 2 and IgM antibodies against phase 1, detectable by indirect immunofluorescence tests, as well as complement-fixing antibodies to phase 2. The IgM antibody titer declines rapidly after 2 to 3 months. Phase 1 IgG, IgA, and complement-fixing antibodies may be detectable after about 4 weeks, but do not reach high titers unless chronic infection ensues. In chronic Q fever, there are usually high titers of IgG antibodies detectable by immunofluorescence and complement fixation to both phase 1 and 2. However, IgM antibody is either absent or present in very low titers, and there are high titers of IgG to phase 1.

The presence of IgG antibodies is associated with immunity, but cell-mediated immunity is known to be important as well. The phase 1 antigen used in vaccines gives far better protection than phase 2 vaccines. The intradermal skin test using diluted vaccine may be employed to identify patients who are already immune and who are more likely to have hypersensitivity reactions to the vaccine. Vaccination is followed by a rise in phase 1 IgM antibodies and phase 2 IgM, IgG, and complement-fixing antibodies at low levels.

Clinical Manifestations and Pathology

Subclinical infection is common. Only 191 of 415 newly infected persons were symptomatic in an outbreak in Switzerland in 1983, caused when infected sheep were driven from mountain pastures through several villages on the way to market. The clinical features of acute Q fever are shared by several other infectious agents, and diagnosis depends upon serologic confirmation. Illness begins 2 to 4 weeks after exposure, with the incubation period possibly varying with the infecting dose. There is sudden onset of fever, sweating, shivering, rigors, malaise, joint and limb pains, very severe frontal headache, retro-orbital pain and photophobia, and a mild nonproductive cough. Rash is uncommon. Untreated fever usually lasts 1 to 2 weeks, but pneumonia may persist for several weeks. Abnormal liver function tests are usual, but jaundice is less common. More than half of patients show "ground glass" infiltration due to pneumonitis on chest X-ray, even though severe respiratory symptoms are unusual. Rarer complications of acute Q fever are meningoencephalitis, cerebellar ataxia, coma, myocarditis, pericarditis, infiltration of the bone marrow by granulomas leading to bone marrow failure, orchitis, and placentitis. There may be splenomegaly and lymphocytosis.

Liver biopsy reveals small granulomas containing fibrinoid material. In animal models, coxiellae persist for long periods in liver, spleen, and lymph nodes and may multiply in the placenta during pregnancy and so be excreted in vast numbers during parturition. There is some evidence that this may occur also in humans.

Chronic Q fever is usually considered a rare occurrence, particularly, but not exclusively, affecting patients with preexisting aortic or mitral valve malformations or disease and occurring from several months up to many years after acute infection. However, the absence of a history of acute Q fever, preexisting heart valve disease, or exposure to animals and animal products does not exclude the possibility of chronic Q fever. Illness begins as a low-grade fever with night sweats, anemia, joint pains, finger clubbing, heart murmur, and developing heart failure. There is usually hepatosplenomegaly. Coxiellae can be isolated from vegetations on damaged or prosthetic heart valves. Vegetations may embolize. Abnormal liver function tests are usual, and chronic Q fever may sometimes present as chronic liver disease.

Acute Q fever can be treated successfully with tetracyclines, chloramphenicol, and erythromycin, but chronic Q fever is difficult to treat. Prolonged administration of combinations of tetracyclines, rifampicin, lincamycin, clindamycin, and cotrimoxazole have been recommended, but eventually heart valve replacement may be unavoidable. Reinfection of prosthetic valves has been described, possibly occurring as a result of persistent extracardiac infection.

History and Geography

In 1935, an outbreak of a febrile illness among meat workers in Brisbane, Australia, was investigated by E. H. Derrick, director of the Laboratory of Microbiol-

ogy and Pathology, Queensland Health Department, at the request of the director-general of Health and Medical Services for Queensland. In 1937, Derrick published the first report of a new disease which he called Q fever "until further knowledge should allow a better name." He went on to show that guinea pigs could be infected by inoculating blood or urine from febrile patients, and that extracts of guinea pig liver and spleen could transmit infection to other guinea pigs. In collaboration with Derrick, F. M. Burnet and Mavis Freeman (1937) searched for a virus in extracts of guinea pig liver using animal inoculation experiments and identified a rickettsia-like agent that was called *Rickettsia burnetii*. In the United States, G. E. Davis and H. R. Cox (1938) reported the isolation of an organism from *Dermacentor andersoni* ticks collected at Nine Mile Creek in Montana in 1935, which they called *Rickettsia diaporica* because of the ability of the agent to pass through bacterial filters. It was later proved to be identical with *R. burnetii*. Its infectivity for humans was unhappily demonstrated by laboratory-acquired infections. Cox showed that the Q fever agent differed significantly from other rickettsias, and it has been placed in a separate genus, *Coxiella*.

The most significant aspects of the history of Q fever, following its discovery, were the discovery of the importance of the domestic animal cycle, the recognition of the military significance of Q fever, the high risk for laboratory workers, and the development of vaccines.

In his original paper, Derrick speculated that transmission was due to blood-sucking insects and that the organism had an animal reservoir. He identified the bandicoot as a reservoir of infection. However, the wildlife cycle initially suspected by Derrick has not proved to be a significant source of human infection. The domestic animal cycle is far more important and explained the epidemic of Q fever during and after World War II when thousands of troops in the Balkans and Italy were infected.

The epidemic in question began in southern Yugoslavia in March 1941, and involved more than 600 troops. Further outbreaks occurred in northern Yugoslavia, the Crimea, Greece, the Ukraine, and Corsica. A German physician, H. Dennig (1947), described more than 1,000 cases, half of whom had pneumonia. Risk of illness was associated with sleeping on hay or straw. Further outbreaks in 1942, 1943, and 1944 were noted in German troops exposed to sheep and goat flocks. Following the Allied invasion of Italy, Allied troops shared the Q fever epidemic. From February to March 1945, 511 cases

of atypical pneumonia were admitted to two military hospitals in Naples. Other outbreaks occurred in Italy, Greece, and Corsica.

The military significance of Q fever was now clear. The attack rate among exposed troops was very high and illness was prolonged. For example, of 160 men billeting in a hay barn, 53 (or 33 percent) developed Q fever. Of 900 men on a training exercise, which included sitting in a barn loft to watch training films, 267 (or 30 percent) became ill. From December 1944 to June 1945, more than 1,700 cases were diagnosed in Allied forces. After the war, outbreaks occurred from 1946 to 1956 among Greek and Swiss troops, in 1951 among U.S. servicemen in Libya, and in 1955 among French soldiers in Algeria. The factors contributing to the epidemic among troops were the sudden exposure of susceptible people to infection, particularly by sleeping on straw and hay (the local indigenous population was apparently unaffected by the epidemic), the rapid movement of infected flocks during wartime, and the mixing of infected and uninfected flocks. This was well illustrated in 1974 and 1975 in Cyprus. An outbreak of abortion affected sheep and goats from flocks herded together to escape the Turkish invasion. In a camp near the place where the flocks grazed, 78 British soldiers developed Q fever.

The importance of domestic animals as the reservoir for human infection was further emphasized by outbreaks in the United States, where the first naturally acquired U.S. cases were reported in 1941 in two patients from western Montana who had not received tick bites. In March 1946, 55 of 132 livestock and meat handlers in a plant in Amarillo, Texas, developed Q fever, and two died. In August of the same year, a similar outbreak occurred in Chicago. Further studies revealed sporadic cases, particularly in California. During outbreaks that occurred in 1947, city residents living near dairy farms were infected, probably by dust carried in the wind. In northern California, cases were associated with sheep. *Coxiella* was isolated from cow and sheep milk as well as from air and dust.

Laboratory-acquired infection was one of the earliest problems caused by Q fever. During 1938–55, 22 incidents involving over 250 cases were recorded. In one military institution, 50 cases were recorded during 1950–65. In 1940 an outbreak occurred in the U.S. National Institutes of Health in which 15 workers were infected. In this and other laboratory-associated incidents, infections occurred not only in those directly handling the organism but also in those who worked near or walked through the labora-

tory buildings, an observation that emphasized the importance of the respiratory route of infection. In the 1970s, attention was drawn to the serious risk of working on infected animals in research institutions, and interest in developing a safer and more effective vaccine was restimulated in the United States. In the 1980s, in both the United States and the United Kingdom, large outbreaks occurred that were associated with operative procedures on pregnant sheep.

The first vaccines for Q fever were developed principally to protect laboratory workers from infection. Used in the late 1940s and early 1950s, they had the drawback of provoking severe local skin reactions. In the 1950s, M. G. P. Stoker and P. Fiset (1956) reported the unique phenomenon of phase variation of *C. burnetii* (see Immunology section), which has proved of great value not only in diagnosing chronic Q fever but also in developing an effective vaccine. The first killed vaccines used were predominantly phase 2 antigens. In the 1970s in Australia, an upsurge of infection in abattoir workers as a result of a high number of feral goats slaughtered for export led to renewed efforts in vaccine development. Vaccines currently undergoing trials in Australia are derived from phase 1 organisms.

Following the original work in Australia, the United States, and the Mediterranean area, many other countries quickly identified cases. The first recorded human case of Q fever in the United Kingdom occurred in 1949, but seroprevalence surveys of domestic animals in 1952 showed infection to be widespread, with about 6 percent of dairy farms and 2 percent of cattle and sheep infected. These were statistics that did not significantly differ from surveys done in the 1970s. By 1953, 23 countries were known to be infected, and further surveys sponsored by the World Health Organization revealed that by 1956, 51 countries in all continents were infected. Only Scandinavia, Ireland, New Zealand, and the Netherlands were said to be free of infection. Since then, in Ireland there is good evidence that infection was introduced through importation of infected sheep from England in the 1960s, with the first indigenous cases being identified, retrospectively, in 1962. Today Q fever is known to be global in distribution, and it is likely that any patchiness in distribution reflects as much the differing levels of awareness of the disease as differences in disease incidence.

Rabies

Rabies is an acute viral encephalomyelitis or inflammation of the brain and spinal cord of humans and other mammals, especially carnivores. The disease, known since antiquity, is almost always transmitted to human beings in the saliva of biting animals and is almost invariably fatal. The name *hydrophobia*, "fear of water," and the French term *la rage* illustrate two common symptoms.

Distribution and Incidence

Rabies occurs in most of the world, including Africa, Asia, the Americas, and most of Europe. It has never occurred in, or has been eliminated from, Britain, Ireland, Sweden, Norway, Japan, Australia, New Zealand, Hawaii, and many other islands in the Pacific and the Caribbean. Rabies is primarily a disease of wild carnivores, particularly canids such as the fox, wolf, jackal, and coyote. Skunks and raccoons are also common hosts, as are many species of bats. Virtually any species of mammal can contract the disease when bitten by an infected animal. Domestic dogs are the major threat to humans; cats are a growing danger in North America. Cattle, horses, sheep, and other livestock may also be affected. Outbreaks among farm animals may cause considerable economic loss, but bovine or equine rabies usually poses little danger for humans.

Rabies is a relatively uncommon disease in humans, occurring sporadically as isolated cases or in small clusters. Epizootics develop at irregular intervals in wild carnivores, and may infect humans mainly through dogs or rarely directly. Persons working alone in remote areas, such as hunters, trappers, or shepherds, are vulnerable to attack by infected animals. Wolves are especially dangerous because their size and strength allow them to inflict multiple bites. Most human cases, particularly in developing countries, are acquired by the bites of "mad dogs," which were themselves victims of attacks by feral animals. Vampire bats in Trinidad and parts of northern South America are a source of rabies for cattle and, on rare occasions, human beings. Elsewhere, other species of bats can infect people and terrestrial animals, but this seems to be uncommon.

Human rabies has become a rare disease in developed countries. There were 236 cases in the United States between 1946 and 1965; only 11 occurred after 1960, and no cases at all have been reported in many of the subsequent years. Canada reported only 21 cases from 1924 to 1986, but Mexico recorded 76 fatalities in 1985 and 81 in 1986. In Africa, Ghana confirmed 102 cases from 1977 to 1981, whereas Ethiopia recorded 412 in 1982. India reported the highest annual number of cases in the early 1980s – that is, 20,000 – as well as the highest rate of infection – 28.8 per million individuals.

Etiology

Rabies is caused by a virus of the rhabdovirus group. The virus is a rod-shaped particle with a single strand of RNA for its genetic material. Large concentrations of virus are present in the saliva of sick animals and enter a new host through bite wounds. The virus is neurotrophic; it migrates along nerves to the brain, where it multiplies, causing grave damage manifested in part by behavioral changes in the victim. New viruses descend through efferent nerves to the salivary glands and hence into the saliva.

Epidemiology

Rabies circulates primarily in wild carnivores and only incidentally attacks domestic ones. Canids – notably foxes, wolves, and jackals – are the major reservoir in much of the world, although skunks, raccoons, mongooses, and other carnivores can also be significant hosts. Human beings are accidental and terminal hosts. The spread of rabies in skunks and raccoons, two species that have adapted with great success to suburban habitats, has caused concern in the United States during the 1970s and 1980s, but so far no human cases have been attributed. Opossums, rabbits and hares, rodents, and hoofed mammals can suffer and die from rabies, but they rarely transmit it.

Bats in Europe and the Americas are commonly infected, but, except for the blood-feeding "vampire" bats that plague cattle and even people in the Caribbean and parts of northern South America, their epidemiological significance is unclear. Transmission to humans and other animals is possible, but serologic studies of viral strains in the United States and Canada suggest that bat rabies is largely self-contained. Slightly different area-specific strains are found in terrestrial species in given areas, suggesting, for example, that foxes and skunks exchange a specific viral type. Species of bats in the same region tend to have a greater variety of strains, with none identical to that prevailing in local ground-dwelling animals. High-resolution serologic studies have been possible only since the early

1980s, and much more research will be needed to clarify fully the epizootiology of wildlife rabies.

Wildlife rabies tends to occur in irregular waves, and may spread over thousands of miles in a matter of a few decades. Control of rabies in wild animals by population reduction has generally been unsuccessful, and vaccines for use in wild mammals are still in the experimental stage. Monitoring local reservoir hosts can, however, alert public health authorities to the danger of possible cases among dogs and cats, and provide time to warn people to avoid wild animals and to control and vaccinate their pets. In the United States, where canine rabies has steadily declined for decades, the number of cases in cats began to exceed cases in dogs in 1980. This has resulted in widespread campaigns to vaccinate felines.

Animals may exhibit either "furious rabies," with agitated, aggressive behavoir preceding paralysis and death, or "dumb rabies," where the victim is lethargic and progressively immobile. The classic "mad dog," foaming at the mouth and wandering menacingly in the streets, does exist, but not all sick dogs display such dramatic symptoms. In northern Canada rabid foxes and wolves may become "crazy," wandering about settlements, mingling with sled dogs, and sometimes attacking the dogs or their owners. Normally nocturnal animals like skunks or raccoons may wander through inhabited areas in daytime and exhibit little or no fear of people or other animals. Unfortunately, such abnormal behavior can make small furry creatures seem "tame" and "cute"; many people have had to undergo an expensive series of rabies vaccine shots after handling "friendly" raccoons.

Although infection by virus-laden saliva is the only common way to contact rabies, two other mechanisms have been reported. Inhalation of virus in dust and contamination in surgery are possible, but both are very rare. High concentrations of virus may occur in dust in caves heavily populated by bats, and spelunkers have died of rabies after inhaling the virus. Laboratory inhalation of virus-laden aerosols has also caused infections. Cornea transplants from the cadavers of undiagnosed rabies victims have caused at least two deaths in recipients, but immunologic testing of donors should prevent future incidents.

Pathology and Clinical Manifestations

If infective saliva enters a break in the skin, viruses are carried from the site of the wound through the nerves to the brain. The incubation period of the disease varies from 2 to 16 weeks, depending on the site, severity, and location of the wound, and the size of the viral inoculation. Severe bites on the face and head are the most dangerous and have the shortest incubation periods, because the virus does not have far to travel. Infection results in destruction of cells in several regions of the brain and spinal cord and damage to the myelin sheaths of nerves. Clumps of viruses called Negri bodies are often seen on microscopic examination of affected cells and are useful in diagnosis.

Rabies patients commonly show restless, agitated behavior and hypersensitivity to minor stimuli. They frequently become extremely apprehensive or aggressive shortly after the onset of the disease. Convulsions and excessive salivation are common. Patients often suffer intense thirst, but have severe muscle spasms in the throat when they attempt to drink. This frequently develops into extreme hydrophobia, with the sight or even mention of liquids inducing terror and spasms. Within a few days this "furious" phase is followed by depression, paralysis, and death. The gruesome symptoms and the inevitability of death have made rabies one of the most frightening diseases in any culture where it is known.

There have been a handful of reports of survivors, but even the most intensive supportive care is generally futile, and there are no specific drugs or other therapies. Prevention is the only solution. Vaccinating dogs and cats, controlling strays, monitoring wildlife populations, and education are all essential. A preexposure human vaccine is available for persons at special risk, such as game wardens, veterinarians, and laboratory workers.

Fortunately, persons bitten by a rabid or possibly rabid animal can still be effectively vaccinated before the disease completes its long incubation period. If the biting animal is captured and shown to be rabid, or if it escapes but there are grounds to suspect that it might be rabid, prompt treatment is essential. Careful cleansing of the wound to remove as much virus as possible is followed by a series of injections of a serum (gamma globulin) that contains preformed antibodies to the virus. Human rabies immune globulin (RIG) has replaced an equine preparation in recent years. The key measure, a series of shots with a specific vaccine, is then begun.

The earliest vaccines were developed by Louis Pasteur in the 1880s, using rabbit spinal cord tissue. Preparations from brain tissues of sheep, goats, or mice are still used in some developing countries, but these vaccines are being replaced because they can cause severe allergic reactions. Duck embryo cultures were used to produce vaccine until human

diploid cell vaccine (HDCV) was developed in France and the United States in the late 1970s. This vaccine is cheaper and safer, and requires a shorter series of injections. A new, improved vaccine was released in the United States in 1988.

Proper postexposure prophylaxis is very effective, and must be given if there is any reasonable possibility of infection. It is, however, time-consuming and expensive. In the United States, where cases have averaged only one or two per year since 1965, some 20,000 to 30,000 people are treated annually, at a cost of about $400 each. India provided treatment to about 3 million victims of animal bites annually in the early 1980s, whereas El Salvador treated the world's highest rate of 4,570 persons per million population. A World Health Organization survey of 30 developing countries in 1980 showed an average of 3.7 rabies cases and 867 treatments per million population. The costs of rabies in lives, terror, and medical resources are considerable, especially in the Third World.

History

Literature

Rabies is one of the oldest documented diseases of humankind. Rare, but with spectacular symptoms and fatal outcome, it was and is an easily observed disease. Although some cases (particularly when an animal bite was not documented) could be confused with tetanus or with a neurological disorder like epilepsy, rabies cases are generally easy to recognize, even in old accounts.

Antiquity. Rabies may have been described in Mesopotamian texts as early as 2300 B.C., and was well known to ancient writers from China to Rome. The first certain reference in Chinese texts dates from the sixth century B.C., and the disease is described in a first-century Indian text. Rabies is also mentioned in a number of literary works from ancient Greece, including plays by Euripides, Xenophon's *Anabasis,* and perhaps Homer's *Iliad.* Aristotle's fourth-century *History of Animals* describes rabies in dogs and other domestic animals.

Roman medical writers of the first and second centuries, such as Dioscorides, Pliny, Galen, and especially Celsus, wrote extensively on rabies and established a number of ideas about the disease, which were influential in European and Islamic medicine well into the eighteenth century. In accordance with prevailing humoral doctrines, it was believed that dogs (or other animals) developed the disease from a

"corruption" of their humors, due to factors such as stress, cold, heat, or poisoning. Their saliva became poisonous, and bites carried the rabies poison or "virus" to humans or other animals. Celsus advocated bloodletting and cauterizing the wound with hot irons, a practice that, although harsh, might at times have cleansed the bite and one that was followed well into the nineteenth century. Celsus also suggested sudden immersion of the victim in hot or cold water, a practice that was also employed, at least sporadically, into the nineteenth century. Like his contemporaries, Celsus described a wide array of internal and external remedies of animal, mineral, and vegetable origins, none of which, based on modern knowledge, could have done any good. Pliny's unfounded belief that a "tongueworm" of dogs was responsible for rabies lasted as long as the ideas of Celsus.

Medieval Period Through the Sixteenth Century. Rabies continued to interest many medical and other writers after the fall of Rome and into the Middle Ages. Jewish authorities wrote about rabies in several passages of the Talmud. Numerous Christian writers in the West and the Byzantine Empire discussed the disease, following the humoral theories of Classical times. Medieval Islamic authorities such as Rhazes in the tenth century and Avicenna (Ibn Sina) in the eleventh century also worked in the Galenic humoral tradition and were strongly influenced by the views of Celsus. Avicenna gave good accounts of rabies in dogs, wolves, foxes, and jackals. He thought that their humors, notably the black bile, were disrupted by heat, cold, or ingesting putrified food or polluted water, resulting in rabies and "mad" behavior.

As in most medical matters, commentators on rabies in medieval western Europe had little to add to the comments of ancient and Islamic writers. In the thirteenth century, Arnold of Villanova wrote wrongly that dogs became rabid after eating corpses, but he did rightly stress the importance of thoroughly washing the bite wounds. Once symptoms of rabies appeared, many persons resorted to religious methods of healing. In much of western Europe, pilgrimages and prayers were directed to the shrine of Saint Hubert (who died in 727), a patron of hunters whose relics were kept in the Ardennes. Other saints were invoked elsewhere in Europe and among the Coptic Christians of Egypt.

Early modern medical authorities had little to add to the works of their predecessors. Girolamo Fracastoro, sometimes hailed as a sixteenth-century

forerunner of the formulators of the germ theory, considered rabies one of many diseases caused by "seminaria," something more like a seed or a self-replicating poison than a microorganism. He thought that it affected the heart and advocated cauterization of the wound. The sixteenth-century French surgeon Ambrose Paré gave a good clinical description and recognized central nervous system involvement.

Eighteenth Through Mid-Nineteenth Century. Perhaps because the disease was more common, or perhaps because of the growing volume of medical research and writing in general, the literature on rabies became much more abundant in the eighteenth and early nineteenth centuries. Autopsy studies were done (although without results, as the lesions are microscopic) and many more case reports and epidemiological observations were published. The growth of the literature was especially notable in France, where the Société Royale de Médecine, founded in 1776, took considerable interest in the problem. As of about 1750, many French and other physicians believed in the spontaneous appearance of rabies, possibly because some apparent cases were really tetanus, resulting from puncture wounds rather than animal bites. But within a few decades it was generally recognized that rabies resulted only from bites of rabid animals and that not all such bites, especially bites through clothes, transmitted the disease. Joseph-Ignace Guillotin, the inventor of the execution device popularized during the French Revolution, proposed an experimental approach to therapy. He wanted condemned criminals to be bitten by mad dogs so that clinical trials of various remedies could be conducted on them.

This scheme was not adopted, but some important experiments were undertaken in the 1790s and the first two decades of the 1800s. The prominent English physician John Hunter proposed saliva inoculation experiments in 1793 and in 1799. An Italian investigator, Eusebio Valli, claimed that the "virus" in saliva was made less virulent by gastric juice from frogs. He did not, however, publish his results, and his work seems to have had little impact. The first saliva inoculation experiments are credited to the German investigator Georg Gottfried Zinke, who published in 1804. Zinke, who was aware of Hunter's work and may have been inspired by it, was able to infect dogs, cats, rabbits, and birds; saliva treated with acids was not infective. In 1813 the French researchers François Magendie and Gilbert Breschet infected dogs and several other animals with saliva from a human rabies victim. Such results, repeated

and extended by others, discredited the views of some students of mental disease, who believed that rabies was not a physical disease but only the product of terror and imagination.

Nineteenth-century therapy, however, remained a hopeless melange of useless remedies, many inherited from medieval and ancient times. Doctors tried every possible treatment from drugs and purges to electric shock and immersion in the sea. Sedatives were often employed to ease the patient's suffering, and euthanasia may have been practiced.

Late Nineteenth Century. Modern knowledge of rabies etiology and prevention dates from the last half of the nineteenth century and is closely linked to the rise of experimental methodology and germ theory. Rabies was not common enough to be a major public health hazard, but it was spectacular enough to attract a fair amount of research. The work of Pierre-Victor Galtier, a French veterinarian, was especially important. In 1879 he published the results of experiments in which he maintained rabies in a series of rabbits. Galtier continued to publish on rabies, but the development of a vaccine was the climax of the career of another person, Louis Pasteur.

Pasteur published his first paper on rabies in 1881. Working with rabbits as advocated by Galtier, Pasteur was able to use dried spinal cord material as a dependable source of infectious material. By 1884 he had developed a method of attenuating the still unknown agent in dried rabbit spinal cords. The weakened infective agent, suspected by Pasteur of being a "microbe of infinite smallness," was injected into dogs. Unlike fresh preparations, it did not cause sickness, but instead provided protection against injections of virulent virus.

The first human trials were conducted in 1885. Pasteur and his associates could not inject a person with the virus in order to test the vaccine but, rather, had to treat a victim of a recent attack in hopes that the weakened virus in the vaccine would convey immunity before the virulent virus from the bite could cause disease. In July 1885, a 9-year-old boy, who had been badly bitten by a rabid dog, was brought to Paris within 2 days of exposure. Doctors were convinced that he had been infected, and Pasteur knew that the prognosis was hopeless unless the new vaccine was effective. The boy was given a series of injections with progressively fresher rabbit spinal cord vaccine. He lived, and eventually became concierge at the Institut Pasteur. A second victim was treated successfully in October, and 350 others were inoculated over the next several months. Only

one died – a girl who did not receive vaccine until over a month after exposure.

The Pasteur treatment was a major theoretical and practical breakthrough. It caused a public sensation, and people bitten by rabid or suspicious animals flocked to Pasteur's laboratory from all over Europe. Success rates were consistently high, especially if vaccine was promptly administered and if wounds were not on the head. Even with a long train ride to delay treatment, 35 of 38 Russians who had been bitten by rabid wolves were saved by injections. The French government promptly began to fund the work of the Institut Pasteur, branches of which were soon established elsewhere in France and its empire as centers of vaccine production and medical research.

Pasteur's associates, notably Emile Roux, and other workers developed methods of vaccine production and treatment. Research suggested a route from the bite through the nerves to the brain, but this was not proven until well into the twentieth century. The etiology of rabies remained a mystery.

Twentieth Century. In 1903 Adelchi Negri working in Italy discovered microscopic dark bodies in nerve cells of rabid dogs. He thought they were protozoans that caused the disease, but, although this proved erroneous, the Negri bodies were a useful diagnostic sign. Tests with mouse inoculation of suspect tissue, introduced in 1935, and various serologic methods have largely replaced histological examination for Negri bodies as tests for rabies in dogs and other animals.

Although Negri's protozoan theory attracted some attention, the search for the etiologic agent centered around the concept of "filterable viruses" – entities too minute to be retained by filters with pores small enough to hold bacteria. The virus was first seen in 1962; electron microscope studies in 1965 showed that the Negri bodies were clumps of viruses and antibodies.

Epidemics and Epizootics

Rabies epidemics and epizootics are difficult to trace before the twentieth century. In Europe, although there are many case reports, most descriptions are of isolated cases or small outbreaks. In 1271 rabid wolves invaded towns in Franconia (Germany), attacking herds and flocks and killing 30 persons. There was a fox epizootic in Frankfurt in 1563. Rabies seems to have been widespread in western Europe during the eighteenth and nineteenth centuries, possibly because population growth was disturbing the wildlife habitat and causing greater contact be-

tween feral mammals and domestic dogs. In 1701 Nancy, France, was beset by canine rabies and enacted laws against stray dogs. Paris responded to rabies cases in 1725 with a leash law, and other European cities followed with similar ordinances. Such restraints, as well as campaigns to rid the streets of strays, were seldom strictly enforced until there was a rabies scare.

A widespread epizootic in 1719–28 involved France, Germany, Silesia, and Hungary, and there also were many animal and human cases in Britain in 1734–5. Rabies was common in the greater London area in 1759–62 and in France, Italy, and Spain in 1763. A major epizootic developed in foxes in the Jura region of France in 1803; this outbreak apparently lasted until the late 1830s and spread over Switzerland and much of Germany and Austria. Outbreaks among wolves, foxes, and dogs continued throughout the century and caused hundreds of human deaths.

Rabies declined in the twentieth century, in wild and domestic animals as well as in humans. The disease was exterminated in Britain in 1922 and became rare throughout western Europe. In the early 1940s, however, a fox epizootic developed in Poland and since then has spread westward at a rate of 30 to 60 kilometers a year, reaching France in 1968. Denmark has defended itself by intensive fox control in a belt of territory near the German border; Britain is still protected by the Channel.

The history of rabies on other continents is little known. Sporadic cases and scattered epidemics occurred in Ethiopia prior to the twentieth century, a pattern that must have been common in other African and Asian countries. Rabies did not exist in Australia or New Zealand prior to English colonization in 1788, and seems to have been absent from the Pacific islands as well.

The antiquity of rabies in the New World is unclear. It is certainly possible that bat rabies existed in pre-Columbian times, and Arctic foxes and wolves could just as possibly have carried the virus from Siberia to Alaska and northern Canada centuries or millennia ago. Eskimo oral traditions suggest that the Eskimos were aware of rabies long before European contact. However, early European sources do not mention rabies among the American fauna, and a Spanish work published in 1579 specifically denied the existence of rabies anywhere in the "Indies." The first accounts of the disease are from Mexico in 1709, Cuba in 1719, Barbados in 1741, Virginia in 1753, North Carolina in 1762, New England in 1768, Jamaica and Hispaniola in 1783, and Peru in 1803. Because rabies is such

an obvious disease, at least when it afflicts domestic animals and people, and because it was so well known to both lay and medical observers, the absence of early reports could well indicate that rabies, at least in temperate and tropical America, was a late biological importation from Europe.

Fox rabies was known in the eighteenth century, and the disease was widespread in North American wildlife populations in the nineteenth century. Rabid skunks (hydrophobic or "phobey cats") were described in the Great Plains in the 1830s and in California in the 1850s. Most U.S. cases in the twentieth century have been reported in dogs, but since canine rabies is in decline as a result of vaccination and animal control measures, greater attention has been given to wild animals. Raccoon rabies was first described in 1936, and bat rabies, now recognized in 47 states, was first detected in 1953. An epizootic developed among raccoons in Florida in 1955, and spread slowly northward into Georgia and South Carolina in the 1960s and 1970s. Sportsmen transported infected raccoons from this focus to the Virginia–West Virginia border for hunting in the mid-1970s; and rabies has spread in both states and into Pennsylvania, Maryland, and Washington, D.C. Skunk rabies has been spreading slowly from two foci in the Midwest for several decades, and now extends from Texas and Tennessee to Montana and Manitoba. Fox rabies is widespread in the Appalachians. In Canada, an epizootic was recognized in the far north in 1947, but probably began in the 1930s or earlier. Foxes and wolves are the primary victims, and the epizootic has spread south into Ontario, Quebec, and the northeastern United States.

Wildlife rabies still represents a potential threat to Europeans and North Americans, but vaccination of pets should prevent more than an occasional human case. In developing countries such as Mexico or India, canine rabies is still a real danger, and relatively little attention has been given to wildlife reservoirs of the virus.

Relapsing Fever

Relapsing fever is a disease characterized by the occurrence of one or more relapses after the primary febrile paroxysm has subsided. Various types of relapsing fever are caused by blood parasites of the *Borrelia* group. There are two chief forms of the disease: the *endemic,* transmitted to humans by various ticks of the genus *Ornithodoros,* and maintained among a variety of rodents; and the *epidemic,* caused by a parasitic spirochete, *Borrelia recurrentis,* which is transmitted by human head and body lice. *B. recurrentis* is less virulent than the tick-borne forms. Under favorable conditions, mortality is about 5 percent, but in times of distress, as in war or famine, it can reach 60 to 70 percent.

It is also known as famine fever and tick fever, and in the past as yellow fever, because of associated jaundice. The term "relapsing fever" was first used by David Craigie of Edinburgh in 1843. The disease was often, and frequently is still, confused with malaria and typhus, whose symptoms are similar.

Etiology and Epidemiology

Tick-borne relapsing fever is normally contained within the relationship between tick and rodent

host; human beings become affected only when they accidentally become involved in that relationship. For example, if human shelters such as log cabins attract rodents, they may in turn become tick habitats. Transmission of relapsing fever is through the infected saliva or coxal fluid of the tick, making it essentially a disease of locality. In the case of louse-borne relapsing fever, the only reservoir of *B. recurrentis* is human beings, despite the fact that the disease is spread by lice, either in the bite, or by contact with the body fluids of the louse through scratching. The louse is infected by ingesting infected human blood; once infected, it remains so for the rest of its life which is generally about 3 weeks. The infection is not congenital in the offspring. As in typhus fever, the febrile condition of the patient encourages the departure of lice because they are sensitive to temperature and, consequently, prefer the temperature in the clothing of healthy persons.

Tick-borne relapsing fever tends to be more severe than the louse-borne variety, but both types vary greatly in severity and fatality. In 1912, for example, louse-borne relapsing fever was very severe in Indochina and India but very mild in Turkey and Egypt. There are also indications that levels of individual and residual immunity are important. Illustrative are *Borrelia* infections, which are severe in European populations in North and East Africa, but mild in the local populations. On the other hand, in West Africa the disease is equally severe among Europeans and the local inhabitants. Case fatality depends not only on the type of infection and the availability of treatment, but also on the individual's nutritional status and resilience. Thus after World War II, adult fatalities from the disease averaged 8.5 percent among the poorer classes but only 3.6 percent among the well-to-do. Children suffered the most, with death the outcome for 65 percent of cases.

Because mortality varies inversely with living conditions, louse-borne relapsing fever is a true famine fever, generally manifesting itself in times of distress, when overcrowding, diminished personal hygiene, and undernutrition encourage its spread and increase its deadliness. It is said to be "the most epidemic of the epidemic diseases" (Topley and Wilson 1984); and Alexander Collie (in 1887) noted that it rarely occurs except as an epidemic. The factors involved in the survival of the disease between epidemics are still not fully understood.

Distribution and Incidence

Endemic foci of tick-borne relapsing fever exist in most parts of the world, but not in Australia, New Zealand, and the Pacific islands. Louse-borne relapsing fever has been reported worldwide, but since 1964, Ethiopia is the only country that has continuously reported large numbers of cases. Foci of the disease appear, however, to be present in other African countries, and no information on its prevalence is available for the Soviet Union or China.

As with tyhpus fever, there is a marked seasonal incidence coinciding with the winter months. Warm winter clothes (and in the past, deficient winter hygiene) favor the growth of louse populations, whereas rising heat and humidity in spring and summer cause lice to die.

Clinical Manifestations

After an incubation period of some 5 to 8 days, the disease manifests itself suddenly, with shivering, headache, body pains, and high temperature. Nausea and vomiting are occasionally present. The spleen and liver are enlarged and tender; bronchitis is present in 40 to 60 percent of cases and jaundice in 20 to 60 percent. In cases with a favorable outcome, there is a crisis of 1 to 2 hours or longer within 3 to 9 days, followed by a fall in temperature. Relapse, shorter and less severe than the primary attack, follows in 11 to 15 days. A diminishing proportion of patients suffer up to four relapses. Not all cases relapse, however, and in some epidemics no more than 50 percent of the patients suffer relapse. Death is due to liver damage, lobar pneumonia, subarachnoid hemorrhage, or rupture of the spleen.

The causal organisms are present in the blood during the febrile attacks, but absent in the intermissions. After one or more relapses, the active immunity produced by the patient is sufficient to prevent further invasion of the blood by the spirochetes. It is doubtful, however, that this represents a true end of the disease for the patient. Rather it would seem that an equilibrium is established between host and parasite, and like all equilibria is liable to disturbance.

History and Geography

The history of relapsing fever is difficult to trace with any certainty before the louse-borne form was clinically distinguished from typhus and typhoid by William Jenner in 1849. Louse-borne relapsing fever was the first of the communicable diseases to have its causal organism identified, when Otto Obermeier made his observations of spirelli in the blood of patients during the Berlin epidemic of 1867–8. His findings were publicized in 1873. The louse was identified as the vector by F. P. Mackie (1907), then working in India, and the epidemiology of the dis-

ease was finally worked out by Charles Nicolle and his colleagues at the Institut Pasteur in Tunis between 1912 and 1932.

Moving back in time, Hippocrates describes an apparent outbreak of relapsing fever on the island of Thassus, off Thrace, and it is possible that the "yellow fever" of seventh-century Europe may have been relapsing fever. The disease may also have been among those constituting the epidemics of "sweating sickness" that affected England in 1485–1551. There were probably a series of relapsing fever epidemics in late-eighteenth-century Gloucestershire, and the first reliable observation of the illness was recorded in Dublin by John Rutty in 1739. The disease was observed principally in Britain and Ireland before the mid-nineteenth century, when it became more active. An outbreak in Scotland in 1841 spread south into England, and from there to the United States. The disease was present, with typhus, in Ireland during the Great Famine of 1846–50. Epidemics also occurred in Prussia (1846–8) and Russia (1864–5), which presaged repeated outbreaks in Germany and Russia during the remainder of the century.

Relapsing fever was reintroduced into the United States by Irish immigrants, resulting in outbreaks in Philadelphia in 1844 and 1869, and in New York in 1847 and 1871. There was an extensive epidemic in Finland in 1876–7. Egypt, Russia, central Europe, and Poland all suffered great epidemics during World War I, and widespread outbreaks occurred in Russia and central Europe in 1919–23. There were further outbreaks in the Middle East, notably in Egypt, after World War II. The disease was shown to be endemic in China along the Yangtse River in the 1930s, and its appearance in Korea after the Korean War suggests that a Chinese focus persists.

Since the 1950s, however, the major continuing focus of louse-borne relapsing fever has been in Africa. In 1910 it was present in Tunisia and Algeria; in 1921 a virulent outbreak appeared in North Equatorial Africa, and spread across the continent as far as Sudan. In 1943 a serious epidemic in North Africa spread into the eastern Mediterranean and Europe. From the 1950s, at least, the disease has had an endemic focus in Ethiopia, making excursions into neighboring Sudan. A. D. M. Bryceson and his colleagues (1970) believed there to be not less than 1,000 cases in Addis Abbaba every year, with a mortality of 5 percent, and they suggested a figure of some 10,000 cases annually for Ethiopia as a whole. The most recently available World Health Organization statistics suggest a modest 2,000 cases in Ethio-

pia in 1980, but an enormous rise to over 22,000 cases (from fewer than 50 in 1978–9) in Sudan in 1981.

Conditions in Ethiopia and the Sudan during the last 10 years have not been conducive to the collection of satisfactory statistical information. Reports from the field, however, suggest a continuing low endemic prevalence of relapsing fever, while at the same time indicating confusion of the disease with malaria and typhus by fieldworkers. It seems likely, however, that any major epidemic escalation would have received attention, and thus the fear of an epidemic escalation in Sudan, expressed by Bryceson (1970) and W. Burgdorfer (1976), have so far proved unfounded.

The history of tick-borne relapsing fever is less well documented, probably because of the local, non-epidemic character of the disease. It was first recognized in Africa in 1847, and in the United States soon after the West had been settled. Among recent recorded outbreaks are two from the western United States among people occupying tick-infested log cabins. The first took place among a group of 42 Boy Scouts and scoutmasters camping at Browne Mountain in March 1968, of whom 11 became ill. The second and the largest outbreak known in the Western Hemisphere resulted in 62 cases among visitors and Park Service employees who spent the night in log cabins on the north rim of the Grand Canyon in Arizona, during the summer of 1973.

Rheumatic Fever and Rheumatic Heart Disease

Acute rheumatic fever is a noncontagious disease characterized by febrile, nonsuppurative inflammation, primarily of articular and cardiac tissues, less frequently affecting the skin and brain. The cerebral manifestation – Sydenham's chorea – and the superficial manifestations – subcutaneous nodules and erythema marginatum – are limited to children and young adults.

Etiology and Treatment

The disease is caused by infection, most often of the throat, with type A beta-hemolytic strains of streptococcus. Fever, migratory joint pains and tachycardia, the most frequent symptoms, typically begin 1 to 3 weeks after the onset of untreated streptococcal pharyngitis. However, only 0.1 to 3.0 percent of untreated bouts of this infection result in a first attack of rheumatic fever. Consequently, various largely unidentified permissive factors must participate in initiating the immunologic pathogenesis of the disease.

First attacks of acute rheumatic fever can be prevented by timely treatment of the streptococcal infection with penicillin or another appropriate antibiotic, but such treatment does not influence the course of the disease once it has begun. Rheumatic fever recurs only as a result of a new infection with a pathogenic strain of streptococcus. Prophylactic antibiotic treatment diminishes, but does not eradicate recurrences (Taranta et al. 1964). The shorter the interval since the previous bout of rheumatic fever, the greater is the likelihood that a new attack will be elicited. An infection that occurs within 2 years of an attack has a 20 to 25 percent chance of inducing a recurrence. If the first attack does not affect the heart, a recurrence usually spares it as well, but if the heart has been involved, a second bout it likely to result in greater damage (Spagnuolo, Pasternack, and Taranta 1971). An attack of rheumatic fever usually lasts several weeks, but is rarely fatal. Death most often is a consequence of chronic heart failure, which is the end result of damage to heart

valves (predominantly the mitral and aortic valve). Rheumatic heart disease in about one-half the cases develops in the absence of any history of acute rheumatic fever, the infection having slightly initiated the pathogenic immunologic mechanism in the heart (Vendsborg, Hansen, and Olesen 1968).

History

Clinical Manifestations and Diagnosis

The major clinical manifestations of rheumatic fever were first described separately, their relationships not being recognized until the nineteenth century. Thomas Sydenham in 1685 distinguished an acute, febrile polyarthritis "chiefly attacking the young and vigorous" from gout. One year later, he described as "St. Vitus' dance" the neurological disorder that is now called Sydenham's chorea (Murphy 1943). It was Richard Bright who in 1839 first connected the condition with rheumatic fever (Schechter 1935).

In 1797, Matthew Baillie of London noted a thickening of some heart valves in autopsies of patients who had had acute rheumatism, and a few years later David Dundas, surgeon to King George III, described nine cases of "a peculiar disease of the heart" that "is always the consequence of, or is connected with, rheumatic affection" (Dundas 1809). Four years later, William C. Wells, also of London, published a series of 16 cases of "rheumatism of the heart" (median age, 15 years), and added the description of subcutaneous nodules. However, the occurrence of nodules was largely ignored until a comprehensive study by Thomas Barlow and Francis Warner was published in 1881 (Benedek 1984).

Before the introduction of auscultation by René T. Laennec in 1818, rheumatic heart disease was recognized from abnormalities of the pulse, respiration, and palpation of the chest in the presence or recent history of fever and joint pains. Laennec had described murmurs caused by deformities of the mitral valves. In 1835 James Hope also described murmurs that originated from the other valves and concluded that rheumatic fever is the most frequent cause (Hope 1846). This opinion was soon confirmed by Jean B. Bouillaud. The "Aschoff nodule," the myocardial granuloma that came to be considered pathognomonic of rheumatic carditis, had been recognized as early as 1883, but was described definitively by Ludwig Aschoff of Marburg only in 1904 (Benedek 1984).

Bacteriologic studies, beginning in the 1870s, were made on blood and joint fluid aspirates. This approach was justified in 1883 by the demonstration

of the cause of gonococcal arthritis. The normal bacterial flora of the throat was not understood. Yet contrary to most investigators of the time, a Berlin physician writing at the turn of the twentieth century concluded that because one finds the same bacteria in the throats of persons with or without rheumatic fever, the disease must be caused not by a specific microbe but by a peculiar reactivity of susceptible individuals.

When Homer F. Swift of New York began his investigations of the cause of rheumatic fever in 1916, he was still culturing blood and joint fluid. In retrospect, the successful cultures that prolonged efforts to find a directly infectious agent (rather than an immunologic incitor) were due either to contamination or to the presence of bacterial endocarditis, an infection that usually is superimposed on rheumatic or congential heart disease. By 1928 Swift had concluded that an allergic response to repeated streptococcal infections is the most likely cause of rheumatic fever, but erroneously believed that nonhemolytic strains were the principal pathogens. The investigations begun by Alvin F. Coburn in New York in the mid-1920s resulted in the correction and extension of Swift's conclusions. On the basis of detailed epidemiological correlations of the bacterial flora of the throat with the onset of initial and recurrent bouts of rheumatic fever, Coburn inferred that the true pathogen is the hemolytic streptococcus, serologic type A (Benedek 1987). The hypothesis that the disease is mediated immunologically was supported by the discovery by E. W. Todd in London of antibodies to streptococci in the blood of rheumatic fever patients (Todd 1932).

Early Epidemiological Studies

The first statistical report, by John Haygarth in 1805, found that 4.5 percent of the admissions to the Chester Infirmary between 1767 and 1801 had "rheumatism" and that 36 percent of those, or 1.6 percent of the total, had acute febrile rheumatism or "rheumatick fever." How many of these actually were cases of this disease is uncertain (a problem that continued to vex many surveys). Eleven of the 70 cases of whom age was recorded involved patients 50 to 70 years old, and unequivocal symptoms of heart failure were not described even in fatalities.

Most reports since then have also described the experience in an individual hospital. Regional surveys and mandatory reporting of rheumatic fever have been rare, occurring mainly in Great Britain, Scandinavia, and the United States. Nearly a century after Haygarth's monograph, a report on the occurrence of "rheumatism" at St. Bartholomew's Hospital, London, demonstrated the vagaries of diagnosis in more detail, as well as the great prevalence of rheumatic fever. During the 15-year span 1863 to 1877, an average of 323 patients with "rheumatism" were admitted annually. This constituted about 14 percent of all medical admissions. Beginning in 1867, gonorrheal rheumatism and rhematoid arthritis were diagnosed separately. However, this change only slightly reduced the cases of presumed acute rheumatic fever with or without heart disease – to 311 per year. The associated mortality was 1.3 percent (Southey 1878). This result is consistent with more recent U.S. data according to which the acute mortality has ranged from 3.5 percent during 1935–42 to 0.9 percent during 1951–8 (Mayer et al. 1963). At St. Bartholomew's during 1867–77, a total of only 716 cases of scarlet fever (also caused by infection with the hemolytic streptococcus) were admitted, and the mortality among these was 14.0 percent (Southey 1878).

Acute rheumatic fever occurred more frequently in older persons in the nineteenth century than in the more recent preantibiotic period. A questionnaire sent to physicians by the British Medical Association during 1882–6 regarding their cases of rheumatic fever indicated the mean age of an attack among 647 cases to have been 25.4 years, with 4 percent of the patients over 60 years of age (Whipham 1888). Of 400 cases admitted to Roosevelt Hospital in New York during 1872–82, 7 percent of the attacks occurred in patients older than 55. By contrast, 25 percent of first attacks occurred between ages 20 and 25, whereas 49 percent of first attacks and 34 percent of all attacks occurred in the third decade of life (May 1884). The latter is similar to the experience at Bellevue Hospital in New York 40 years later, where, as Table VIII.117.1 shows, 34.5 percent of the cases of acute rheumatic fever were in the third decade. By the 1930s, however, only 13.8 percent of patients admitted to Philadelphia hospitals for acute rheumatic fever were in their third decade. Similarly, a review of 3,129 cases in New York, the majority of whom had their first attack between 1920 and 1940, showed a mean age of onset of 15 years (Lambert 1920).

In the 1880s, it was estimated in London that about 20 percent of patients without symptoms or history of rheumatic fever who were admitted to a hospital for any reason had a sibling or parent who had had rheumatic fever; such familial cases were present in about 35 percent of the patients who were hospitalized because of rheumatic fever (Garrod and

Cooke 1888). It had been noted in a British Medical Association survey that rheumatic fever "greatly preponderates in the lower over the middle and upper classes" (Whipham 1888). The occurrence of multiple cases in a family was at first attributed to inheritance. As bacteriologic findings came to be accepted in the 1880s and 1890s, however, the concept that both familial occurrence and the association with poverty could best be explained by the easier spread of an infectious agent in crowded living conditions also became accepted. The possibility of racial predisposition was considered because of the greater prevalence of rheumatic fever in populations as disparate as American blacks, South African Bantus, and New Zealand Maoris as compared to white nationals. Most investigators, however, concluded that susceptibility was due to the greater poverty and poorer housing of certain racial groups in various societies, although several investigations have suggested that there is a heritable factor that influences susceptibility to rheumatic fever (Wilson and Schweitzer 1954).

The importance of crowded living conditions gained further attention because of the prevalence of the diagnosis of rheumatic fever in military encampments during the First World War. Between April 1917 and December 1919, for example, 24,770 U.S. soldiers, representing 27 percent of all rheumatologic cases, received this diagnosis. Crowded train-

ing camps were believed to have contributed to the disproportionately large percentage of cases (Hench and Boland 1946). The development of epidemiological data about rheumatic fever has been difficult because the acute phase of the disease may be brief or actually imperceptible, so that its occurrence may become recognized only from findings of valvular heart disease, perhaps years later in an uncertain proportion of the cases. Many estimates of the prevalence of rheumatic fever have been extrapolated from the prevalence of heart disease in those between the ages of 5 and 19 years, because their disease is most likely to be rheumatic. Widely differing diagnostic criteria, examining techniques, and reporting practices have made epidemiological comparisons unreliable. This problem began to be addressed in 1943 by the Cardiovascular Diseases Subcommittee of the [U.S.] National Research Council, which sought more precise diagnostic criteria so as to assess the problem of rheumatic fever in military training camps. In response, T. Duckett Jones, a Boston cardiologist, devised a set of five "major" and seven "minor" criteria and proposed that "any single major manifestation with at least two of the minor manifestations would seem to place the diagnosis on reasonably safe grounds." The Jones criteria received international acceptance quite rapidly and have been modified twice. The main revision in 1955 altered the importance that was assigned to some clinical signs, whereas the revision in 1965 placed increased importance on laboratory evidence of recent streptococcal infection (Stollerman et al. 1965).

Treatment

Salicylate preparations introduced between 1876 and 1879 were found to be particularly effective in counteracting the fever and joint pain of acute rheumatic fever. In 1899 aspirin came on the market, and for the next 50 years the basic treatment consisted of the maximum tolerated dose of either sodium salicylate or aspirin (Rodnan and Benedek 1970). Greater understanding of the cause of rheumatic fever did not have an immediate effect on its treatment because there was no way to eradicate a streptococcal infection. Sulfanilamide was found to prevent recurrences when taken prophylactically (Swift, Moen, and Hirst 1938; Thomas and France 1939). Penicillin became available in 1945 and quickly proved to be safer and more reliable as a preventive agent (Spink et al. 1946). The most reliable prophylactic method, a monthly injection of slowly excreted benzathine penicillin, was introduced in 1951.

The introduction in 1949 of cortisone and cortico-

tropin was perceived as the first possible improvement over salicylate therapy for acute rheumatic fever. During the first few years in which these hormones were available, most investigators found that control of fever and joint pain was achieved more rapidly with these drugs than with salicylates; moreover, if given early enough, they seemed to minimize heart damage. Uncertainty about the latter impression, however, led to the establishment in 1955 of an elaborate Anglo-American prospective therapeutic comparison of salicylate with cortisone or corticotropin therapy. After 10 years, it was concluded that the long-term results from both modalities were similar (U.K. and U.S. Joint Report 1965).

Decline of Rheumatic Fever

London physician G. B. Longstaff (1905) may have been the first to suggest that the prevalence of rheumatic fever was decreasing. He deduced this from death certificates in England and Wales during 1881–1900. During these 20 years, 51,666 deaths were attributed to "rheumatic fever" or "rheumatism of the heart," and 3.3 times as many (171,298) to "valvular disease of the heart." In comparing the 5-year periods 1881–5 and 1896–1900, death rates per million due to rheumatic fever declined 15.6 percent, from 97.6 to 82.4, and those for "residual rheumatism" declined 19.1 percent from 35.0 to 28.3. Data collected by J. A. Glover (1930) for the same region showed a lower incidence of deaths for 1901 than Longstaff had calculated (67 per million), but indicated continuity of the decline: to 46 per million in 1910 and 38 per million in 1928.

The two most common sources of epidemiological data other than death reports have been hospital admissions and recurrence rates among patients who were being followed in rheumatic fever clinics. In order for hospitalization data to be intrinsically comparable, one must assume a socioeconomically stable service area and consistent admissions policies, both of which assumptions are risky. Clinic data tend to yield the most detailed information, but if the clinic is effective, its prevalence information cannot be extrapolated to communities that lack similar services.

Annual admissions data for rheumatic fever were recorded between 1906 and 1925 for hospitals in Montreal, Boston, New York, New Orleans, and the Panama Canal Zone. A comparison of the proportion of total admissions for rheumatic fever between 1906–8 and 1923–5, as reflected in Table VIII.117.2, shows a decline from 59 percent (New York Bellevue) to 79 percent (New Orleans Charity) (Seegal and Seegal 1927).

Table VIII.117.2. *Cases of rheumatic fever per 1,000 admissions, various hospitals*

Source: Data from Seegal and Seegal (1927).

A comparison of the prevalence of rheumatic fever among U.S. military personnel during the two world wars shows that, as serious as the problem was during World War II, this diagnosis was made in only 10 percent as many army and 38 percent as many navy personnel. The contribution of more precise diagnosis and prophylactic programs to this improvement is uncertain.

The lengthiest clinical evaluation of rheumatic fever patients was carried out by M. G. Wilson and collaborators (1958) in New York. Beginning in 1916 and continuing in the same area for 40 years, it reported a steady decline in recurrences of rheumatic fever, unrelated to treatment. During 1921–43, 25 percent of children 6 to 13 years of age and 6.1 percent of those aged 14 to 20 suffered recurrences, whereas during 1944–56 only 15.1 percent of the younger and 2.8 percent of the older age group were so affected.

Antimicrobial prophylaxis began to be used in 1952. Yet the age-adjusted recurrence rate for the 5 years 1942–6 was 7.9 percent, and for 1952–6 it was 6.1 percent; this difference was not significant. The socioeconomic circumstances of the area served by the clinic had improved during these decades, but no improvement in the recurrence rate was observed in the poorest segment of the population (Wilson, Lim, and Birch 1958).

A study of the economic correlates of the occurrence of primary and recurrent rheumatic fever in Baltimore during 1960–4 also demonstrated a strong correlation between low economic status and the occurrence of the disease, but only among the white subjects. The annual incidence was consistently greater among blacks, with only slight improvement related to higher socioeconomic category, whereas

the incidence among whites diminished markedly with higher socioeconomic category. Thus, the annual incidence of rheumatic fever among blacks in the lowest fifth on the socioeconomic scale was 56 percent greater than among comparable whites, whereas the difference reached 478 percent when the most affluent fifths were compared (Gordis, Lilienfeld, and Rodriguez 1969).

In weighing the relative importance of rheumatic fever and rheumatic heart disease against other potentially lethal problems of childhood, we find that in the United States during 1939–41, the pair still ranked second, behind accidents, as the leading causes of death in the 10- to 14-year age group. There was a significant sex- and race-related gradient, from 11.2 deaths per 100,000 white boys to 17.4 deaths per 100,000 nonwhite girls (Wolff 1951). This amounted to an average of 4,000 deaths per year for that period. But by 1972–4, an average of only 179 deaths were reported annually, and by 1982–4, deaths had declined to 78 cases per year. Similarly, as Table VIII.117.3 indicates, the reported national incidence of rheumatic fever declined from 10,470 cases in 1961 to 2,793 cases in 1971 and 264 cases in 1981.

Geography
Rheumatic fever was thought to be rare in the tropics, as judged by observations on English troops and native populations in India in the mid-nineteenth century. Seeming to confirm that view were clinical and autopsy reports, primarily from India and the Malay Peninsula, which started to appear in the 1890s and were still cited in the 1930s (Clarke 1930). But these publications are somewhat perplexing, for beginning in 1925, substantial numbers of cases of rheumatic heart disease were being reported from tropical India.

Nevertheless, rheumatic fever has been found to occur less frequently in tropical than in temperate regions despite the fact that poverty, aspects of which appear to facilitate the occurrence of the disease, is in general more prevalent in the tropics. Thus, observations on military personnel that minimize the economic factor have shown a lower incidence in tropical encampments. For example, the mean incidence of rheumatic fever among white U.S. Army enlisted men stationed in the United States during 1913–25 was 5.00 plus or minus 2.46 per 1,000, whereas the incidence among similar personnel stationed in the Philippines was 1.74 plus or minus 1.23 per 1,000 (Faulkner and White 1924). Paradoxically, however, during the decade 1914–23

there were slightly more admissions for rheumatic fever to the General Hospital of Manila than to the Johns Hopkins Hospital in Baltimore – 7.90 versus 7.19 per 1,000 medical admissions (Seegal and Seegal 1927).

A north-to-south declining gradient of rheumatic fever within the United States was suggested during the 1920s (Harrison and Levine 1924). This was confirmed by numerous studies, including one in which the prevalence of rheumatic heart disease was compared among Indian children on reservations in Montana, Wyoming, and Arizona (Paul and Dixon 1937). A similar gradient has been reported from China. An altitude gradient has been demonstrated in Kenya for hospitalizations for acute rheumatic fever, and in Mexico for the proportion of rheumatic heart disease among cardiac patients. In both countries there was significantly more disease in the more temperate highlands.

The "classical" manifestations of rheumatic fever were described in northern Europe, and whether its acute manifestations differ in the tropics has long been debated. If one considers, however, the wide variation in the frequency with which various acute manifestations of the disease have occurred in temperate regions, as presented in Table VIII.117.3, it seems doubtful that there are consistent biological differences in the presentation of rheumatic fever in the tropics. Some of the reported inconsistencies reflect selection biases related to cultural attitudes and medical and other resources, whereas others reflect over- or underdiagnosis. For example, the fact that virtually all of the patients in a small series of cases from Nigeria and Uganda had carditis probably indicates that childhood cases of lesser severity were simply not seen rather than nonexistent.

The wide range of the occurrence of "arthritis" in rheumatic fever cases may be attributed in part to the differentiation by some authors between objective signs of joint inflammation and mere arthralgia. Nevertheless, there can be striking differences in the occurrence of arthritis, even when rigorous diagnostic criteria may be assumed; for example, 42 percent and 71 percent of the patients had arthritis in two series of cases at two different times from Toronto. But the extreme variations in the occurrence of chorea – ranging from 2 percent to 52 percent – are the most inexplicable. Erythema marginatum is rarely described in dark-skinned children, but this eruption is sufficiently uncommon in fair-skinned individuals that, assuming some underdiagnosis in the former, a significant difference seems unlikely.

The relationship of subcutaneous nodules to carditis may indicate real geographic differences in disease expression. Nodules have occurred in 8 to 12 percent of several large series of cases from temperate regions (Benedek 1984), whereas they have been less common in others and have consistently been rare in the tropics. In temperate climates nodules are almost always associated with acute carditis and may be predictive of more severe valve damage. Thus, according to the long-term experience of Wilson and W. Lim (1957) in New York, 3 percent of cases of mitral insufficiency, 9 percent of cases of combined mitral insufficiency and stenosis, and 30 percent of cases of combined mitral and aortic valve damage had exhibited nodules during the acute phase of illness. In tropical areas there is a weaker association between the occurrence of nodules and carditis and a difference in the valvular involvement, or at least this seems to be the case of India. There, carditis not only results in permanent valve injury more rapidly and is more likely to be acutely fatal, but also has a peculiar tendency to cause pure mitral stenosis. This has been described repeatedly since 1935. According to the largest reported experience involving 2,050 cases of rheumatic heart disease in New Delhi, 81 percent of whom were below 30 years of age, 43.5 percent had pure mitral stenosis (Wilson et al. 1958). Reports from other countries do not resolve the question of whether this finding represents an ethnic difference or is a result of delayed initial medical care.

Rheumatic Heart Disease and Its Surgical Repair

Wilson and associates evaluated 385 patients up to 49 years of age who had heart murmurs and had had rheumatic fever before the age of 20. Fully 89 percent were asymptomatic; 45 percent of the cohort had pure mitral insufficiency; 41.8 percent had combined mitral insufficiency and stenosis; 10.3 percent had both mitral lesions and aortic insufficiency; and 2.9 percent had double mitral and double aortic valve defects (Gordis et al. 1969). Of 78 fatal cases from the population of which those just mentioned were among the survivors, 15.4 percent had only mitral insufficiency, 37.2 percent had mitral insufficiency and stenosis, and 47.3 percent also had aortic insufficiency (Magida and Streitfeld 1957).

The surgical treatment of rheumatically damaged heart valves began in the late 1940s when Dwight E. Harken in Boston performed the first successful mitral commissurotomy (Harken et al. 1948). The procedure was improved by Charles P. Bailey of

Philadelphia a year later (Bailey et al. 1960). This was "closed" heart surgery. No attempt to repair a damaged aortic valve was possible until an oxygenating system to bypass blood temporarily around the heart was developed; this technique made "open" heart surgery possible. The first practical apparatus was employed by John W. Kirklin. The first valve operations to ameliorate aortic insufficiency were performed by Bailey in 1959 and to correct aortic stenosis in the same year by Donald G. Mulder in Los Angeles. The next technical phase was the replacement of an active valve. This began with the ball valve devised by Albert Starr and Lowell Edwards (1961). Such plastic valves, however, tend to destroy red blood cells, and thus valves were developed with leaflets of pig, cattle, or sheep tissue. This type of prosthesis was first inserted to replace an aortic valve in 1965, and a mitral valve in 1967, both by A. Carpentier in Paris.

In 1983 about 16,000 mitral and 33,000 aortic valve replacements were performed in the United States. However, the cause of the injury, particularly of the aortic valve, has gradually shifted from rheumatic to other varieties of heart disease (Gillum 1986).

VIII.118
Rickets and Osteomalacia

Rickets and osteomalacia are diseases with multiple etiologies primarily related to abnormal metabolism of vitamin D and secondarily to calcium and phosphate metabolism. Of the many causes, by far the most important relate to dietary vitamin D deficiency and the activation of vitamin D precursors by the kidney and sunlight. Rickets and osteomalacia are characterized pathophysiologically by a failure of normal mineralization of bone and epiphyseal cartilage and clinically by skeletal deformity. Rickets occurs in growing infants and children, and both bone and epiphyseal cartilage are affected. Osteomalacia occurs in adults after closure of the epiphyses, and its manifestations are often much less prominent.

History
Historically, rickets was among the earliest diseases to be described. As early as 300 B.C., Lu-pu-wei described crooked legs and hunchback; however, these can occur with other disorders. More specifc references are found in the separate writings of three Chinese physicians of the seventh and eighth centuries A.D., including enlarged head, body wasting, pigeon breast, and delayed walking. By the tenth century, Chien-i, the Father of Chinese pediatrics, described many cases of rickets (Lee 1940).

In the second century A.D., Soranus of Ephesus mentioned characteristic deformities of the legs and spine in young children and remarked on the higher frequency in urban Rome compared to Greece. Slightly later, Galen's work included a description of skeletal deformities in infants and young children, particularly the knock-knee, bow leg, and funnel-shaped chest, and pigeon breast seen in rickets. Sporadic and somewhat ambiguous references to the disease were made until the mid-seventeenth century, when the classic descriptions of Daniel Whistler and Francis Glisson appeared.

In 1645 Whistler published his medical thesis in Latin, *On the Disease of English Children which is Popularly Termed the Rickets*. Five years later, Glisson wrote the classic text on the subject, still unsurpassed as a clinical description of rickets. Both physicians considered the disorder of recent origin, and indeed the northern climate, crowded living conditions, and socioeconomic changes may have influ-

enced its prevalence at that time. Glisson himself noted a number of cases affecting the "cradles of the rich," perhaps related to the use of swaddling clothes and the vitamin D-deficient diet of pap and starch.

The word "rickets" was first used in the London Bill of Mortality report for 1634. The derivation of the word has been a source of contention since that time. Possibilities include *rucket* in Dorset dialect, meaning "short of breath"; the verb *rucken*, meaning "to rock or reel"; the Middle English word *wricken*, denoting "to twist"; the Saxon word *rick*, meaning "heap" or "hump"; or the Norman word *riquets*, for hunchback. Glisson suggested the term "rachitis" derived from the Greek word for spine, and this term remains in use in many countries today.

Nearly 250 years passed before the specific role of vitamin D and its active metabolites was elucidated via biochemical studies. L. Findlay (1908) reproduced the disease in puppies raised in a confined, darkened space. A year later, Georg Schmorl (1909) demonstrated the striking seasonal variation of the disease by autopsy findings. In 1917 Alfred F. Hess and L. J. Unger described the prevention of rickets by use of cod liver oil or by ultraviolet irradiation. Shortly thereafter, a number of researchers, particularly the group of Elmer V. McCollum (1922), isolated vitamin D and related compounds. A better understanding of the exact mechanisms and conversion of vitamin D metabolism into more active forms was gained only since the mid-1960s and 1970s (Lund and DeLuca 1966; Fraser and Kodicek 1970).

Vitamin D is classified more accurately as a prohormone rather than a vitamin. It is formed by the interaction of ultraviolet light with a cholesterol derivative in the deeper layers of the skin, but small amounts of vitamin D may also be derived from dietary sources such as dairy product and fish liver oils. Vitamin D is then hydroxylated once in the liver, and a second hydroxylation into the highly active hormone occurs in the kidney. It acts upon the target organs, intestine, and bone to regulate serum calcium and phosphate levels and the mineralization of bone.

Paleopathology
As a disease producing characteristic skeletal deformities, rickets can be traced back to antiquity by direct examination of the skeletal evidence. As expected, the disease was extremely rare in ancient Egypt. Only one or two possible cases have been described in skeletal remains from North and South America. Most reported examples of ancient rickets

come from Europe. A few date back to Neolithic times in Norway, Sweden, and Denmark. Examples become more plentiful during the Middle Ages in cities across northern and central Europe, again confirming the central role of inadequate sunlight in causing the disease (Steinbock 1976).

Epidemiology, Distribution, and Geography

As early as 1890, Theobald A. Palm gathered data via correspondence with medical missionaries worldwide and concluded that the main etiologic factor in rickets is the lack of sunlight. It was much later before scientists linked the variable pigmentation in the races of men with the regulation of vitamin D synthesis (Loomis 1967). The processes of pigmentation and keratinization of the outer layer of the skin (stratum corneum) directly affect the amount of solar ultraviolet radiation reaching the deeper stratum granulosum, where vitamin D is synthesized. White or depigmented skin of the northern latitudes allows maximum ultraviolet penetration. Black or heavily pigmented skin and Oriental or keratinized skin minimize UV penetration in southern latitudes to maintain vitamin D synthesis within physiological limits. The skin pigmentation or keratinization also plays a role in preventing sun-induced skin cancer, a greater problem among light-skinned groups who move to sunnier climates.

A cautionary note should be included when discussing the incidence or prevalence of rickets. The diagnosis of rickets will vary, depending on the nature of the criteria utilized – clinical, radiographic, or biochemical. Moreover, the sensitivity of each of these methods varies considerably according to the stage of the disease or age of the individual.

Historically, the incidence of rickets increased with the rise of sunless, crowded urban centers as part of the Industrial Revolution. Indeed, rickets may, among other things, be considered as an air pollution disease since factory-produced smog filters and decreases the available ultraviolet light (Loomis 1970). As Palm (1890) deduced from this worldwide correspondence: "It is in the narrow alleys, the haunts and playgrounds of the children of the poor, that this exclusion of sunlight is at its worst, and it is there that the victims of rickets are to be found in abundance."

In 1899 Theodor Escherich reported that in Vienna 97 percent of infants between 9 and 15 months had clinical evidence of rickets. An autopsy analysis in Dresden, Germany, by Schmorl (1909) showed that 89 percent of all children between 2 months and 4 years of age exhibited evidence of active or healed rickets. Schmorl also noted a striking seasonal variation in the presence of rickets. Similar high numbers were reported near the turn of the century for Oslo, Bergen, Berlin, Glasgow, Dublin, Belfast, Edinburgh, Paris, Florence, and Moscow (cf. Owen 1889; Hess 1929). Some authorities noted a general decrease in rickets at higher altitudes in the Scottish Highlands and Swiss Alps, related to the increased ultraviolet component of solar radiation. However, cases became more numerous and severe at the highest altitudes, presumably related to the practice of keeping the infants heavily bundled or indoors nearly year round (see Feer 1916).

Large American cities also had a high prevalence of rickets. In 1900 John L. Morse estimated that 80 percent of all infants under 2 years of age in Boston had rickets. Hess reported in 1921 that 75 percent of New York City children had clinical evidence of rickets (see also Hess 1929). Martha M. Eliot (1925) found that 83 percent of infants under 8 months of age in New Haven had radiographic findings of mild rickets. L. R. Du Buys (1924) noted that rickets was widespread in New Orleans, and the clinical manifestations were more marked in blacks than whites.

As a deficiency disease involving sunlight and diet, cultural and socioeconomic factors interacting with climate are important in the epidemiology and geographic distribution of rickets and osteomalacia. In general, rickets is uncommon in sunny climates; however, even sun-rich areas may have rickets. For example, nearly 30 percent of children seen at an Ethiopian clinic had clinical evidence of rickets, primarily related to a shortened period of breast feeding and swaddling of infants to avoid the "evil eye" (Mariam and Sterky 1973). In many Moslem countries, the custom of *purdah* – the complete shielding of women and young children indoors or with veils – is a major factor in rickets and osteomalacia. A study of 1,482 Moslem girls in India, aged 5 to 17 years, showed that 40 percent had skeletal evidence of rickets (Wilson 1931).

Among many Asian groups the use of Chupatti flour as a dietary staple also contributes to the prevalence of rickets. The high phytate content in the wheat fiber binds calcium and zinc, resulting in decreased intestinal absorption of these minerals. In addition, the lignin component of wheat fiber binds to bile salts and ingested vitamin D, decreasing their absorption (Reinhold 1976). The use of *raghif*, an unleavened bread rich in phytates, is also a factor in osteomalacia among Bedouin women of childbearing age (Shany et al. 1976).

An unfortunate synergistic effect of decreased sunlight and high cereal, rice, or maize diet has been reported in both epidemiological and experimental studies (Robertson et al. 1984; Sly et al. 1984). Indeed, the effects of phytates, lignin, and other components in these grains may be rachitogenic even in the presence of adequate sunlight (Wilson 1931; Pettifor et al. 1978).

With the addition of synthetic vitamin D to dairy products and bread in the United States, there has been a dramatic decline in the incidence of rickets. Between 1956 and 1960, fewer than 0.4 cases per 100,000 pediatric admissions were for rickets. Vitamin D supplementation is not practiced in Britain, and 9 percent of young children in Glasgow had radiographic evidence of rickets (Richards et al. 1968). Osteomalacia among the elderly remains a significant public health problem related to decreased exposure to sunlight, intestinal malabsorption, poor diet, and decreased hydroxylation of vitamin D by the liver and kidneys. Osteomalacia in combination with osteoporosis is therefore an important factor in the occurrence of hip fracture among the elderly.

Rickettsial Diseases

The rickettsial diseases are a group of related maladies with common characteristics such as arthropod vectors, obligate intracellular etiologic agents, and similar symptoms, including skin rashes, high fever, and headache. The prototype is classic, epidemic, louse-borne typhus fever. Most other rickettsial diseases were originally described as "typhus-like" and were differentiated from the classic disease during the twentieth century.

Those whose etiologic agents share the *Rickettsia* genus with the historic disease are murine, or flea-borne typhus, Rocky Mountain spotted fever and other members of the spotted fever group of diseases, and scrub typhus or tsutsugamushi. Two other diseases, Q fever and trench fever, are also known as rickettsial diseases. In recent decades, however, key differences in the clinical manifestations, in mode of transmission, and in the physiology of the etiologic agents of these two diseases have caused them to be placed in separate genera.

Pathological rickettsiae were discovered early in the twentieth century and named after Howard Taylor Ricketts, a University of Chicago investigator, who lost his life in research on typhus in Mexico after several years of fruitful research on Rocky Mountain spotted fever. Although smaller than most bacteria, rickettsiae are visible under the light microscope. Unlike common bacteria, they are obligate intracellular parasites – that is, they metabolize and multiply only inside living cells, a characteristic shared with the viruses. This peculiar combination of traits caused the rickettsiae to be classified for several decades as organisms midway between bacteria and viruses. By the late 1960s, however, research revealed that they were true, if highly fastidious, bacteria.

Most of the rickettsial maladies are "diseases of nature," normally existing as infections of arthropods (insects, ticks, and mites) and their mammalian hosts. Humans are accidental intruders into the natural cycle. Like bubonic plague and yellow fever, the manifestations of infection are often more severe in humans than in the arthropods and mammals to which the organisms have adapted over eons. The geographic distribution of the rickettsial diseases is linked to environments favorable to host arthropods. In addition, these diseases tend to be found in "islands of infection" within favorable environments. This phenomenon has been attributed to ecological conditions in the case of scrub typhus or tsutsugamushi and to antigenic incompatibility between pathogenic and nonpathogenic rickettsiae seeking to establish themselves in the ovaries of female ticks in Rocky Mountain spotted fever.

The common clinical manifestations of these diseases reflect their pathological physiology as infections of the human circulatory system. Their etiologic agents multiply inside endothelial cells lining small blood vessels. Affected cells become swollen and may impede blood flow. Electrolyte imbalance and capillary permeability establish a vicious circle that progresses to circulatory collapse in fatal cases. Blood seeping from the capillaries into the skin causes the typical rash, and capillary blockage in the brain contributes to the neurological symptoms. Since the introduction of broad-spectrum antibiotics in 1948, the rickettsial diseases have been curable, if diagnosed before the diseases have progressed too far.

VIII.120
Rocky Mountain Spotted Fever and the Spotted Fever Group Diseases

---

Rocky Mountain spotted fever is a severe, acute, rickettsial disease transmitted by ticks and limited to the Western Hemisphere. Its major symptoms are similar to those of epidemic typhus, but its rash covers the entire body, including the face, the palms of the hands, and the soles of the feet. Between 20 and 25 percent of untreated victims die, making Rocky Mountain spotted fever the most severe rickettsial infection in the Americas. First identified in the Rocky Mountain region of the United States, this place name has never been dislodged, even though it is inaccurate and even misleading.

Etiology and Epidemiology

The severity with which Rocky Mountain spotted fever treats its victims underscores its natural existence as an infection of ticks and their mammalian hosts. The microbial cause of the disease, *Rickettsia rickettsii,* normally inhabits *ixodid,* or hard shell, ticks, apparently causing little harm to the host. Although small mammals are susceptible to a mild infection with *R. rickettsii* and may transmit it to uninfected ticks, the principal means by which the organism is maintained in nature is from one generation to the next in the eggs of the female tick.

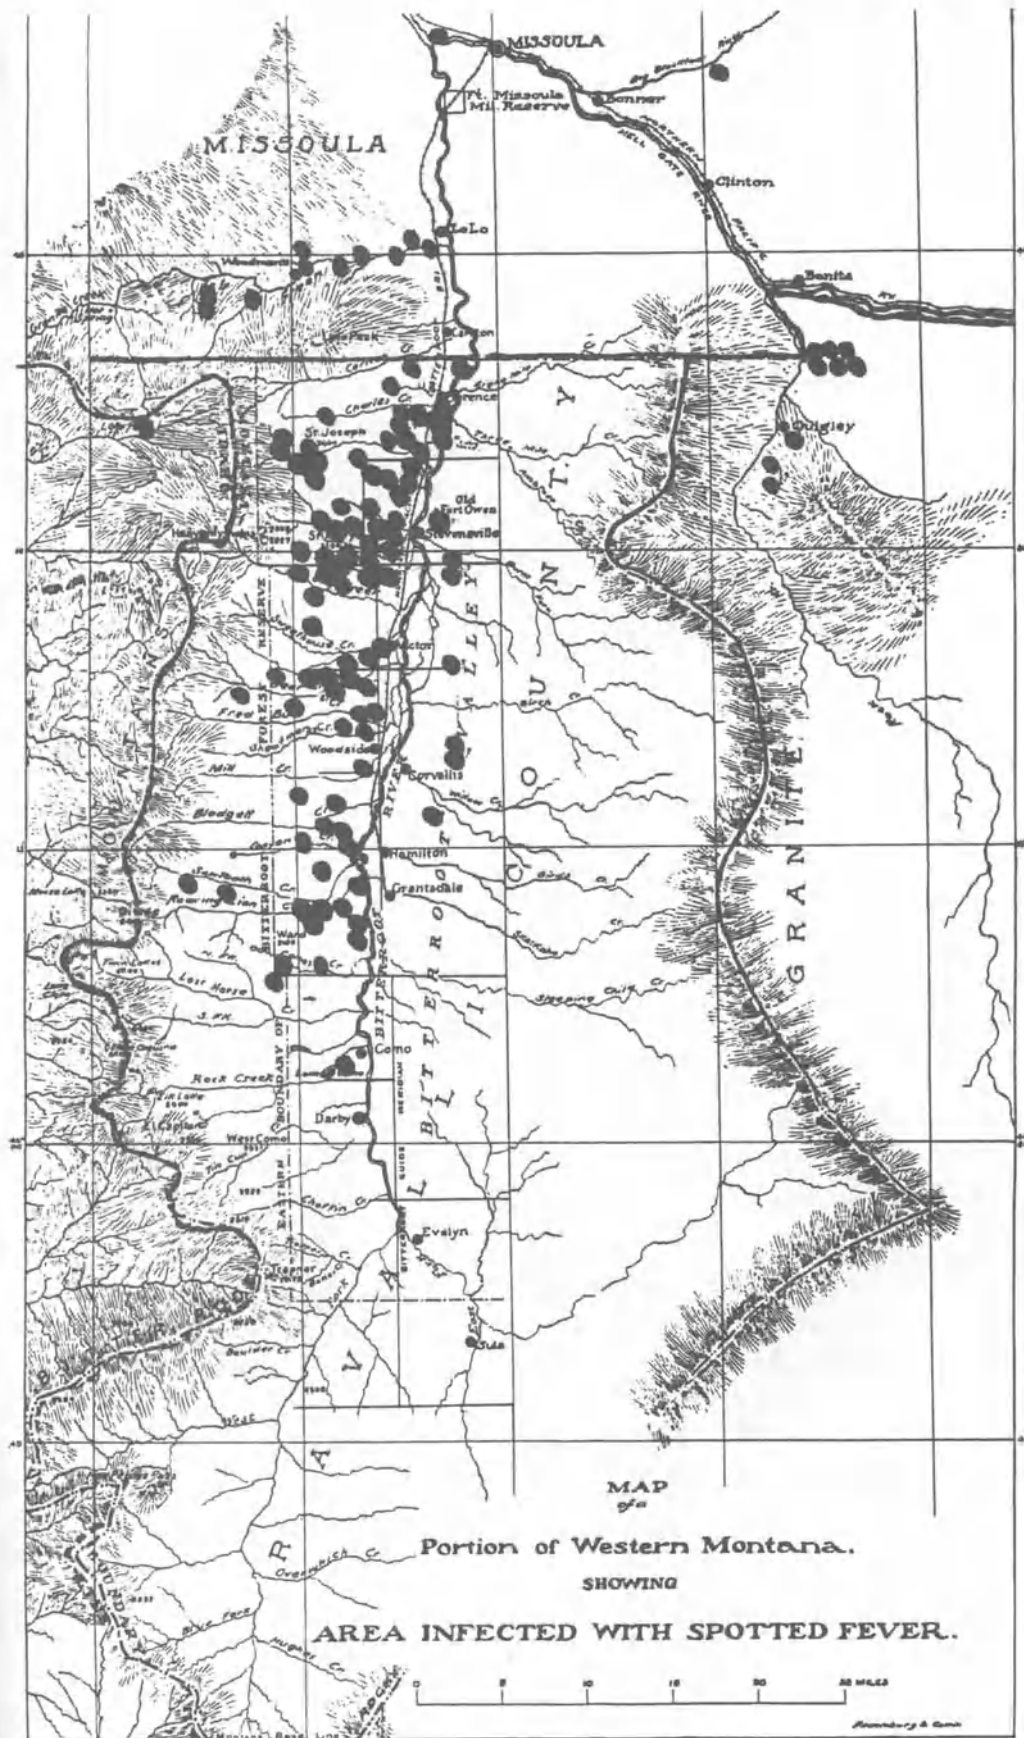
The epidemiology of Rocky Mountain spotted fever is linked to areas favorable for the habitation of the vector ticks. The Rocky Mountain wood tick, *Dermacentor andersoni,* and the American dog tick, *Dermacentor variabilis,* are the most common vectors in the United States, although the Lone Star tick, *Amblyomma americanum,* also transmits the disease in the south central and southeastern parts of the United States. Two other ticks, *Rhipicephalus sanguineus* and *Amblyomma cajennense,* also carry the disease in

Mexico, Central America, and South America. Only a small percentage of ticks – generally less than 5 percent – are usually infective.

Humans typically contract Rocky Mountain spotted fever when they accidentally become a part of the disease's biosystem. In the western United States, hikers, backpackers, and the like may become subjected to infection when traveling in areas where ticks are plentiful, especially during the spring months. In the eastern United States, where most cases now occur, changing land-use patterns have brought humans into the habitat of the tick. The development of suburban housing developments and the transformation of agricultural land into wooded recreation areas are two examples.

Rocky Mountain spotted fever characteristically appears in "islands" of infection. During early research on a particularly virulent form in Montana's Bitterroot Valley, for example, investigators were baffled by the fact that Rocky Mountain spotted fever appeared on the west side of the Bitterroot River but not on the east side (see Map VIII.120.1). Recently, Rocky Mountain Laboratory investigator Willy Burgdorfer has shown that this peculiar epidemiological occurrence is related to an antigenic "interference phenomenon." Nonpathogenic rickettsiae in the ovaries of ticks on the east side of the river "interfere" with the establishment of pathogenic rickettsiae in these tissues, thus preventing the pathogenic *R. rickettsii* from being passed on to the next generation of ticks.

Distribution and Incidence

Known only in the Western Hemisphere, Rocky Mountain spotted fever has been identified in Canada, the United States, Mexico, Costa Rica, Panama, Brazil, and Colombia. Before 1940, most cases were reported in the Rocky Mountain region, but since that time, the number of cases in the southeastern and southwestern United States (sometimes called the "tick belt" region) has far outstripped those reported from the west. In the 1970s, case incidence in the United States began to rise, reaching a peak of 1,192 cases in 1981. In recent years, the number of cases has declined slightly and leveled off. At present, Oklahoma has the highest infection rate in relation to its population, whereas North Carolina reports the largest number of cases. A small number of cases continues to occur in Canada. In Mexico and Central and South America, the disease is poorly reported, and consequently it is difficult to estimate its actual incidence in these areas.


Map VIII.120.1. Epidemiological map of Rocky Mountain spotted fever in Bitterroot Valley, Montana, 1902. Recorded cases are highlighted to show the predominant distribution of cases on the west side of the valley. (From Wilson and Chowning 1904.)

Clinical Manifestations

After an incubation period of from 3 to 12 days, typical typhuslike symptoms appear abruptly: severe headache, joint and back pains, prostration, and a high fever. About the fourth day of fever, the characteristic skin rash appears. Usually beginning on the wrist and ankles, it spreads to cover the entire body. Because few diseases cause rashes on the palms of the hands and the soles of the feet, this sign, when accompanied by high fever and history of tick exposure, is considered diagnostic. The fever continues for 2 to 3 weeks, usually subsiding gradually in cases that recover. In fatal cases, neurological symptoms of deafness, confusion, delirium, and coma are accompanied by circulatory collapse, and, often, kidney failure. In addition, the rash may darken, becoming almost black, and may spread, becoming confluent in some cases. These characteristics contributed to two early names for the disease, "black measles" and "blue disease."

If diagnosed early in the course of illness, Rocky Mountain spotted fever may be treated effectively with broad-spectrum antibiotics. Patients at risk of dying are usually those in whom the disease is not diagnosed in time to begin effective treatment. On their first visit to a physician, such patients do not report a history of tick exposure, do not yet have a visible rash, and often complain of abdominal symptoms that may be confused with other illnesses. At special risk are people who suffer from glucose-6-phosphate dehydrogenase (G6PD) deficiency, a genetic-linked disorder, which has a high frequency in black males relative to most other peoples and to black females. Thus mortality rates from Rocky Mountain spotted fever are significantly higher for black males than for the general population.

History and Geography

Rocky Mountain spotted fever as a specific disease entity is essentially twentieth century in origin. Retrospective diagnoses have identified the disease in the eighteenth and nineteenth centuries, but the first reports differentiating it from other fevers were published only in the late 1890s. Pioneers traveling the western trails of North America encountered a disease in the spring variously known as "trail typhus," "spotted fever," "spotted typhus," or other such descriptive names. Mortality varied from under 5 percent in Idaho to approximately 70 percent in the Bitterroot Valley of western Montana.

In 1901, public outcry for action against the deadly disease in the Bitterroot Valley stimulated the newly created Montana State Board of Health to launch a scientific investigation of the disease. In 1902, two pathologists from the University of Minnesota suggested that the wood tick might be the vector of the disease, which they believed was caused by a protozoan organism. Their etiologic theory was discredited, but in 1906 the tick was independently confirmed as the disease vector by Howard Taylor Ricketts of the University of Chicago and by Walter King of the U.S. Public Health Service. Ricketts continued the investigations, seeking to produce a vaccine or therapeutic serum against the disease. In 1909, when funding for Ricketts's research was delayed in the Montana state legislature, he accepted an invitation to study tabardillo, the Mexican typhus fever, in Mexico City. Tragically, he contracted typhus and died in May 1910.

Between 1910 and 1920, efforts to combat Rocky Mountain spotted fever focused on tick eradication programs. Modeled on the successful tick control program that had eliminated Texas cattle fever throughout the South, the campaign failed against Rocky Mountain spotted fever for two reasons. The Texas cattle fever tick was a one-host tick, whereas the Rocky Mountain wood tick chose different hosts for each stage in its life cycle. This characteristic made control much more difficult. Second, cold spring weather in Montana interfered with livestock dipping when the ticks first emerged.

In 1916 S. Burt Wolbach of Harvard University Medical School described the etiologic agent of Rocky Mountain spotted fever, which he labeled "a wholly new kind of micro-organism." Wolbach originally named it *Dermacentroxenus rickettsi,* the genus name after its vector tick and the species name after Ricketts. Taxonomists later classified this organism in the same genus with the typhus germs, changing its name to *Rickettsia rickettsii.*

In 1921 the U.S. Public Health Service renewed the effort to prepare a vaccine against Rocky Mountain spotted fever. Working jointly, physician Roscoe R. Spencer and entomologist Ralph R. Parker succeeded in 1924 in preparing a vaccine from infected ticks, the first successful vaccine made from the bodies of arthropod vectors. From 1925, when clinical trials began, through 1948, when effective antibiotics were introduced, the Spencer–Parker vaccine was the chief means of fighting Rocky Mountain spotted fever.

In 1931 the disease was discovered to exist on the eastern seaboard of the United States, and shortly thereafter, pockets of infection were identified in São Paulo, Brazil; in Tobia, Colombia; in Choix, Mexico; as well as in Canada and other areas of the Western

Hemisphere. The original names by which the disease was known sometimes underscored its character as a "place" disease. For example, it was called *febre maculosa brasileira* but also "São Paulo typhus" in Brazil, "Tobia petechial fever" in Colombia, and *fiebre de Choix* as well as *fiebre manchada* in Mexico. As additional information became known about other rickettsial diseases, numerous investigators suggested more appropriate names for the disease, such as tick-borne typhus, tick spotted typhus, American spotted fever, or, simply, spotted fever. None successfully supplanted Rocky Mountain spotted fever.

After the introduction of the broad-spectrum antibiotics in 1948, Rocky Mountain spotted fever incidence in the United States dropped to about 250 cases per year, with only about 24 deaths. To some extent, the early and widespread use of antibiotics may have obscured the true incidence of the disease. Beginning in 1969 and continuing through the 1970s, the incidence of Rocky Mountain spotted fever rose inexorably in the United States, probably as a result of the development of suburban housing and the transformation of agricultural land into wooded recreational areas. Although this phenomenon was not reported from other countries of the hemisphere, it was reported in the Mediterranean basin, where *boutonneuse fever*, a related but milder spotted fever group disease, was known. The increase in Rocky Mountain spotted fever cases and deaths during the 1970s stimulated new research into diagnosis and prevention of the disease.

Unlike epidemic typhus, Rocky Mountain spotted fever poses no threat of erupting into epidemics. As a disease of nature, however, it is unlikely to be eradicated as a human hazard. If the public and physicians are alert to the possibility of infection during "tick seasons," effective antibiotic therapy can be administered and Rocky Mountain spotted fever need not cause unnecessary loss of life.

Other Diseases of the Spotted Fever Group

Three other major tick-borne rickettsioses are known throughout the world. Usually mild diseases, these three spotted fever group maladies are generally fatal only to the aged or debilitated patients. All exhibit a distinctive diagnostic characteristic, an *eschar*, or dark scab, that forms over the wound caused by the initial tick bite. Lymph nodes draining the eschar also swell and become tender.

Boutonneuse fever, named for the buttonlike eschar, was the earliest of these spotted fever group diseases identified. Described by Alfred Conor in

North Africa in 1910, the disease has also been known by many other local names, including Mediterranean spotted fever, *fièvre boutonneuse*, Marseilles exanthematic fever, Indian tick-typhus, South African tick-bite fever, and Italian eruptive fever. Its most common etiologic agent is *Rickettsia conorii*, the species name given in honor of Conor. In recent decades, other variant spotted fever group strains have also been identified as causing this disease. A number of different ticks are responsible for its transmission, the most common being *R. sanguineus*. In Africa, many people apparently gain immunity during childhood through a mild infection, for the disease is primarily seen in tourists or in new residents. From its local names, it is apparent that boutonneuse fever is known from Africa throughout the Mediterranean basin and into India. During the 1970s an increase paralleling that of Rocky Mountain spotted fever in the United States was reported in the Mediterranean basin.

Siberian tick-typhus was first documented during the 1930s, when exploitation of Siberian forest and steppes brought many people into the habitat of its vector ticks. Transmitted by several species of ixodid ticks, it is believed to be far more widespread than reported statistics indicate. Its etiologic agent is *Rickettsia siberica*. Known as well as North Asian tick-typhus, this disease is also found in China and in other north Asian republics.

Queensland tick-typhus, caused by *Rickettsia australis*, was first reported in North Queensland, Australia, in 1946. Its vector tick, *Ixodes holocyclus*, parasitizes marsupials in addition to wild rodents. In general, people working in forest and scrub areas in northern and southern Queensland are at risk of contracting this disease, although in 1979 an urban focus was reported in Sydney.

The final member of the spotted fever group of diseases is unique in being the only member not transmitted by a tick. Its name, *rickettsialpox*, clearly reflects its history as a disease defined by the investigators who first studied it. In 1946 a strange disease resembling mild chickenpox and exhibiting an eschar, or initial lesion, was reported in a New York apartment building. Charles Pomerantz, a local exterminator and amateur entomologist, had alerted New York health authorities to the possibility of some sort of arthropod-borne disease after he found mite-infected mice in the apartment-complex basement. New York investigators collaborated with the U.S. Public Health Service, and within 8 months the entire picture of the disease had been elucidated. The etiologic agent of the disease was shown to be a

hitherto unknown rickettsia of the spotted fever group. Because the organism was found to inhabit the mite *Allodermanyssus sanguineus,* a parasite of the house mouse, it was named *Rickettsia akari,* the species designation meaning "mite." Epidemiological research determined that the disease was contracted wherever mites had access to human living areas. In the case of the original apartment complex, the mites climbed up a central incinerator and infested the carpeting in apartments, thus rendering young children especially susceptible. In 1949–50 the illness was also identified in the Soviet Union, and was known there as *vesicular rickettsiosis.* A mild, nonfatal disease, rickettsialpox has not been reported in recent years in the United States and only sporadically in the former Soviet Union.

> ### VIII.121
> # Rubella

Rubella (German measles; 3-day measles) is a common, acute, viral infectious disease, principally of children and young adults, with worldwide distribution frequently characterized clinically as a mild rash illness. Inapparent infection is common and may occur in as many as half of infections. Rubella has special significance when a pregnant woman contracts the disease in early pregnancy because fetal infection can ensue and result in developmental abnormalities known as the congenital rubella syndrome (CRS). Rubella is a vaccine-preventable disease, but the vaccine is not yet widely used on a global basis.

Etiology and Epidemiology

Rubella is caused by the rubella virus, which is in the genus *Rubivirus* of the family Togaviridae. Rubella virus is 50 to 60 nanometers in diameter and contains a single-stranded RNA genome.

Rubella is a highly contagious disease transmitted by contact of susceptible individuals with the nose and throat secretions of infected persons, primarily by droplet spread. Infection also occurs by direct contact, by indirect contact through freshly soiled articles, and by airborne transmission. There is no reservoir for rubella other than human beings, which means that a continuous chain of susceptible contacts is necessary to sustain transmission. The period of communicability is from about 1 week before rash onset to at least 4 days after. There is no carrier state except for infants with congenital rubella, who may shed virus for many months after birth. Rubella's incubation period from time of exposure to onset of rash is 16 to 18 days, with a range of 14 to 23 days.

In populated areas with no or low vaccination coverage, rubella is primarily an endemic disease of children with periodic epidemics. However, a significant proportion of adults remain susceptible, and thus congenital rubella may result if a pregnant woman contracts rubella. In more remote isolated populations, rubella is not endemic and disease is dependent upon introduction of the virus from the outside, at which time an epidemic may occur, affecting all age groups born since the last epidemic. There is no evidence for a sex difference in incidence or severity of rubella, although more cases may be

reported in women because of concern for congenital rubella. There is no evidence for a racial difference in incidence or severity.

The risk of congenital rubella is related to gestational age at the time of maternal infection. Fetal or placental infection has been shown to accompany 85 percent of maternal infections that occur during the first 8 weeks of pregnancy. Data from the last major epidemic in the United States, which occurred from 1964 to 1965 and resulted in 20,000 infants born with congenital rubella syndrome, showed that the risk of developmental defects was about 50 percent in infants whose mothers were infected during the first month of pregnancy, 22 percent during the second, 6 percent during the third, and about 1 percent during the fourth month of pregnancy. Other investigators have shown that infection in the first 8 weeks of pregnancy also leads to high rates of abortion or stillbirth.

Distribution and Incidence

Rubella has a global distribution. Although it is not a reportable disease in most countries, is underreported in countries where it is a notifiable disease, and may be clinically inapparent in as many as 50 percent of infections, serologic surveillance demonstrates its existence throughout the world. In populated areas where rubella is both endemic and epidemic, between 80 and 90 percent of the adult population will show serologic evidence of prior infection. In remote or island populations where rubella is not endemic, a significant proportion of the population can be susceptible, which may lead to large outbreaks when the virus is introduced from the outside.

In some countries with extensive use of rubella vaccine and where rubella is a reportable disease, such as the United States and the United Kingdom, there have been impressive declines in reported cases of rubella and congenital rubella syndrome.

Immunology

Infants usually have a passive immunity to rubella because of maternal antibodies acquired transplacentally from immune mothers. This passive immunity protects the infant from infection for 6 to 9 months, depending on the amount of maternal antibody acquired.

Rubella infection in both clinically apparent and inapparent cases induces a lifelong immunity. Because a significant percentage of rubella infections are clinically inapparent, persons may develop immunity without recognizing that they have been infected. Several serologic tests for confirming infection or immunity have been developed, and it is also possible to isolate the virus from patients during the acute phase of the disease.

A single dose of live attenuated rubella virus vaccine confers long-term, probably lifelong, immunity in approximately 95 percent of susceptible individuals.

Clinical Manifestations and Pathology

The prodromal phase of postnatally acquired rubella usually occurs from 1 to 5 days prior to rash onset, but may be completely lacking, especially in children. Prodromal symptoms may include headache, low-grade fever, malaise, conjunctivitis, mild rhinitis, and lymphadenopathy (most commonly tender swelling of the lymph nodes behind the ears and at the base of the skull). The rash phase of illness begins with a reddish, discrete rash, sometimes itchy, usually appearing first on the face and then spreading to the hands and feet. Although the progression, duration, and extent of the rash vary greatly, it typically covers the whole body within 24 hours and has disappeared completely by the end of the third day – hence the name 3-day measles. It is important to note that the variability and sometimes the absence of prodromal symptoms as well as rash make a clinical diagnosis uncertain, and laboratory serologic tests are necessary for confirmation of the diagnosis.

Complications in postnatally acquired illness may include arthritis and arthralgia, which are more common in adults and women than in prepubertal children and men. Neurological involvement, including encephalitis, is a rare complication of rubella.

In congenitally acquired rubella, the fetal infection may result in abortion, stillbirth, congenital malformations, or growth retardation. The congenital rubella syndrome is the result of inhibition of cell multiplication in the developing fetus and a chronic infective state that may persist for many months after birth. Some consequences of fetal infection may not become apparent until years after birth. Common congenital abnormalities and active infective processes at birth include cataracts, deafness, central nervous system defects leading to mental retardation, structural defects of the heart and myocarditis, bone lesions, pneumonitis, and hepatitis.

History and Geography

The early history of rubella is confused with that of other illnesses that produce a rash such as measles

and smallpox. Although it has been suggested that the early Arabian physicians differentiated rubella as a form of measles known as *Hhamikah,* the disease appears to have been first described in 1619 by Daniel Sennert, who used the term *Rotheln (röteln)* and attributed the name, which seems to have been a popular term, to the red color of the rash. Two German physicians are generally credited with clinically describing rubella as a separate entity during the 1750s, and it continued to be called *Rotheln* by German investigators from the mid-eighteenth to the mid-nineteenth century. The early interest in the disease by German physicians apparently led to the use of the term "German measles" in other countries. It has, however, also been suggested that the word may have actually been "germane" rather than "German," with derivations meaning "closely akin to." In other words, "germane measles" was intended to indicate a disease similiar to measles.

In 1866 Henry Veale, a Scottish physician serving in India, published a description of 30 cases of rubella and proposed the name "rubella" as being "short for the sake of convenience in writing, and euphonious for ease in pronunciation." At the International Congress of Medicine in London in 1881, a general consensus was reached that rubella was an independent entity. William Squire summarized this consensus, noting, "A century was required to complete the separation of measles from smallpox. Another century passed from Thomas Sydenham to William Withering before scarlet fever was finally distinguished from measles. . . . The century is fulfilled that should give autonomy to rubella." During the next 60 years attention was focused on differentiating the characteristics and further describing the symptomatology and course of rubella, which was considered an inconsequential infection of childhood. The fact that rubella was due to a virus and transmissible by the injection of throat washings was established by Y. Hiro and S. Tasaka in 1938.

Then, in 1941, Norman McAlister Gregg, an Australian ophthalmologic surgeon, published a landmark work on his observations of an epidemic of congenital cataracts and other ocular and cardiac abnormalities in infants of mothers who had contracted rubella in the first trimester of their pregnancy. Although skepticism at first prevailed in the medical community, his observations were confirmed by other investigators in Australia, the United States, and the United Kingdom who also described other congenital abnormalities associated with rubella in pregnancy. The comprehensive paper on rubella published by Conrad Wesselhoeft in 1947 helped to draw world attention to the importance of Gregg's findings, and in 1953, Saul Krugman, Robert Ward, and their colleagues were able to document, through volunteer studies, that rubella infection can occur without rash.

The rubella virus was isolated and propagated in tissue culture in 1962 simultaneously by T. H. Weller and F. A. Neva at the Harvard School of Public Health in Boston and by P. D. Parkman, E. L. Buescher, and M. S. Artenstein at the Walter Reed Army Institute of Research in Washington, D.C. In addition to providing the tools needed to further understanding of the epidemiology of the disease, including the hemagglutination-inhibition test introduced in 1967, this isolation also led to subsequent research and development of vaccines. In 1969 a live attenuated rubella virus vaccine was licensed for use in the United States, and shortly thereafter other vaccine virus strains were adopted for use in the United States and in several European countries.

The World Health Organization (WHO) has coordinated collaborative seroepidemiological studies of rubella documenting geographic patterns. In countries without any sustained, large-scale immunization programs, it has been shown that rubella infection is widespread. It was also possible to show through serial seroepidemiological studies that rubella epidemics may occur even when clinical records do not document an outbreak of overt rubella. Urban areas demonstrate sustained circulation of virus, whereas rural areas may show patterns of lower immunity rates. In island or remote communities, many persons may be susceptible. In countries with sustained, large-scale immunization programs, the impact of control efforts has been demonstrated by a decrease in the numbers of cases of reported rubella and congenital rubella syndrome and of susceptibles in the population.

St. Anthony's Fire

This disease is generally associated with *ergotism,* a disease resulting from the ingestion of the ergot fungus that grows on rye. Most authorities assume that the name St. Anthony's fire refers to St. Anthony the Great, a third-century A.D. hermit and founder of Christian ascetic monasticism. This saint renounced the world for the deserts of Egypt and, according to hagiographers, there combatted the devil numerous times. His visions of the devil took the form of worldly pleasures, seductive women, dragons, banquet tables, and the like. However, St. Anthony of Padua, born in the late twelfth century, may also be connected to the name of the disease. This saint was a noted preacher, popular for his ability to exorcise demons. He was also known for restoring the insane to health, and was credited with miraculously healing an individual whose limb had been amputated.

Supposedly the "fire" part of the name refers to the painful skin infections, gangrene, and neurological disturbances that occur with ergot poisoning. Thus, in France north of the Loire where rye was a traditional staple grain, attributing most cases of *mal des ardents* to ergotism has seemed reasonable to historians. Sufferers there reportedly lost limbs, attributable to the gangrenous form of ergotism, if they survived both the initial inflammatory process and the generalized famine that accompanied epidemics of the disease. On the other hand, it is also quite possible that erysipelas and other bacterial skin infections were at the root of the symptoms mentioned, for these diseases also flourish under conditions of famine.

The disease we think of as St. Anthony's fire was commonly described in western Europe from 900 to 1700. During the eleventh century, recurrences of the "sacred fire" (usually associated with erysipelas in classical medicine) led to the creation of hospitals and also to an appeal to many different interceding saints, of whom Anthony was only one. In the Dauphiné region of France, however, Count Gerlin II acquired the relics of St. Anthony the Great and returned them in 1070 to Vienne (on the Rhône River). By 1090 healing miracles were being attributed to the bones, and local nobles helped a small group of lay hospitalers to form a pilgrimage site for sufferers of "fire." By the twelfth century, this hos-

pice was run by regular clergy, calling themselves "friars of the blue Tau," for the large Greek letter that came to symbolize Anthony iconographically. Wine or water steeped in the bones of the saint was offered sufferers as the miraculous cure; however, additional food supplements at the hospices of St. Anthony may have arrested ergot intoxication.

During the later Middle Ages, the cult of St. Anthony spread well beyond the regions of southern France and Savoy, where it had gained rapid popularity, into central Europe as far east as Russia. There the people often commemorated cures with votive art that has come to symbolize the disease to posterity. For example, in Figure VIII.122.1, a victim stretches his fiery hand toward the saint for help.

The earliest unambiguous references to the ergot fungus occur in the late sixteenth century; by the late seventeenth century, ergotism was described independently of the popular attribution to St. Anthony. The older name – perhaps the older "disease"

as well – rapidly disappeared from learned descriptions, in part because of the association of ergot fungus on rye and other grains with epidemics of convulsive and other neurological disorders, rather than with the skin infections and subsequent gangrene that characterized "St. Anthony's fire."

Scarlet Fever

Scarlet fever is an acute infectious disease, caused by certain types of group A hemolytic streptococci. The disease is characterized by sudden onset of soreness on swallowing, with fever and headache. A rash appears within 2 days of onset, and desquamation follows.

The term "scarlet fever" was supposedly first used by Thomas Sydenham in 1683, but it appeared in a diary of Samuel Pepys in an entry for November 10, 1664. From the seventeenth to the early twentieth century, the word *scarlatina* was popularly used to denote a mild form of the disease.

Distribution and Incidence

Like the streptococcal sore throat to which it is closely related, scarlet fever is a disease of temperate climates, prevailing generally in the winter months. It occurs principally in young children, although adults may suffer sore throats as a result of the same infection.

Etiology and Epidemiology

The group A hemolytic streptococci are responsible for a range of afflictions other than scarlet fever,

including erysipelas, rheumatic fever, and the sore throats known as tonsillitis in Great Britain and as pharyngitis in the United States. Scarlet fever is caused only by certain strains that produce (or release) a soluble toxin, whose absorption causes the rash characteristic of the disease. Different strains of streptococci produce different amounts of toxin. Epidemics thus vary greatly in severity, with mortality rates ranging from 0 to 30 percent. Transmission of the infection is by intimate contact, such as occurs in overcrowded homes and classrooms, and evidence of airborne or droplet nuclei infection is slight. In the past, scarlet fever occasionally occurred as a hospital infection, and the disease was also transmitted in contaminated milk.

Susceptibility to the skin rash differs according to the immune and hypersensitivity status of the individual. Those who have experienced scarlet fever once are unlikely to do so again, but remain vulnerable to streptococcal sore throats when exposed to infection with a new serologic type. Research on the susceptibility of different population groups, as defined by a positive skin test (Dick test), suggests that more than half of young infants are immune to the disease, but that by the age of 2 years, only some 20 percent remain so. Thereafter the proportion of immunes rises steadily through childhood, reaching 77 percent at 10 to 15 years and 86 percent in adults.

The rare occurrence of second attacks of scarlet fever with rash is probably due to infection with a new antigenic erythrogenic toxin. The available evidence suggests that the geographic dominance of particular strains of scarlet fever streptococci is long-term, varying from country to country and from time to time. In Britain, during the years 1936 to 1956, type 4 streptococci were isolated more often from scarlet fever than from tonsillitis cases. In 1964–5, the commonest type associated with scarlet fever was type 4 in Britain, type 22 in East Germany, and type 1 in the former Soviet Union and Holland. With all types, the disease appears to follow a general pattern of alternate severity and mildness. At present, it is very common, though very mild, in both Europe and North America. Fatalities have ceased to occur, and the prevailing mildness of type means that cases tend to escape notification.

Clinical Manifestations

The initial symptoms of scarlet fever are the same as those of streptococcal sore throat: sudden onset of soreness on swallowing, accompanied by fever and headache. Vomiting and nausea are often early symptoms in young children. The characteristically erythemateous and punctuate rash appears within 2 days, at first on the upper chest and back, then spreading to the rest of the body. In white patients the rash does not commonly appear on the face, but in about half of all black patients it does. The rash is accompanied by the characteristic raspberry tongue. In general, the rash is variable in its manifestations. Desquamation usually occurs, beginning sometimes as early as the fifth day, sometimes as late as 4 to 5 weeks after the onset of the disease. A range of complications, principally affecting young children, add to the dangers of the disease. These include anemia, otitis media, rheumatic fever, and meningitis. In rare cases, scarlet fever appears in severe septic or toxic forms.

History and Geography

The early history of scarlet fever prevalence is obscure. It is possible that outbreaks were observed by Near Eastern practitioners of the Arabian school, but the first undoubted account of a disease with a fiery rash as a characteristic was provided by Giovanni Filippo Ingrassia of Palermo in 1553. The disease was apparently present in Germany and Italy in the early seventeenth century, and we know of a severe outbreak in Poland in 1625. At that time, the disease was variously known as *rossalia, purpurea epidemica maligna,* and *febris miliaria rubra.* It is clear from observations by Daniel Sennert in 1619, Michael Düring in 1625, and Johann Schultes in 1665 that the scarlatinal manifestations of desquamation, nephritis, and dropsy were well known before the disease received its modern name. Although in 1683 Sydenham wrote of the disease as having a mild character, he nevertheless established its autonomy, and distinguished it from other acute exanthema, notably measles, by naming it. By the end of the seventeenth century, the identity of scarlet fever was well recognized, although much epidemiological confusion remained, and still remains, over the respective roles of scarlet fever, streptococcal sore throat, and diphtheria (cynanche maligna) in seventeenth-century and eighteenth-century epidemics.

During the eighteenth century, scarlet fever was present in epidemic form throughout Europe and the United States. It appeared in Copenhagen in 1677, in Scotland in 1684, in the United States in 1735, and in Sweden in 1744. In general, however, the evidence suggests that the disease made irregular epidemic appearances, and that its mortality varied considerably. During the early eighteenth century, it seems to have been of fairly mild character, but

Dutch and Swedish evidence suggests that by mid-century a very virulent strain was also present.

The character of scarlet fever as a relatively new disease may be reflected in the age incidences reported during this period. Sydenham noted that it attacked whole families, though more especially the infants, whereas Nils Rósen von Rosenstein observed in 1744 the simultaneous occurrence of sore throat without rash in children in infected households. This pattern was observed in adults by Maxmilian Stoll in 1786. In the last years of the century, scarlet fever was extensive and virulent in Europe, with severe outbreaks in Denmark and Finland in 1776–8, and in central Germany in 1795–1805. By 1814 it was again very mild, but continued its global spread, appearing in South America in 1892, in Greenland in 1847, and in Australia and New Zealand in 1848.

During the 1820s and 1830s, however, a more virulent form reappeared, and consequently, the disease was the leading cause of death among infectious childhood maladies until 1875. During the 1880s, the disease continued to be widely prevalent but began to decline as a cause of death, and by the 1890s its character was again relatively mild, although not as mild as it has become today. This decline in severity was first apparent in Britain and western Europe, although a malignant form was still present in Poland, Russia, and Romania during the 1930s. Observations by Edward Wilberforce Goodall made in the Metropolitan Asylums' Board's Eastern Hospital, London, showed that as fatality dwindled, so did the more serious clinical forms.

Streptococci were first isolated from the blood of scarlet fever patients by Edward Klein in 1887, but he failed to reproduce the disease in animals. In 1911 Kari Landsteiner produced a similar disease in monkeys by inoculating them with faucial exudate from scarlet fever patients, but until about 1922 the streptococci were generally considered to be secondary invaders.

It was ultimately observation of human beings that proved scarlet fever to be a result of streptococcal infection. Seminal work by George Dick and Gladys Dick in the early 1920s proved scarlet fever to be primarily a local infection of the throat caused by type A hemolytic streptococci. In 1923 the Dicks successfully inoculated volunteers, and in 1924 developed the *Dick test:* the intradermal injection of a diluted filtrate of a broth culture of a scarlatinal strain of streptococcus which, by the resultant appearance or not of a local erythemateous reaction, determines the susceptibility of the subject to scarlet fever. In other words, a negative Dick test is an indication of antitoxic immunity.

Schistosomiasis

Schistosomiasis (bilharzia), known also by many local names such as "red-water fever," "snail fever," "big-belly," and "Katayama disease," is an "immunologic disease" induced by eggs of blood-vessel-inhabiting worms of the class Trematoda, genus *Schistosoma.* These eggs induce an immunologic response after they become trapped in the body organs, especially the liver, gut wall, and urogenital tract.

There are three major human schistosome species: *Schistosoma haematobium,* which inhabit the veins of the bladder area and whose eggs are discharged in the urine; and *Schistosoma mansoni* and *Schistosoma japonicum,* which inhabit the mesenteric veins supplying the intestines and whose eggs are discharged in the feces. In every case, however, the worms may also be found in the liver and portal system. There are also a few other species that can parasitize humans. These include the japonicum-like *Schistosoma mekongi* from the lower Mekong River basin, and some African schistosomes, such as *Schistosoma intercalatum,* that normally parasitize cattle and wild animals.

Terminology
The terminology of this disease is very confusing. Theodor Bilharz, the discoverer of the trematode worm responsible for the disease, placed it in the genus *Distoma,* a broad genus that was soon abandoned as more trematode species were discovered. Numerous generic names were thereafter invented to label the worm, including *Schistosoma* in 1858 (the name that must stand according to the rules of zoological nomenclature), *Gynaecophorus* in 1858, *Bilhar-*

zia in 1859, and *Thecosoma* in 1860. Before World War II, however, in an understandable desire to honor the name of Bilharz, the disease was commonly called *bilharziasis*. But in 1949, members of the World Health Organization's Study Group on Bilharziasis in Africa, ignorant of the tight rules of zoological nomenclature, recommended that the name *Bilharzia* be used for the worm and "bilharziasis" for the disease. A recommendation to this effect was made to the International Commission of Zoological Nomenclature which ruled, in 1954, that the disease should be called bilharziasis, while retaining the name *Schistosoma* for the worms.

This ruling makes little sense. The name bilharziasis would be used only for the disease if the generic name of the worm were *Bilharzia,* just as trypanosomiasis is used to denote the disease caused by protozoans of the genus *Trypanosoma.* But because the generic name *Schistosoma* must be retained, the term "bilharziasis" becomes invalid, although the word "bilharzia" could be used to denote the disease.

Logic, however, has frequently ruled over historical awareness, and since World War II, the Americans, in particular, have used the word "schistosomiasis," or even its ugly derivative, "schisto," to denote a disease whose causal agent belongs to the genus *Schistosoma.*

Distribution and Prevalence

The disease has an almost worldwide tropical distribution, but is mercifully absent from the Indian subcontinent. *S. haematobium* is highly endemic in the Nile Valley, and has an irregular distribution in the Middle East and North Africa (Map VIII.124.1). It occurs in most West and Central African countries, along the coastal countries of East Africa from Somalia to Natal, and in the islands off the east coast. *S. mansoni* is highly endemic in the Nile Delta and now seems to be spreading into the Nile Valley (Map VIII.124.2). In Africa it has a distribution similar to (although more irregular than) that of *S. haematobium.* But, unlike *S. haematobium, S. mansoni* also occurs in South America (Brazil, Surinam, and Venezuela) and in some islands in the Caribbean (Dominican Republic, Puerto Rico, St. Lucia, and others) (Map VIII.124.3); the parasite was transported from Africa to the New World as an unintended by-product of the slave trade. Oriental schistosomiasis, caused by *S. japonicum,* is endemic to the Yangtze Valley and many coastal provinces of mainland China (Map VIII.124.4). It also occurs in Central Sulawesi and the Philippines, and there are

a series of smaller foci in Malaysia, Thailand, and Japan.

Over 200 million people are said to be infected with the disease, although the data on which such figures are based are extremely variable and unreliable. There is little doubt, however, that in villages of the Nile Delta and other areas where there is constant contact of the human host with water, the prevalence can be as high as almost 100 percent. On a worldwide scale, a recent World Health Organization survey revealed that in 42 countries surveyed, 21 percent of the population was infected.

Etiology

The worms are acquired in fresh water by contact with their larval stages. The worm eggs, which are highly diagnostic for each species, are shed in the urine or feces of the human host and hatch to produce a minute short-lived larval stage called a *miracidium*. The miracidium of each species invades the tissues of a specific snail host where it undergoes asexual reproduction, eventually to produce the final larval stage. The final stage, the *cercaria,* is released daily in very large numbers from the snail, swims freely in the water, and then bores into the skin of the human host. In the human the parasite migrates to the liver via the heart and lungs, eventually to mature in the veins of the liver, gut, or bladder. Eggs appear in the urine or feces approximately 30 to 40 days after infection.

Epidemiology

The disease has a very complex epidemiology, resulting in part from a quite intricate relationship between the parasite and the snail intermediate host. Not only are there strains of each schistosome species, but also there are a multiplicity of snails that vary in their susceptibility to these strains and have a taxonomy that is in a constant state of revision. Historically this has long been a source of total confusion.

In very general terms, the snail hosts of *S. haematobium* belong to the genus *Bulinus,* which has been divided into two subgenera: one with three species complexes, including the *Bulinus truncatus–tropicus* group; and the other with one species complex, the *Bulinus africanus* group. The *B. truncatus–tropicus* species complex act as intermediate hosts to *S. haematobium* in Egypt and other countries north of the Sahara, whereas the *B. africanus* species complex generally serve as the most important intermediate hosts south of the Sahara. The genus *Biomphalaria* acts as the intermediate host for *S. mansoni.* As in

Bulinus, the genus has been divided into species complexes, with the *Biomphalaria pfeifferi* group acting as the most important complex in Africa south of the Sahara and in the Middle East, and *Biomphalaria alexandrina* the host in the Nile Delta. In the Americas, *Biomphalaria glabrata* acts as the most effective host. Whereas *S. haematobium* and *S. mansoni* are transmitted by species of pulmonate freshwater snails, *S. japonicum* is transmitted by amphibious prosobranch snails belonging to the species *Oncomelania hupensis,* of which there are six geographic subspecies. The aquatic prosobranch snail, *Tricula aperta,* endemic to the Mekong River, acts as the intermediate host of *S. mekongi.*

Schistosomiasis can be a serious chronic disease in poor rural areas, where children and adults, because of recreational, domestic, religious, and occupational reasons, come regularly into contact with fresh water contaminated with the schistosome cercariae. In most endemic areas, the prevalence of the disease and the intensity of infection (i.e., the number of eggs released, which is an indication of the number of worms carried) peak among those in their teenage years. Indeed in areas of high endemicity virtually all children become infected at some time. Thereafter, a decrease in prevalence and a decline in intensity occur. Even in highly endemic areas the rate of transmission of the disease is low. This follows, in part, from the patchy distribution of the surprisingly low numbers of infected snails.

Reservoir hosts play an important role in Oriental schistosomiasis, where the parasite is naturally transmitted between humans and other vertebrates, including many domesticated animals such as cattle, pigs, and dogs. Although animals are believed to play little if any role in the transmission of the two schistosome species in Africa, rodents are thought to act as important reservoirs of *S. mansoni* in South America.

The human schistosomes belong to a large family of trematodes, the Schistosomatidae, which also parasitize birds and mammals. In many parts of the world, particularly in the lake country of the central and western United States and Canada, the cercariae of these nonhuman schistosomes can penetrate the skin of humans by accident. Although these cercariae are destroyed in the skin, they nevertheless cause a harmless but very irritating rash – "swimmer's itch" or "schistosome dermatitis."

Pathology
Disease pathology is due to embolized eggs that induce inflammatory reactions in various body organs,

from which arise the classic symptoms of chronic schistosomiasis. This pathology is, however, very variable and is generally related to the intensity of infection. There are also pathological differences among the various species and among strains of the same species.

In *S. haematobium* lesions occur in the bladder and ureter around the entrapped and calcifying eggs, with the eventual laying down of fibrous connective tissue. The symptoms include blood in the urine (hematuria), painful and excessive urination (dysuria), and various symptoms associated with obstructions of passages, such as distension of the ureters (hydroureter) and distension and atrophy of the kidneys through blockage of the urethras (hydronephrosis). In the intestinal schistosomes, the lesions occur in the gut wall and liver, leading to the deposition of fibrous connective tissue. The venous obstruction produced by these lesions results in a compensatory increased arterial flow that leads to portal hypertension and the classic enlargement of the liver and spleen (hepatosplenomegaly). Eggs of all three species may also become trapped in the lungs, and with *S. japonicum,* nervous disorders or "cerebral schistosomiasis" can also occur if egg aggregates come to rest in the brain.

Immunology
The post-teenage decline in the disease has often been taken as evidence for a gradually acquired immunity, but this probably plays a less significant role in the decline than do changing patterns of water contact. However, "concomitant immunity" is known to occur in experimental animals. The adult worms induce an immune response that has no effect on the adult worms but that protects the host from reinfection by destroying many of the invading cercariae. The adult worms, themselves, are able to circumvent this immune response 2 to 3 days after boring into the skin by acquiring host antigens that become bound to the surface of the parasite; the host is no longer able to recognize the worms as foreign organisms. Whether concomitant immunity plays any significant role in humans has yet to be determined.

History

Pre–World War I
Human schistosome worms were first described from Egypt by Theodor Bilharz in 1851, and their presence was related to disease symptoms by Wilhelm Griesinger shortly thereafter. Both men naturally assumed the worm to be a single species,

Distoma haematobium (later named *S. haemato-bium*), occurring in the blood vessels of the gut or bladder. That there were two Egyptian species with different egg types was first suggested by Louis Sambon in 1907, who named the second species *S. mansoni*. A year later, Piraja da Silva in Brazil gave the first description of *S. mansoni,* but unfortunately assumed it to be another species distinct from both *S. mansoni* and *haematobium.* A long and testy controversy over the existence of two species in Egypt, with different morphologies and egg types, was finally resolved by Robert Leiper in 1915. Meanwhile, in 1905 Fujiro Katsurada had described eggs and worms from patients and cats in the Yamanashi district of Japan, and named them *Schistosoma haematobium japonicum.*

The life cycles of the worms long remained a mystery, although it was usually assumed that an intermediate host was involved. But Arthur Looss, the foremost authority on the disease at the turn of the century, argued in 1894 that there was no intermediate host, and that the miracidia bored directly back into human beings. This bizarre theory likewise generated a controversy that was finally resolved by experimental work in Japan. There, in 1913 Keinosuke Miyairi and Masatsuga Suzuki discovered the snail host into which the miracidia penetrated, and for the first time described the fork-tailed schistosome cercariae emerging from the snails a few weeks later.

Leiper had been sent to China at this time to uncover the mysterious life cycle of the worm, and, hearing of the Japanese success, had hurried to Japan to confirm the life cycle. In 1914 he was posted to Egypt, where he quickly resolved the life-cycle problem in that country, distinguishing the two species of schistosome worm in Egypt not only by their morphologies and egg types but also by their different snail hosts.

With these problems resolved, interest in schistosomiasis subsided a bit, particularly because the disease was thought curable by the drug antimony tartrate and preventable by the snail-killing chemical copper sulfate.

The Interwar Years

Between the two world wars, campaigns against the disease using these chemicals were carried out in Egypt, the Gezira irrigated area of the Sudan, Southern Rhodesia, and South Africa, particularly after schistosomiasis was found among the children of "poor whites" in rural Transvaal. In addition, the high prevalence of the disease among African mine

laborers recruited for the South African mines generated research on the disease by members of the South African Institute for Medical Research. The interwar years also witnessed the first involvement with the disease by the International Health Division of the Rockefeller Foundation, which financed an attempted eradication campaign against hookworm and schistosomiasis in Egypt between 1929 and 1940. Moreover, in 1924 Ernest Faust and E. Meleney, two faculty members at the Rockefeller-funded Peking Union Medical College, first discovered the life cycle of *S. japonicum* in China.

Post–World War II

After World War II, interest in the disease dramatically increased, especially in the British, French, and Belgian colonies in Africa. By 1950, schistosomiasis, previously considered to be unimportant outside Egypt, Sudan, South Africa, and to some extent China, was recognized as the most important tropical disease in the world, after malaria. In America this interest followed from an outbreak of the infection among American troops in Leyte, in the Philippines, where in 1944 over 1,000 troops of combat engineering companies involved in bridge building and road construction came down with the disease. The scientists and physicians, who were posted to Leyte to deal with the problem, brought the disease to the attention of American academics immediately after the war and initiated the growth in schistosomiasis research.

In British Africa, where medical work had long been hampered by the policies of a penny-pinching empire, a series of Colonial Development and Welfare Acts passed every 5 years between 1940 and 1955 transformed the Colonial Office into an agent of colonial development. Money was made available for medical research, most of which was allocated for work on trypanosomiasis and the tsetse fly. But a helminth subcommittee of the Medical Research Advisory Committee was also formed, which began to stress the danger of schistosomiasis, particularly as new irrigation schemes, built as part of the new emphasis on colonial agricultural development, threatened to spread the disease. The subcommittee initiated, for example, testing of a new drug, Miracil D, discovered by the British after occupation of the Bayer laboratories in Elberfeld toward the end of World War II.

The first major British work on the epidemiology of the disease in colonial Africa took place between 1955 and 1965, a period that saw the East Africa Medical Survey conducted while the Nationalist Gov-

ernment of South Africa initiated surveys of the disease and supported laboratory research on experimental schistosomiasis in animals.

The 1950s also witnessed the first mass campaign against the disease that involved more than the usual introduction of latrines, drugs, and mollusc-killing chemicals by foreign experts. In 1958, as part of the Great Leap Forward, the Schistosomiasis Subcommittee of the Chinese Communist Party initiated another such campaign against schistosomiasis. Utilizing a host of methods including the mass reclamation of swamp land, the Chinese eradicated the disease from many areas of the country. In 1949 perhaps 10 million Chinese were heavily infected with *S. japonicum,* whereas today the number is reported to have dropped to 2.4 million lightly infected cases.

The threat posed by irrigation schemes led to the postwar development of better molluscicides to replace the ineffective copper sulfate. Niclosamide, selling under the trade name of Bayluscide, became the chemical of choice, but results were disappointing. Chemotherapy has now become the favored weapon, particularly after the important 15-year experimental control campaign in St. Lucia (1966–81), sponsored by the Rockefeller Foundation, and after the development of single-dose drugs to replace the highly toxic antimony compounds and Miracil-D, used earlier. Oral oxamniquine proved effective against *S. mansoni,* and metrifonate against *S. haematobium,* whereas the newly developed praziquantel is emerging as a "wonder drug" effective against all schistosome species.

Today, with major support from the McConnnell Clark Foundation, a great deal of emphasis is being placed on problems of schistosome immunity and the development of vaccines.

Scrofula (Scrophula)

Scrofula can be defined only historically. That is, scrofula is a term about which there was some measure of consensus in the past, but one that has now been largely superseded by terms that indicate some form of tuberculosis. It must be emphasized, however, that scrofula is *not* simply an old name for what we call tuberculosis. Our ontology of disease centers on the tubercle bacillus, and we would commit a grave historical error if we assume that with its aid we can know what was actually there in old discussions of scrofula. To understand these old discussions, we need to know how and why the old picture of scrofula was put together.

The distribution of scrofula, as we shall see below, has much more to do with the religious and political convictions of those who saw it than with physical geography or economic conditions or other circumstances normally considered conducive to diseases. Likewise in regard to its clinical manifestations, we may note, first, that this term itself implies an underlying entity that becomes manifest. But, second, scrofula, historically, *was* its collection of symptoms and signs. What we need to understand is what went into that collection, and why.

History and Geography
"Scrophula," like "scurvy" and "syphilis," is not a term that was used by the ancients. Whereas there may be special reasons why the latter two were unknown (a distribution to the north of the ancient Mediterranean and a possible Columbian origin, respectively), there seems to be no reason to suspect that scrofula was a new disease. Or, at least, so it seemed to many of the humanist doctors of the Renaissance, trying to reconstitute Greek medicine. In fact, the best they could do in the case of scrofula was to claim that one of its chief symptoms, tumors in the neck, was to be identified with the *struma* of the classical physicians. But simple strumae in the ancient descriptions were not associated with the other features that Renaissance physicians knew were part of scrofula. But how did they "know" this? Where did their picture of scrofula come from?

The answer is that there were medieval descriptions of scrofula. Partly these came from a surgical tradition, which was less Hellenizing than the physicians' medicine of the Renaissance. And in part they came from a popular tradition in which scrofula was

identified as the "King's Evil," and it was believed curable by the touch of a king. The essence of the medieval ceremony of touching in order to dispel the evil was that it demonstrated the quasi-sacerdotal nature of the office of kingship. The political advantages were clear, for a king, in performing the cure, showed that he was king in accordance with God's will. This was the important point in the seventeenth and eighteenth centuries, when the nature of scrofula was most energetically explored: The power of curing by the Royal Touch was a power vouchsafed by God only to the *true line* of kings. It could therefore be used to legitimate claim and accession to the throne. The kings of France continued to touch until the Revolution, and were emulated by other monarchs. In France and pre-Reformation England, the religious nature of the ceremony cemented the relationships and mutual stability of church and throne. It was a ceremony too miraculous for the taste of some Protestants, although the English Puritans at first tolerated it, and James I, although of a Calvinist background, found it increasingly expedient to use the Touch. But by the time of Charles I, his opponents saw it as a justification of absolute royal rule by a king who claimed to act as a representative of God. The Stuarts, whether on the throne or in temporary or permanent exile, continued to touch for the King's Evil, and their supporters continued to claim that their success in curing scrofula was a sure sign of their descent in the true line and thus the only legitimate monarchs. The Puritans and Parliamentarians saw the Touch as politically dangerous and tried to suppress it. Queen Anne was the last British monarch to use the Touch. The Hanoverians, as kings of political convenience, made no attempt to practice it, and their Whig supporters professed horror at a medieval and superstitious ritual.

The strongest passions were aroused in the conflicts that surrounded the issue. Crowds pressing around the Stuart kings to receive the Touch contained thousands of individuals; and there is no need to emphasize that in the Civil War the questions that split families were ones of religion and personal salvation, and of liberties and duties on Earth. Because the King's Evil was intimately bound up with the person of the king, if we look for a "distribution" of scrofula – for example, by examining seventeenth-century medical works – we find abundant references to the disease in Britain and France. But elsewhere the texts may be completely silent about the disease. Thus in Holland, recently freed from the rule of an absolutist and Catholic monarch, and a republic of

sorts, scrofula had no place in the medical consciousness. Nor did Italian or German medical men, with no national attachment to a true line of kings, have much reason to emphasize scrofula as a disease entity, but rather viewed its separated symptoms as different entities. By the eighteenth century, some medical reference works betray an Enlightenment embarrassment in identifying scrofula as a disease that had a nonmedical cure, the Touch. In discussing the disease, British writers of the eighteenth century drew on a tradition of literature that rested on the works of Richard Wiseman, surgeon to Charles II. In the earlier nineteenth century, with the disappearance of the French line of kings, scrofula continued to be identified, although perhaps more regularly in its adjectival form and applied to a symptom. The notion that lay behind the name did not long survive germ theory, when attention turned away from collections of symptoms to causative microorganisms.

Clinical Manifestations: Contemporaneous Observations

To this point we have seen something of the nature, geography, and history of scrofula. We should next examine what it was that contemporaneous observers saw when describing the disease. The classic description was that of Wiseman (1705), a passionate royalist, to whom the Restoration seemed an expression of God's will, which had placed the rightful line of kings back on the throne. The power of the king to cure by the Touch was triumphantly demonstrated again, and if it was good to show that the king cured, it was better to show that he cured a disease that medicine or surgery could not. Thus Wiseman selected only the most extensive and difficult cases to go forward to the king. He rejected the simple identification of scrofula and struma and said that "none of these definitions seem to describe sufficiently the Disease which we in England call the Kings-Evil." Scrofula, he insisted, included more than the tumors-in-their-own-membranes that was struma: There were the bifurcated swelling of the upper lip; the tumors of the muscles, ligaments, tendons, and bones; the fistulae of the tonsils and of the lachrymal region of the eyes; together with ophthalmia. The cases sent to the king had a characteristic tumor near the mastoid muscle, and protrusion of the eyes – *lipitudo*.

Wiseman, of course, was in a position to insist on his definition of scrofula in that he both chose who would receive the Royal Touch and published the most authoritative account of the condition. But he drew together his description of the disease partly from descriptions made by other practitioners, and there must have been something like a national consensus of what the disease consisted of. There would not otherwise have been any perception of the disease or the king's role in its cure among the thousands of ordinary people, or among their parsons or squires who, we may suppose, encouraged them to go to London for the Touch.

The term "scrofula" remained in use in mainly British and French medical texts through the eighteenth century, and we can gather more information from medical practice in hospitals about what physicians saw the disease to be. The voluntary hospitals of the eighteenth century were charitable institutions of one form or another. Demand for effective use of charitable funds (and the utility of recovered patients for advertising purposes) often led to pressure for a quick turnover of patients. This meant that chronic cases were generally not admitted, nor were infectious cases, on the grounds that they would endanger the other patients. So when we see scrofulous patients being admitted to an eighteenth-century hospital, we can assume that the physician or surgeon who made the admissions did not think that the disease was chronic or infectious. In practice, admissions to hospitals show the same ambivalence about the nature of scrofula as the eighteenth-century medical world at large. Sometimes the term simply did not exist in the language of the physician in charge or in his hospital, and at other times scrofulous men and women were refused admission as incurable or even infectious. Often a physician could not tell whether the patient's symptoms were scrofulous, and took in the patient for tests. Sometimes admittedly scrofulous patients were taken into hospitals in the belief that they were not infectious and that a course of mercury-sweats would cure them.

From the records we can see that the physician or surgeon was looking for a number of things to establish that his patient was scrofulous: an itch and tumors in the glands, joints, and other tissues. As the disease progressed, the physician saw these tumors change into ulcers, which became deep and ultimately produced caries in the bones. Exploratory surgery was used to discover whether the last stage of the disease had been reached and what, accordingly, the prognosis was. Sometimes patients were sent home as incurable, sometimes they were treated in a hot room with mercury-sweats to unblock their glands and vessels of the impediment that was held to cause scrofula. Which of these many alternatives was used probably depended on where the doctor had been trained.

The politics of early-nineteenth-century Europe no longer supported the idea of the "true line of kings." Without true kings, there was no King's Evil, and scrofula was seen as a disease entity less often than in the preceding century. It is true that a system so influential as that of William Cullen retained the disease entity, but in fact his subdivision of it helped to destroy the unit of scrofula as a term. He distinguished, first, "scrofula vulgaris" as the disease in its external form, without complications. This is probably the scrofulous itch of the hospitals. Cullen's second type was "scrofula mesenterica," the internal form of the disease, with swelling abdomen, pale countenance, and loss of appetite. The third type was "scrofula fugax," consisting of swelling about the neck and corresponding to the old struma. Cullen's fourth category was "scrofula americana," which by the 1830s was thought of as European scrofula combined with the yaws.

The term "scrofula" survived largely in the adjectival form, so that scrofulous tumors or ulcers could be seen and described on their own without a necessary connection to the other defining characteristics of the seventeenth-century disease. With the new emphasis on postmortem pathological anatomy of the first half of the nineteenth century, cases of internal scrofula were often found to be characterized by tubercles in the lungs. The discovery (by Robert Koch in 1882) of the bacillus responsible for these created an ontology of disease around tuberculosis, thus rendering scrofula peripheral to medicine and accessible only to the historian.

Scurvy

Scurvy is a deficiency disease, arising from a lack of vitamin C (ascorbic acid) in the diet. It occurs most characteristically in the absence of fresh fruit and vegetables, but can still be avoided when these are not consumed if the diet is rich in uncooked meat as in the case of Eskimos (heat destroys the vitamin). Scurvy does not appear in a regularly recognizable way in the ancient medical literature, and its name is not classical but, rather, derived from the north European vernaculars of the Renaissance. It was, for example, *schverbaujck* in Dutch and *scorbuck* in Danish, and Latinized in 1541 by Johannes Echthius, a Dutch physician living in Cologne, as *scorbutus*. In the slave trade it was often called the *mal de Luanda.*

Etiology, Epidemiology, and Distribution

Human beings, like guinea pigs and monkeys but unlike many other animals, do not synthesize vitamin C. No doubt this reflects a period of evolution in a vitamin C–rich environment; and, with the expansion of the species to all parts of the Earth, less generous climates have inevitably taken a toll due to scurvy. The disease occurs where economic, social, or climatic factors prevent access to an appropriate diet, and frequently has appeared under circumstances where diets are circumscribed, including long sea voyages, during military operations, in prisons, with the failure of crops, and during the Gold Rush. In the modern period, infantile scurvy has been a problem, for example, in Canada during the decades 1945–65, where it occurred mostly among the lower socioeconomic groups. As with other occur-

rences of infantile scurvy, this period was associated with a trend away from breast feeding, combined with maternal ignorance about substitute foods. The same causes were at work in cases in Australia.

Scurvy occurs occasionally in slavish followers of fad diets, and more commonly in middle-aged men living on their own and neglecting their diets. The disease is not widely reported from the Third World, perhaps because of a comparatively greater availability of fresh fruit and vegetables in some countries, but more generally no doubt because of a lack of the medical services that would be the normal route of reporting the disease.

It can be said in general that scurvy is a disease of northern countries although, as observed, the traditional diet of the Eskimo is sufficient to prevent it. Until recent times adult scurvy was endemic in Russia. This was not the case with infantile scurvy, however, for properly suckled infants do better than adults when the general diet tends toward the scorbutic.

Clinical Manifestations

Various individuals in the modern period have subjected themselves experimentally to a diet free of vitamin C, and the characteristic features of the disease have been carefully monitored. At about 12 weeks the first sign, a feeling of lethargy, appears. The first physical sign appears at 19 weeks, when the skin becomes dry and rough and the hair follicles form lumps. Small hemorrhages in the legs begin at about 23 weeks, and a bit later fresh wounds will no longer heal. One of the classical signs of scurvy, the swollen, purple, and soft gums, does not appear until about 30 weeks of a diet free of vitamin C. In a wartime study on a group of conscientious objectors, one of the volunteers developed a tubercular lesion at 26 weeks, and two more suffered what seems to have been cardiac hemorrhage, at 36 and 38 weeks. They were clearly close to that stage of the disease that had killed another self-experimenter in the eighteenth century, not to mention many thousands of sailors. At this point, the volunteers were given large doses of ascorbic acid, and all made complete recoveries.

In the young, scurvy produces reabsorption at the end of the long bones and a disappearance of cartilage. Postmortem examination, particularly in animals, reveals a characteristic subperiosteal hemorrhage. Historical evidence, which includes cases far more severe than modern cases, reveals loss of elasticity of the flesh, loosening of the teeth, and the reopening of old wounds and fractures.

History

Outbreaks

Antiquity. No doubt scurvy appeared often in ancient times – perhaps during sieges – and no doubt was treated by medical personnel. But we cannot claim that the disease was really known to the ancients unless we can give evidence of some sort of consensus about it. To discuss an illness and write about it means, at least, that the disease has a name; but the ancients did not seem to have had a name for scurvy. In any event scurvy could not be found in the writings of Hippocrates or Galen by individuals of the late fifteenth and sixteenth century, to whom the disease was so obvious, and for whom medicine was founded on Hippocrates and Galen. As with the other apparently new disease of the Renaissance, syphilis, it was important for humanist physicians to believe that, notwithstanding a change of name, the old writers had known the disease. Only then could it be fitted into the newly classical body of theory and practice of medicine and an effective treatment sought. Attempts were made by scholars to show that Hippocrates was not ignorant of scurvy, but the disease was treated as new by practical persons like the ships' surgeons who saw so much of it.

Renaissance Through the Eighteenth Century: Maritime Scurvy. Of course, the circumstances surrounding scurvy's appearance during the Renaissance and Early Modern Europe were very different from those that surrounded the diseases discussed by Galen and Hippocrates. The economic power of northern European countries was growing rapidly, and their desire to trade was matched by the technical developments of shipbuilding and navigation. The Europeans' theater of action was the Atlantic, not merely the enclosed Mediterranean, and all of these factors meant that the ships stayed at sea for periods long enough for scurvy to develop. In 1498 Vasco da Gama, reaching the east coast of Africa, found that many of his men suffered from what appears to have been scurvy. Twelve weeks at sea on the return journey renewed the disease.

The earliest battles for trade routes were between Spain and Portugal, and Fernando Magellan, for example, saw much scurvy among his crew when at sea for 15 weeks in 1519. These two nations established control over the southern routes to the Far East, but were quickly followed by the French and English, who tried to find a northern route.

A French expedition of 1523 explored the east

coast of North America, and a second expedition sent in 1534 that had to overwinter on the Saint Lawrence River suffered a great deal of scurvy.

The English, too, were interested in North America since making an expedition to Newfoundland under the command of John Cabot in 1497. Francis Drake's circumnavigation of 1577–80 indicates the extent of the technical developments in shipbuilding and navigation since the previous century, and the defeat of the Spanish Armada in 1588 was a stimulus to trading voyages. The next century saw the expeditions of the big trading companies like the East India Company, and the establishment of colonies by countries other than Spain and Portugal. It also, as a consequence, witnessed more and more sea voyages of long duration. The East India Company, for example, sent out an expedition to trade with Sumatra in 1601; it was 29 weeks at sea before reaching the Cape, and scurvy was widespread, almost to the point of paralyzing the expedition. The only ship exempted from the disease was that of the expedition's general, Sir James Lancaster, who had provided lemon juice for his sailors.

Observers of the early voyages noted the surprisingly rapid recovery of scorbutic sailors on reaching a port where fresh food was available. Empirical experience showed in particular the value of citrus fruits (the variant forms of "lime" and "lemon" in the different vernaculars are easily confused). In the subsequent history of maritime scurvy, the question looms as to why this knowledge was not used to prevent the disease.

The answer lies partly in the logistical and technical problems of provisioning the ever larger ships and squadrons: Citrus fruits are not native to the northern countries where big merchant fleets were based; these fruits did not keep well over long voyages; and attempts to concentrate or preserve the juice must have often reduced its effectiveness. The Dutch East India Company tried to ensure regular supplies by planting orchards at Mauritius and St. Helena, and even attempted laying out gardens on board ship. The Dutch Company's statistics show that the mortality in its ships over a 5-year period during the last decade of the seventeenth century, from all causes, was a little more than 13 percent, although where distilled water was used, the rate dropped to 9.5 percent. It is not known what proportion of these deaths were due to scurvy, but it appears that in regular trading voyages at least, with known landfalls and provisions for the crews including fruit juice, scurvy was not very deadly.

This was not the case, however, in the European navies, particularly during the following century. Their business was military, not commercial, and their operations were far from regular. In any military operation there is the expectation that the lives of men will have to be expended, and experience showed that disease would take many. Control of the seas rather than mere coastal defense was now the prize of naval warfare, and fully 855 men out of 1,000 succumbed, largely to scurvy, when Commodore George Anson fulfilled his commission of 1740 to capture the Spanish treasure-galleon.

Subsequent wars involved navies not only in long-distance operations but also in blockades of long duration. The supply of citrus fruits was simply not adequate for operations on this scale, when a complement of 500 men for a single ship of the line was not unusual. Although some physicians even advised against lemons or limes, generally a substitute was sought. One was found in cider, to which a land-based tradition attributed antiscorbutic properties. Edward Ives, a ship's surgeon in the early 1740s, was losing the usual large number of men to scurvy, when he persuaded his admiral to provision with the best Devon cider. While it lasted, he lost none of the 500 men aboard: The scurvy came only afterwards, all other conditions remaining the same.

This was essentially a forced clinical experiment, a technique taken up (after correspondence with Ives) and used in a more elaborate way by the better known James Lind. Lind divided his scorbutic patients into those taking fresh oranges and lemons, those taking cider, and those to whom he gave other current remedies. The first group improved rapidly, followed by those drinking cider; the remainder did not improve. Lind has been much celebrated for this early clinical trial, but doubt has recently been cast on his results on the grounds that modern research shows no vitamin C in cider. Yet modern cider is generally preserved in some way to give it a longer shelf life, whereas cider made in the eighteenth-century manner is high in vitamin C.

By 1753 Lind had incorporated his results into a large and very scholarly historical, bibliographical, and clinical work entitled *A Treatise of the Scurvy*. It was the most authoritative argument that had been made for the use of citrus fruits to prevent scurvy, but it was not until the end of the eighteenth century that, because of the work of an administrator, Sir Gilbert Blane, lime juice was issued to British sailors as a matter of course.

Nineteenth Century. The lessons learned at sea enabled the occasional small-scale outbreak of scurvy

in the prisons of the earlier nineteenth century to be handled adequately. But there was no remedy for the scurvy produced by the great failure of the potato crop in 1845–6. Potatoes are rich in vitamin C, and the population of Ireland, more than other European countries, depended upon them as food. Scotland also suffered. Scurvy later in the century appeared regularly where conditions prevented access to fresh fruit and vegetables. Examples are the California Gold Rush of 1848 and later, during which the long trek over mountains much resembled a long voyage at sea and the war in the Crimea (1854–6) and the siege of Sebastopol, when the French and British armies' supply routes were interrupted. American experiences with scurvy also occurred during a circumnavigation in 1838, during a blockade of the Mexican coast in 1846, and during the Civil War, particularly in prisoner-of-war camps, where the mortality rose to 9 percent per month.

The circumstances that made scurvy a disease of the northern countries made it a special danger in the Arctic regions. When there was regular commerce – for example, by the Hudson Bay Company – scurvy was only a minor threat, and, since its origin in the seventeenth century the Company had shipped out lime juice. Fresh meat killed locally was also recognized as valuable, a truth that had been learned the hard way in some early overwintering disasters. Government-backed explorations, however, generally encountered scurvy, particularly when small parties left the iced-in ship for exploration on foot.

Perhaps the least expected occurrence of scurvy was that of the infantile variety from the 1870s to the First World War, in Europe and America. The odd feature was that infantile scurvy occurred in the higher social classes, where there was no economic reason for vitamin C deficiency. The reason was that mothers of the upper classes tended to avoid breast feeding their own children, and the various forms of preserved milk newly available did not contain vitamin C. Thus scurvy often occurred before the child began consuming adult food. In previous periods, upper-class mothers also avoided breast feeding, but then the infants would have been given to a wet nurse as a substitute mother.

Etiological Theories

Changing Concepts and Implications for Treatment. Theories on the causation of scurvy were, on the whole, more destructive than helpful to its successful treatment in the period before the discovery of vitamin C. By and large, government officials, offi-

cers, and surgeons of big trading companies, and eventually naval and military administrators, were convinced of the empirical fact that certain fruits prevented and cured the disease. But when they took advice about scurvy from educated physicians, it was sometimes bad. Because medical theory had its impact upon practice, we must look briefly at theories about scurvy.

There is one central feature of the story of scurvy theories which had an enormous effect. This was the rise of the germ theory of disease in the second half of the nineteenth century, which changed medicine more than anything else had done in the preceding 2,000 years. Disease was now seen to be caused by a living organism, in some cases visible under a microscope. The organism was s species of living thing, perceptible (perhaps) and classifiable. Here was the essence, the cause of the disease: Clinical symptoms were now viewed as secondary reactions, varying with the nature of the patient. And the new medicine, by the end of the century, proved spectacularly successful in combatting infectious diseases. The effect was a whole new ontology of disease, centered on the infective organism; thus for scurvy, the effect of this revolution was to encourage a search for a causal organism, or at least a poison. In other words, the research ran counter to the previous consensus that incomplete diets could cause scurvy, and led to numerous disputes about the nature of the disease.

To understand why, we must look at the nature of medical theory in the earlier period. Up to and even including the eighteenth century in some places, the medical person had seen the human body as a microcosm located in a similar but larger macrocosm. Traditional European medicine, based on Galen's rationalization of Hippocratic principles, recognized the body as consisting of seven "Naturals" – its humors, spirits, faculties, and parts. The "Non-Naturals" were the points at which the body intereacted with the macrocosm and the results of its activity – the regimen of diet, exercise, sleep, and so on. "Contra-Naturals" were things that caused disturbance in the body. The microcosm corresponded to the macrocosm because they both consisted of the same principles, the four elements and four qualities, appearing in the body as the four humors. Food was elementary and qualitative and needed only refining to become the substance of the body. The effect of the environment – its airs, waters, and places – was similarly qualitative. The notion that scurvy was a disease that arose from an improper diet fitted naturally into this scheme. An impropriety of the diet was generally believed to affect bodily organs, and early writers

such as Echthius in 1541 made scurvy a melancholic disease of the spleen.

He attributed it to the spleen because in discussing splenetic diseases Hippocrates listed some symptoms that look scorbutic; and Echthius's argument was the Hippocratic–Galenic one – that a disordered spleen could not fulfill its normal function of excreting black bile (melancholia, one of the four humors), and that the excess of black bile in the body in turn caused scurvy. Similar humoral theories of scurvy were widely held, and many writers attributed the presumed damage to the spleen to a dietary cause – the salt meat, stale water, and preserved food of long sea voyages.

The theory of the disease changed with the theory of medicine. In the later seventeenth century, when chemical notions of the body were proving attractive, some writers distinguished an "acid" from an "alkaline" scurvy. When mechanism was employed in the medicine of the eighteenth century, doctors talked about sharp, corrosive particles in the blood. These were still humoral theories, and although the humors were no longer viewed as qualitative in action, their vice still derived from diet. Hermann Boerhaave, the most authoritative voice of the eighteenth century, blamed salt; dried and smoked meats, including fish and sea birds; ships' biscuits (*panis biscoctum*); dried peas and beans; old, sharp, and salty cheese; and so on. Such a diet, he argued, led to the proximate cause of the disease: The blood became thin and sharp, whether acid or alkaline. From this all the symptoms could be deduced, and all treatment was to be directed to restoring the proper nature of the blood. Boerhaave had the whole armory of eighteenth-century medical techniques with which to attempt this, because some kind of disturbance of the blood was believed to be at the root of many diseases in the medical theory of the time.

Citrus fruits were mentioned by Boerhaave, but only in a long list of other remedies and without special attention, and without an explanation of how such remedies work. The use of citrus juice, after all, was a mere empirical discovery, which had little part in a medicine so rational as that of Boerhaave. Perhaps Boerhaave, like Beaudouin Ronsse (Ronsseus) more than a century before, was embarrassed at something so empirical. His rationalist view attributed the cause of scurvy not to anything necessary lacking in the diet, but to the excess of things undesirable. His student Gerard L. B. van Swieten, however, took the more usual line that the cause of the disease was the lack of something.

Scurvy, he argued, appeared more often in besieged cities than in the army besieging, which had access to fresh provisions.

The practice of treating scurvy was again affected by medical theory later in the eighteenth century. Contemporary interest in medical chemistry centered on the nature of various "airs" (in our terms, "gases") of which "fixed air" was sometimes held to prevent putrefaction. It was also commonly held that scurvy was a putrefactive disease, and attention naturally was given to the possibility that it could be treated with fixed air. There were attempts to use water impregnated with fixed air on board ship, and a wider movement to treat scurvy with malt. It was argued that just as malt digested in water became a wort that ferments into beer, giving off fixed air, so wort drunk by scorbutics would ferment in their bodies, correcting the tendency to putrefy.

Captain James Cook's report to the Admiralty in 1776 spoke highly of malt, and also of sauerkraut, both of them in his view being preferable to the contemporary citrus fruit concentrate – "rob" – of oranges and lemons. The expense of the latter was clearly the reason for the search for substitutes. Cook's apparently empirical observations agreed with theories of fermentation shared by his influential colleagues in the Royal Society and elsewhere, and helped to lengthen the period of the use of malt-wort in the navy. In 1795, however, Gilbert Blane was appointed commissioner of the Board of Sick and Wounded Sailors, and, supported by some recent experiments with lemon juice, he persuaded the Lords of the Admiralty to authorize a daily dose of three quarters of an ounce of the juice to each sailor. Over the next 20 years, this amount totaled more than 1.5 million gallons; Admiral Horatio Nelson alone accounted for 50,000 gallons for the Mediterranean fleet.

Although, after this, scurvy virtually disappeared from the British fleet (but not from other fleets as, for example, the French, during the Napoleonic Wars), on land the theories of medical professionals continued to threaten practice. The Seige of Paris (1870–1) produced an outbreak of scurvy and once again focused attention on its cause at a time when ideas about contagion and germs were becoming more widespread. At a debate in the French Academy of Medicine in 1874, the view was aired that scurvy was a contagious miasm, and was no more caused by a lack of fresh fruit than malaria was caused by a lack of the medicine quinine. The revolution in medical thought about disease causation now made *positive* causes of scurvy (the presence of a

noxious agent) more attractive than a *negative* (the absence of a factor).

A British expedition of 1894 spent three winters in Franz-Joseph Land, remaining healthy on a diet that included fresh meat but very little lime juice. The medical explanation for the absence of scurvy was that the disease was caused by chemical products resulting from bacterial action in poorly kept meat, and it was realized that no one had studied scurvy in the light of Louis Pasteur's germ theory. This new line of inquiry was made possible by a grant from the Royal Society, whose president was Lord Joseph Lister, the man who revolutionized surgery by killing Pasteurian germs with carbolic acid. It was Lister who presented the results of the inquiry to the Royal Society, and those results were taken to support a germ theory of scurvy. So thoroughly was germ theory implicated in the etiology of scurvy that one naval surgeon, at least, explained that the benefit obtained from lime juice was simply that it acted as an antibacterial mouthwash.

Evolution of the Deficiency Disease Concept. The final recognition of scurvy as a deficiency disease is a twentieth-century story. From the last years of the nineteenth century, there had been concern in Norway at the incidence of "ship beriberi." It was studied by Axel Holst, who had had experience at the Pasteur Institute and had also worked with Robert Koch. He knew of the experimental use of chickens in a study of beriberi in the Dutch East Indies, but chose guinea pigs as his experimental animals, feeling them to be more convenient and closer to humans in physiology. Under a restricted diet, the animals developed the symptoms of scurvy as it appeared in humans. Guinea pigs had also been used in Germany as models for "Barlow's disease" (infantile scurvy, long thought a separate condition).

The work (up to 1913) of Holst and his collaborator Theodor Frölich (a specialist in infantile scurvy) was to show that scurvy was indeed a disease of a deficient diet. Meanwhile, in 1912, Casimir Funk, working at the Lister Institute in London, proposed that scurvy was one of a group of four diseases (the others were beriberi, rickets, and pellagra) that were caused by dietery deficiency. Each missing factor, he believed, was a nitrogenous base, for which he coined the name "vitamine." At the same time, in the United States E. V. McCollum and others showed that some fats contained a factor necessary for the growth of rats. The "deficiency" thesis met some opposition from bacteriologists, and in 1916 and 1917 workers in the United States cultured bacteria from the tissues of scorbutic animals. Inoculated into healthy animals, this culture produced some signs of scurvy. Related to the bacterial theory was the "positive" notion of McCollum that scurvy was due to poisons developing by bacterial action in the accumulating feces in the intestines of the experimental animals. (The animals were rats, which synthesize their own vitamin C.)

Despite all these opposing doctrines, however, the results obtained by Holst and Frölich prompted later efforts to identify and isolate the active component. McCollum had already identified a fat-soluble factor – "A" – and a water-soluble factor – "B" – necessary for the growth of experimental rats, and it was natural for those who believed in the deficiency thesis to look for a "vitamine C."

The presence of scurvy during the First World War and its aftermath in central Europe prompted systematic assays on various antiscorbutics, particularly in guinea pigs at the Lister Institute. There too, from 1918, S. S. Zilva and others attempted to isolate the active component of vitamin C. This was achieved by the Hungarian Albert Szent-Györgyi, who was working in Hopkin's laboratory in Cambridge on a different problem. He was interested in the powers of chemical reduction of organic substances, including the sugars of lemon juice. Between 1928 and 1932, Glen King at the University of Pittsburgh also had been trying to isolate vitamin C, and in the latter year published results that combined the findings of Szent-Györgyi with his own and with trials with guinea pigs. Vitamin C had been discovered, and scurvy was vanquished.

Sickle-Cell Anemia

Sickle-cell disease is an inherited disorder resulting from an abnormality in the structure of a protein in the red blood cell called hemoglobin. It represents a spectrum of disorders ranging from the full-blown form, sickle-cell anemia, to the carrier state called sickle-cell trait. Also included in this spectrum are several other variant hemoglobin disorders, which all have the sickle hemoglobin. Sickle-cell anemia is the prototype for most molecular diseases and was the first disease to have its cause isolated to a single molecular change in the human genetic structure. This single change is responsible for all of the dramatic physiological changes and clinical events that occur in this disease.

Sickle-cell trait occurs when the individual is heterozygous for the sickle-cell gene and results in red blood cell concentrations of the abnormal hemoglobin (hemoglobin S) of less than 50 percent. It generally does not result in serious illness although this generalization has recently been disputed. In addition to sickle-cell trait, several sickle-cell syndromes occur when hemoglobin S is present in a heterozygous state with other hemoglobin variants – some with similar properties. Common examples of these include hemoglobin C and hemoglobin E.

Distribution and Incidence

Sickle-cell anemia is found in as many as 4 percent of Africans and in 1 percent of black Americans (1 per 500). Upward of 40 percent of Africans carry the sickle-cell trait as compared to 9 percent of black Americans. In some Mediterranean cultures the trait is also present. It is now generally believed that the sickle-cell gene mutation occurred independently in several areas of Africa. Therefore, its presence across several different peoples is easily explained.

Hemoglobin S is transmitted as an autosomal recessive gene. So if both parents have sickle-cell trait, the chances are 1 in 4 that any child born to them will have hemoglobin SS and thus sickle-cell anemia; 1 in 4 that it will have hemoglobin AA and be normal; and 2 in 4 that it will have hemoglobin AS and have the sickle-cell trait.

The pattern of death in persons who have sickle-cell anemia is bimodal, with the first peak occurring in childhood and the second occurring among people in their late 30s. Deaths during childhood are related to infectious causes, whereas those during adulthood are due to organ failure from repeated tissue destruction.

Etiology

Hemoglobin is responsible for carrying oxygen in the bloodstream and is found inside the red blood cell. It is a protein made up of four chains called globins and four iron groups called heme. Each globin chain is composed of a series of building blocks called amino acids that in turn are built from the genetic material known as deoxyribonucleic acid (DNA). The structure of a particular piece of DNA determines the structure of a particular protein. In the case of sickle-cell anemia the structure of the DNA molecule is changed through a single genetic mutation and results in a change in the amino acid composition of the protein chain. This change is a substitution of valine for glutamic acid in the sixth position of the amino end of the molecule. This simple substitution causes marked changes in the solubility and interactive properties of hemoglobin. Under appropriate conditions, this results in a dramatic conformational change in the red cell from a flexible biconcaved disk to an inflexible sickled cell.

Sickling results from a low oxygen state and tends to occur in the acidotic and hypertonic milieu of small blood vessels. It is a two-step process. Initially, small submicroscopic aggregates of hemoglobin form, followed by rapid polymer formation into long tubular helical fibers that twist the red cell into the sickle shape. This fiber formation is reversible and results from noncovalent chemical bonds between hemoglobin molecules.

Sickling is also accompanied by a dynamic process at the cell membrane. Ion fluxes that occur normally at the membrane become disrupted during sickling, and a rapid influx of calcium occurs. This calcium is later pumped out of the cell by an energy-dependent mechanism utilizing an intercellular energy source known as adenosine triphosphate (ATP). Recurrent sickling results in early depletion of ATP and is one contributor to premature cellular death. Recurrent sickling can cause the cellular membrane to become permanently calcified, resulting in rigid, irreversibly sickled cells. These cells are found in all persons afflicted with sickle-cell disease and may represent from 5 to 50 percent of the red cell mass.

Functionally, hemoglobin S has a lower affinity for oxygen especially at low hydrogen-ion concentrations and increased tonicity. This results in early release of oxygen and the inability to oxygenate tissues adequately. In the sickled form, these cells have significant difficulty traversing the small vas-

culature of the capillary bed. Vascular occlusion and destruction of tissues result. The life-span of a single cell is also decreased from 120 to 60 days and is manifested as a hemolytic anemia. This condition results from a combination of acquired membrane abnormalities from recurrent sickling and destruction of irreversibly sickled cells. There is also increased incidence of infection owing to gradual destruction of the spleen and alterations in the immune system.

The presence of other forms of hemoglobin can modify the ability of hemoglobin S to form fibrils. One such hemoglobin is fetal hemoglobin. Hemoglobin F is normally present at birth in large concentrations. After birth its production is decreased and is replaced with adult hemoglobin (hemoglobin A), such that by 6 months of life the individual has hemoglobin in adult percentages. In some individuals, however, hemoglobin F persists in abnormally high levels. This persistence of hemoglobin F alters the final hemoglobin concentration in the red blood cell and reduces the percentage of hemoglobin S in patients with sickle-cell disease. Hemoglobin F is a poor participant in hemoglobin S fibril formation and thus inhibits sickling. Clinically this results in a milder form of the disease and in some patients produces an asymptomatic state.

Clinical Manifestations

Sickle-cell disease can be diagnosed prenatally by a procedure known as amniocentesis. After birth the diagnosis is generally made by hemoglobin electrophoresis using cord or peripheral blood. Early diagnosis is now encouraged because of the benefits of new preventive therapies for infection.

Sickle-cell anemia is characterized clinically by a chronic hemolytic anemia and recurrent states called *crises*. These crisis states are further divided into three types: *pain, sequestration,* and *aplastic*.

Pain crisis is the most common and occurs on the average of three times a year. It first presents after 6 months of life when the level of fetal hemoglobin has decreased to a low level. At this age the first signs are often a painful inflammation of the bones of the hands or feet, known as the hand–foot syndrome. Older patients generally develop a recurrent syndrome of joint, back, abdominal, or long-bone pain, which may last for approximately 7 days. Other serious manifestations of vascular occlusion include strokes, heart attacks, leg ulcers, priapism, and pulmonary infarcts.

Splenic sequestration occurs when a large portion of the red cell mass becomes trapped in the spleen,

resulting in acute shock. With age, recurrent vascular occlusion of small blood vessels in the spleen results in functional destruction of this organ. Because the spleen is required for destruction of certain types of bacteria, patients with sickle-cell anemia are at increased risk of bacterial infections.

In rare instances, the blood-forming bone marrow becomes exhausted or suppressed for short periods of time, resulting in an acute reduction in red blood cells. This is known as red cell aplasia. This is a temporary condition but one that may require blood transfusions until the bone marrow recovers.

By contrast, sickle-cell trait occurs when individuals' genes carry only one hemoglobin S gene. These persons are phenotypically normal in most respects, although sickling has occasionally been reported to occur in these individuals at high altitudes or low oxygen tension, resulting in splenic infarction. Bleeding from the kidney and a gradual decrease in the concentrating ability of the kidneys have also been shown to occur with increased frequency in people with sickle-cell trait. This condition is almost always benign in nature, however. Nevertheless, concerns have been raised recently that individuals with sickle-cell trait are at increased risk for acute muscle destruction and sudden death. These reports require further confirmation and are highly controversial.

Various other hemoglobins have been shown to sickle in a manner similar to hemoglobin S. Careful chemical analysis is required to differentiate these from sickle hemoglobin.

History and Geography

Sickle-cell anemia has been traced back to at least 1670, where it was noted to be present in the Krobo tribe in Ghana. This disorder was first described clinically by James B. Herrick, a Chicago physician, in 1910. During the 10 years following Herrick's report, three cases of sickle-cell anemia were reported. Thirteen years later, J. G. Huck reported a series of 14 patients and first noted the reversibility of sickling. In 1939 J. Bibb and L. W. Diggs described irreversibly sickled cells, and in 1946 M. Sherman demonstrated that hemoglobin S has an ordered structure. This finding encouraged Linus Pauling to investigate the physical chemistry of hemoglobin S by electrophoresis. On the basis of his findings he reasoned that the genetic basis of sickling was due to a single gene. V. M. Ingram, using peptide mapping techniques, then demonstrated that the condition resulted from a single amino acid substitution of valine for glutamic acid. M. Murayama noted that this change resulted in the loss of two negative

charges and postulated that noncovalent interactions took place, resulting in hemoglobin stacking. In 1949 A. B. Raper noted the high incidence of sickle-cell trait in areas endemic for malaria and suggested that the trait protected against infestation. But it was not until 1954 that geneticist A. C. Allison correlated sickle trait with regions in which falciparum malaria was or had been endemic.

Further analysis of this observation showed that this gene change was the result of a genetic principle known as balanced polymorphism. Generally a gene such as the sickle-cell gene, which results in severe morbidity and mortality, dies out in a population unless certain conditions result in a more favorable survival. Such is the case with the sickle-cell gene. Africa and the Mediterranean are areas endemic for the parasite *Plasmodium falciparum*, which causes a malignant form of malaria. But when persons with sickle-cell hemoglobin are infected with malaria, the infected cells tend to sickle and are selectively destroyed by the body's immune system. Therefore, the sickle-cell gene promotes survival in persons infected with a disease that is potentially fatal and, paradoxically, prolongs survival. In parts of the world such as the United States where *P. falciparum* is no longer endemic, the sickle-cell gene becomes the sole determinant of morbidity and does not prolong life. This explains why the frequency of the sickle-cell gene has decreased in much of the Americas.

Smallpox

Smallpox (*variola*) no longer is an active infection. Its virus exists only in laboratories. It was an acute viral disease usually transmitted by airborne droplets and entering the body through the upper respiratory tract. It infected as many as 90 percent or more of people at risk. It affected all races, and neither age nor gender seems to have influenced susceptibility directly. There never was a cure, but during its last decades of existence antibiotics were often prescribed to prevent or limit secondary infections. Closely related diseases exist, like cowpox and monkeypox, but smallpox appears to have been an exclusively human infection. Virologists recognized two kinds of smallpox: *Variola major*, with a mortality rate commonly of 25 to 30 percent; and *Variola minor*, with mild symptoms and a death rate of 1 percent or less. The characteristics of smallpox viruses varied over the centuries, and strains intermediate in virulence between *V. major* and *V. minor* in all probability existed. The worst strains, of course, attracted the most attention, and the recorded history of smallpox is for the most part a history of *V. major*.

Etiology and Epidemiology

Within the range of recorded history, as far as we know, the source of smallpox was always a human being with the infection. There was no animal reservoir. The virus could survive in scabs for consider-

able periods, and laundry workers on occasion contracted the disease from clothing and bedding of smallpox patients, but most transmissions were airborne and occurred over distances of no more than a few meters. In the second to the very last recorded transmission – in Birmingham, England in 1978 – the virus must have drifted from a laboratory on one floor of a building through an air duct to an unimmunized person on the floor above. Quarantine was effective against this malady, as long as it was applied early (even before the appearance of symptoms) and strictly enforced.

Clinical Manifestations and Pathology

The incubation period was about 12 days. Onset was abrupt and prostrating: high fever, headache, and pain in the back and muscles; and, in children, sometimes vomiting and convulsions. In the severest infections, extreme toxemia and massive hemorraging into the skin, lungs, and other organs could cause death swiftly before the appearance of more than a slight rash. In the great majority of cases, the sufferer survived to experience the characteristic rash 2 to 5 days after onset. In most cases the rash appeared more densely on the face, palms, and soles than on the trunk. In another few days, the small pimples of the rash turned to pustules, which in extreme cases were confluent, almost always indicating a lethal infection. William Bradford observed cases like this among Amerindians near Plymouth in North America in 1633–4. He describes their pustules as "breaking and mattering and running one into another." Complications may have been common in Amerindians. Those cited just above seem to have had a pneumonic secondary infection: "And then, being very sore, what with cold and other distempers, they die like rotten sheep."

Drying and crusting of the pustules began on the eighth or ninth day after the first eruptions. The scabs fell off 3 or 4 weeks after onset, and the victim was well again, barring complications. Among the possible sequelae were blindness and, at least occasionally, male infertility. The probable sequel was a pocked and scarred face, appalling to others as well as to the survivor. Literature is full of references to women thus robbed of their smooth skins, from Ben Jonson's cry – "Envious and foule Disease, could there not be One beautie in an Age, and free from thee?" – to Charles Dickens's heroine of *Bleak House*, who after recovery remarks bravely, "It matters very little . . . I hope I can do without my old face very well."

Immunology

Except in the rarest instances, smallpox infection ended in one of only two ways: death or long-lasting immunity. Lacking an animal reservoir and the ability to remain latent within the human body, smallpox existed only as an active infection. It was one of the classic epidemic diseases, surviving in many eras and parts of the world only as rolling waves of infection. It could achieve endemicity only in large and, often, cosmopolitan populations, where it could pass in unbroken sequence through the bodies of travelers newly arrived from areas free from the malady, and through the bodies of the immunologically innocent newborn. Where it was endemic, it was usually a childhood disease, and trial by smallpox was a prerequisite for adulthood for all but a small minority.

History

Antiquity

Because it only persisted by passing from one human to another, smallpox could not have existed with its historical characteristics among the sparse populations of the Paleolithic Age. It may have first appeared sporadically among the village dwellers of the Neolithic Age, derived from pox diseases of livestock, or from similar infections circulating among wild animals with whom humans were often in contact. In our own time, Africans occasionally contract monkeypox, which has symptoms similar to smallpox, but which is, fortunately, very unlikely to spread from human to human.

Smallpox may well have circulated among the ancient Egyptians. The face, neck, and shoulders of the mummy of Pharoah Ramses V, who died in 1157 B.C., are disfigured by a rash of elevated pustules like those of smallpox, but researchers cannot be absolutely sure of the infection that caused them. Dreadful epidemics rolled back and forth through the Old World in ancient times, but rarely were the symptoms described clearly enough for researchers to make diagnoses confidently. In the second and third centuries A.D., two pandemics devastated the Roman Empire, one or both of which may have been smallpox, but we know very little about the diseases clinically. There is some indication of smallpox in China by the fourth century, and stronger evidence for its arrival in Japan in the 730s.

Ninth Through Fifteenth Century

With *The Treatise on Smallpox and Measles* at about the turn of the ninth century by Rhazes, a Baghdad

physician, we are finally on solid ground. He clearly differentiated between the two diseases, and revealed smallpox to be a common childhood disease in southwest Asia in his time. The density of population centers extending west to the Mediterranean and Atlantic and east to China and the Pacific in that era suggests strongly that smallpox was prevalent, at least in epidemic form, throughout the area of advanced Old World civilizations before the end of the first Christian millennium. In the same general period, the malady may have invaded peripheral areas: sub-Saharan Africa, northern Europe, and the Indonesian archipelago.

Smallpox, though widespread in the first millennium and a half of the Christian era, seems not to have been among humanity's chief curses in those centuries. It ranked behind plague, tuberculosis, and probably other maladies prevalent in the Old World in the period Europeans call the Middle Ages, and did not become a major demographic check in Europe until the sixteenth and seventeenth centuries.

Sixteenth Through Seventeenth Century
The most important effect of smallpox historically was as a solvent exuded by dense populations of the Old World. For example, it was an important ally of the Russian invaders of Siberia, as it was of the Hollanders in Cape Colony, South Africa. On the other hand, smallpox was a merciless enemy of barbarians trying to penetrate concentrations of dense population. The Manchus, who rode south into China and founded the Ch'ing Dynasty in the seventeenth century, were obliged to excuse princes and dignitaries from the thinly populated steppes (who had not yet contracted smallpox) from coming to Beijing to make obeisance to the Emperor. For their safety and survival, special audiences were provided in Jehol, north of the Great Wall.

No later than 1519, smallpox crossed the Atlantic to a New World still free from the disease; decimated the Arawaks of the West Indies, a people already in steep decline; accompanied the Spaniards to Mexico; and rolled on ahead of them into the Incan Empire. Amerindians had, at very best, no more resistance to the disease than did Europeans, and they must have suffered similarly high or even higher morbidity rates. The Spanish estimates of death rates among Amerindians in this, the first of their many pandemics of smallpox, ran from about one-fourth to one-half – that is, rates comparable to those of European children afflicted with the disease. The psychological effect of such experiences on peoples who believed in a direct connection between pestilence

and the supernatural was considerable. The Amerindians quaked in confusion and terror; and the Europeans preened themselves as the chosen people. John Winthrop, first governor of Massachusetts Bay Colony in North America, noted on May 22, 1634: "For the natives, they are neere all dead of the small Poxe, so as the Lord hathe cleared our title to what we possess" (Winslow 1974).

Eighteenth Century
The final major chapter in the history of the expansion of smallpox opened in 1789, when the infection appeared among the Australian aborigines in contact with the newly arrived English settlers at Sydney Harbor. It destroyed half the indigenes, by English estimate, and spread over the Blue Mountains into the interior, although no one knows how far. This epidemic was probably the single greatest demographic shock ever dealt the Aborigines.

By the eighteenth century, smallpox accounted for 10 to 15 percent of all deaths in some European countries annually, 80 percent of the victims being under 10 years of age. It is likely that similar rates were common in major cities in North Africa and civilized Eurasia. Outside these areas of dense population the disease was epidemic, killing high percentages of adults essential to the functioning of the economy and society. The peoples of the Old World, living in the presence of this threat for generation after generation, were bound to devise means of defending themselves, if such could be found.

Variolation. Our modern techniques of inoculation and vaccination began – no one knows when or where – with *variolation* (the artificial infection with smallpox of healthy people) in the hope that this would produce mild cases of the disease but solid immunity. In China, smallpox scabs were blown up the nostril, seemingly a very dangerous method because it might produce infection through the upper respiratory tract, as in naturally incurred smallpox, but the scabs were apparently aged first, attenuating the virus. Elsewhere in the Old World, variolation was generally accomplished by obtaining material, usually fluid, from pustules of an active case of smallpox and then scratching this into the skin. If variolation was done expertly, the infection was mild, and the death rate no more than 3 or 4 percent and, when done by the most skilled practitioners, as low as 1 percent.

Variolation was practiced for a long time, not by formally trained physicians, but by folk healers. For example, Cotton Mather, a minister in the Massachu-

setts Bay Colony in North America, first heard of it about 1706 from his African slave, who told him that smallpox and variolation were both common in Africa. Peasants in remote parts of Scotland, Wales, Greece, the Middle East, and elsewhere in Eurasia were "buying the smallpox," as those who spoke English put it, long before the rich and well-born learned of variolation. The most famous figure of that latter event was Lady Mary Wortley Montagu, a woman whose brother died of the disease and who, attacked by smallpox as an adult, lost her beauty and even her eyebrows. While in Constantinople as wife of the British ambassador, she learned of a method practiced there of "ingrafting" the disease, which usually led to a mild infection and yet stout immunity. Lady Montagu had her son variolated in Constantinople in 1717, and her daughter, in London in 1721.

In that same year, smallpox broke out in Boston, Massachusetts, where the people, too few to maintain the disease endemically, periodically suffered terrifying epidemic waves of it. Mather knew nothing of Lady Montagu's experiments, but he had heard of variolation from his slave and had read reports about it. He persuaded Zabdiel Boylston to experiment with the new practice in Boston. Despite fierce opposition from those who viewed the practice as dangerous (which it certainly was), Boylston scratched pus from a smallpox pustule into the skins of his son and two slaves. In all, he variolated 244 people, while in nearby Cambridge and Roxbury other physicians variolated 36 more. This was the first large-scale test of the practice, at least in the West. Also – amazingly – it may have been the first example of careful quantitative analysis of the effects of a medical procedure. Boston had a population of about 11,000, thousands of whom fled during the epidemic. Of the remainder, 5,980 caught the disease naturally, and 844 – or 14 percent – died. But only 6 – or just 2.4 percent – of the 244 variolated by Boylston died.

The practice of variolation was not adopted as rapidly as the statistics above suggest that it should have. After an initial flurry of variolating among some members of the upper classes and their domestics in the 1720s, the spread of the new procedure slowed and may even have retreated. British North Americans resorted to it only during epidemics, when contracting the disease naturally seemed just as likely as, and a good deal more dangerous than, embracing it via variolation.

Acceptance of the practice was contingent on several developments. One was a rise in the fear of smallpox, which a surge of the disease around 1750 stimulated. Others were the reduction of what were at first high fees for variolation, and the improvement in technique so as to reduce the chances of dying from this procedure to a tolerable minimum. These changes were accomplished by a handful of physicians, among them the American James Kirkpatrick, and more importantly, the Britons Robert Sutton and his sons, especially Daniel. The Suttons reduced variolation to a slight pricking of the skin, rather than, as had previously often been the case, deep incisions that thrust the virus directly and dangerously into the bloodstream and that increased chances of secondary infection. The establishment of smallpox hospitals, where variolated patients could be isolated, helped to quell fears of artificially triggered epidemics.

In the 1760s and for the rest of the century, variolation became increasingly common in the British Empire, and on the continent of Europe, as well, though more slowly. The death of Louis XV of smallpox in May and the variolation of Louis XVI in June of 1774 spurred the practice everywhere. By the end of the century, many thousands had been variolated in Europe and America. How many we will never know because physicians kept poor records, and there were many itinerant inoculators, who kept no records at all. Some experts claim that the spread of this new way of promoting immunization was one of the chief causes of the beginnings of our present population explosion in the last half of the eighteenth century, but it is impossible to tease out this factor from others, such as improved nutrition. In addition, there is the question of how many deaths were caused by epidemics unintentionally started by variolation. Yet we can be sure that in the long run variolation stimulated population growth, at least indirectly, by accustoming people in general to the benefits of producing immunity by deliberately incurring mild infections.

Vaccination. The greatest windfall of variolation (and the greatest in the history of medicine) occurred in the last decades of the eighteenth century when an experienced English variolator and scientist, Edward Jenner, noticed that the variolation failed to produce symptoms of illness in people who had previously contracted a mild pox disease from livestock, usually cattle. He *vaccinated* (a new word derived from the Latin for "cow") several people, including his own son, with cowpox matter, and then attempted variolation. Inoculation with smallpox matter uniformly failed to produce pustules or much

else in the way of illness. He published his results in June of 1798 as *An Inquiry into the Causes and Effects of Variolae Vaccinae, a Disease, Discovered in some of the Western Counties of England, particularly Gloucestershire, and known by the Name of Cow Pox.* Vaccination may have been practiced before by common folk, like variolation, but now a member of the elite had introduced an account of the technique into print for the whole world to read, and that made all the difference.

Nineteenth Century

It was as if, to quote a nineteenth-century historian, "an Angel's trumpet had sounded over the earth" (Winslow 1974). England led the way in the new practice – more than 100,000 were vaccinated there by 1801 – and the rest of the world came treading on her heels. Within 3 years of the publication of Jenner's *Inquiry*, it was translated into German, French, Spanish, Dutch, Italian, and Latin. In France 1.7 million were vaccinated between 1808 and 1811, and in Russia about 2 million in the decade ending 1814, and so on across the world.

Getting potent vaccine across the great oceans as scabs or bits of thread soaked in matter from pustules was problematical, and often the virus proved dead and useless when scratched into transatlantic arms. Sometimes the virus survived and did the job, to the benefit, for instance, of the clients of Benjamin Waterhouse of Boston, Massachusetts, in 1800. The surest way of preserving the infectiousness of cowpox virus while traveling great distances was by the *serial method:* Recruit a number of unimmunized people, vaccinate one, and then, when his pustules are ripe, transfer the disease to another, and so on in sequence until the destination is reached with an active case on board.

This was the technique used by Don Francisco Xavier Balmis who, empowered and financed by the Spanish monarchy, led an expedition around the world from 1804 to 1806, from Spain to the New World and thence to the Philippines, China, and St. Helena, vaccinating thousands as he went. He used young boys, usually orphans, as reservoirs of the cowpox, the first set obtained in Spain and the others as required in America and elsewhere.

During the 1800s, humanity began to win its battle with smallpox. Vaccination continued to spread, and in some countries was even made compulsory, at least for infants. Its benign effect on death rates, unlike that of variolation, was obvious, and literally millions of children, who would have died without Jenner's discovery, lived to enrich their societies

with their skills and labor, and to fuel the population explosion. In a few advanced and disciplined societies, such as England and Prussia, where doctors, officials, and the public cooperated to smother smallpox, deaths due to the disease were near zero by the end of the century. Elsewhere success was equivocal, even though the benign influence of vaccination was supplemented by the appearance of *V. minor* toward the end of the century, displacing the more virulent form of the disease in some regions of the world.

Twentieth Century

Jenner realized that his discovery could mean "the annihilation of smallpox – the most dreadful scourge of the human race" – but not until the middle of the twentieth century did this seem not just a theoretical but also a practical possibility. By 1950 a number of wealthy societies in the temperate zones with strong governments, large numbers of skilled medical personnel, and scientifically sophisticated populations were free or nearly free of the disease. But most of the smallpox in the world raged in the tropics, where few or none of the factors just cited existed, and where smallpox vaccine lost its potency quickly in the heat. Freeze-drying, invented in the 1940s and adapted for mass production of vaccine in the 1950s, solved that problem.

In 1966, the Nineteenth World Health Assembly issued a call for the eradication of smallpox from the Earth. Donald A. Henderson, an officer of the World Health Organization, took charge of the Smallpox Eradication Programme. During its first year, 1967, smallpox existed in every continent except North America and Europe, and the estimate was that 10 to 15 million people contracted the disease each year. By 1972 it was gone from South America, as well. By the end of 1973 it was restricted to the Indian subcontinent and the horn of Africa, Ethiopia, and Somalia. In October of 1975, Rahima Banu of Bangladesh came down with *V. major,* the last case of smallpox in Asia. On October 26, 1977, the rash of *V. minor* appeared on the skin of Ali Maow Maalin of Somalia. This was the last case of this kind of smallpox and the last case of naturally occurring smallpox in the world. In August of 1978, smallpox virus somehow escaped from a laboratory in Birmingham, England, infecting Janet Parker and, subsequently, her mother. The daughter died; the mother survived. The director of the laboratory committed suicide while in quarantine. These were the last deaths associated with the ancient and now defunct scourge of smallpox. In 1979 the Global Commission for the Certification of Smallpox Eradica-

1013

tion officially announced the demise of the disease. As of 1980, stocks of vaccine sufficient for 200 million vaccinations were being maintained in the unlikely case that smallpox should somehow arise again.

Humanity won the victory against the smallpox virus by displacing it with the vaccine virus. Almost everyone for nearly a century and a half believed that virus to be the organism of cowpox, but in 1939 careful comparison of vaccinia virus (which does not exist naturally) of cowpox virus and of smallpox virus showed them to be related but clearly distinct entities. One expert claims that the Jenner strain of vaccinia virus was contaminated with a mild strain of smallpox very early, and that vaccination was a continuation of variolation not only in technique but also in the identity of the virus, as well. Decades of variolation, according to this theory, produced a very attenuated strain (or strains) of smallpox virus, and vaccinia virus is no more than one of these tamed varieties. Other experts suggest that Jenner was not dealing with cowpox, but horsepox, which cattle occasionally contracted. Unfortunately, horsepox died out early in the twentieth century, and so we have no way of testing this hypothesis. Still others suggest that vaccinia virus was the product of hybridization of two or more pox viruses in the nineteenth century. Careful analysis of the DNA of the viruses of vaccinia and possible "parents" has uncovered little indication of a close and recent relationship. The stuff of smallpox vaccination is a mystery, perhaps the greatest happy accident in the history of the relationship of humans and pathogens.

Streptococcal Diseases

Streptococci are responsible for many common and not so common human and animal diseases. Streptococcal pharyngitis, scarlet fever, impetigo, erysipelas, neonatal meningitis and sepsis, puerperal sepsis, and bacterial endocarditis all follow infection with streptococci. In addition, some streptococci provoke two peculiar postinfectious conditions: acute rheumatic fever and acute glomerulonephritis. Rebecca Lancefield (1933) divided streptococci into distinct serologic groups, labeled *A, B, C, D . . .* , each with a number of separate subgroups. In addition to these groups, microbiologists further classify streptococci on whether and how they hemolyze red blood cells (*alpha:* incomplete or green hemolysis; *beta:* complete or clear hemolysis). According to this tradition, the streptococcus responsible for pharyngitis is known as a "group A beta-hemolytic streptococcus." Another member of the genus *Streptococcus* is the *Streptococcus pneumoniae,* the bacteria responsible for pneumonia.

The streptococcus has a number of biological peculiarities that alter its ability to infect humans. The genetic insertion of a bacteriophage produces a toxin responsible for the rash of scarlet fever. A group of proteins, known as the M protein, renders the streptococcus impervious to the normal bodily defense of phagocytosis. Hemolysins and enzymes, when present, help the streptococcus to invade the host. One can speculate that this potential biological variability is responsible for the abrupt changes that streptococcal illnesses have made in the past (Gallis 1984).

Streptococcal illness can be extremely common. Few have escaped streptococcal pharyngitis or superficial impetigo of the skin. Alternately, some forms of streptococcal illness are rare. An example is streptococcal endocarditis. Most streptococcal diseases are spread through respiratory droplets. Others can be spread by bacterial contamination of food or milk, by soiled hands or instruments touching open wounds, or when normal resident bacteria invade the bloodstream (for example, when endocarditis follows dental work).

Group A streptococci produce several common illnesses. *Streptococcal pharyngitis* presents a clinical picture of fever, headache, sore throat, and abdominal discomfort. Before therapy with penicillin, the disease was often self-limited, but in certain cases the streptococci could disseminate to other ana-

tomic sites, producing otitis media, mastoiditis, tonsillar abscesses, or osteomyelitis. *Puerperal sepsis,* or childbed fever, occurs when streptococci, introduced at delivery, invade the internal lining of the uterus. Group A streptococci can cause *impetigo* (a superficial skin infection), *cellulitis,* and *erysipelas* (a life-threatening, rapidly progressing soft tissue infection).

Group A streptococci are responsible for two striking postinfectious conditions: The first is *acute rheumatic fever,* which follows streptococcal pharyngitis after 2 to 3 weeks. Rheumatic fever can include one or more of the following: carditis (pericarditis, myocarditis, and/or endocarditis); migratory, nondeforming arthritis; chorea; subcutaneous, fibrous nodules; and erythema marginatum. The second postinfectious condition is *acute glomerulonephritis,* a usually temporary form of renal failure.

Group B streptococci form part of the normal flora of the vagina and usually do not produce illness in adult women. These bacteria, however, can infect babies during delivery, producing meningitis and sepsis.

Group C streptococci are usually pathogenic only for animals.

Group D streptococci, normal residents of the human body, can produce endocarditis in people with deformed heart valves. Some streptococci cannot be so readily grouped, such as *Streptococcus viridans.* These can also cause endocarditis, and they play a role in the formation of dental caries.

History and Geography

Women have suffered from puerperal fever, presumably due to streptococci, since ancient times. Many case studies in the books of *Epidemics* within the Hippocratic corpus indicate that women suffered from postpartum fever, debility, and death. Nevertheless, childbed fever was probably never common. Oliver Wendell Holmes, in his masterfully argued "Contagiousness of Puerperal Fever" (1842–3), claimed that childbed fever was rare. When it occurred, it clustered around the practice of an individual physician. Holmes pointed to the need for cleanliness to prevent further victims.

Similarly, in the other classical study of puerperal sepsis first published in 1861, Ignaz Semmelweis (1983) demonstrated that physicians who followed their dead patients to the autopsy room and then returned to the lying-in room to deliver more babies had more of their patients die of puerperal fever than did midwives who did not perform autopsies. These observations of Holmes and Semmelweis (each un-

aware of the work of the other) point to the tremendous gulf in personal cleanliness that existed between the pre- and post-germ-theory practitioners.

Holmes, for example, tells of distinguished obstetricians who carried pelvic organs removed at autopsy in their street coat pockets. Both accounts also underscore the irony in the fact that the most scientifically oriented physicians, the ones who performed autopsies, were responsible for spreading the illness! Those accounts, however, treat with silence the plight of infants born of infected mothers. We know from twentieth-century experience that many infants emerged unscathed. But in the past, some may have developed a fatal infection, and even the lucky surviving infants would have faced an uncertain future if their mothers were unable to nurse them.

Erysipelas's role in history was an inevitable accompaniment of wounds, whether accidental or surgical (Simpson 1872). Any deep cut through uncleansed skin risked injecting streptococci into susceptible tissue. Erysipelas also accompanied other streptococcal-related illnesses, such as childbed fever. Scarlet fever (streptococcal pharyngitis produced by peculiar strains of streptococci that release a toxin yielding a rash) crosses medical history in a number of places. In the early years of bacteriology, Friedrich Löffler (1884) had to sort out scarlet fever cocci from diphtheria bacilli (both produced sore throats). Scarlet fever often occurred in epidemics passed both in the usual droplet fashion and in contaminated food – especially milk – supplies.

Streptococcal pharyngitis, with or without rash, provoked a prominent postinfectious state: acute rheumatic fever. For a period of about a century, rheumatic fever injured more hearts than any other disease. It struck children and young adults, usually less than 25 years of age, in temperate climates. Although mentioned by prominent seventeenth-century writers, such as Thomas Sydenham, rheumatic fever appears not to have become a major problem until the late eighteenth and early nineteenth centuries, when carditis emerged as the major component of rheumatic fever. This seems to have been the result of a biological change in the way the streptococcus provoked the body to respond (rheumatic fever is not an infection in the usual sense, but rather an immunologic response to the streptococcus), coupled with the introduction of the stethoscope that made diagnosis easier (Cheadle 1889).

All streptococcal diseases, except newborn sepsis and meningitis, have become less virulent since the end of the nineteenth century, a phenomenon that has yet to be explained. Their incidence was clearly on the decline before the arrival of specific measures to treat these illnesses. The puzzle to be sorted out is the possibility that the streptococcus, with its biological variability, could have become less inherently invasive in natural fashion. But it did so at the precise time in history (at least in Europe and the United States) when nutrition, housing, and standards of living substantially improved.

Today, however, the streptococcus is usually sensitive to sulfonamides and to penicillins; thus most infections are curable with appropriate antibiotics.

Strongyloidiasis

Strongyloidiasis, or *Cochin-China diarrhea,* is caused by a minute nematode, the threadworm *Strongyloides stercoralis.* The organism was first discovered in 1876 in French troops who had suffered severe diarrhea in the Cochin-China region of Vietnam. *Strongyloides* occurs around the world, with a range similar to that of the hookworms. Millions of people harbor the organism. Because poor sanitation and going without shoes favor transmission, it is especially prevalent in poor tropical countries. Like hookworm disease, strongyloidiasis prevalence has declined greatly in the southern United States since the early twentieth century, but it still exists in foci in Kentucky and other states.

The worm has a complex life cycle. Parasitic males may not exist, but if they do, they are eliminated from the body shortly after infection. The females burrow in the mucosa of the intestine, where they feed and lay their eggs, apparently by parthenogenesis. The eggs pass into the lumen of the intestine, where they hatch into a rhabditiform larval stage. In most cases these larvae are voided in the feces to the soil and either transform themselves directly into an infective filariform larval stage, or, if conditions are favorable, undergo one or more generations of sexual reproduction before filariform larvae appear. Like the hookworms, the filariform *Strongyloides* larvae penetrate human skin, often on an unshod foot, enter the venous circulation, and are carried through the heart to the lungs. Here they burrow through the walls of the air sacs, ascend to the throat, and are swallowed. The adult females bore into the walls of the small intestine and sometimes into the wall of the large intestine as well. Autoinfection is also possible and can maintain the parasite for years after the host has left endemic areas. In this variation of the life cycle, rhabditiform larvae develop into infective filariforms while still in the intestine. These larvae penetrate the mucosa, enter the bloodstream, and are eventually swallowed to continue the cycle.

Migrating larvae may produce itching when they penetrate the skin, and cough and chest pain when they are active in the lungs. Light intestinal infections are often asymptomatic, but heavier worm loads may cause abdominal pain, nausea, alternating diarrhea and constipation, anemia, weight loss,

and low fever. Autoinfection can produce an enormous number of worms and can be fatal. Persons with immune deficiencies from diseases such as cancer or acquired immune deficiency syndrome, or whose therapy requires immune suppression, may develop devastating hyperinfections from mild or inapparent strongyloidiasis.

Diagnosis is made by detection of larvae in stool specimens. Therapy is usually effective, although side effects from drugs are common. Prevention is largely a matter of education and better living conditions. Improved rural sanitation and wearing shoes break the worm's life cycle in most cases, and treatment prevents autoinfection.

Strongyloides fülleborni, a parasite of monkeys, has been found in many people in Zaire, Zambia, and other central African countries; larvae may possibly be transmitted in mother's milk. The same or a very similar species has been found in 80 to 100 percent of infants in a region of Papua New Guinea.

The sudden infant death syndrome (SIDS) is a difficult condition to define because medical scientists do not yet fully understand its nature. In the typical SIDS case, an apparently healthy infant, who may recently have suffered some minor respiratory ailment, is put to bed in the evening and is found dead in the crib next morning. The baby shows no signs of having been distressed; autopsy reveals no significant findings to explain the cause of death (Bergman et al. 1974; Golding, Limerick, and Macfarlane 1985).

The Second International Conference on Causes of Sudden Death in Infants, held in Seattle in 1969, described SIDS as "the sudden death of any infant or young child which is unexpected by history, and in which a thorough postmortem examination fails to demonstrate an adequate cause for death" (Bergman, Beckwith, and Ray, eds. 1970). That definition still applies. Physicians make the diagnosis of SIDS by excluding other causes of death in infants between one month and one year.

In attempting to understand SIDS, medical professionals have identified epidemiological patterns that characterize its victims, their parents, and the settings in which SIDS death occur. These characteristics will be discussed in subsequent sections.

Distribution and Incidence

The vast majority of reported and published SIDS cases come from countries and continents in the Earth's temperate zones (e.g., the United States, Canada, Europe, Australia, New Zealand, Japan, Hong Kong, and Israel) (Golding et al. 1985; Culbertson, Krous, and Bendell, eds. 1988; Guntheroth 1989; Irgens, Skjaerven, and Lie 1989; Lee et al. 1989). But SIDS occurs worldwide, in countries in tropical and frigid zones, in the mountains and at sea level (Golding et al. 1985; Culbertson et al. 1988; Guntheroth 1989). SIDS tends to receive less attention in countries with high infant death rates from problems such as infectious diseases and malnutrition. Autopsies are rarely performed on adults, much less on children, in these countries, making it almost impossible scientifically to label a sudden infant death as SIDS (Bergman 1986). SIDS becomes a significant factor in a country when the infant death rate approaches

approximately 15 per 1,000 live births. The lower the death rate from other causes of infant mortality, the higher the proportion of deaths from SIDS (Culbertson et al. 1988).

The occurrence of SIDS has probably not changed much over the centuries around the world (Bergman 1986; Culbertson et al. 1988). Rates range generally from 1.5 to 3.5 cases per 1,000 live births per year, though the incidence varies from country to country. It is difficult to compare these rates because of differences in the way each study team obtains and analyzes its data (Culbertson et al. 1988). In the United States, SIDS rates have ranged from 1.2 to 3.4 deaths per 1,000 live births. The range is higher in Britain (2.1 to 4.0) and the Antipodes (New Zealand and Australia) (1.6 to 4.1), and lower on the European continent (0.5 to 2.7), in Israel (0.3 to 0.7), Japan (0.5 to 1.2), and Hong Kong (0.036 to 0.3) (Golding et al. 1985; Culbertson et al. 1988; Guntheroth 1989; Irgens et al. 1989; Lee et al. 1989).

SIDS accounts for approximately 6,000 to 7,000 infant deaths per year in the United States (Bergman 1986). It is the greatest killer of infants between 1 month and 1 year of life (Culbertson et al. 1988).

Epidemiology

SIDS' outstanding epidemiological characteristic is the age at which it strikes children. Most deaths occur at between 1 month and 6 months of age, with a peak between ages 2 and 3 months. Very vew cases occur before 1 month; the incidence drops significantly after 6 months old. SIDS deaths thus occur at an age when babies are undergoing their most rapid systemic development, and when their needs for efficient bodily processes and outside sources of energy to fuel them are greatest. Infants at this time are adjusting, for example, their sleep patterns to changing internal needs and to the outside environment, their gastrointestinal systems to changing foods, their immune systems to new antigens and pathogens, and their nervous systems to a variety of new motor and sensory stimuli. Life outside the womb is very different from life inside the womb.

SIDS strikes children of both sexes, of all social, economic, ethnic, and racial groups, and at all times of the year. The distribution of SIDS within these groups and seasons is not equal, however. About 60 percent of SIDS deaths occur among boys. SIDS occurs more commonly, but by no means exclusively, during the colder months of the year (autumn and winter), in both the northern and southern hemispheres. Members of lower socioeconomic

groups generally suffer a higher incidence of SIDS than do others. The distribution of SIDS also seems to follow racial lines in the United States: Afro-Americans (blacks) show the highest incidence, followed by Euro-Americans (whites), followed by Asian-Americans. That racial distribution may be deceptive, as it probably reflects more the generally lower socioeconomic status (SES) of blacks in the United States compared to other groups. Low SES does not always translate into high risk for SIDS, however. Studies in both Chicago (Guntheroth 1989) and California (Grether and Schulman 1989) show, interestingly and, at present, inexplicably, that Hispanics of low SES have a SIDS rate comparable to or lower than that for whites.

Certain other characteristics of babies, mothers, and families appear to be risk factors associated with a higher incidence of SIDS in infants. None of these factors is predictive of SIDS and none will be found in all SIDS cases, but all increase the risk in a child vulnerable to SIDS. All, it should be noted, can be related to low SES. Prematurity and low birth weight are both important risk factors in SIDS. SIDS occurs more frequently in children of the following: multiple births (increased risk due to small birth size or prematurity), younger mothers, mothers who smoke, mothers of greater parity, higher birth rank in the family, single mothers, mothers who are drug abusers, mothers with poor prenatal care, and families in which a SIDS death has previously occurred (slightly increased risk).

Etiology and Pathology

At present, the etiology of SIDS remains a mystery. It is not even clear whether SIDS has a single cause, has several causes, or is the result of a combination of factors working together.

Before the medical profession took an interest in the sudden, unexplained deaths of infants in the eighteenth century, people attributed the demise of these children to accidental suffocation in bedclothes, or to accidental smothering and overlaying by sleeping parents. Less charitable people accused parents or nursemaids of infanticide. These theories persisted throughout the nineteenth and early and mid-twentieth centuries concomitantly with medical theories that ascribed sudden infant deaths to an enlarged thymus or a thymic condition (see the History section for more on this). Since the 1940s, when researchers took a renewed interest in the etiology of sudden unexplained infant deaths, medicine has proposed numerous theories to explain why these children die.

When medical examiners in the 1940s and 1950s tested the blood of infants who had died suddenly and inexplicably, they often found fulminant infections that could easily have caused death. For the next several years, bacterial and viral infections were considered a major cause of sudden infant deaths. But when those deaths from infection were weeded out, there still remained a large number for which pathologists could find no infectious agents. Researchers then found other possible causes of death, including the following: powerful allergic reactions to cow's milk, to house dust mites, or to some unidentified allergen; botulism, beginning in 1976 when a number of infants infected with *Clostridium botulinum* were discovered in California; a severe, undetected respiratory viral infection; a response to vaccination against childhood diseases; overheating; hypothermia; high sodium in the blood; deficiency of a trace element like magnesium, zinc, copper, calcium, selenium, or manganese; a vitamin deficiency; and high or low levels of thyroid hormones. Some physicians reiterated the old view that a proportion of parents committed infanticide. Further research into these and other proposed etiologies continues.

Most current research relates the "final pathway" of SIDS to a malfunctioning or immaturity of the respiratory or cardiovascular system. Etiologic theories under consideration include preexisting hypoxia, heart conduction problems (arrhythmias), and apnea (Culbertson et al. 1988; Schwartz, Southall, and Valdes-Dapena 1988; Guntheroth 1989). Evidence indicates that children who die of SIDS possess physical risk factors such as small size, slower growth rate, fatty changes in the liver, and thymic changes campatible with previous infection. These risk factors are not specific to SIDS but, like the social factors listed in the Epidemiology section, reflect increased risk to all infant deaths. When a young patient possesses what Abraham Bergman (1986) calls a "critical mass" of these physical and social factors, all that is needed is a trigger to cause SIDS to occur. "Something must happen during sleep to tip the balance," he speculates, because virtually all SIDS deaths occur during sleep. The nature of that trigger is the mystery of SIDS.

SIDS leaves few pathological footprints in its young victims' bodies. Postmortem examination reveals little for the physician to use in understanding the pathology of the condition. The very definition of SIDS incorporates this fact, stating that negative postmortem findings help to classify an infant's cause of death as SIDS. Pathologists studying large numbers of SIDS cases have, over the

years, noted only a few consistent postmortem findings that might at some time help explain the nature of SIDS. These include, according to one SIDS researcher (Guntheroth 1989), "intrathoracic petechiae, patchy pulmonary edema and emphysema," indicative of respiratory problems; "histopathology suggesting pre-existing hypoxia, such as changes in pulmonary arteries and right ventricle, smaller thymus, extra-medullary erythropoiesis, increased peri-adrenal brown fat cells, [and] enlarged adrenal chromaffin cells"; and neuropathological changes such as "astroglial proliferation in brain stem, leukomalacia, and delayed loss of dendritic spines in reticular substance," consistent with underdevelopment or a subtle chronic disorder. The pathological changes so far discovered fail to provide enough information for medical scientists to understand the etiology or mechanism behind SIDS deaths.

History

The medical profession and society did not recognize SIDS until the late twentieth century. And yet people from Biblical times onward described sudden unexplained infant deaths that matched the typical history of a SIDS death of today. Because the deaths almost always occurred at home or in private situations, and to seemingly healthy children, most people, including parents and caregivers, generally ascribed the cause of death to accidental or intentional smothering or suffocation. When discovering their infants, with whom they regularly slept, dead next to them after a night's sleep, with no signs of any disease or disturbance, and no cries during the night, parents believed that they had unknowingly overlaid and smothered their children. Or, if they had not slept with their infant, but found it lifeless where they had put it down for the night or for a nap, parents assumed the child had suffocated in its bed clothes. In either circumstance, parents blamed themselves for the tragedy. Worse, community members suspected not just parental negligence, but overt infanticide. Because SIDS leaves no telltale marks on its little victims, no one could determine if the infant's demise was truly accidental or if it was intentional. As a result, society assumed parental negligence and punished the parents or whoever was responsible for the child's care. Medical people were not consulted in these situations except perhaps to confirm the death. It was purely a societal matter dealt with by religious, and later by secular, authorities.

Perhaps the first recorded Western case of SIDS is found in the famous Bible story in 1 Kings 3:19 of the two women who went before King Solomon with claims to motherhood of an infant boy. One of the women had awakened, found her son dead, thought she had overlaid him, and secretly switched the child with another. Solomon's proposed solution was to cut the living boy in half so each mother could have part of the child. Medieval church rules enunciated specific punishments for those who overlaid their children, and forbade parents from taking infants to bed with them. As early as the sixteenth century, Florentine craftsmen designed a wooden arch that fit over, and kept blankets away from, the child, thus preventing potential suffocation with bed clothes.

The power of ecclesiastical courts began to wane in the Renaissance. As secular authorities gained power during the subsequent centuries, civil courts investigated cases of overlaying and smothering to determine causes of death. At this same time, medicine was learning more about human anatomy and physiology. In 1761 an Italian physician, Giovanni Morgagni, published his book *On the Seats and Causes of Disease,* which correlated specific autopsy findings with disease signs and symptoms during a patient's illness. The resultant development of pathological anatomy in the early nineteenth century helped medicalize the previously nonmedical conditions of sudden unexplained infant death. As autopsies of these children revealed large thymuses (actually a normal finding), physicians explained death on the basis that the thymus gland cut off the tracheal airway or overly reduced the size of the thoracic cavity in which the heart and lungs had to function. Such explanations relieved parents of blame for their children's deaths. Despite evidence presented by other physicians during the nineteenth and early twentieth centuries that neither an enlarged thymus nor a similar but more complex condition called status thymico-lymphaticus could cause sudden infant death (Cone 1979), many people, including judges in courts, used thymic death to absolve parents of guilt. By the end of the nineteenth century, medical people were divided over sudden unexplained infant deaths. For example, a police surgeon in Dundee, Scotland, in 1892 openly accused parents of neglect, ignorance, carelessness, and drunkenness in overlaying their children (Templeman 1892), whereas William Osler (1904) still wrote of thymic enlargement as a cause of sudden infant death in the 1904 edition of his influential and widely used textbook of medicine.

Recognition of the condition now known as SIDS began to occur in the 1940s and 1950s with the publication of studies (e.g., Werne and Garrow 1953)

demonstrating the extreme difficulty of overlaying a child or smothering a child in bed clothes, and the importance of performing full autopsies on these children. As medical scientists and epidemiologists gathered information during the 1960s and 1970s, they better characterized SIDS (Bergman 1986; Guntheroth 1989). Public awareness and political campaigns since the 1970s have succeeded in removing much of the parental stigma associated with sudden infant deaths (Bergman 1986).

Sudden Unexplained Death Syndrome (Asian)

Sudden unexplained death syndrome (SUDS) occurs when a relatively young healthy person, usually male and Asian, dies unexpectedly while sleeping. The victim has no known antecedent illnesses, and there are no factors that might precipitate cardiac arrest. At autopsy, no cause of death can be identified in the heart, lung, or brain. Postmortem toxicologic screening tests reveal no poisons. A sudden fatality during sleep in a previously healthy member of an ethnic group subject to SUDS, but whose death is not investigated with an autopsy, is defined as a presumptive case of SUDS.

Distribution and Incidence

SUDS has occurred in the 1980s among Southeast Asian refugees and immigrants in the United States, mainly among Laotians, Hmong, Kampucheans, and Filipinos. In Asia, SUDS has been described in the Japanese and Filipino medical literature and is also observed in refugee camps in Thailand. In 1983 the death rate ascribed to SUDS in the 25- to 44-year age group of Laotian and Hmong males in the United States, 87 per 100,000, was comparable to the sum of the four leading causes of natural death among other U.S. males in that age group. The incidence of SUDS has decreased since 1983, and there is evidence that

the longer a refugee has been in the United States, the lower the risk.

Epidemiology

The first comprehensive report of SUDS in the United States was published by the Centers for Disease Control (CDC) on December 4, 1981; it described 38 victims, all Southeast Asian refugees. All but one of the cases were males: 25 Hmong, 8 Laotian, 4 Vietnamese, and 1 Kampuchean. Median period of time in the United States was 5 months (range, 5 days to 52 months) before death. Geographic distribution of the deaths reflected the distribution of the Southeast Asian refugees in the United States. The deaths occurred between 9:30 P.M. and 7:00 A.M.

Clinical Manifestations and Pathology

The victims whose deaths were witnessed by relatives appeared to be asleep prior to death or were just falling asleep. None of them had complained of illness or symptoms before going to bed, and all were considered by family members to have been in good health.

Witnesses of SUDS deaths become aware of abnormal breathing sounds, in some cases preceded by a brief groan. Victims cannot be aroused. Terminal respirations are said to be labored and deep, irregular and without wheezing or stridor. The victims remain flaccid during these events, although a few are described as having tonic rigidity. Some of the victims are incontinent of urine or feces. Witnesses recall no signs of pain or terrifying dreams. A few of the victims who are still alive when paramedics reach them are found to be in ventricular fibrillation.

Interviews with family members yield no clues as to why the victims have died. Spouses have not noted symptoms consistent with sleep apnea syndrome.

Etiology

In discussing the significance of SUDS cases, CDC investigators note that they "may constitute a new syndrome" because of the differences in the epidemiological pattern between these cases and other victims of sudden death. The quickness of the deaths is unusual, and there is a lack of any ascribed cause after extensive postmortem investigation.

The etiology of SUDS remains unknown. In 1982 researchers at the CDC performed a case control study using the first 26 cases of SUDS among Hmong and Laotians in the United States. Results were meager. No single variable was found that differentiated cases from controls. The victims tended

to have been in the country less than 6 months, to have left Laos less than 3 years earlier, to have spent a greater proportion of their income on housing, and to have acquired fewer possessions in the United States than had other immigrants. Although cases had similar amounts of English training, they had less job training. Cases had gained weight less frequently than controls and lost weight more frequently. The authors of the study concluded that factors that enhance emotional stress or result from such stress are a "possible precipitating element in these deaths."

History and Geography

Sudden death in healthy individuals is a phenomenon that has occurred throughout history and in many cultures. Because of their sudden and unexpected nature, many of these deaths have been attributed to supernatural or psychological causes. There has been speculation that SUDS among Southeast Asian refugees in the United States may be triggered by such factors as stress, night terror, evil spirits, or culture shock.

Yet a number of older reports in the medical literature of the Philippines have identified a sudden nocturnal death syndrome known as *Bangungut*. Previously healthy males die during the night, making moaning, snoring, or choking noises. *Bangungut* means "to rise and moan in sleep" in Tagalog, reflecting the folk belief that the deaths are caused by terror from nightmares. The victims are men 20 to 50 years old. No consistent cause has been found for these sudden deaths, even though they have been extensively evaluated with autopsies. The main postmortem finding is hemorrhagic pancreatitis, a condition most observers believe is not a cause of the syndrome but, rather, an effect after death.

Physicians in the Emergency Department at Philippine General Hospital in Manila state that they see numerous cases of SUDS every year. The typical profile of a victim is a young male adult with a stocky build, usually a poorly educated construction worker who migrated from the Visayan Islands to work in Manila and who had either been on a drinking spree shortly before sleeping or had just eaten a fatty meal prior to retiring for the night. The victim is brought to the Emergency Room by fellow workers who are unable to wake him, but who remember his moaning and groaning in sleep. Nearly universally Filipinos have heard about *Bangungut* and believe in its authenticity. Many of them describe experiences as children being assigned to watch over their fathers' afternoon naps.

Similar episodes of sudden death among Filipinos living in the Hawaiian Islands were described in the medical and popular literature during 1930–60.

In Japan, there is a disease referred to as *pokkuri,* which is a sudden death similar to those described in Southeast Asians in the United States and in the Philippines. A study of 18,515 consecutive autopsies in Japan found cardiac death of unknown etiology in 76 cases. Almost all of these deaths occurred in young men who had been considered to be in good health and who died suddenly during sleep. Some Japanese pathologists believe that the cause of death is a fulminant deletion of myoglobin from myocardial fibers during a state of acute cardiac failure.

An American anthropologist and epidemiologist has studied SUDS in the refugee camps in Thailand. Although autopsies are not common in such settings, the deaths were very similar to SUDS deaths occurring among similar refugees in the United States.

Emotional trauma, voodoo, spirits, and magic have all been suggested as important factors for sudden unexplained death in folk cultures. Modern biomedical beliefs prescribe that psychological factors cannot cause deaths per se, but may trigger a fatal event. A different emphasis occurs in reports of sudden death among persons living in cultures where the concept of psychological sudden death has greater currency than in scientific Westernized cultures. For example, in Australia there was a belief among the northern Aborigines that a person who has been pointed at with a bone will die as a result. A government surgeon among the people of that region in 1897 wrote that he had witnessed three or four such cases. A phenomenon of wishful dying has been described among rural Bantu people in South Africa.

Several studies of the Hmong, the group hardest hit by SUDS in the United States, have proposed psychological triggers as explanations for their deaths. An extensive cultural study of SUDS focused on Hmong religion and its relationship to health concepts, but no correlation could be found between the deaths and religious preference, degree of belief in traditional religion, or anxiety over religious questions. The author concluded that one possible triggering mechanism for SUDS might be overwhelming and inescapable stress. Another study conducted in the United States by two anthropologists also considered stress as a potential trigger in SUDS. The authors interviewed relatives of 28 victims of the syndrome and concluded that night terror might have contributed to their deaths. The researchers specu-

lated that such terror was brought on by exhaustion, culture shock, family quarrels, or even the violent images found on television.

VIII.133
Sweating Sickness

History and Geography

The sweating sickness, or *sudor anglicus,* is one of the great puzzles of historical epidemiology because no modern disease corresponds very well to its principal epidemiological and clinical features. Thus it is a topic that has generated much speculation and debate in the understanding of what caused the five English epidemics attributed to the "Sweat."

The first description was written in 1486, which indicated that the earliest epidemic occurred (northern England) during June of 1485, where strictly contemporary accounts use the words "plague" and "pestilence" to describe the local mortality crisis (Wylie and Collier 1981). However, Charles Creighton (1891), whom most authors follow, claims that the initial outbreak began later, in London, on September 19, 1485, brought back with Henry VII's mercenaries from France and Flanders.

Once in London the epidemic displayed some of its most characteristic and consistent features: higher mortality among men than women, peaking during middle adulthood among the economically advantaged, and a sudden, acute fever accompanied by profuse sweating. Its victims generally lapsed into coma and died within 24 to 48 hours. Similar outbreaks have been identified: in 1508, 1517, 1528, and 1551. Oddly, the disease favored Englishmen at home and abroad. In the British Isles, Scots, Welsh, and Irish were spared.

The "Sweat" had no important demographic repercussions, as the numbers affected were always small in comparison to the poxes and plagues of this period. Nonetheless, each recurrence of the disease produced widespread fear (Gottfried 1977; Slack 1979). In 1528–9, the Sweat uncharacteristically extended to Calais and to many German regions, but was clearly associated with severe famine, as well as an epidemic of typhus (petechial fever) and plague. As might be expected, a body of literature on the disease had accumulated at the time as well as later, and it has fueled continued interest in the Sweat's identity.

In 1508 Sir Thomas More informed Cardinal Wolsey of the Sweat's progress among young scholars at Oxford and Cambridge, but little discussion was generated. In fact, the 1517 and 1551 epidemics are the only two epidemics for which we have substantial contemporary accounts. Edward Hall's chronicle re-

ports that in 1517, "this malady was so cruel that it killed some within three houres, some within two houres, some merry at dinner and dedde [dead] at supper. Many died in the Kynges court, the lord Clinton, the lorde Gray of Wilton, and many Knightes, gentlemen and officers" (Wylie and Collier 1981).

Court historian Polydore Vergil's graphic description of the disease was based on his experience during the Sweat's 1508 and 1517 appearances and written from memory. First published in 1534, it directly follows this text. In addition, there is some speculation that Vergil may have had access to chronicled reports contemporary with the 1485 outbreak. The earliest description provided by a physician was not written until 1552, when noted humanist John Caius published his *Boke, or Counseill against the Disease Commonly called the Sweate or Sweatyng Sicknesse* (text in Hecker 1844). His advice, however timely or expert, was to no avail, for the disease never recurred.

Etiology

The early nineteenth-century historical epidemiologist J. F. K. Hecker, who was fascinated by the Sweat's abrupt appearances and disappearances, felt that English methods of therapy were partly responsible for the high case-fatality rates. Writing over a century later, Maurice Strauss (1973) concurred, arguing that efforts to encourage perspiration and to stimulate vigorous purging of the bowels would have exacerbated fluid and salt losses associated with a high fever and led to circulatory collapse. Hecker (1844), however, also blamed the English climate and the habits of the English nobility.

[T]he English sweating sickness was a spirit of the mist, which hovered amid the dark clouds. Even in ordinary years the atmosphere of England is loaded with these clouds during considerable periods, and in damp seasons they would prove the more injurious, as the English of these times were not accustomed to cleanliness, moderation in their diet, or even comfortable refinements. Gluttony was common among the nobility as well as among the lower classes; all were immoderately addicted to drinking.

Building on the suggestion that peculiarities of the sixteenth-century English diet might account for the disease, Adam Patrick (1965) argued that the Sweat resembled a shock reaction, with its hyperacute *pyrexia* (fever) and sweating, occasionally associated with evidence of circulatory collapse. Among the most likely toxins, he passed over bacterial endotoxins and exotoxins in favor of fungal toxins associated with food poisoning. Ultimately, he felt that the sweating sickness was a form of ergotism.

Writing in 1891, Creighton, by contrast, denied the possibility that local conditions could alone explain the appearances of the Sweat, and he was loath to identify it with any one known infection. He was, however, convinced that it was introduced by the Flemish mercenaries hired by Henry Tudor, "a swarm of disreputable free-booters from Normandy, natives of a soil which developed the sweat as an indigenous malady in the long course of generations." An opponent of the germ theory of disease, Creighton believed that the soil of the lower basin of the Seine perennially harbored the disease, its epidemic appearances dictated by variations in weather conditions. He concluded firmly that "it must have come from the persons of the foreign soldiers": He contrasted the ability of the French to host the disease and survive, and the partial immunity many Africans displayed when exposed to yellow fever, with the susceptibility of the English and drew a parallel with the effect, on unprotected flocks of cattle, of bringing an animal infected with Texas cattle-fever into the fold.

Most recent authorities concur with Creighton that whatever caused the Sweat, it was a disease that found "virgin soil" in England or among the English. In so doing, they follow Hans Zinsser's assessment that the Sweat was caused by a viral illness to which the uniquely susceptible English population gradually acquired immunity (Zinsser 1935). Zinsser departed from earlier twentieth-century physicians in ascribing the cause of the Sweat to influenza (Hamer 1906; Crookshank 1919), and today there seems to be agreement that the Sweat was not an influenza virus, although it spread in a similar manner (Shaw 1933; Roberts 1965).

Finally, John Wylie and Leslie Collier (1981) speculate that a novel arbovirus infection, transmitted by an insect vector, accords with most of the clinical and epidemiological information. By the mid-sixteenth century, the disease was becoming endemic in England, affecting children more than adults and in the process losing some of its terror.

Ann G. Carmichael

Polydore Vergil's (1534) description of the Sweating Sickness (from Shaw, 1933, 270–1)

The same year (1485), a new disease pervaded the whole kingdom, during Henry's first descent into the island, a pestilence horrible indeed, and before which no age could endure, a well-known fact; suddenly a fatal sweat attacked the body wracking it with pains in the head and stomach, moreover there was a terrific sensation of heat. Therefore the patients cast off the bed coverings from the beginning, as some of them suffered less heat if they lay in bed; if they were dressed they stripped off their clothes, the thirsty ones drank cold water, others suffering from this fetid heat, provoked a sweat which had a foul odor, by adding bed clothes, all of them dying immediately or not long after the sweat had begun; so that not one in a hundred evaded it. Nor did any art of medicine or science avail to help it, meanwhile, for this strange disease escaped all their knowledge. In fact, after twenty four hours (the severity of the disease continued for that length of time) the sweat departed bringing this conclusion, i.e., that they were not cleansed by the sweat, as many of them perished. But that fact pointed out a final measure in the treatment for this great torture; those who had sweat once, since they sickened again put into use those things which they had discovered to have been beneficial in the first attack. Even so, when the calamity befell the sickly race again (1508), from earlier observations they had forgotten how to care for themselves, in order that they might bear more easily the strenuous sweating. Thus from experience, after such a huge slaughter of human beings, it follows that the most prompt relief should have been found, which was this: if anyone was seized during the daytime he should go to bed forthwith, with his clothes on; if, while he was in bed at night, he should lie quietly and not move from that place, remaining so for twenty four hours exactly, covered with not enough bed clothes to provoke the sweat but just enough to allow him to sweat spontaneously, taking no food, if possible to bear the hunger, and drinking no more water than usual or of less warmth, which should satisfy in a way and quench the thirst; in the first stages of this treatment care should be taken that there should be no occasion either for warming up or cooling off the hands or feet as to do so means death. Such was the treatment found for this plague which covered so much of England at this time and in times past has so often afflicted it, for the first year that Henry began to reign was remarkable for the plague, which was taken by many as a bad omen.

Syphilis

Syphilis or, more properly, venereal syphilis is a chronic communicable disease, which, until the acquired immunodeficiency syndrome emerged in the early 1980s, was the most serious and dreaded of the so-called sexually transmitted diseases (STD) – formerly, venereal diseases (VD). Caused by *Treponema pallidum* subspecies pallidum, a spirochetal bacterium, the only known natural host of which is the human being, venereal syphilis is thus one of the human treponematoses – along with pinta, yaws, and endemic syphilis. Although predominantly transferred by sexual contact, *T. pallidum* is also capable of being transmitted from an infected mother to her fetus across the placenta at any stage of pregnancy (congential syphilis).

Syphilis develops naturally through three clinical stages (primary, secondary, and tertiary or late), each separated by a subclinical period. Of the subclinical periods, the one between the secondary and tertiary stages (latent syphilis) is the most pronounced. Clinical manifestations of syphilis are extremely protean, and capable, at the tertiary stage, of affecting any system of the human body.

Syphilis took its name from Girolamo Fracastoro's well-known poem, *Syphilis, sive morbus gallicus* (1530), in which the Italian humanist-physician invented this phrase to name the disease then known all over Europe as *morbus gallicus*. However, the term syphilis did not become widely used until the late eighteenth century, and that usage was vague and applied to many other symptoms besides those of venereal syphilis until the development of the germ theory in the late nineteenth and early twentieth centuries.

Distribution and Incidence

Unlike human nonvenereal treponematoses (pinta, yaws, and endemic syphilis), venereal syphilis has managed to establish a worldwide distribution, although its incidence patterns are somewhat different in developed and developing countries.

The incidence of syphilis, for example, has continuously declined in the Western world since the 1860s, although major wars have momentarily interrupted this trend. After the Second World War, late and congenital syphilis almost disappeared, mainly as a result of public health measures and penicillin. Since the 1950s, however, both primary and secondary syphilis have steadily increased (nearly 29,000 cases in the United States in 1984) with its peak incidence in the 15- to 34-year age group. A strikingly high male/female ratio (2.6:1 in the United States in 1983) is due to a considerable incidence of syphilis in male homosexuals. In 1980, 58 percent of all syphilitic men in England were homosexuals as were 50 percent in the United States (Csonka 1987; Holmes and Lukehart 1987).

In developing countries, syphilis continues to be a widespread disease, although interpretative problems of serologic tests for syphilis make it difficult to estimate the numbers of infected people in those regions. Syphilis is increasing in areas where yaws was previously endemic, such as tropical and equatorial America and Africa, and Southeast Asia. Infected prostitutes seem to play an important role in the spread of syphilis in these areas, most noticeably in the Far East. The risk of congenital syphilis continues to be considerable in many developing countries, resulting in fetal wastage, neonatal mortality, and infant morbidity (WHO 1986; Csonka 1987).

Etiology and Epidemiology

Although syphilis is transferred predominantly by sexual contact, it may also be transmitted in nonsexual ways, such as by close contact with either an open lesion of early syphilis or infected fomites, by

Table VIII.134.1. *Etiology, epidemiology, and clinical manifestations of the human treponematoses*

	Venereal syphilis	Endemic syphilis	Yaws	Pinta
Organism	*T. pallidum*	*T. pallidum endemicum*	*T. pertenue*	*T. carateum*
Occurrence	Sporadic, urban	Endemic, rural	Endemic, rural	Endemic, rural
Geographic distribution	Worldwide	Southwest Asia, sub-Saharan regions of Africa, Bosnia	Africa, Southeast Asia, Western Pacific, South America, Caribbean	Central and South America, Mexico
Climate in which the disease mostly occurs	All types	Arid, warm	Humid, warm	Semiarid, warm
Age group with peak incidence (years)	18–30	2–10	2–10	15–30
Transmissibility	High	High	High	Low
Reservoir of infection	Adults	Children 2–15 years old; contacts in home, school and village; latent cases capable of becoming active	Children 2–15 years old; contacts in home, school and village; latent cases capable of becoming active	Cases with long-standing skin lesions
Mode of transmission	Sexual, transplacental[a]	Household contacts: mouth-to-mouth or via drinking, eating utensils	Skin-to-skin; ? insect vector	Skin-to-skin; ? insect vector
Usual age	Adult	Early childhood	Early childhood	Adolescent
Primary lesion	Cutaneous ulcer (chancre)	Rarely seen	Framboise (raspberry), or "mother yaw"	Nonulcerating papule with satellites
Secondary lesion	Mucocutaneous; occasional periostitis	Florid mucocutaneous lesions (mucous patch, split papule, condyloma latum); osteoperiostitis	Cutaneous papulo-squamous lesions; osteoperiostitis	Pintides
Tertiary lesion	Gumma, cardiovascular, and CNS lues	Destructive cutaneous osteoarticular gummas	Destructive cutaneous osteoarticular gummas	Dyschromic, achromic macules

[a]Because the nonvenereal treponematoses are usually acquired in childhood, and because treponemal bacteremia ceases with time, only in adult-onset venereal syphilis is there any likelihood of a mother giving birth to an infected child.

infection of an unborn infant in utero, and by transfusions of infected blood.

As noted above, *T. pallidum,* the causal agent of syphilis, is a member of the order Spirochetales. This order of bacteria includes three genera pathogenic for humans and several other animals: (1) *Borrelia,* responsible for Vincent's angina (*Borrelia recurrentis*), relapsing fever (*Borrelia vincentii*), and Lyme disease (*Borrelia burgdorferi*); (2) *Leptospira,* which causes human leptospirosis; and (3) *Treponema,* responsible for a group of diseases known as treponematoses (Holmes and Lukehart 1987).

The *Treponema* genus includes several pathogenic species and subspecies responsible for four different human diseases: (1) *pinta,* a Central and South American disease, which affects the skin, caused by *Treponema carateum;* (2) *yaws,* a disease of skin and

bones occurring in rural populations of the humid tropics, caused by *Treponema pallidum* subspecies *pertenue;* (3) *endemic syphilis,* similar to yaws, but found only in warm, arid climates, and caused by *T. pallidum* subspecies *endemicum;* and (4) *venereal syphilis,* which has no climatic restrictions and may affect any tissue of the body including internal organs, and is caused by *T. pallidum* subspecies *pallidum.* These and other major features concerning the human treponematoses are indicated in Table VIII.134.1. Surprisingly, in spite of the differentiated (both clinically and epidemiologically) disease entities they produce, these four treponemes cannot be morphologically distinguished from one another. Moreover, they elicit the same immunologic reactions, and are all susceptible to penicillin (Hackett 1963; Perine et al. 1984; Csonka 1987).

Almost from the time of Columbus's arrival in America, but particularly from the European Enlightenment, the uncertain geographic and historical origins of syphilis have been the object of scholarly controversy (Guerra 1987). Since the 1950s, however, the rise of molecular biology has pushed anthropologists and historical epidemiologists to frame this problem progressively in terms of the evolutionary origins of all the human treponematoses. At present, two major theories – the unitarian and the nonunitarian – contend with each other in providing an explanation for the surprising similarities of the human treponematoses.

For E. H. Hudson, the most outstanding defender of unitarian theory, there is only one treponematosis, although it assumes different clinical patterns under different epidemiological conditions. Thus, the changing physical and sociocultural environment of human beings has caused treponematosis to change into one or another of those four different clinical syndromes already mentioned: pinta, yaws, endemic syphilis, and syphilis. From the unitarian viewpoint, then, it does not make sense to talk about transmission of syphilis from the New World to the Old, or vice versa (Hudson 1965).

By contrast, C. J. Hackett, the main upholder of nonunitarian theory, maintains that the clinical variety of human treponematoses is probably due to *mutational changes* in the treponemal strains themselves. His thesis is that successive mutations have been responsible for the different human treponematoses starting from a lost ancestral animal treponematosis. The earliest of the treponematoses seems to have been pinta, which might have extended from Africa and Asia into America about 15,000 B.C.; that is, during the last part of the last glaciation and before the subsequent melting of the polar icecaps that formed the Bering Strait.

By about 10,000 B.C., a warm humid environment caused either the pinta treponemes themselves (hypothesis A) or the lost ancestral animal treponemes (hypothesis B) to mutate in Afro-Asia, bringing forth yaws, a disease that extended through Africa, Southeast Asia, and eventually Australia and the Pacific islands, but that did not reach the Americas.

Around 7000 B.C., in the warm arid climates that developed after the last glaciation, another mutation occurred, this time from yaws to endemic syphilis. The latter appeared in northern and Saharan Africa, southwestern and central Asia, and central Australia, whereas yaws itself remained unchanged in the warm and more humid climates.

Finally, about 3000 B.C., the development of large
Figure VIII.134.1. Two hypotheses as to the possible evolution of the organisms responsible for human treponematoses (according to C. J. Hackett 1963, 25). [From C. J. Hackett. 1963. On the origin of the human treponematoses (pinta, yaws, endemic syphilis, and venereal syphilis). *Bulletin of the World Health Organization* 29: 7–41.]

urban areas and the increasing use of clothing in the eastern Mediterranean and southwestern Asia became selective agents for still another mutation as syphilis changed from a nonvenereal disease of rural children (endemic syphilis) to a venereal disease of urban adults (venereal syphilis). According to Hackett, at any rate, by the first century B.C., as Figure VIII.134.1 indicates, syphilis had spread throughout the Mediterranean. He suggests, however, that this early venereal syphilis was a "mild" form of the disease, which may explain why there is no evidence of the illness in Europe before the end of the fifteenth century, when a new successful treponeme mutation – probably favored by environmental and social conditions in congested European cities at

that time – gave rise to a far more serious disease. Initially extremely virulent, this form of syphilis is supposed to have become progressively less destructive from around the 1530s onward (Hackett 1963). As will be discussed below, however, still other scholars trace the sudden epidemic of venereal syphilis to the post-Columbian importation of an American parasite to Europe, and thence to Asia and Africa.

Immunology

There is no natural immunity to infection by pathogenic treponemes. However, "only about 50 percent of the named contacts of primary and secondary syphilis become infected," and 25 percent after a single exposure. The chance of infection is influenced – in undefined proportions – by sexual and hygienic practices, inoculum size, environmental and body temperature, and other factors.

Acquired immunity is related to inoculum size and duration of infection prior to treatment. Intradermal inoculation of *T. pallidum* usually causes primary lesions and serologic response in those who have previously been treated for early syphilis. By contrast, it produces no symptoms or responses in those with untreated latent syphilis, or in those previously treated for late latent (more than 1 year's duration) syphilis (Holmes and Lukehart 1987).

Clinical Manifestations and Pathology

When William Osler asserted that "who knows syphilis, knows medicine," he was doing no more than stressing the extreme clinical variety of this disease, which is capable of affecting any system of the human body. As noted previously, the natural course of venereal syphilis includes three consecutive clinical stages, each stage separated by a latent period with no visible signs of infection (Perine et al. 1984; Csonka 1987; Holmes and Lukehart 1987).

Primary Syphilis

T. pallidum penetrates intact mucous membranes and abraded skin. After an incubation period ranging from 2 to 6 weeks (average 3 weeks), the primary lesion – the *chancre* – appears at the site of entry. it is a single, small, and painless ulcer with undurated edges, usually appearing in the genitalia (penis, vulva, labia, cervix) and, less frequently, in other regions such as the anus, mouth, buttocks, and fingers. Chancres of the penis and vulva are usually accompanied by moderate bilateral enlargement of inguinal lymph nodes. The chancre heals spontaneously over a period of 2 to 6 weeks.

Secondary Syphilis

In most patients, after a brief latent period (6 to 8 weeks), there is a secondary clinical stage characterized by the appearance of disseminated lesions on the skin and in the internal organs. In women, these lesions are often the first overt clinical sign of syphilis. Secondary lesions consist of a symmetrical, evolutive, and painless rash, very variable in appearance and localization, and usually accompanied by fever, malaise, aches in the bones (often worse at night), and generalized enlargement of lymph nodes. After a few weeks – generally 2 to 6 – secondary lesions and symptoms spontaneously disappear. In 25 percent of untreated patients, however, there is a recurrence of secondary lesions during the first 2 years of infection.

Tertiary or Late Syphilis

The tertiary stage develops only in about one-third of untreated cases, and only after another latent period lasting from 1 to 20 years, or even longer. This stage is characterized by progressively destructive lesions of the skin and mucous membranes, bones, and internal organs. The most typical lesion is the *gumma,* a small rubbery tumor that is a benign manifestation of tertiary syphilis, which can develop in any part of the body.

Particularly serious forms of late syphilis involve the cardiovascular and central nervous systems. Cardiovascular syphilis may cause aneurism of the thoracic aorta, and dilatation of the aortic valve. Neurosyphilis includes a loss of positional sense and sensation (tabes dorsalis, locomotor ataxia) or a form of insanity (general paresis [GPI], dementia paralytica).

As a result of the introduction of antibiotic therapy, tertiary syphilis has almost disappeared. Thus the most reliable information available on it today has been provided by two major studies on the course of untreated syphilis, the Oslo Study (1891–1951) and the Tuskegee Study (1932–72). The former surveyed retrospectively a group of nearly 2,000 patients with primary and secondary syphilis diagnosed clinically before immunologic tests came into use. The latter studied prospectively 431 black men with seropositive latent syphilis of 3 or more years' duration, who were deliberately kept untreated. Because of the ethical issues raised by this racist experiment, the Tuskegee Study has been crucial in formulating the present guidelines concerning medical experimentation on humans (Jones 1981; Holmes and Lukehart 1987).

Congenital Syphilis

The risk of congenital syphilis to the fetus is high during the first 2 years after the mother has acquired the infection. An infected fetus may die during pregnancy, be stillborn, or be born prematurely. Secondary-type lesions are present at birth or appear within the first 6 months of life (Perine et al. 1984; Csonka 1987; Holmes and Lukehart 1987).

History and Geography

Medical historiography has in the past usually identified the disease known today as venereal syphilis with the morbus gallicus that was mentioned for the first time in European medical and lay writings of the late fifteenth century. Indeed, nineteenth- and twentieth-century medical historians, in looking at past medical and lay descriptions of morbus gallicus, have systematically practiced a retrospective diagnosis of syphilis.

According to them, the history of syphilis began with the eruption of morbus gallicus in Europe in the 1490s, and can be traced throughout the centuries until today, although neither its geographic origins nor the precise date of its appearance has been established. Since the European Enlightenment, both of these questions have been the object of a continuous – and often tart – controversy between the defenders of an American origin of syphilis and those who have claimed that syphilis *did* exist in the Old World long before Columbus arrived in the New World. The most varied documental proofs (medical and lay writings, iconography) and – increasingly since the late nineteenth century – material proofs (paleopathological remains) have been wielded in this debate. It is an unfinished debate, however, for in claiming that present-day venereal syphilis was already known and had been described under several names before or after the Europeans' arrival in America, historians have produced the kind of contradictory conclusions that serve only to keep it alive (Guerra 1978; Wood 1978).

A second way of approaching the history of syphilis has already been referred to in the section on the etiology and epidemiology of syphilis. This approach lies in studying the disease and the germ responsible for it in the broad biological and epidemiological context of the development of human treponematoses, and integrates results provided by both paleopathological and historicoepidemiological studies. A result of this approach has been some attractive and promising hypotheses on the history of syphilis, but at the moment, no definitive conclusions have
Figure VIII.134.2. Infectious diseases considered as a dynamic triangular interaction among host, parasite, and environment (according to E. H. Hudson, 1958, 8–9.) (Adapted from E. H. Hudson. 1958. *Non-venereal syphilis*. Edinburgh-London.)

been reached (Hackett 1963; Hudson 1965; Wood 1978).

Given these circumstances, a third approach seems appropriate, which actually deals with the history of the concept of syphilis, rather than with the history of the disease itself. This third way renounces retrospective diagnosis of syphilis and insists on the need to contemplate the disease entity called syphilis within the strict historicocultural context in which it occurs, and from which it receives its true significance. Put plainly, every disease entity is an intellectual construction that is peculiar to some form of medicine; and every form of medicine is nothing but a historical variable in any human community. Thus the disease entity known today as venereal syphilis can be conceived of, at this point, as a paradigmatic example as was demonstrated by a Polish microbiologist, Ludwik Fleck, in the mid-1930s in a monograph in which there has been renewed interest since the late 1970s (Fleck 1979).

Furthermore, in looking at what we call infectious diseases, we must distinguish between what may be termed disease entities and the diseases themselves. As disease entities, infectious illnesses assumed their present shape only in late nineteenth- and early twentieth-century Western medicine as a result of the development of germ theory. But as diseases in themselves they have existed for a long time.

Infectious diseases, moreover, cannot be regarded ontologically as natural beings in the same way as the microbiological agents that cause them can be regarded (Reznek 1987). Rather, as Hudson (1958) has demonstrated, in the case of human treponematoses, they should be considered the result of a dynamic interaction among host, parasite, and environment, as portrayed in Figure VIII.134.2. Moreover, any such interaction that has occurred in the past

can neither be reproduced under experimental conditions, nor be easily reconstructed historically.

To be precise, venereal syphilis took shape in Western scientific medicine only as a result of deep changes, both intellectual and social, during the second half of the nineteenth and the first decade of the twentieth century; foremost among these changes was the formulation of germ theory. Yet an exhaustive bibliographical survey on venereal diseases done by J. K. Proksch in 1889–1900 makes clear that the term syphilis, though invented by Fracastoro in the sixteenth century, did not become widely used until the late eighteenth or early nineteenth century. So, it may be anachronistic to refer to as syphilis either *the* disease entity that we call "venereal syphilis" before the late nineteenth or early twentieth century, or *a* disease entity named "syphilis" before the late eighteenth or early nineteenth century.

Let us now consider the origins, emergence, and development of the concept of syphilis. Our departure point will be the disease entity that began to be called *morbus gallicus* in late fifteenth-century Europe. Although for the above-mentioned reasons we cannot agree with those who have identified morbus gallicus with syphilis, it is obvious that the former may well be considered the earliest identifiable conceptual ancestor of the disease entity that we now call venereal syphilis (Fleck 1979).

1400–1600

Morbus gallicus is the name that soon became dominant in designating a disease generally considered as new in Europe of the 1490s. It was perceived as an incurable and loathsome disease consisting of severe aches in the bones, and of sores usually beginning in the genitals, but eventually covering most or all of the body. Contemporary medical and lay evidence concurred in including it among the numerous calamities (floods, earthquakes, epidemics, famines, wars) that Europeans – especially Italians – suffered at the end of the fifteenth century.

Italian sources show us that the "French Pox" spread in Italy during the period 1494–5, after the clash between the armies of France and Spain over the question of the kingdom of Naples. The notoriety the phrase *morbus gallicus* soon achieved all over Italy was closely associated with the tragic consequences of the impact of the French invasion on the fragile Italian political equilibrium. Similarly, the prompt acceptance in early sixteenth-century Italy of the theory of an American origin for morbus gallicus may be explained by the fact that Spaniards

were regarded as the newest *barbari stranieri* to devastate Italy. The great prestige of Renaissance Italy and its cultural hegemony throughout Europe were important factors, among others, in ensuring the rapid popularization of both the term morbus gallicus and the theory of its American origin.

Through the sixteenth century, the phrase "French Pox" achieved in Europe and overseas an overwhelming dominance over any other names for the disease, not only in the medical academic world, but also at popular levels. Only French physicians – those native to or settled in France – seem, understandably, to have rejected this name, and put forth others. For example, in 1552 Thierry de Héry of Paris suggested *maladie vénérienne* or *grosse vairolle;* in 1553 Auger Ferrier of Toulouse proposed *pudendagra* or *lues hispanica;* in 1560 Antoine Chaumette of Paris put forth the denomination *morbus venereus;* and in 1563 Leonardo Botallo, also of Paris, used the term *lues venerea,* as did Jean Fernel in posthumous publication in 1579.

1600–1750

During the seventeenth century this new term, *lues venerea* (venereal disease), was adopted all over Europe, sharing an *ex aequo* leadership with that of morbus gallicus. In eighteenth-century Europe the term "lues venerea" eventually superseded that of morbus gallicus, and the use of the latter declined dramatically.

Two points may be raised about the expression lues venerea. First, the adjective "venerea" stresses the direct relationship existing between the French Pox and the pleasures of Venus and, thus, the individual responsibility of those who contract the disease. Applied to the morbus gallicus, this adjective seems to have appeared for the first time in 1527 in a work by French physician Jacques de Bethencourt, entitled *Nova poenitentialis Quadragesima, nec non Purgatorium in Morbum Gallicum sive Venereum.* Both the title and contents of this book evoke the climate of religious exaltation and of moral rearmament present in Reformation Europe (Temkin 1977). The second point has to do with the name "lues," which underscores the perception of the disease, at that time, as a contagious and calamitous one from a physical, and even from a moral, viewpoint.

A good example of the dominance exerted by the expression "lues venerea" on eighteenth-century European university medicine is offered to us by an influential work of the French royal physician Jean Astruc, *De Morbis Veneris,* published in 1736, which was reissued many times and translated into a great

number of European languages before the end of the nineteenth century. The work argues that the lues venerea was caused by a unique and specific virus venereum. It treats the particular morbi venerei as species making up the genus *Lues venerea,* and it differentiates between *lues venerea incipiens* and *confirmata.* The first was composed of different morbi venerei (gonorrhea, hernia venerea, bubones venerei, caries pudendorum, and porri, among others); whereas the second, the lues venerea confirmata, also called morbus venereus universalis, comprised numerous complaints affecting the whole human body. Among these were morbi genitalium, vitia cutis, morbi oris et narium, dolores venerei, morbi ossium, tumores, glandulosi et lymphatici, oculorum morbi, morbi aurium, and lesiones functionum.

1750–1850

Whether venereal disease was caused by an animated contagion or by a chemical poison, until the mid-eighteenth century almost every intellectual stream in European academic medicine seems to have defended the unity of lues venerea on the basis of a unique and specific virus venereum. However, after 1750 the concept of lues venerea began to be challenged as a result of nosographic and nosological efforts made by Enlightenment pathologists, who (with the support of clinical observations, anatomopathological analyses, and inoculation experiments) began to question whether lues venerea was a single disease entity after all. The result of this challenge was the progressive disappearance of the expression lues venerea from the literature. And although it did not entirely disappear until the nineteenth century, it was increasingly replaced by the plural expression *morbi venerei* (venereal diseases), which began to be used at the beginning of the eighteenth century. At about the same time, specific denominations given to each one of the "morbi venerei" (chancre, gonorrhea, bubo, and syphilis, among others) started to appear with increasing frequency. From the early nineteenth century, the number of medical works specifically devoted to certain among these diseases – mainly to gonorrhea and syphilis – began to proliferate.

Let us look in more detail at how the concept of lues venerea was destroyed during the period 1750–1850, while keeping in mind that it was during this period that specialized hospitals emerged, including those for the treatment of venereal disease and that dermatovenerology was born as a medical specialty. Enlightenment controversies over lues venerea came to concentrate mostly on whether the blennorrhagic

discharge – usually called gonorrhea – happening in many venereal patients, constituted a disease entity different from lues venerea, or (as thought before), was just a peculiar clinical form or stage of lues venerea (Flegel 1974). The beginning of this process of disease differentiation, which, roughly speaking, took place in Europe and North America throughout the century 1750–1850, may be found in the influential work by Giovanni Battista Morgagni, *De Sedibus et Causis Morborum per Anatomen Indagatis,* published in Venice in 1761. He found at autopsy that venereal patients with blennorrhagic discharge and no evidence of chancre rarely had hidden in the genital passages the expected chancre, which was supposed to provoke the discharge in the first place.

During the following decades, numerous physicians argued the single or dual nature of lues venerea, resorting to anatomoclinical observations and to autoinoculative and heteroinoculative experiments with pus from venereal lesions. This controversy did not end until the 1830s in part, at least, because there was tremendous ambiguity in the use of terms referring to venereal complaints. Although terms like syphilis, *maladie(s) syphilitique(s),* and so forth spread rapidly in the European medical literature during the first two decades of the nineteenth century, the term syphilis became almost dominant after the 1820s. The word nonetheless continued to appear in some works as an alternative term or one complementary to that of "venereal diseases."

The controversy, however, over whether venereal disease was a single disease entity or more than one illness was brought to an end in the late 1830s. During this period the French venereologist Philippe Ricord had developed a vast clinical and experimental program at the Paris Hôpital du Midi, including both the systematic use of the uterine speculum and numerous (more than 2,500) autoinoculative experiments with pus from venereal patients. In 1838 he presented his results and conclusions in *Traité pratique sur les maladies vénériennes, ou recherches critiques et experimentales sur l'inoculation appliquée à l'étude de ces maladies.* These experiments, asserted Ricord, had permitted him to demonstrate the existence of the so-called *virus syphilitique,* so that chancre and blennorrhagia could be definitely separated. Moreover the expectations had also allowed him to distinguish the primary lesions of *vérole* from those that are not primary, and primary symptoms from secondary symptoms. As a result, Ricord proposed the division of syphilis symptoms into primary, successive, secondary, transitional, and tertiary.

1850–1950

During the second half of the nineteenth and the beginning of the twentieth century, Ricord's concept of syphilis was gradually reshaped, as other disease entities recognized today as sexually transmitted diseases (gonorrhea, chancroid, lymphogranuloma venereum, genital herpes, venereal warts, and others) were emerging. If most of these new disease entities were first shaped according to anatomoclinical criteria, each one of them (syphilis included) eventually got its definitive "identity card" when the relevant germ causing it was isolated.

Gonorrhea and chancroid are two illustrative examples in this respect. Ricord, who definitely separated chancre and blennorrhagia, asserted that the latter might be the result of local irritation, excessive sexual intercourse, or excessive sexual excitement. The present clinical picture of gonorrhea was completed only in 1879, when Albert Neisser discovered the germ responsible for it, which he called gonococcus. On the other hand, chancroid or soft sore (ulcus molle) emerged as a disease entity in 1852, when a pupil of Ricord, Léon Bassereau, demonstrated that the two kinds of luetic chancre – one hard, painless, and unique; the other soft, painful, and frequently multiple – resulted from exposure to a like lesion. In addition, the latter was autoinoculable. Almost 40 years later, in 1889, August Ducrey identified the bacillum responsible for it (Kampmeier 1984).

As for the concept of syphilis, it developed and changed profoundly during the second half of the nineteenth century as the disease became a major research area in Western scientific medicine. Perhaps the person who contributed most to the development of the concept of syphilis during this period was the French venereologist Jean-Alfred Fournier. It was Fournier who propounded the concept of latency in both acquired and congenital syphilis, definitely established the relationship between syphilis and so-called parasyphilitic affections (mainly tabes dorsalis and general paresis of the insane), and began a social campaign against the disease.

But the discovery of the germ responsible for syphilis did not occur until 1905, when Fritz Schaudinn and Erich Hoffmann isolated it in serum from a lesion of secondary syphilis. In 1906 the collective work of August von Wassermann, Albert Neisser, Carl Bruck, and others made possible the invention, in Germany, of the first serologic procedure for the diagnosis of syphilis. This was the complement-fixation test, which soon became well known as the *Wassermann Reaction* (WR). In the following years,

T. pallidum was also found in lesions of tertiary syphilis, verifying Fournier's theory. Karl Reuter, for example, in 1906 found the germ in the wall of a syphilitic aorta, whereas Hideyo Noguchi in 1913 proved its presence in brain tissue from paretics (Quétel 1986).

By way of conclusion it should be emphasized that, as has been the case with many other disease entities, a crisis of a disease entity concept based upon its specific biological cause (Laín-Entralgo 1982) has also ensnared venereal syphilis. In 1935, whereas most bacteriologists and pathologists still claimed specificity of a causal microorganism to be the definitive nosographic criterion for an infectious disease, Fleck lucidly insisted upon the essential incompleteness of the concept of syphilis (Fleck 1979).

Time has confirmed Fleck's insight. Put plainly, it should be obvious from the foregoing that Western medicine has had enormous difficulties in establishing scientific criteria that delimit precisely the so-called venereal syphilis from the remaining human treponematoses (Hackett 1963; Hudson 1965; Perine et al. 1984).

VIII.135
Syphilis, Nonvenereal

Nonvenereal syphilis has apparently occurred in many forms and places, and one interpretation of this phenomenon is that venereal syphilis can revert to nonvenereal transmission. Others see it as a discrete disease with its own etiologic epidemiology. The most common and enduring form of the disease is called *bejel;* it occurs in the arid regions of North Africa, the Middle East, and the eastern Mediterranean, and seems to have antedated venereal syphilis as a disease entity by a considerable period of time. It is one of the endemic treponematoses caused by spirochetes, bacteria belonging to the genus *Treponema.* Other diseases in this group are *yaws* and *pinta.* Like yaws, bejel is essentially a disease of children, although those who escape the illness as children are likely to acquire it as adults, often from their own children. Its specific cause seems to be *Treponema pallidum,* the same agent as that of syphilis, although it may be a treponema intermediary between *T. pallidum* and *Treponema pertenue,* the agent of yaws. Although treponemal disease has been transferred experimentally to animals, humans appear to be the only natural reservoir.

Etiology, Epidemiology, and Clinical Manifestations

Because the treponemas that cause yaws, nonvenereal syphilis, pinta (an American disease), and syphilis are morphologically and serologically indistinguishable, it is believed that at least the Old World diseases may represent an evolutionary continuum running from south to north. Yaws, thought to be the oldest, spreads by skin-to-skin contact and flourishes in the hot and moist regions of Africa south of the Sahara where individuals have historically worn little clothing. Syphilis, by contrast, seems to be the newest of the treponematoses. Venereal transmission allows it to spread among peoples of colder climates whose clothing would frustrate skin-to-skin transmission.

Bejel or nonvenereal syphilis seems to be intermediate between the two both bacteriologically and geographically. It has been conceived of as yaws modified by a desert environment, and as juvenile, nonvenereal syphilis. It is not transmitted congenitally. The disease spreads from child to child in dry, mostly rural areas where a lack of cleanliness facili-

tates transmission. The spirochetes of nonvenereal syphilis, like those of yaws and syphilis, perish in the presence of atmospheric oxygen, soaps, detergents, and antiseptics, and are very sensitive to drying. *T. pallidum* is able to penetrate mucous membranes, but intact skin presents it with a formidable barrier. The primary lesion is often in the region of the mouth, probably the result of sharing drinking vessels or eating utensils or by direct mouth-to-mouth contact. It can also spread from direct nonsexual contact, and flies, lice, and fleas may also have a role in transmission.

The stages of the disease – primary, secondary, and late or tertiary – are not so pronounced as are those of syphilis. In the case of bejel, the primary lesion is soon followed by the appearance of moist papules in skin folds and by drier lesions on the trunk and extremities. Late lesions, when they occur, can be ugly. Huge ulcers may form, and ulceration of the palatal and nasal bones can cause them to erode. Other possible physical symptoms are changes in pigment distribution and in the deformity of other bones, especially long bones such as the tibia.

Immunology and Pathology

Although pinta has been given experimentally to syphilitics, a high degree of cross-immunity between *T. pallidum* and *T. pertenue* seems to exist. Thus, one who has suffered nonvenereal syphilis is not only safe from another attack but is also at least partially protected against syphilis and yaws.

The pathogenic mechanisms in this and other treponemal infections are not yet fully understood. The pathogens do not kill cells, and they produce no known toxic substances. Thus it would seem that much of the pathology stems from the immune response of the host. Nonvenereal syphilis or bejel is similar to yaws in some respects, among them, juvenile acquisition, an absence of chancres, and congenital transmission. Moreover, both diseases rarely involve the cardiovascular and the central nervous systems. Yet nonvenereal syphilis resembles syphilis in its affinity for the mucous membranes, and in many of its pathological aspects. And, like syphilis, it occurs outside of the tropics. Finally, the usual serologic tests for syphilis are positive in non-venereal syphilis.

History and Geography

The story of bejel is intimately bound up with the work of Ellis Herndon Hudson, a physician and medical historian. He first described the disease in 1928, after observing it among the Bedouin Arabs. In 1937

he summarized all available information on this form of nonvenereal syphilis and stated that the Arab word *bejel* had been introduced into the literature to distinguish this nonvenereal and endemic form of syphilis from the venereal variety.

In 1946 he emphasized the intermediary nature of bejel between yaws and syphilis and presented a unitarian concept of treponematosis, which stressed the evolutionary relationship among yaws, endemic syphilis, pinta, and venereal syphilis, and held that they were all varieties of a single disease caused by one parasite, *T. pallidum*.

Not all agree. Some, for example, argue that the various treponemal infections are due to changes in the treponemal strains themselves – to mutations. Others feel that the treponemal infections are essentially different diseases, caused by different parasites, whereas E. I. Grin has advanced the argument that venereal syphilis has reached villages (in the Sudan at least) from towns, only to become endemic (i.e., nonvenereal) in a rural environment.

There is, however, general agreement that nonvenereal syphilis is a very old disease. Hudson argues that it flourished in the villages that first appeared during the early Neolithic period and that it was the "venereal leprosy" of the Middle Ages, the "sibbens" of Scotland, the "button-scurvy" of Ireland, the *radesyge* of the Scandinavian countries, and the *skerljevo* of the Balkans. Apparently, it never took root in the Americas.

Because endemic syphilis fades in the face of the cleanliness associated with civilization, and because of the high efficacy of penicillin as a cure, the disease has withdrawn from most of Europe. But the bejel of the Middle East has its counterparts in the *njovera* of Rhodesia, the *dichuchwa* that plagues the Bushmen, and the *irkintia* of the Australian aborigines.

VIII.136
Tapeworm

Tapeworms are flatworms in the class Cestoda of the phylum Platyhelminthes. The body of an adult worm consists of a small head or *scolex,* which is usually armed with hooks or suckers to attach the animal to the wall of its host's small intestine, and a chain of segments or *proglottids.* New proglottids arise by budding from the scolex region. As they mature, they are pushed away from the head by the formation of new proglottids and develop both male and female sex organs. After fertilization, eggs or gravid proglottids are excreted with the host's feces. Tapeworm life cycles are complex. In general, the eggs must be ingested by an intermediate host, where they typically become saclike larvae in the tissues. When the host of the adult form (the definitive host) eats an infected intermediate host, adult worms develop in its intestine. Some species have two or more intermediate hosts and can use several species as the definitive host. Serious clinical disease often occurs when a parasite becomes established in an atypical host or when larval forms are able to develop in what is normally a definitive host.

History

Because tapeworms can exceed 30 feet in length and strings of segments are often passed in the feces, it is not surprising that they were described by ancient writers in China, India, and the Mediterranean world. Encysted larvae – bladderworms or cysticerci – have been known in beef and pork for millennia, but their relationship to adult worms was not suspected until the eighteenth century and not proved until 1855, when F. Küchenmeister fed larval pork tapeworms concealed in food to condemned criminals and recovered adult worms on autopsy. The three large species that infect humans were not clearly differentiated until 1782. The notion of spontaneous generation of adult tapeworms in the human intestine was widely accepted until

about 1820, and the theory was not inconsistent with the then known facts.

Diagnosis, Treatment, and Prevention

Intestinal infections are discovered when proglottids are passed or when eggs are found by microscopic examination of the feces. Diagnosis of larval infections is much more difficult and depends on serologic tests or surgery. Drugs are effective against adult tapeworms, but larval infections are much more difficult to treat and may require surgery. Prevention is basically a matter of personal hygiene, especially in rural areas, and thorough cooking of meat or fish.

Important Species

Five species are important parasites of humans: *Echinococcus granulosis* and *Taenia solium* are dangerous as larvae; *Taenia saginata, T. solium, Hymenolepsis nana,* and *Diphyllobothrium latum* live as adults in the intestine. Several other species can also infect humankind, but usually have other hosts. For example, *Dipylidium canium,* the dog tapeworm, can spread to children who accidentally eat fleas. Larval stages of several species of the genus *Spirometra,* normally parasitic in other vertebrates, can cause a dangerous condition called *sparaganosis* if a person swallows them in their copepod hosts. The Oriental custom of treating wounds or inflamed eyes with a poultice of fresh frog flesh can permit larvae to become established in the patient.

T. saginata, the beef tapeworm, inhabits human intestines around the world, although it is no longer common in developed countries. Cattle and other bovids are the intermediate hosts. If a cow or water buffalo eats grass contaminated with feces and eggs, the eggs hatch in the animal's intestine into a larva that migrates through the intestinal wall and forms a bladderlike sac, a *cysticercus,* in the muscles. Humans acquire the worm by eating raw or poorly cooked beef, as in steak tartare. Infections are sometimes asymptomatic, but many people experience mild to severe abdominal discomfort and a few have convulsions and develop problems of malnutrition. Prevention is by meat inspection, improved rural sanitation, and proper cooking. In the last instance, as is the case with many other parasites, higher prices for fuels in poor countries are often accompanied by increasing incidence.

T. solium, the pork tapeworm, is much less common than the beef tapeworm, but potentially is a considerably more dangerous parasite. It occurs around the world, except where Islamic or Jewish customs restrict pork consumption. The life cycle

resembles *T. saginata*, except that wild and domestic swine are the intermediate hosts. Human infection usually results from eating poorly cooked pork; sausages can be especially dangerous. People can also serve as intermediate hosts if they ingest eggs in food or water or from soiled hands. The resulting larval infection, *cysticercosis,* can be very serious and even fatal, especially if cysticeroids develop in the brain. Adults cause symptoms like those of the beef tapeworm. Inspection and thorough cooking or freezing of pork are important for prevention, and adult infections should be treated to avoid the danger of cysticerosis.

H. nana, the dwarf tapeworm, is only 1 to 1½ inches long. It occurs around the world, including the southern United States, and is a common parasite of domestic mice was well as humans. Infection results from eating larvae in fleas or in the grain beetle *Tenebrio*. Autoinfection is also common. In this direct life cycle, eggs hatch in a person's intestine, and the larvae attach to the intestinal wall to mature. Heavy infection can cause severe diarrhea, abdominal pain, and convulsions, especially in young children.

D. latum, the broad fish tapeworm, was described in 1602 and recognized as a distinct species in 1758, but its complex life cycle was not fully worked out until 1917. *D. latum* is an old parasite of humankind; eggs have been discovered in pre-Christian archaeological sites in northern Germany. This large tapeworm is found in the Baltic region, the Alps, the lower Danube, in much of European Russia, in scattered places in Central Asia, the Far East, Africa, and Alaska, and in the Great Lakes area of North America. The worm was probably introduced into the United States and Canada by Scandinavian immigrants. *D. latum* has a complex life cycle, with the first larval stage in small freshwater crustaceans and the second stage, the *pleurocercoid,* in the muscles of fish of the trout, pike, and perch families. People become infected by eating raw or undercooked or undersalted fish. Cooks preparing gefilte fish or pickled or salt fish dishes become infected as they sample the product to see if it is properly seasoned. Adult worms produce as many as a million eggs a day. If the host defecates in or near water, motile larvae emerge that seek a crustacean to complete the cycle. A related species with a life cycle involving marine fish and sea lions has afflicted inhabitants of coastal Peru and Chile since pre-Columbian times.

D. latum may exceed 35 feet in length and, like the beef and pork tapeworms, can thrive for many years in its host's gut. Symptoms are similar to those of other tapeworms, but in rare cases this worm can produce a form of anemia by robbing the host of vitamin B_{12}. There seems to be a genetic component to this complication, with Finnish populations most vulnerable. Treatment is effective, and prevention consists of better sanitation and cooking fish to kill the pleurocercoid larvae.

VIII.137
Tay–Sachs Disease

Tay–Sachs disease (TSD) is the best known of the sphingolipidoses, a group of genetic disorders that includes Niemann–Pick disease, Gaucher's disease, and others. Specifically, TSD is G_{M2} (beta) gangliosidosis, an autosomal recessive disease with complete penetrance. Affected individuals (recessive homozygotes) produce virtually no functional hexosaminidase A (hex A), an enzyme necessary for normal neurological development and function. TSD is very rare in most populations, but is, overall, about 100 times more prevalent among Ashkenazi Jews. This indicates that the TSD gene frequency is about 10 times higher in the Ashkenazi Jewish population. Persons with the disease usually show clinical symptoms of neurological degeneration by 6 months of age. Their condition steadily deteriorates, and they seldom live beyond the age of 4 years. There is no

cure, but heterozygous "carriers" of the defective gene can be identified by clinical test, and amniocentesis can detect an affected fetus.

History

The British ophthalmologist Warren Tay (1881) first reported some of the early clinical signs of TSD. In the United States, Bernard Sachs (1887) further documented the clinical course and pathology of the disease he later called "amaurotic family idiocy" (Sachs 1896). It was Sachs who first noted the familial nature of the disease, and its seemingly exclusive occurrence in Jewish families. However, reports were soon made of non-Jewish cases. D. Slome (1933) was the first to survey the literature on the population characteristics of TSD and confirmed the disease's autosomal recessive mode of transmission as well as the TSD gene's higher frequency among Jews. E. Klenk (1942) discovered that the nerve cells of individuals who died from TSD contained an excess of a lipid he called *ganglioside*. L. Svennerholm (1962) later described the specific G_{M2} ganglioside. The hexosaminidase enzyme was discovered by D. Robinson and J. L. Stirling (1968) to have two components, A and B, and S. Okada and J. S. O'Brien (1969) found that hex A deficiency was associated with high levels of G_{M2} ganglioside in the neurological tissues of TSD patients. L. Schneck and colleagues (1970), R. Navon and B. Padeh (1971), and O'Brien and colleagues (1971) demonstrated that prenatal diagnosis of hex A deficiency was possible. More recently, the hex A gene has been mapped to chromosome 15 (see Kidd, Klinger, and Ruddle 1989), and different variants (alleles) of the hex A gene, each one of which leads to TSD, have been discovered.

Clinical Manifestations and Mortality

E. H. Kolodny (1979) gives a concise outline of the symptoms and course of TSD. Between birth and age 6 months, the affected child may begin displaying apathy, hypotonia, and an exaggerated startle reaction to noise. Between 6 and 12 months of age, the characteristic cherry-red spot in the eye becomes evident, and the child also displays psychomotor retardation, spasticity, and rigidity. From 12 to 18 months of age, the child may have excessive drooling, bouts of unmotivated laughter, and convulsions. Between 18 and 24 months, megacephaly, cortical blindness, and quadriplegia commonly occur. After age 2 years, the child is in a vegetative state, and most affected children die sometime during the next 2 years. Until then their condition steadily worsens, with flexor contractures, episodes of autonomic dysfunction, neurogenic bladder, and skin yellowing being common signs.

Pathology

B. W. Volk, Schneck, and M. Adachi (1970) and Adachi and Volk (1975) detail the pathology of TSD. The key pathological features of TSD are most apparent in the brain and related structures, and become more obvious as the disease progresses. The most striking gross change in the brain is its marked increase in weight, especially in individuals who live beyond 2 years of age. Another gross change, most apparent in later stages of the disease, is cerebellar atrophy. At the cellular level, the most noticeable changes involve the neurons, especially those in the cortex. After about 1 year of age, the cerebral neurons have lost their characteristic angular shape and are swollen with material. Later in the disease process there is loss of these neurons. These characteristic neuronal changes are also seen in the spinal cord. The cherry-red spot in the eye observed by Tay (1881) is caused by the loss of ganglion cells and thinning of the nerve cell layer in the macula, which exposes more of the underlying choroidal coat to ophthalmologic examination (Adachi and Volk 1975).

Biochemistry

Gangliosides are a family of acidic complex lipids called *glycosphingolipids*. Gangliosides are present to some degree in most of the body's tissues, but are found primarily in the brain (Svennerholm 1980). More than 40 different molecular forms have been discovered, four of which comprise 65 percent to 85 percent of the total ganglioside content of mammalian brains (Rapport 1981). Though the role of gangliosides in neural physicology is not completely understood, the basic biochemical cause of TSD remains straightforward. In persons with TSD, unusually large amounts of G_{M2} ganglioside accumulate in the brain and associated tissues, thus disrupting their normal development and function. This accumulation is due to the lack of a functional specific enzyme, hex A, that breaks down the G_{M2} ganglioside. Hex A activity can be assessed by a serum enzyme assay (O'Brien et al. 1970). This has led to the discovery by many investigators that heterozygous carriers of the TSD gene have roughly only half the hex A activity of individuals homozygous for the normal allele. This is apparently enough, however, for normal catabolism of the G_{M2} ganglioside. In fact, G. Bach and colleagues (1976) reported a

healthy adult TSD heterozygote woman with only 22 percent hex A activity.

Molecular Genetics

P. A. Lalley, M. C. Rattazzi, and T. B. Shows (1974) and F. Gilbert and colleagues (1975) used somatic cell hybrids to determine that the hex A gene is linked to genes on chromosome 15. Using the same technology, but with cells from a person with a translocation of the distal half of the long arm (q) of chromosome 15 to chromosome 17, C. J. Chern and colleagues (1977) were able to assign the hex A gene to the q22–qter region of chromosome 15. R. Myerowitz and colleagues (1985) isolated a cDNA clone (a copy of a particular length of DNA) that contains the entire hex A gene. This cDNA clone can be used as a "probe" to look for variants of the normal Hex A gene. Myerowitz and N. D. Hogikyan (1986) used the probe to find that different mutations of the Hex A gene result in TSD in Ashkenazi Jews and non-Jewish French Canadians. H. Nakai, M. G. Byers, and Shows (1987) also used this probe to narrow down the location of the hex A gene to 15q23–q24. B. L. Triggs-Raine and colleagues (1989) used molecular genetic techniques to screen for TSD gene variants in the Ashkenazi Jewish population, and in the Ashkenazi Jews tested they found two different mutations of the hex A gene that result in the usual infantile onset TSD. They also found a different mutation of the hex A gene that gives rise to a rare adult-onset TSD. The use of molecular genetic methods is leading to a more complete understanding of the genetic basis of TSD (see Tanaka et al. 1990).

Genetic Epidemiology

Certainly contributing to the amount of attention paid to TSD over the last century is the enigma it (and other deleterious genetic disorders such as sickle-cell anemia) presents: How can a lethal gene get to a high frequency in a population? How can that high frequency be maintained? Why is that gene found at a relatively high level in a particular population? In addressing this problem, one first examines in turn the basic evolutionary forces that change gene frequencies: mutation, gene flow, genetic drift, and natural selection.

Forces of Evolution Affecting Gene Frequencies

Mutations. Mutations are the original source of all genetic variability, occurring at generally very low, but constant, rates. Thus (at least once, but probably more than once) mutation gave rise to each TSD gene variant found among the Ashkenazim and non-Ashkenazim. Mutation alone, however, cannot explain the unusually high frequency of the TSD genes in the Ashkenazim. The reason is simply that there would need to be an unprecedentedly high mutation rate of this gene in Ashkenazi Jews to account for its presently observed frequency in that population. There is no evidence of this being the case.

Gene Flow. Gene flow, the movement of genes from one population to another as individuals move, plays a greater or lesser role in the various explanations of the high TSD gene frequency in the Ashkenazim. Gene flow could have its biggest role if the intriguing scenario proposed by A. Koestler (1976) is correct. He suggests that the Ashkenazim are in large part descended from members of the Khazar Empire. The Khazar Empire existed from the seventh to the tenth century A.D. in an area north of the Caucasus Mountains, and during that time some Khazars converted to Judaism. It is speculated that after the fall of the Khazar Empire, those converts moved northwestward into areas of central Europe where Jews from western Europe were also emigrating. Thus, if those Khazars carried the TSD genes, they delivered them as part and parcel of their contribution to the Ashkenazi gene pool. As was the case with mutation, though, it is unlikely that gene flow in and of itself can account for the high frequency of the TSD genes among Ashkenazi Jews. The reason is that such an explanation would suggest that there was a group (perhaps the Khazars, perhaps some other group) with a high frequency of the TSD gene that provided the Ashkenazi Jewish population with a large number of carriers. There is no evidence of such an occurrence (see Neel 1979), which leaves natural selection and genetic drift as more likely reasons for the high frequency of the TSD genes among Ashkenazi Jews.

Natural Selection. N. C. Myrianthopoulos (1962) and A. G. Knudson and W. D. Kaplan (1962) first suggested that heterozygote carriers of the TSD gene may have a selective advantage over the normal homozygote. Myrianthopoulos and S. M. Aronson (1966, 1967) calculated that a selective advantage of about 1.25 percent on the part of the heterozygous carrier of the TSD allele would be sufficient to maintain the allele at its present frequency of approximately 1.3 percent among the Ashkenazim, despite the loss of TSD genes through deaths of recessive homozygotes afflicted with TSD.

They then showed that over the course of 50 generations (roughly from the time of the Diaspora to the present), a heterozygote-selective advantage of about 4.5 percent would increase the TSD allele frequency from 0.13 percent to 1.3 percent, again despite losses of TSD alleles through the deaths of recessive homozygotes. In order to provide support for their hypothesis, they compared sibship sizes of the parents of TSD offspring to the sibship sizes of a control group. They found the former to be slightly larger than the latter. Although the differences were not statistically significant, they indicated a heterozygote advantage sufficient to result in the observed present-day TSD gene frequency in the Ashkenazi population (assuming that the heterozygote advantage had remained more or less constant over time).

Two conditions are essential for a natural selection explanation to hold: (1) a selective agent of sufficient magnitude to affect negatively the reproductive success of individuals, and (2) a physiological basis for the advantage one genotype has over the others. Following up on their earlier work, Myrianthopoulos and Arsonson (1972) suggested that heterozygous carriers of the TSD allele were less susceptible to tuberculosis, a disease especially common in many urban centers of Europe during the nineteenth century. Although they found a negative association between indirect estimates of TSD and tuberculosis prevalence, the association was too small to be statistically significant. Furthermore, no physiological basis was offered to explain why heterozygote carriers of the TSD allele might have a selective advantage with regard to tuberculosis. More recently, J. Zlotogora, M. Zeigler, and Bach (1988) have posited that selection is the reason for the high prevalence of not only TSD in the Ashkenazi population, but also sphingolipid storage disorders in general among all Jews. However, they conclude that the nature of the hypothesized selective forces has yet to be fully elucidated.

Founder Effect and Genetic Drift. G. A. Chase and V. A. McKusick (1972) suggested that founder effect and genetic drift, rather than heterozygote advantage and natural selection, explain better the high TSD gene frequencies in the Ashkenazi Jewish population. D. C. Rao and N. E. Morton (1973) calculated that it was possible that drift could account for the high frequency of the TSD genes in the Ashkenazim, and D. Wagener and colleagues (1978) came to a similar conclusion. T. E. Kelly and colleagues (1975) studied a semi-isolated non-Jewish population with a high frequency of TSD, concluding that founder effect is the most likely cause and suggesting that this case illustrated, in microcosm, how the high frequency of the TSD genes might have occurred. A. L. Fraikor (1977) also favors a genetic drift explanation in a detailed study in which genetic drift (broadened to include founder effect as well as some other population processes) is argued to be the most parsimonious explanation for the high TSD gene frequency among the Ashkenazim.

Genetic drift refers specifically to random changes in gene frequencies from one generation to the next (i.e., "sampling errors"). Sampling error is most pronounced in small populations in which, simply because of the chance combination of a relatively small number of gametes out of millions of genetically different contenders, the offspring generation's gene pool may not contain the same genes in the same frequencies as the parental generation's gene pool. Thus, gene frequencies "drift" up or down through time. Unfortunately, there is no way to tell whether or not genetic drift has occurred in a population. Nonetheless, the probability of genetic drift of a certain magnitude occurring under certain circumstances can be estimated. Population size and changes in population size through time are the most important parameters in these calculations (see Wilson and Bossert 1971). A process related to genetic drift, *founder effect,* refers to the genetic impact that one or a few individuals may, by chance, have on the genetic structure of a new population after either migration or population decline. It is because of the chance factor that founder effect is usually considered in the context of genetic drift.

Fraikor (1977) chronicles the population history of Ashkenazi Jewry and finds that the conditions most conducive for genetic drift (especially small and semi-isolated local populations and large fluctuations in overall population size) were present throughout much of Europe for hundreds of years. However, A. Chakravarti and R. Chakraborty (1978) calculate that even in some situations highly conducive to genetic drift, the probability of observing the present discrepancies in TSD gene frequencies between the Ashkenazim and non-Ashkenazim is low. They conclude that heterozygote advantage and genetic drift should be considered together as the most probable explanation for the high TSD frequency in the Ashkenazi Jewish population. This conclusion serves as a worthwhile reminder that the forces of evolution are not necessarily mutually exclusive explanations of genetic variation, a point made explicit

by S. Wright (1977) in his "shifting balance" theory of evolution.

Up to now the difference between Ashkenazi Jews and non-Ashkenazi Jews (and non-Jews) in TSD prevalence and gene frequencies has been emphasized. Indeed, in the extensive literature on TSD, this difference is often the only one considered. There is, however, evidence of considerable disparity among Ashkenazi Jewish groups in the prevalence of TSD. These differences are also important in assessing the reasons for the overall high frequency of TSD genes among the Ashkenazim. Aronson (1964) found that the ancestors of the majority of Jewish TSD cases in the United States came from the northeastern provinces of Poland and the Baltic States. Myrianthopoulos and Aronson (1967) confirmed this finding, stating that with regard to TSD prevalence in central Europe "some variation, as high as fivefold, existed between Ashkenazi communities of these areas and that this variation is not random but shows a definite geographic trend."

As it happens, these findings can be incorporated into both the natural selection hypothesis and the genetic drift hypothesis. The search for natural selection is made somewhat easier because a selective agent in the environment that might give the heterozygote a reproductive advantage no longer needs to exist across Europe, but needs only to be shown to exist in a delimited geographic area. TSD genes spread out from there through gene flow, and it would have been some time before they would have been removed in appreciable numbers through the deaths of the recessive homozygotes; by then the carrier frequency may have become rather high. The case for genetic drift is made somewhat stronger because the Ashkenazim no longer need to be considered a large interbreeding population, but instead can be viewed as a subdivided population made up of a number of smaller semi-isolates in each of which genetic drift is more likely to take place. The TSD genes spread from areas of high frequency to neighboring areas of low frequency through gene flow, thus explaining the geographic distribution observed by Myrianthopoulos and Aronson (1967) of the ancestors of TSD-affected individuals.

A Combination of Factors. In the absence of much substantive data, and the fact that evolutionary forces most often work in concert, the conclusion reached by Chakravarti and Chakraborty (1978), that a combination of heterozygote advantage and genetic drift is the most probable reason for the high TSD gene frequencies in the Ashkenazim, is appeal-

ing. In a similar vein, although not incorporating heterozygote advantage, Fraikor (1977) does not rely solely on genetic drift, but favors a combination of factors. She writes of Ashkenazi Jewish communities over the last few hundred years:

The combination of polygamy, inbreeding, small effective population size, and large numbers of progeny could have elevated the frequency of the TSD allele in the descendants of these populations. The subsequent period of seminomadism resulted in numerous individual carriers being scattered in many parts of Eastern Europe. Some carriers probably also remained in Germany or Western Europe. During the Golden Age of the sixteenth century, the rapid population expansion and freedom of migration within the territory of Poland greatly enhanced the chances for carriers to marry noncarriers. Such marriages would further increase the number of carriers in the total population, and selection against the gene would be reduced because affected homozygotes were not being produced in significant numbers. (Fraikor 1977)

Alternative Theories

Before leaving this issue, we must consider other explanations for the high frequency of TSD in the Ashkenazi Jewish population. One of these, inbreeding, was mentioned previously. *Inbreeding* does not change gene frequencies, but because it increases homozygosity generally (dependent on the level of inbreeding), it increases the probability of deleterious alleles coming together in individuals. Inbreeding is, in fact, the likely cause of the high prevalence of other sphingolipid disorders in other Jewish populations (see Zlotogora et al. 1980; Towne 1987; Zlotogora, Zeigler, and Bach 1988), and as Fraikor (1977) hypothesizes, may have played a role in some of the smaller and more isolated Ashkenazi Jewish communities.

Finally, Wagener and Cavalli-Sforza (1975) suggest that either "hitchhiking" or *epistasis* may have increased TSD gene frequencies in the Ashkenazim. When two genes are in close proximity to each other on a chromosome, they are likely to be inherited together over the generations. Thus, a deleterious allele may "hitch" an evolutionary ride with a selectively favorable allele. With the human genome map becoming more and more detailed, some hitchhiking hypotheses can increasingly be tested. What remains to be seen in this case is whether a highly favorable allele can be found in the Ashkenazim that happens to be on chromosome 15 in the area of q23–q24. Epistasis refers to the interactions between unlinked genes. J. V. Neel (1979) notes the following:

[An] epistasis hypothesis is theoretically possible but difficult to visualize as a general explanation for recessive deleterious genes in high frequencies in defined groups, given what we know about the usual heterozygous effects of these genes. Specifically, in the case of TSD, it is difficult to visualize a genetic interaction that converts half-levels of hex-A into a selective advantage.

The Disease in the Future

There has been some debate on whether or not the incidence of TSD is increasing. R. F. Shaw and A. P. Smith (1969) argue that it is, basing their conclusion on a calculation that assumes a heterozygote advantage of approximately 5.3 percent, a value slightly higher than that calculated by Myrianthopoulos and Aronson (1966). On the other hand, Myrianthopoulos, A. F. Taylor, and Aronson (1970) doubt that the TSD gene is increasing because the conditions (high prevalences of tuberculosis) that may have offered the heterozygote an advantage in the past are no longer present. Chase and McKusick (1972) suggest that the present high incidence of TSD is "a transient phenomenon due to the chance encounter of recessive genes whose frequency has reached a high level partly as a consequence of diminished inbreeding." It must also be kept in mind, though, that present-day high levels of TSD may be an artifact of better diagnosis and case reporting.

Aside from the continuing study and debate about the different aspects of TSD touched on here, there are some more immediate concerns. At the present time, there is no cure for TSD. However, because heterozygote carriers of a TSD gene can be identified by a clinical test, as can an affected fetus through amniocentesis, individuals have available to them some important options. M. M. Kaback and R. S. Zeiger (1972) conducted the first major effort to identify TSD heterozygote carriers. Kolodny (1979) gives three reasons for the success of this screening program:

1. The testing program was targeted toward a defined subgroup of the population, namely, Ashkenazi Jews in their childbearing years.
2. A relatively simple, accurate, and inexpensive method was available for determining heterozygote status in an individual.
3. An in utero test for Tay–Sachs disease existed.

Kolodny (1979) went on to note that as a result of this and other screening programs more than 100 TSD births had been averted. Kaback and colleagues (see his 1979, 1981) present detailed information and updates on various aspects of TSD

screening programs. D. A. Greenberg and Kaback (1982) report that at the time of their writing, over 200,000 adults in the United States had been screened for TSD carrier status. Estimates of TSD carrier frequencies vary somewhat from one study to another. O'Brien (1983) predicts a U.S. Ashkenazi Jewish population carrier frequency of 2.6 percent, whereas Kolodny (1979) estimates the frequency to be 3.7 percent.

VIII.138
Tetanus

Tetanus is an acute disease caused by the production of a neurotoxin, *tetanospasmin*, by a bacterium, *Clostridium tetani*, when the spores of the organism enter a wound, and develop into the toxin-producing vegetative form. The case-fatality rate averages 50 percent in adults and is higher in neonates (especially those in developing nations) and in patients over 60 years of age.

Etiology and Epidemiology

C. tetani is an obligate anerobe, a spore-forming, gram-positive motile rod. The terminal spore caused the organism to be called the "drumstick" rod. The protein toxin, tetanospasmin, blocks acetylcholine release at the motor end-plates. The toxin travels up the nerve trunks, as well as fixing directly on nerve cells. The spinal cord is the primary target organ, with chromatolysis of the motor neurons and inhibi-

tion of antagonists accounting for the spasm and rigidity that characterize the disease. Toxin fixation to central nervous system neurons may lead to seizures; involvement of the sympathetic nervous system may evoke vascular irregularities.

Humans may be considered accidental interveners in the life cycle of the organism, which is a soil saprophyte and a harmless inhabitant of the intestines of many herbivores. The organism requires a wound to invade mammals. Traumatic, surgical, dental, umbilical, burn, and cosmetic wounds are the most common causes of infection in humans. "Skin popping" of addictive drugs, insect bites, and nonmedical abortions are less common causes of infection. As an obligate anaerobe, the organism can reproduce and produce toxin only when local oxidation–reduction processes reduce tissue oxygen to near zero; deep, infected wounds are thus ideal culture media.

There may be 300,000 to 500,000 cases of tetanus a year worldwide, with perhaps 120,000 of those being neonates whose umbilical wounds become infected. The United States reported 101 cases in 1987 and 1988.

Clinical Manifestations, Diagnosis, and Pathology

There is no special characteristic or diagnostic pathology. Lysis of myofibrils and muscle bleeding are secondary to the muscle spasm. The usual incubation period ranges from 2 to 14 days after wounding. Cases of "dormant" tetanus have been reported after several months, probably because spores have remained in a closed wound as a silent abscess. The diagnosis is based entirely on the history and the clinical findings; there are no specific laboratory findings. The differential diagnosis includes strychnine poisoning and dystonic reactions to phenothiazines and metoclopramide.

The clinical manifestations are usually classified into three forms:

1. *Localized tetanus* presents with spasm near the site of the injury, usually in an extremity. The fatality rate is 1 percent or less.

2. *Generalized tetanus,* the more common form, is marked by the classic trismus (lock jaw), fixed grin (risus sardonicus), and backward arching of the trunk (opisthotonos). Tonic seizures of the muscle groups occur in spasms, lead to rigidity, and are very painful. They may be precipitated by any stimulus. Pneumonia may follow respiratory muscle involvement or laryngeal spasm with as-

piration. Cardiovascular disturbances are common, especially vasoconstriction and a labile blood pressure. Severe spasms may cause vertebral fractures. The course of this form, in survivors, is from 1 to 2 weeks.

3. *Cephalic tetanus,* an uncommon form of the disease, follows facial wounds, involves the facial nerves, and may be followed by generalized tetanus.

4. *Neonatal tetanus* following infection of the umbilical cord (discussed in the next chapter) usually begins by the third to tenth day after birth, and then progresses to generalized tetanus.

Death from tetanus is usually due to respiratory failure with hypoxia or pneumonia, and occasionally to circulatory collapse, especially in patients over 60 years old.

Treatment

Treatment may be summarized as measures to decrease the presence of the organism: debridement of the wound and antibiotics; neutralization of the toxin by antitoxin; and control of the effects of the toxin by drugs with specific neuropharmacological effects. Curarization and artificial respiration for 2 weeks have been used in severe cases. Careful continuous nursing care is essential.

History

A man who was struck from behind by a sharp dart a little below the neck had a wound which did not look serious because it did not go deep. But sometime later when the point had been extracted the patient was seized with backward-bending convulsions like those of opisthotonus. His jaws were locked, and any liquid that he attempted to swallow was returned through his nostrils. He died on the second day.

So Hippocrates recorded an obvious case of tetanus. At least one other case is recorded in the same volume. In *Diseases III,* the general case is given: "[W]hen tètanus occurs, the jaws become as hard as wood, patients cannot open their mouths . . . their backs become rigid . . . he suffers great pain . . . generally dies on the third, fifth, seventh or fourteenth day – if he survives that many, he recovers." Further it is noted that "the patient is drawn backwards . . . his pains are violent . . . his elbows become flexed . . . he holds his fingers in a fist . . . vomits through his nostrils. If one survives for fourteen days, he recovers." The treatment regimens varied: "pepper, black, hellbore, fat bird soup, vapour baths, cold water baths," and "phlobotomy relieves lumbar tetanus."

But the terseness of the aphorism "A convulsion supervening upon a wound is deadly" may mark the more general outcome of a case of generalized tetanus. Certainly Aretaeus (Adams 1956), writing some 700 years later, found tetanus to be "An inhuman calamity! An incredible sight! A spectacle painful even to the beholder! An incurable malady!" He believed the prayers of spectators for the death of the patient to be useful, "being a deliverance from the pains." He also pitied the attending physician's inability to afford relief, "for if he should wish to straighten the limbs, he can only do so by cutting and breaking those of a living man." It is a "great misfortune of the physician." Aretaeus, after an excellent clinical description of the disease, urged a wide variety of therapeutic maneuvers, including special diets, forcing liquids, a quiet house, phlebotomy, massage with oils, fomentations, cupping, specific treatment of any wound, and more.

The clinical descriptions have not been bettered. Therapy has changed, but it is possible that the number of survivors "after the fourteenth day" may not have markedly improved. William Osler (1892), in his seminal text, noted the clinical and epidemiological data given above, cited Hippocrates, and summarized the unchanged clinical findings. He found an 80 percent rate mortality within 4 days. Therapy had improved: The nasogastric tube was in use for feeding and hydration, morphine for sedation, and chloroform for muscle relaxation. He emphasized antiseptic care of the wound. It is fair to say that from Hippocrates to Osler – and to today – there have been no changes in diagnostic techniques, and there has been only a small reduction in mortality rates in established cases. Tetanus is a disease that must be prevented, and prevention had to begin with isolation of the organism and advances in immunology.

Isolation of the Tetanus Organism

The discovery of the tetanus organism was part of the microbiological revolution that proved the theory that a specific organism caused a specific disease. In 1884 Arthur Nicolaier produced tetanus-like symptoms and death by injecting soil samples into animals. He isolated a rod-shaped bacillus and suggested that it secreted a toxin resembling strychnine in its action. He did not isolate the organism in pure culture. Neither did D. Rosenbach in 1886, although he was able to produce classic tetanus in guinea pigs by injecting tissue from a fatal human case. He did describe the "drumstick" appearance and correctly deduced that these were terminal spores. It remained

for Shibasaburo Kitasato to isolate the organism in pure culture, in 1889, from a fatal case of a soldier in Berlin. He described the anaerobic culture requirements, said he had confirmed Nicholaier's observations, and also concluded that the clinical effects were due to a toxin. The study of tetanus toxin and antitoxin followed directly and in parallel with the research of Emil Behring and Kitasato on diphtheria toxin, a much more important disease.

Tetanus Toxin and Antitoxin

Tetanus and diphtheria investigations provided the framework upon which Behring built his understanding of the principles of serum therapy. In an 1892 (1892b) paper, he argued that the serum of a patient should contain material protective and curative for another individual with the disease. In a series of studies, he and his co-workers proved this point in animal studies, but did not recommend serum use in humans until the mechanism of action was better understood. They noted that even if treatment of the animal began very early, at least 1,000 times as much antitoxin was needed to cure as to protect before infection, and that, as the symptoms became general, the antitoxin was useless in any amount.

The availability of horse antitoxin soon led to clinical trials, with widely varying results. Analysis eventually showed that antitoxin had to be given very early in the disease; that dosage – empirical at first – was critical; and that it was essentially useless once the toxin was fixed to neurons and the patient was symptomatic. As Henry Parish (1965) and E. Haberman (1978) both suggest, better understanding of wound care and more aseptic surgery accompanied the rising rate of successful use of antitoxin and a decreased death rate, especially in selected populations like soldiers.

Given that soldiers often have fought in well-manured farmland and do not have clean skins, and that until very recently armies lived in close proximity to horses used for transport and cavalry, it is not surprising that tetanus was a common problem in wounded soldiers. In 1808, for example, the rate of tetanus before immunization was 12.5 per 1,000; by contrast, the rate was only 0.04 per 1,000 in World War II (Boyd 1958).

It was World War I that saw the general introduction of early, near-universal use of antitoxin, accompanied by meticulous debridement of wounds. The effect of these measures may be seen in the British army. There was an incidence of 8 per 1,000 wounded from August to October 1914. As improved wound

management and routine antitoxin use developed, the rate fell to 1.5 per 1,000 wounded. World War I patients, perhaps because the antitoxin produced a *forme fruste,* had a syndrome of "local tetanus" – not fatal, and usually confined to one extremity. U.S. forces, entering the war in 1917, had the advantage of the experience of their allies and thus had an incidence of only 0.16 per 1,000 wounded. Allergic reactions to horse serum occurred, more commonly after repeated doses of antitoxin.

Tetanus Toxoid

Although Arthur Silverstein (1989) credits Paul Ehrlich with the first discussion of toxoids, the practical use of formaldehyde to produce a toxoid (a *formalin-inactivated antitoxin*) was introduced for tetanus by Gaston Ramon in 1927 following the preliminary work by P. Descomby in 1924. As opposed to the passive immunity conferred by antitoxin, the toxoid produced an active immunity that would protect against tetanus. Also in 1927, Ramon along with Charles Zoeller tested the immunogenicity of the toxoid in humans, and later worked out the duration of immunity and the timing and effect of booster doses.

A fluid toxoid was in use because of its harmlessness and its efficacy (although it caused more local reactions than does the modern aluminum phosphate absorbed vaccine). This toxoid, a combined diphtheria–tetanus toxoids vaccine, was given to infants in parts of France in the late 1920s and, by regulation, to French soldiers in 1931.

Immunization with the much more epidemiologically important diphtheria toxoid began in the 1920s in parts of the United States and just before World War II in Britain. The absorbed tetanus toxoid was used by the armies of Britain, France, and Canada by 1939; the United States began its use in 1941. During World War II, the American army had 5 fatal tetanus cases (2 in nonimmunized patients) and 7 nonfatal cases (all in immunized patients) in over 500,000 wounded soldiers. The reaction rate to the immunization series of three doses was 21 per 100,000, none fatal.

After World War II, the routine use of a combined vaccine of diphtheria and tetanus toxoids (DT) was urged for childhood immunization. Soon the triple vaccine, with pertussis added (DPT), became legally required for school admission in the United States. Childhood immunization programs in Europe vary, but tend to be on similar schedules and under similar laws. Nonfatal anaphylactic reactions occur at a rate of 1 per 1.5 to 2 million doses. The benefit/risk

ratio for tetanus immunization is thus extraordinarily good. A worldwide infant and child immunization campaign, coupled with a booster upon injury, would essentially eliminate the disease as a clinical entity.

Tetanus, Neonatal

Neonatal tetanus is a form of tetanus, an acute toxic illness confined to the newborn. It is characterized as a neurological disease resulting in severe muscle spasms, which can persist for at least a week and commonly results in death. The agent is *Clostridium tetani,* which usually enters the bloodstream or motor nerves through an infected umbilicus. *C. tetani* produces two toxins, including tetanospasmin, the extremely potent neurotoxic component causing spasms. This toxin reaches the nervous system and eventually becomes fixed in the ganglion cells of the spinal cord or cranial nerves. Neonatal tetanus differs from numerous other bacterial diseases in that it is not transferred from person to person; instead, *C. tetani* is found in soil and is introduced into the body through an exposed area. The disease has been known by various names, including *tetani neonatoria, trismus nascentium, lockjaw,* and the "9-day illness" or "fits" because it normally occurs during the first 9 days of life. Its association with filth and rural conditions means that neonatal tetanus is still

common in Third World nations and is one of their greatest public health problems. Mortality rates are high, even with modern treatment, and preventive measures are essential to avoid the disease.

Distribution and Incidence

Neonatal tetanus today is a problem confined primarily to Africa, Asia, and the West Indies, although before the twentieth century, it was global in occurrence. The bacillus, found in soil, water, intestines, and the feces of animals and humans (where it can survive for years if not exposed to sunlight) is ubiquitous. Although it was once common in rural areas like much of Ireland and the southern United States, this disease is virtually unknown anywhere in North America and western Europe today. Its incidence depends on soil conditions, type of agriculture and animal husbandry, level of economic development, available health services, and quality and type of obstetrical procedures.

The most important reasons for the decline of neonatal tetanus in the past century have been improved standards of living, urbanization, and an understanding of sepsis. Efforts are being made by the World Health Organization to educate women and birth attendants on preventive measures and to bring obstetrical procedures and concepts of cleanliness to areas where the disease still exists. Statistics have shown that higher standards of obstetrical hygiene significantly decrease the chance of infection.

Neonatal tetanus occurs when *C. tetani* enters the body as a result of a dirty dressing or poor care of the umbilicus. Where the disease is common, the umbilicus is often cut with an unclean instrument such as a knife, razor, sickle, or piece of sharpened rock or bamboo. Often the umbilicus stump is covered with ashes, charcoal powder, cow dung poultices, ghee, powdered pepper, snail saliva, turmeric, or other contaminated substances, and is dressed with leaves or dirty rags, or is left exposed. Rural tribes might blame evil spirits for the disease, but efforts to keep spirits away from a new baby often increase unhygienic postnatal procedures. Observers have found the disease to be more common among male newborns than among females, although this reported difference may reflect greater parental concern for the health of sons than daughters in some cultures. There is a question of whether race affects the frequency of neonatal tetanus, but unclean habits and living conditions of certain populations are probably much more important reasons why some people seem to suffer from it more than others. It seems to occur more often in warm months, perhaps because during these times babies are more exposed to soil and possible infection. All infants are susceptible unless they receive passive immunity from mothers who have been previously immunized.

Next to prematurity, neonatal tetanus is the most frequent cause of infant death in poor communities where traditional birth attendants serve mothers. Current estimates are that it kills some 10 percent of those being born alive in these areas. It has taken an enormous toll in developing nations and, during the first half of the nineteenth century, accounted for many infant slave deaths in the southern United States.

Mortality rates of infants developing the disease vary from 40 to 80 percent in Third World nations, although accurate statistics are difficult to obtain, since many infants are delivered outside a hospital or clinic, and numerous deaths are never registered. Current estimates are that 750,000 newborns die annually from neonatal tetanus. The mortality rate is inversely proportional to the age of the infant. It is often as high as 90 percent if it is contracted by the newborn during the first week after birth, and 50 percent if contracted during the second.

One of the paradoxes concerning neonatal tetanus, and a major problem in eradicating the disease, is that immunization is more difficult in areas where the illness is most common. Such populations are often suspicious of modern obstetrical procedures or are located far from clinical care. Yet the actual cost of preventing the disease is minimal and uncomplicated.

Epidemiology and Etiology

Because neonatal tetanus is usually caused by an infection of the umbilicus (though circumcision leads to a few cases), it does not occur as an epidemic. It strikes individuals rather than communities and, therefore, is difficult to study and does not generate the kind of public interest that epidemics do. Consequently, the disease has not yet received the attention it deserves.

C. tetani is an obligate anaerobe (a microorganism that can grow only in the complete absence of molecular oxygen), a gram-positive, nonencapsulated, slender, motile rod. It is introduced into an injured area as spores. The disease develops if the spores are converted to vegetative organisms, producing the potent toxin, tetanospasmin. The toxin reaches the nervous system via the bloodstream or by traveling along the axon cylinders of motor nerves, eventually

becoming fixed in the spinal cord and cranial nerves. Reflex convulsive activity follows.

Clinical Manifestations

A baby with neonatal tetanus is beset with symptoms that are easy to recognize and usually appear 3 to 10 days after birth. Signs include difficulty with feeding and swallowing, generalized stiffness, spasms, and convulsions. The newborn can develop special problems relating to ventilation, hydration, and sedation. The first and most distinctive sign of neonatal tetanus is *trismus,* or a stiffening of the jaw, resembling a smile. The mouth will not open fully, resulting in a condition that has become known as *risus sardonicus.* Patients often have their legs and arms partially flexed, arms crossed over their abdomen, hands clenched, excessive flexion of the toes, stifled cry, and wrinkled face. Their body temperatures can reach 100° or higher. Sucking is impaired, thus making regular nursing impossible. That and general fussiness are the first symptoms most mothers notice. Respiratory complications commonly arise. Infants who die within 48 hours generally succumb to uncontrolled spasms or intense congestion of the liver, lungs, or brain. Newborns who die from the disease after 2 days generally die from bronchopneumonia. Other complications include aspiration pneumonia, acute gastroenteritis, and umbilical hernia.

Treatment

The best means of controlling the disease are those that prevent the organism from entering – namely ensuring sterile conditions for the birth. The umbilicus should be treated conservatively and cleaned with hydrogen peroxide; foreign objects should be removed, and thimerosal (Merthiolate) applied.

Most medical observers conclude that in order to lessen the incidence of neonatal tetanus in Third World nations, obstetrical procedures must be improved by teaching traditional birth attendants about sepsis. The transfer of maternal tetanus antibodies across the placenta has been found to be effective in conferring passive immunity to the neonate for several months, though it is better if the mother is immunized before, rather than during, pregnancy. Nevertheless, researchers have recently discovered that injections of absorbed tetanus toxoid given to pregnant women who have not been inoculated previously for tetanus (at least 2 injections spaced about 6 weeks apart) can successfully prevent infant infection.

Babies who do develop neonatal tetanus are often sedated with phenobarbital and chlorpromazine given intramuscularly, although diazepam is frequently used now because it works quickly. Antibiotics are also administered. The infant should be kept quiet, fed through a tube, and, if having difficulty breathing, given mouth-to-mouth resuscitation. The aim is first to control muscle spasms with sedatives and then to keep the baby breathing with a tracheotomy and a respirator if available. Medical attendants in hospitals or clinics commonly place the infant in intensive care, give an antitoxin, apply antibacterial therapy, and ensure airway clearance.

History and Geography

The term tetanus is from the Greek verb *tano,* meaning "to stretch." Hippocrates described three varieties of the infant disease. Aristotle noted infant convulsions that occurred before the seventh day. Galen first named the disease *trismus.* Moschion (Muscio), writing about three centuries later, claimed that it was caused by stagnant blood in the umbilical cord, as did André Levret and others some 1,500 years after Galen. Indeed, by the early nineteenth century, doctors were still attributing neonatal tetanus to this cause as well as a variety of others, including irritation within the intestinal canal, poverty, filth, poor diet, falls, impure atmosphere, rough handling, a vaginal disease, cold or sea air, costiveness, smoke from chimneys, and mismanagement by female midwives. In 1793 M. Bartram of South Carolina ascribed the disease to the umbilicus, and his theory generated much debate. Some physicians urged cleanliness and washing the umbilicus with a weak solution of silver nitrate and dressing the area with an ointment formed of lard and lead acetate.

But attention strayed again from the umbilicus. A study at the Dublin Lying-In Hospital in 1782 noted that of 17,650 infants born, 2,944 died within a fortnight from neonatal tetanus. The institution's impure atmosphere and poorly ventilated chambers were blamed for the high rate. In 1846 J. Marion Sims concluded that a depression of the occipital bone during birth caused the disease, and he urged his colleagues to observe bone formation closely in newborns.

In 1818 Abraham Colles, however, first noted the similarity between neonatal tetanus and tetanus and attributed its incidence to inflammation and ulceration of the umbilicus. He suggested that air be purified, that the umbilicus be dressed with spirits of turpentine, and that the baby be plunged into cold water. Efforts were made to bleed patients to remove the noxious influences and produce relaxation. During the nineteenth century, accounts demonstrate a

99 percent fatality for those who were affected. No disease of infancy was more fatal, and few parents saw any reason to call a doctor.

The bacterial theories of Louis Pasteur and Robert Koch have been important in eradicating the disease in the twentieth century. In 1884 Arthur Nicolaier found the bacillus in soil, and was able to produce the disease in animals. He found the same bacillus in human wounds. Shibasaburo Kitasato (1889) obtained the germ in pure culture. The tetanus toxoid was first used effectively during World War II. Immunization, along with the benefits of urbanization and industrialization, and a rise in the standard of living, have helped to eradicate the disease from developed nations.

Another preventive measure evolved when in 1923 C. T. Broeck and J. H. Bauer showed that tetanus antitoxin could cross the placenta. L. Nathan-Larrier, G. Ramon, and E. Grassett (1927) suggested that this could protect the newborn from tetanus by providing passive immunity. Later F. D. Schofield, G. R. Westbrook, and V. M. Tucker (1961), studying the disease in New Guinea, and K. W. Newell and others in Colombia (1964), proved that immunizing a pregnant woman with two or three injections of tetanus toxoid would decrease incidence of the disease. Unfortunately, it is difficult to provide such medical services to the people who need it most.

The World Health Organization continues to monitor the incidence of neonatal tetanus, to survey mortality rates of home and clinic deliveries, and to hold worldwide conferences to discuss means for improving the care of newborns. Its goal is to eradicate neonatal tetanus by the year 2000.

Tetany

Tetany is a symptom complex characterized by painful and prolonged contractions of the (generally smooth) muscles. These often appear as convulsions and are usually triggered by hypocalcemia. Adult varieties of the condition that result from calcium or magnesium deficiencies include maternal tetany, parathyroid tetany, osteomalacic tetany, and magnesium tetany. Alkalosis can also produce tetany. Examples include gastric tetany and hyperventilation tetany, following a lengthy period of forced inspiration and expiration. Another form of the disease – grass tetany caused by magnesium deficiency – is found in cattle. Despite these many forms, however, the disease occurs chiefly in infants (*neonatal* tetany) and young children (*infantile* tetany) in whom it is normally associated with rickets. It affects males far more than females and, in the absence of proper treatment, frequently proves deadly.

Distribution and Incidence

Because tetany has so often been confused with tetanus, very few data are available on the geographic distribution of the disease. It probably occurs worldwide in the temperate zones, with the highest frequency of neonatal tetany among bottle-fed, black, and prematurely born infants. An abundance of year-round sunshine and, hence, vitamin D may have the effect of reducing the incidence of infantile

tetany in the tropics. The incidence of neonatal tetany recorded at New York Hospital between 1940 and 1958 was between 1 per 500 and 1 per 700 births.

Etiology

Tetany is a disease whose etiology is incompletely understood. It was originally associated with calcium deficiency and more recently with magnesium deficiency, although it can also be produced by alkalosis. The disease can follow the removal or incapacity of the parathyroid glands and can be a complication of alcoholism and a consequence of prolonged diarrhea and vomiting. Protein–energy malnutrition (PEM) may also precipitate the disease.

As a rule, neonatal tetany strikes during the first 14 days of life, and the spasms, twitches, rigid body, and turned-down corners of the mouth (carp mouth) that it produces are nearly identical to the symptoms of neonatal tetanus. Full-term newborn infants generally have significantly higher levels of serum calcium than do their mothers. However, these levels fall rapidly during the first 2 or 3 days of life, and perhaps the high phosphorus content of cow's milk places the bottle-fed baby at special risk from tetany because it impairs the alimentary absorption of calcium. Another contributing factor is, doubtless, parathyroid immaturity, whereas still another can be the poor nutritional status of the mother. Maternal tetany can develop in malnourished and multiparous mothers whose serum calcium falls with each succeeding pregnancy. Thus there is a positive correlation among frequent pregnancies, maternal dietary deficiency, and hypocalcemic (or hypomagnesemic) convulsions in infants.

At greatest risk are infants born prematurely, born with low birth weights, and born of multiparous or diabetic mothers as well as those who are products of a difficult labor. Males are much more susceptible than females, suggesting that an androgen may be involved. The peak incidence of neonatal tetany for full-term infants occurs about the sixth day of life, and the disease seldom appears before the third day. In those who are born prematurely or whose mothers suffered a difficult birth, the condition frequently develops within the first 24 hours.

Infantile tetany, the most common form of the disease, occurs chiefly between 6 months and 2 years of age and is the most prevalent between 4 and 8 months of age. As with neonatal tetany, males again predominate among the victims, and bottle-fed babies are at substantially greater risk than their breast-fed counterparts. In neonatal tetany, vitamin D has the para-

doxical effect of raising the incidence of hypocalcemia, perhaps because of its suppressive effect on the parathyroid glands. But a deficiency of vitamin D to promote the absorption of calcium is strongly implicated in the etiology of infantile tetany, and indeed, evidence of rickets is nearly always present. The disease is much more frequent during the winter months when sunlight and, thus, vitamin D are in shortest supply. Because of pigment, black children in temperate zones have in the past proved the most susceptible to rickets during these months. Doubtless they are also more susceptible to infantile tetany than are their white counterparts.

Clinical Manifestations and Pathology

Tetany, characterized by neuromuscular irritability, is often signaled by a tingling sensation in the fingers, and it may become impossible to open and close the hands. Carpopedal spasms (of the wrist and ankle joints) are common, as are stiffness, pain, and spasms in other muscles. Vomiting is also common. Infants in particular may develop a rigid face, "carpmouth," and body – all symptoms that mimic neonatal tetanus. Mental symptoms include hallucinations, dullness, and distortion. Cardiac spasms may develop, and coma, along with respiratory failure (following asthma-like attacks), leads to death. Mortality from neonatal tetany is low today in developed countries because of treatment with calcium. However, in the 1950s and previously, it has been suggested that over half of the victims died. Necropsy findings of hyperplasia of parathyroid glands are confined to children fed cow's milk.

History

It is probable that tetany due to mineral (and perhaps vitamin D) deficiencies has always plagued humankind to some limited extent. In children the convulsions of tetany in the past were often attributed to "teething." But it was not until the beginning of the nineteenth century, with increased bottle feeding, that a syndrome resembling tetany was first described in England (Clarke 1815). François Rémy Lucien Corvisart gave the syndrome its name in 1852, and in 1854 Armand Trousseau described tetany in lactating women. In 1881 H. Weiss observed that tetany appeared on occasion in patients whose goiter had been removed, and in the 1880s the disease appeared in near-epidemic proportions in Vienna. Yet August Hirsch (1883–6) had nothing to say about tetany in his massive *Handbook*.

In 1913 E. Kehrer penned a description of neonatal tetany and suggested the administration of cal-

cium salts in its treatment, but according to Paul D. Saville and Norman Kretschmer (1960), the first satisfactory chemical study was the work of J. Howland and W. M. Marriott (1918). It was this work that distinguished rickets from tetany and reported a substantial reduction of serum calcium in infantile tetany patients. It also reported that the administration of calcium salts would relieve the symptoms.

Alfred Hess (1929) pointed out that in the United States the peak incidence of tetany was in the early spring, that cases seldom developed in the summer, and that the black young were "markedly susceptible." This suggests a role for vitamin D, given its shortage during the winter months in temperate climates and the difficulties blacks have had historically with vitamin D while wintering in those climates.

During the late 1950s and early 1960s, much attention was focused on the disease, and Arthur Bloomfield (1959) and Saville and Kretschmer (1960) surveyed the literature on what had been an important killer of the young. Subsequently, however, as more has been learned about mineral metabolism and as the disease has gone into decline, so has the name "tetany." Although it is still in the literature, the tendency since the 1960s has been to write of *hypocalcemic* and *hypomagnesemic*, rather than tetanic, convulsions.

Toxoplasmosis

The agent of this disease, the sporozoan protozoan *Toxoplasma gondii,* is a common parasite of many species of birds and mammals. The organism was first seen in 1908 in the tissues of a Tunisian rodent, the gundi, and fully described in 1909. Human disease was first described in 1923 and congenital neonatal disease was reported in 1939, but the complex life cycle of the parasite was not elucidated until 1970. Serologic tests show that humans around the world harbor *T. gondii,* but because almost all infections are asymptomatic, very few have the disease. The protozoan is an intracellular parasite of a variety of tissues in warm-blooded vertebrates. It multiplies by binary fission in a host cell, eventually rupturing the cell and releasing parasites to attack other cells. Sexual reproduction can take place only in cats and other felines. These definitive hosts release oöcysts, the stage infective for herbivores, in their feces. Asexual intracellular replication takes place in the herbivore, and, if the tissues containing *T. gondii* are eaten by a carnivore, asexual reproduction may also occur in their tissues. Humans can become infected by eating poorly cooked or raw meat or poultry, by ingesting oöcytes from the feces of cats, or congenitally.

Clinical Manifestations

Human infections are usually inapparent, although they sometimes can lie dormant for years and flare up in weakened or immunodeficient hosts. Most cases in otherwise healthy people are mild and cause vague symptoms like fever and weakness. The disease often mimics infectious mononucleosis. Chronic

cases can cause diarrhea, headache, and eye damage. Rare fulminating infections cause severe symptoms and may affect the brain. Uterine transmission of toxoplasmosis often has grave consequences. Five to 15 percent of cases result in fetal death, and 18 to 23 percent result in moderate to severe brain and eye abnormalities. Some apparently normal infants later develop severe retinal disease or mental retardation. In persons whose immune systems have been suppressed by therapy or disease, as, for example, organ transplant recipients or acquired immune deficiency syndrome victims, old or latent infections can become activated. Cerebral toxoplasmosis is a fairly common and very serious complication of AIDS.

Distribution and Incidence

The highest known prevalence rate, 93 percent, was found in Parisian women who enjoy eating raw beef. By age 25, roughly 70 percent of El Salvadorians and 30 percent of white residents of New York City harbor antibodies against *Toxoplasma*. It is estimated that about 3,000 babies are born each year in the United States with congenitally acquired toxoplasmosis.

Diagnosis, Treatment, and Prevention

The diagnosis of toxoplasmosis is complicated by its wide range of symptoms and depends on serologic tests. Therapy is often difficult, especially in weak patients, and is ineffective for fetuses. Prevention is by thorough cooking of meat and poultry and by careful handling of cat feces. Pregnant women should not empty cat litter boxes, and children's sandboxes should be covered when not in use.

Trematode Infections

Trematodes or flukes are flatworms of the class Trematoda of the phylum Platyhelminthes. They have complex life cycles that usually involve a snail as an intermediate host. The definitive host that harbors the adult worms, generally a mammal, acquires the parasite by ingesting an encysted form in a second intermediate host or on vegetation. Many species can infect human beings, but most of these are normally resident in other mammals, and humans are just accidental hosts.

Trench Fever

Trench fever is a nonfatal, acute disease first described in 1915 during World War I, when it afflicted at least 1 million soldiers on both sides of the conflict. Although initially known by several names, including Polish fever, Meuse fever, and Russian intermittent fever, the descriptive appellation *trench fever* given to the disease by the British armies in northern France has endured.

Clinical Manifestations

After an incubation period lasting between 14 and 30 days, trench fever elicits typical typhuslike symptoms: sudden onset, chills, headache, dizziness, and body aches and pains. Two of its descriptive names, shin fever and shank fever, recall its characteristic leg pains. Although also known as 5-day fever or quintan fever, the disease usually disables its victims for 5 or 6 weeks. About half of those afflicted suffer only one bout of fever, but the other half may have a number of relapses. Although trench fever is

never fatal, it caused a greater loss of manpower during World War I than did any other malady except influenza.

History and Geography

Also known as Wolhynian fever and His–Werner disease, trench fever occurred in Russia, England, France, the Middle East, Italy, Germany, and Austria. It is carried by body lice; hence it follows the pattern of its more deadly relative, epidemic typhus fever, in plaguing armies where hygiene is substandard. The disease became quiescent after World War I ended, but it appeared again on the eastern European front during the second global conflict.

Etiology

The etiological agent of this disease, *Rochalima quintana*, was first studied during World War I by a commission of the American Red Cross Medical Research Committee. Their report found that the organism, unlike other rickettsiae, would pass through porcelain filters. Later, in another departure from typical rickettsial characteristics, the trench fever organism was cultivated on lifeless, cell-free, blood agar media. Because of these and other differences, in 1961 it was removed from the genus *Rickettsia* and placed in a separate genus, *Rochalima*.

The Treponematoses

The members of genus *Treponeme,* family Treponemataceae, and order Spirochaetales consist of *Treponeme pallidum* (first described in 1905), which causes syphilis and nonvenereal syphilis; *Treponeme pertenue* (first described in 1905), which is responsible for yaws; and *Treponeme carateum* (first described in 1938), which produces pinta. Or at least this is the way that most medical texts would have it. It may be, however, that the three pathogens in question are actually only one, for although they produce different pathological processes, the pathogens themselves are virtually indistinguishable under the microscope, and the diseases they cause respond to the same treatment. The origin of this infamous family and the relationship of its members to one another have been topics of considerable and very interesting debate since the 1970s, largely because such questions bear directly on the centuries-old debate of whether the Americans bestowed syphilis on the rest of the world.

Many agree that the treponemes probably evolved from microorganisms that originally parasitized decaying organic matter, and which later – perhaps hundreds of thousands of years ago – came to specialize in human hosts, but probably only after first parasitizing another animal host (Wood 1978). There is little disagreement that the first treponemes to parasitize humans did so by entering their bodies through traumatized skin and were subsequently passed on to other humans by skin-to-skin transmission. Real disagreement begins, however, over questions of where the first humans were infected, and the identity of the disease they were infected with.

E. H. Hudson (1958) has argued that the first of the treponemal infections was *yaws* and that it probably emerged in Central Africa where it quickly became endemic. Then, about 100,000 years ago, it accompanied migrating humans from Africa to spread around the globe. C. J. Hackett (1963), on the other hand, portrays *pinta* as the first treponemal disease, arising only about 20,000 years ago in Eurasia to spread throughout the rest of the world.

At issue here are two very different concepts of treponematosis. Hudson feels that the distinctions among the treponematoses – *T. pallidum, T. pertenue,* and *T. carateum* – are artificial. In this so-called *unitarian view,* all of the human treponematoses actually constitute a single disease, but one that has different manifestations depending on cli-

mate and culture. Hackett, however, argues that the distinctions are very real – the consequence of *muta-tions* of the treponemal strains themselves. T. A. Cockburn (1961) has shown along Darwinian lines how human geographic isolation, especially after the Ice Age, could have led to treponemal speciation. Similarly, Don Brothwell (1981) has also speculated on the evolution of the treponemes and suggests that there may have been six lines of *Treponema,* which have undergone separate microevolutionary development to reach the four in existence today.

Historically, yaws has been prevalent in the hot and moist regions of Asia and Africa where little in the way of clothing is worn, facilitating transmission from skin to skin. By contrast, nonvenereal syphilis has flourished in hot but dry regions, where it spreads mostly from mouth to mouth. Both of these illnesses are normally rural, fostered by unsanitary living conditions, and are usually endemic and thus diseases of children. Venereal syphilis, on the other hand, is a disease of adults, seems to have first become manifest in the urban areas of temperate climates, and has been portrayed by Hudson, Cockburn, and others as a consequence of improving hygienic conditions. Put succinctly, in colder climates where people were better clothed and washed, the treponemas were denied their established patterns of skin-to-skin or mouth-to-mouth transmission among youngsters. As a consequence, persons reached sexual maturity without exposure to them, and sexual intercourse became one more means of transmission for the treponemas, particularly in urban areas where sexual promiscuity and prostitution were common (Hudson 1958).

The historical gradation of treponemal infections from the yaws of warm, moist Africa south of the Sahara, through the nonvenereal syphilis in hot and dry North Africa, to venereal syphilis in a cooler and urbanizing Europe, has constituted a compelling geographic model for both Hudson and Hackett and their followers. They point out, nonetheless, that yaws, and both nonvenereal and venereal syphilis, may all be present in a relatively small geographic area, with yaws and perhaps nonvenereal syphilis dominating the rural area surrounding a city, which harbors syphilis. Moreover, both views hold that venereal syphilis was present in Eurasia long before the voyages of Columbus, but its symptoms were lumped with those other disfiguring illnesses including yaws and nonvenereal syphilis, usually under the rubric of leprosy.

Needless to say, this challenge to the long-held notion that syphilis was introduced from the Ameri-

cas has encountered some heavy opposition (Dennie 1962; Crosby 1969, 1972). Yet we know that pinta was present in the Americas when Columbus arrived, and both the unitarian and the mutation hypotheses accommodate the notion that other treponemal diseases could have developed there as well. In fact, Brothwell (1981) has argued that Asia was probably the cradle for the evolution of the treponemes pathogenic to humans, and that they diffused from there to the Americas via migrants across the Bering Straits landbridge to the New World, as well as throughout the Old World. In other words, it is conceivable that all the pathogenic human treponemes were present in each of the major land masses of the globe by 1492. Yet Hudson (1964) believes that endemic syphilis and yaws reached the Americans via the slave trade and there evolved into syphilis; Francisco Guerra (1978) holds that all four treponemal infections were present in the New World, but only endemic and venereal syphilis resided in the Old World until yaws, not syphilis, was imported from the Americas; whereas Corinne Wood (1978), after reviewing the arguments and evidence, finds the Columbian hypothesis for the origin of syphilis the most plausible.

Much of the evidence upon which this last conclusion is based is skeletal in nature, embracing both negative and positive findings. Most of the negative findings have to do with the Old World, where it turns out that those buried in leper cemeteries would seem to have been mostly lepers and not syphilitics, as those who placed syphilis in Europe prior to the Columbian voyages felt would be the case. Moreover, there is (at least thus far) a dearth of evidence in Old World skeletal remains that would testify to the presence of syphilis in Eurasia prior to 1493, although the presence of yaws and endemic syphilis has been occasionally reported.

In the New World, by contrast, there is a great deal of positive skeletal evidence of pre-Columbian treponematosis. This evidence is not, however, of pinta (spotted), which causes changes in pigmentation but does not affect the bones as the other treponemal illnesses are capable of doing. Thus yaws, endemic nonvenereal syphilis, and syphilis are all possibilities for the American infection in question, as is perhaps some other treponemal infection now extinct. Of these candidates, however, venereal syphilis seems the least promising, because of an apparent absence of congenital syphilis in the skeletal material.

Brenda Baker and George Armelagos (1988), in providing us with the latest extensive review of the

literature on the treponematoses, have also provided us with the latest hypothesis as to their origin and antiquity. Given the scarcity of skeletal evidence of treponematosis in the Old World, and its abundance in the Americas, they suggest that treponematosis is a relatively new disease that arose in the Americas as a nonvenereal infection that spread by "casual contact." However, after the men of the Columbian voyages contracted the illness and carried it back to Europe, the circumstances of urban environments transformed the nonvenereal American disease into the venereal syphilis that raged across Europe and much of the globe for the next century or so before subsiding into the considerably more tame disease we know today.

Clearly, then, despite decades of debate about the nature of the treponematoses, there is still no agreement on their place or places of origin, nor on their antiquity. It does seem to be generally accepted that a transition in the method of transmission of the treponemal syndromes can be, and was, rather swiftly brought on by changing environmental and social circumstances, and thus, that syphilis is the youngest of these syndromes. But like so many other surveys of the treponematoses this one, too, must end with the hope that more evidence will be uncovered in the future to shed light on the many continuing paradoxes posed by this fascinating family, which may or may not consist of a single member.

Trichinosis

Trichinosis, also known as trichinellosis, trichiniasis, or trichinelliasis, is a disease of humans and of other mammals infected with the nematode worm *Trichinella spiralis.* The pathological changes and the symptomatology of *Trichinella* infection are manifestations of three successive stages in the life history of the worm: (1) penetration of adult female worms into the intestinal mucosa, (2) migration of juvenile worms, and (3) penetration of juvenile worms and subsequent encystment in muscle cells.

Distribution and Incidence

Although trichinosis occurs worldwide, in humans it is found principally in the United States, Canada, and eastern Europe. It is also well known in Mexico, parts of South America, Africa, southern Asia, and the Middle East. People acquire trichinae by ingesting uncooked or poorly cooked meat, especially pork. Home-made sausages have caused many recent outbreaks in the United States. Hence, the prevalence of trichinosis is less in the tropics and subtropics, where less meat is consumed. Trichinosis does not occur among Hindus, Jews, and Moslems, for whom there are religious bans on eating pork.

Although the prevalence of trichinosis in human populations is low (probably 2.2 percent or less in the United States, based on autopsy surveys), epidemic outbreaks are not infrequent. Incidence of infection is likely to be higher than suspected because of the vagueness of symptoms, which usually suggest other conditions.

Epidemiology and Etiology

T. spiralis is unusual in that a single individual animal serves as both intermediate and definitive (final) host, with the juvenile and adult worms located in different organs.

Humans acquire infections by ingesting infective juveniles, which are encysted in striated muscle of

swine or other animals. The worms are freed from their cysts by gastric juices and invade the intestinal mucosa where they copulate. Males die shortly after copulation, and the females migrate through the intestinal epithelium, each giving birth to as many as 1,500 live young over a period of 4 to 16 weeks. Spent females eventually die and are absorbed by the host.

Young juveniles are carried throughout the body via the arterial system. They finally reach skeletal muscle, where they penetrate individual fibers and grow in a spiral fashion, eventually becoming encysted by a blunt, ellipsoidal capsule of host origin. The time required for complete encapsulation is about 3 months. Calcification of the capsule begins as early as 6 months and may take up to 2 years to complete. Eventually the worms also become calcified, although they may remain viable for several years prior to calcification.

Not all striated muscles are parasitized to the same degree. Among muscles most heavily affected are the diaphragm, tongue, and masticatory muscles, intercostals, and muscles of the arms and legs.

Most mammals are susceptible to *Trichinella* infections. Infections are maintained in nature by flesh-eating animals. Humans are regarded as accidental hosts because, barring cannibalism or the consumption of cadavers by other mammals, the infection reaches a dead end. Most human infections result from eating pork or pork products, but numerous fatal cases of trichinosis have been recorded from among those who eat undercooked or underfrozen bear or walrus meat.

Cooking meat is of importance in preventing trichinosis. Pork should be cooked until the pink color turns to gray. Alternatively, freezing of meat at −15°C for 20 days will destroy all parasites.

Immunology

Trichinella infection results in the development of serum antibodies, including IgE, and cell-mediated immune responses. Resistance to reinfection has been demonstrated in experimental animals by an allergic IgE-mediated inflammatory response that expels adult worms from the intestine. Eosinophils may also play a role in immunity to *Trichinella* because experimental depletion of eosinophils has been shown to result in increased numbers of larvae recovered from infected animals.

Clinical Manifestations and Pathology

The first symptoms of *Trichinella* infection occur 1 to 2 days after ingestion of infected meat. Initial symptoms are vague and often lead to misdiagnosis, if apparent at all. As a host reacts to the waste products produced by the worms, lesions develop and enteric bacteria are introduced into them. Nausea, toxic diarrhea, sweating, and vomiting may occur, mimicking an acute food-poisoning syndrome. Respiratory symptoms may follow between the second and sixth day, and last for 6 days. In addition, there may be red blotches erupting on the skin.

During the period of migration of juveniles, there are muscular pains as inflammatory processes develop in the muscles. Difficulty in breathing, chewing, and swallowing develops. Edema around the face and hands is due to endovascular and perivascular inflammation. Edema around the eyes is a common early sign. Lymph nodes become enlarged and tender. Enlarged parotid or sublingual glands often lead to misdiagnosis of mumps. Eosinophilia may be present but often does not occur, even in the most extreme cases. Myocarditis, peritonitis, pneumonia, encephalitis, pleurisy, meningitis, and eye damage may result from migrating juveniles. Death from myocarditis may occur at this stage.

Penetration by juveniles into muscle cells, and subsequent encystment, may result in toxic edema, cachexia, or dehydration. Blood pressure drops rapidly, and the patient may display nervous disorders such as defects of vision, altered or lost reflexes, hallucinations, delirium, and encephalitis. Severe cases can result in death 4 to 6 weeks after infection. Death may occur as a result of toxemia, myocarditis, nephritis, peritonitis, or other complications.

It is important to recognize that most cases of trichinosis go undetected and that in milder cases no special series of symptoms may be present. Accurate diagnosis is made by employing muscle biopsy, pressing the tissue between glass slides, and examining it under a microscope. Alternatively, tissue may be digested in artificial gastric juice and the sediment examined for freed juveniles. *Xenodiagnosis* (feeding biopsy material to laboratory rats) is a useful diagnostic technique. *Immunodiagnostic* techniques may be useful when carried out by competent workers.

There is no thoroughly effective treatment for trichinosis. Thiabendazole has been somewhat effective, but serious side effects are known to occur. Steroids are given if myocarditis develops or if there are central nervous system complications. However, because corticosteroid therapy will inhibit the inflammatory reaction, an increase in larvae in the muscles will accompany this treatment.

History and Geography

Antiquity

Although knowledge of the parasite causing trichinosis was first obtained in 1835, knowledge of the disease dates back to antiquity. Dietary laws prohibiting the eating of swine are thought to have been engendered by the observation that human illness sometimes followed the eating of such flesh. In 1940 Asa Chandler stated: "There can be little doubt that this worm, with the pork tapeworm as an accomplice, was responsible for the old Jewish law against the eating of pork." Historians have surmised that Muhammad recognized that certain epidemics could have been caused by ingestion of pork, and thus followed the example of Moses in prohibiting pork consumption.

Nineteenth Century

The first person to actually see trichinae was James Paget, a 21-year-old freshman medical student at St. Bartholomew's Hospital in London. In 1835 Paget noted a curious pathological condition in the cadaver of a middle-aged man that was brought in for study. The cadaver had "spicules of bone" in the muscles. They were so hard that they blunted the scalpel. Others had seen these gritty particles previously, but it was Paget who had natural history training and the intense desire to observe new things, and thus he was the first to note that the particle was a worm in its capsule. Paget did not have a microscope, but eventually secured the use of one from the botanist Robert Brown of the British Museum. Specimens of the worm were taken to Richard Owen, who was to become England's greatest comparative anatomist. Owen subsequently presented a paper on the worm at the Zoological Society, and gave the parasite its name. Owen's presentation at the Zoological Society occurred just 18 days after Paget's announcement.

Although Paget's discovery was overshadowed by the detailed and complete memoir by Owen, Paget retained his intense spirit of scientific inquiry and published many papers on medical subjects. Later, he became Sir James Paget, one of the most distinguished surgeons of his time.

Trichinae in animals other than humans were first noted in 1846. Joseph Leidy, a professor of anatomy working in Philadelphia, found the worms in the extensor muscles of the thigh of a hog. Leidy had previously seen trichinae in human bodies in a dissection room, and he could perceive no distinction in the worms from the two hosts. In 1850 Ernst Herbst,

working in Göttingen, established that trichinae from meat eaten by an animal may invade its muscles. Herbst infected a badger with trichinous dog meat and then fed the infected badger meat to three dogs. All three dogs were infected at autopsy.

The significance of Herbst's experiments, as well as Leidy's observations, was not appreciated at the time because leading authorities believed that the trichinae from nonhumans were of a different species from those of humans. Herbst himself believed that trichinae were actually the larvae of filarial worms.

The problem of determining the life cycle of trichinae soon caught the attention of two of the leading researchers of their time, Rudolf Virchow of Berlin and Rudolph Leuckart of Giessen. Leuckart, in 1850, observed that the female intestinal trichinae are viviparous, but he believed that the trichinae were derived from the intestinal nematode *Trichuris trichiura*. Virchow, in 1859, fed encapsulated trichinae from a human to a dog, where the worms reached sexual maturity. Virchow refuted Leuckart's claim that the trichinae were identical with *Trichuris*.

Verification of the life cycle of trichinae and the discovery of the pathogenesis of trichinous infections represent monumental contributions by Friedrich Albert Zenker in 1860. Zenker performed an autopsy on a 20-year-old servant girl in Dresden whose illness had been diagnosed as typhoid fever. He examined muscle fibers from the arm and was startled to see "dozens of trichinae, lying free in the muscle, either coiled or extended, and exhibiting the plainest signs of life." Other skeletal muscles examined were likewise inhabited by the worms. Upon examining intestinal contents, Zenker saw sexually mature worms. It was apparent to him that the parasite underwent its entire life cycle in one and the same host.

Zenker subsequently investigated the household in which the servant girl worked, and found the parasite in sausage that had been prepared just prior to the onset of the girl's illness. Furthermore, other members of the household who had eaten the meat had become seriously ill with the same symptoms as shown by the unfortunate servant girl.

Following the establishment of the details of the life cycle and pathogenesis of trichinae, several outbreaks of infection were recorded. Some 140 epidemics of trichinosis were noted in Europe between 1860 and 1877, in which 3,044 persons were known to have fallen ill and 231 to have died.

Beginning in 1863, examination of pork for

trichinae was practiced in parts of Germany, and in 1879 a law was enacted in Prussia whereby all pork was required to be examined for trichinae. In this same year, ordinances were passed in Italy, Austria, and Hungary forbidding the importation of swine or pork products from the United States, and other countries followed with similar bans. Subsequently, the U.S. Department of Agriculture, although not providing for specific examination for trichinae, did specify methods for the processing of pork products that are customarily eaten raw. Such procedures will destroy the infectivity of any trichinae present. Public education, and heat treatment of the garbage used to feed hogs, have also helped to reduce the incidence of the disease in North America and Europe.

Trichuriasis

</div>

The nematode *Trichuris trichiura*, the whipworm or threadworm, is a very common parasite that occurs worldwide but is most abundant in warm, moist climates. It still exists in the southern United States, but it has declined there and in other developed countries in recent decades with improved sanitation; it is now found mostly in poor tropical countries. Adult worms range up to 2 inches in length, so whipworms were probably seen by ancient observers, but they were first clearly recognized by an early Portuguese writer on tropical medicine, Aleixo de Abreu, in 1623. Several scientists described the species in the mid-eighteenth century. Archaeological evidence shows that the worm infected people in the Americas prior to the voyage of Columbus.

Trichuris attaches itself to the wall of the large intestine and passes its eggs in the host's feces. Eggs require 10 to 14 days in the soil to mature or "embryonate." Embryonation is most successful in warm, moist soils in shady places. Like *Ascaris*, which has a similar range, *Trichuris* infects people who have swallowed embryonated eggs in soil or in contaminated food or water. Unlke *Ascaris*, however, the whipworm does not require an elaborate period of larval migration in the host. The eggs hatch in the small intestine, where the larvae spend some time before moving to their home in the cecum.

Trichuriasis rarely causes much harm unless there is a heavy worm load. Severe infections can cause abdominal discomfort, bloody or mucoid diarrhea, weight loss, weakness, and anemia. Masses of worms can cause appendicitis, and prolapse of the rectum can occur in children harboring large numbers of worms. Symptoms, including anemia, tend to be more severe in children. Diagnosis of trichuriasis is by discovery of eggs in the feces. Drug treatment is effective. Prevention of whipworm infection, like prevention of ascariasis, which often coexists with trichuriasis, is by improved sanitation, personal hygiene, and composting of night soil before it is used for fertilizer.

VIII.147
Tuberculosis

Tuberculosis is an infectious disease most commonly associated with the lungs, but which can affect almost any tissue or organ in the body. Its primary cause is an acid-fast bacillus, *Mycobacterium tuberculosis*. It is usually a chronic disease that lingers for months and sometimes years, but acute forms, which most commonly strike infants and young children, can prove fatal in a matter of weeks or days. One acute form is called *miliary* tuberculosis because of the small, grainlike tubercles it creates simultaneously in almost every organ of the body. From ancient times, tuberculosis was endemic in most populations of Eurasia, North Africa, and possibly the Americas, affecting relatively small numbers of people and maintaining low prevalence rates. But with the rise of urban and industrial development between the eighteenth and twentieth centuries, it became epidemic in much of Europe, North and South America, and Africa and Asia. In some places during this time most people were exposed to this disease, and its prevalence rates approached 100 percent of the population. Tuberculosis killed millions of people, placing it, despite its chronicity, on a historical par with the great global epidemic diseases of bubonic plague, cholera, measles, smallpox, typhoid, typhus, and the like. Until 1944, there was no specific drug therapy for it. In that year, researchers discovered streptomycin, which proved effective in inhibiting the disease. Two more drugs, *para*-aminosalicylic acid (PAS) and isoniazid (isonicotinic acid hydrazide, or INH), discovered in 1946 and 1952, respectively, provided an extremely effective treatment when used in combination with streptomycin. Together, they made all but the most advanced cases curable. Tuberculosis is no longer epidemic, but it still afflicts people worldwide, from the most highly industrialized to developing countries; the latter, however, suffer most severely from it because their populations are more likely to be exposed to the bacillus, placing them at higher risk of developing the disease when they are malnourished and/or in old age.

Etiology and Epidemiology

Perhaps no other disease better illustrates the principle of multifactorial causation: The tubercle bacillus is a necessary but not the only condition. In addition, the host and the host's environment contribute numerous other causes central to its pathogenesis.

Species Classification

Over 30 species of the genus *Mycobacterium* have been identified, more than 15 of which can cause disorders similar, but not identical, to tuberculosis. Human disease typically is caused by members of the species *Mycobacterium tuberculosis*. In addition, mycobacteria can cause disease in a wide variety of animals, including birds, fish, rodents, elephants, and cattle. Of its animal forms, only the bovine can infect people. Some bacteriologists consider the bovine form a separate species of the tubercle bacillus, whereas others group it with several variants that they classify together as the *M. tuberculosis* complex.

The human bacillus has also been divided into three types according to immunologic responses (phage types), which show marked variations in virulence. These are *type I,* found in India; *type A,* found in Africa, China, and Japan as well as in Europe and North America; and *type B,* found exclusively in Europe and North America. Type I is the least virulent of the three, making Indians more susceptible to disease when infected with type A or B. These differences probably result from the evolution of widely separated organisms over long periods of time. However, all forms of *M. tuberculosis* show a strong resistance to mutation, and thus it is unlikely that an increase in virulence caused the disease to become epidemic, or that a decrease in virulence prompted the decline in tuberculosis mortality rates that occurred in England, the United States, and other Western nations before the introduction of streptomycin and other specifics.

Transmission

Except for the bovine types, tubercle bacilli reach human hosts almost exclusively through aerial transmissions. By talking, coughing, sneezing, spitting, singing, and other respiratory functions, people produce airborne particles called *droplet nuclei,* which, if emitted by a tubercular individual, can contain between one and three bacilli. Just one is enough to establish a tuberculosis infection when inhaled. Once airborne in a closed space, these particles disperse and some remain suspended like tobacco smoke. Larger ones fall to the floor or ground where they present little threat of infection, al-

though dry tubercle bacilli can remain viable for months. Their transmission in dust particles is possible but rare; yet, from the late nineteenth century, this was believed to be the main form of transmission, and many countries passed laws that forbade spitting in public places. Bovine bacilli are ordinarily ingested through the digestive tract via milk and milk products and usually cause intestinal disease, but infrequently lead to pulmonary or miliary tuberculosis. The pasteurization of milk eliminates this source of infection.

Incubation Period

After entering the body, tubercle bacilli are remarkably durable and persistent. They can remain viable throughout their host's lifetime, dormant until resistance fails, whereupon they can cause active disease even if they failed to do so when they first entered the body. In contrast to most other infectious diseases, tuberculosis has an indefinite and variable incubation period.

Host-Dependent Factors

Whether or not tubercle bacilli cause active disease upon entering the body depends primarily on several host-dependent factors. Age, gender, and immunogenetic factors along with a number of environmental factors such as crowding, quality of nutrition, and working conditions are all of importance.

Age. Once a person becomes infected with the bacillus, age has a powerful influence on what follows. Infancy, puberty, and old age are periods of low resistance and high susceptibility to tuberculosis. The younger the individual, the more likely that primary infection will become active disease and result in death. Infants are particularly susceptible to acute miliary tuberculosis. Unlike the organisms in many infectious diseases, however, the tubercle bacillus does not produce immunity in those exposed to it: Exposure early in life usually leads to relatively high mortality rates from tuberculosis in later middle or old age.

Gender. Gender is also an important determinant. Although the reasons remain as yet undiscovered, more females die from tuberculosis than do males in populations where tuberculosis epidemics are just beginning, and the converse is usually true where the disease is declining. In youth and early adulthood, females generally experience greater mortality from tuberculosis than males, but after age 30 years the mortality of males surpasses that of fe-

males. Biological evidence suggests that the onset of the menses brings on metabolic changes that increase the body's need for protein, and that when it is unavailable, resistance drops. Childbirth can induce or aggravate the disease by lowering resistance to infection and this contributes to increased mortality in females up to age 30.

Genetic Factors. Extensive research on heredity in tuberculosis has produced only ambiguous results. Some families experience more tuberculosis than others in similar circumstances, and specialists do agree that heredity influences an individual's risk of developing the disease, but the mechanisms of heredity have not been demonstrated. The role of race in tuberculosis also presents a difficult problem to researchers. For decades, American scientists attempted to ascertain whether blacks, who long had higher rates of mortality from the disease than whites, were biologically more susceptible to it because of an inherited characteristic. Results have been indeterminate, because in this case constitution and environment remain inseparably intertwined. Nevertheless, a population's genetic pool is an important influence on resistance to the tubercle bacillus. A long history of inhabiting urban environments seems to have made Jews more resistant to the disease than are most other ethnic groups. By contrast, a population's previous lack of exposure to tuberculosis can lead to acute epidemics of the disease, as exemplified by those that occurred among the Maori of New Zealand and the Eskimos of Alaska.

Some epidemiologists assert that natural selection determines the course of tuberculosis epidemics, based on the idea that genetic background and resistance to the disease are of paramount importance. Mortality rates drop, they say, as the more susceptible are weeded out. Others oppose this theory, in part because tuberculosis epidemics in Europe and the United States subsided more quickly than the theory would have predicted. Moreover, although natural selection has doubtless reinforced resistance to the disease, it has not played a leading role in the decline of its epidemics. Rather it would seem that economic and social changes made the most important contributions to the decline in tuberculosis mortality rates until the late 1940s, when medicinal cures became available.

Primary Environmental Factors

Where tuberculosis is present, the specific factors most important in the etiology of the disease

are crowding, quality of nutrition, and working conditions.

Crowding. Crowding, as a function of persons per room, increases a person's chances of infection when diseased individuals are constantly releasing the bacilli into the air of small and cramped quarters. Population density, on the other hand, which is a ratio of persons per measure of land area, has little impact on tuberculosis mortality rates. Indeed, in most industrial nations, those rates are higher in rural than in urban areas because in sparsely populated rural areas, substandard living conditions, including crowded housing, often make the disease a major health problem.

Nutrition. Nutrition also plays a key role in the etiology of tuberculosis. Both epidemiological and laboratory evidence demonstrate the importance of protein in resistance to tuberculosis.

Working Conditions. Occupation and working conditions also can affect its pathogenesis and outcome. Textile mill laborers, masons, pottery factory operatives, metal grinders, and other workers in the "dusty trades" inhale particulate matter that inflames the lungs and increases their risk of developing the disease. The physical exertion and stress of exhausting work also magnify an individual's risk of developing tuberculosis, as does smoking. Socioeconomic status, which obviously has a powerful influence on all of these factors, may indirectly affect a population's tuberculosis mortality rates as well. Numerous studies have shown that groups with the lowest income levels suffer the most from the disease, and also that a rising income greatly reduces tuberculosis mortality.

This combination of factors means that industrialization alternatively exacerbates and improves rates of mortality from tuberculosis. The early stages of an industrial economy are generally those in which crowded and impoverished living conditions prevail for numerous people and lead to increased tuberculosis mortality. Eventually, however, industrialization's material benefits improve housing and nutrition, and reduce risks for infection and reinfection, thereby lowering both morbidity and mortality rates.

Other Environmental Factors. Other environmental factors seem to have little influence on tuberculosis mortality. Researchers long considered climate an important factor in the pathogenesis and treatment of tuberculosis, but recent studies have not found that temperature, humidity, or other climatic factors influence either one's risk of developing tuberculosis or its course once the disease is developed.

Epidemiologists have faced numerous difficulties in the study of tuberculosis, and found it particularly difficult to determine the mortality from the disease until the advent of mass screening programs using tuberculin and X-ray photography. Nonetheless they have played a primary role in unraveling some of the mysteries of tuberculosis and determining the factors, such as age and nutritional deficiencies, which put populations at greater or lesser risk of developing the disease.

Clinical Manifestations and Pathology

Tuberculosis most commonly infects the lungs, but it can infect almost any other part of the body, and frequently causes disease in the meninges, intestines, bones, lymph glands surrounding the neck, skin, spine, kidneys, and genitals. Most of these forms, with the exception of tubercular meningitis, are chronic, taking months and sometimes years before resulting in either recovery or death. Miliary tuberculosis concurrently affects almost every vital organ.

Because pulmonary tuberculosis is by far the most common form of this disease, it usually brings to mind its most familiar symptom: an increasingly frequent and violent cough that produces a purulent sputum sometimes streaked with blood. Coughing up larger amounts of blood hemorrhaged in the lungs is not uncommon in advanced cases, but this is by no means a universal symptom. Indeed, until the disease reaches its advanced stages, many victims are completely free of symptoms or experience only the mild respiratory symptoms similar to those of influenza or a common cold. The systemic symptoms of tuberculosis generally include fatigue, lethargy, anorexia, weight loss, irregular menses, ill-defined anxiety, chills, muscular aches, sweating, and low-grade fevers that continue indefinitely. In the past, however, many people developed mild or even asymptomatic cases of the disease and recovered before realizing it, as autopsies, and later X-rays, revealed.

Because in its early stages tuberculosis has only unalarming symptoms and myriad possible manifestations, diagnosis is difficult even today. Preliminary diagnosis can be made with a *tuberculin test,* which usually indicates whether a person has become infected with the tubercle bacillus. On the other hand, although tuberculin testing is highly reliable today, false-positive responses are not unknown.

The tubercle bacillus by itself does not damage the normal human body; it neither contains nor exudes any toxic materials. Rather cellular and tissue damage arises from an allergic reaction in the body, or *hypersensitivity,* which occurs in response to contact with the bacillus. In other words, after the body has become allergic to invading tubercle bacilli, the immune system destroys them. This process, however, releases proteins and fatty substances that in turn can cause inflammation and can damage surrounding tissue and cells. This same process also creates the *tubercles* that distinguish the disease. Experts sometimes refer to tubercles as caseous areas because they often have a cheesy consistency, although they can become as hard as rocks. Alternatively, caseous areas can liquefy, leaving a cavity. If this occurs close to a major blood vessel, it may result in a hemorrhage.

Immunology

The immune system's role in the development of tuberculosis is complicated, and part of that role still remains obscure. The complexity of the role has made it difficult to determine the extent to which antibodies protect the body against active disease and to what extent they cause it. Individual resistance to tuberculosis undergoes marked fluctuations: Quiescent infections often flare up under conditions that depress resistance, only to be suppressed when resistance is recovered. Acquired resistance to the tubercle bacillus confers no stable and durable protection as it does in diseases such as measles and smallpox, and can, to the contrary, make the development of active disease even more likely.

The efficacy of immunization against tuberculosis is still debated. Antituberculosis vaccination usually consists of administering the famous strain BCG (bacillus Calmette–Guérin), an attenuated form of the bovine bacillus first isolated in 1921 by the French bacteriologists A. Calmette and C. Guérin after years of laboratory cultivation. Clinical tests and epidemiological evidence indicate that it offers some degree of immunity when the recipient has not been infected before.

History

Antiquity

Archaeological evidence indicates that tuberculosis afflicted prehistoric men and women in Eurasia and Africa at least from the Neolithic period. Stone Age skeletons with lesions apparently caused by tuberculosis of the spine have been unearthed in Britain and Germany, and spinal tuberculosis has been found in numerous Egyptian mummies dating from the third millennium before Christ. In China, a woman's mummified body dating from the early Han dynasty (206 B.C. – A.D. 7) clearly displays tuberculosis scars on her lungs. Trade and migration patterns ensured the dissemination of China's chronic diseases throughout East Asia during the first three centuries of the present era. Skeletal evidence strongly suggests that native Americans suffered from the disease as early as 800 B.C., and pulmonary lesions that contain acid-fast bacilli dating from A.D. 290 have been discovered in Chilean mummies.

This physical evidence suggests two important points concerning the prehistory of tuberculosis. First, the disease quite possibly evolved together with humans from the earliest of times. Some specialists have presented the view that tuberculosis was originally limited to animals and first affected humans only after people started to domesticate cattle and other beasts. Others have contested this view, asserting that in the case of such a chronic disease, no animal intermediary is necessary to maintain viable bacilli even in relatively small populations. The second point is that tuberculosis afflicted most people worldwide from prehistoric times, save for small numbers of peoples, such as the Maori, who lived in isolation for centuries. Because of this, most epidemics of the disease resulted not from the introduction of foreign pathogens into virgin populations but from changes in the host population and its environment.

Textual sources support these conclusions, although not always with complete clarity because of marked differences in the ways people in different times and cultures have perceived the symptoms and course of tubercular disease. Until the present concept of tuberculosis – as a single disease caused by the tubercle bacillus – emerged during the last decades of the nineteenth century, its various forms were often known by separate names and thought of as different diseases. For example, the pulmonary forms were commonly called phthisis or pulmonary consumption; infections of the lymph glands surrounding the neck were termed scrofula; and those of the skin referred to as lupus vulgaris. This nosological confusion makes identification of the disease from historical texts difficult, and consequently conclusions concerning tuberculosis based on most written sources up to the mid-nineteenth century necessarily engender some skepticism.

Nevertheless, classical Hindu, Babylonian, Assyrian, Chinese, Greek, and Roman sources all describe

the signs and symptoms of tuberculosis. Hindu texts dating from 1200 B.C. and perhaps earlier, along with Mesopotamian texts from the seventh century B.C., had established procedures for treating pulmonary tuberculosis and scrofula. The first description of the disease in Chinese may date back to 2700 B.C., and texts from around 400 B.C. clearly describe the symptoms of tuberculosis. The first Greek mention of what probably was tuberculosis is that of Homer, about 800 B.C. Hippocratic writings from approximately 400 B.C. discuss *phthisis,* the Greek term for consumption, which they attributed to the effects of evil airs. Phthisis then became the standard European term that signified a cluster of symptoms akin to and including those of pulmonary tuberculosis. Other Greek and Roman writers of both medical and nonmedical texts use the term extensively, including Galen, who during the second century of the Christian era recommended a change of climate as therapy for consumption. René and Jean Dubos, in their classic study of tuberculosis, *The White Plague* (1952), note that the ancient cultures that described the signs and symptoms of the disease were primarily urban, whereas pastoral cultures make scarce mention of the disease. Biblical literature, for example, makes scant reference to it.

Medieval Period

Medieval Europeans suffered considerably from tuberculosis, although contemporary documents mention it more often in its glandular form rather than its pulmonary form – that is, as scrofula or tuberculosis. This was because of the custom of the "king's touch," in which kings of France and England were believed to have the power to cure scrofula simply by touching its victims. The custom originated in the twelfth century and continued through the eighteenth to its demise along with the divine right of kings at the end of that century.

Chinese medical texts that provide the most detailed treatments of the disease were written during the Sui (581–617) and Tang (618–907) dynasties. Japanese physicians appropriated the Chinese texts, and with their aid clearly described the symptoms of tubercular diseases in their own country. By the twelfth century, Chinese Taoist priests had attributed phthisis both to infection by evil airs (*qi*) and to animalculae, which attacked a physically or mentally exhausted individual. The disease was said to pass through six stages in which these animalculae underwent a series of metamorphoses and in the last stage became highly infectious. In positing this systematic germ theory of tuberculosis, the Chinese

anticipated Western medical theorizing by two centuries. In the first half of the sixteenth century, Girolamo Fracastoro, better know as Fracastorius, became the first Western physician to propose such a theory. Unlike the Chinese theory, however, Fracastorius's was not limited to phthisis, which he believed was only one of many diseases caused by the spread of animalculae.

Sixteenth Through Eighteenth Century

During the sixteenth century, mortality from tuberculosis increased noticeably in countries with growing urban populations. In England, for example, it caused about 20 percent of all deaths at midcentury, with the greatest concentrations of the disease found in London. A similar phenomenon occurred in Japan at nearly the same time: Contemporary observers remarked that phthisis had become widespread in the rapidly growing administrative capital of Edo at the beginning of the seventeenth century. It was during the eighteenth century, however, that the world's great epidemics of tuberculosis began, and they were well underway by the beginning of the following century. The nations that suffered most severely from tuberculosis at this time also were experiencing intense urbanization and industrialization. Thus physicians and other writers reported that phthisis was common in the cities of England, the United States, Italy, and France.

Autopsies showed that close to 100 percent of some urban populations, such as those of London, Paris, and other major industrial cities, had at some point in their lives developed the disease, although they had died of some other cause. Rates of mortality from tuberculosis in most major American cities during the early nineteenth century ranged from 400 to 500 per 100,000 of population, and in Philadelphia (1811–20) they reached 618. Women workers in textile industries generally led other groups in tuberculosis mortality in every country where modern textile factories were appearing. When statistics for tuberculosis mortality became available for most industrial countries of western Europe and the United States after 1860, they showed that its epidemics were declining. In the developing countries of the time, however, including most eastern European nations and Japan, tuberculosis epidemics were just starting at the end of the nineteenth century.

Increasing attention was given to tuberculosis by European physicians beginning with the seventeenth century, in part because of major changes in medical theory and in part because of growing mortality from phthisis and scrofula. In 1685 Richard

Morton became the first Western physician to publish a single text on phthisis, a term which he used to embrace a number of wasting diseases, including pulmonary consumption and scrofula. Morton depended on traditional humoral theory to describe the etiology of phthisis. By the eighteenth century, however, physicians were redefining their concepts of diseases, and searching for new explanations for their causes. As a result, the nineteenth century became a period of intense research into and speculation about tubercular diseases. In Europe and especially in the United States, physicians and laypersons alike looked for elements in both life-style and environment that made a person "susceptible" to it. Among those "elements" were dissolute and immoral living, alcohol and tobacco consumption, along with various developmental crises in the host's physical well-being such as puberty or childbirth. In addition, damp soil and filth in general could make an individual susceptible to consumption. Others, however, believed that pulmonary consumption was a hereditary affliction – a belief that became a powerful social stigma in much of the world. Indeed, throughout much of the nineteenth century, popular (and some medical) concepts of tuberculosis resonated with the notion that the disease expressed a person's inherent nature as opposed to just being something that one had. In fact, those considered susceptible to tuberculosis were said to have a phthisical diathesis.

Nineteenth Through Twentieth Century

Theories of Etiology. A major break with previous theories of tubercular diseases occurred at the beginning of the nineteenth century, which initiated a process that had transformed their classification by the 1880s, especially among European medical scientists. From the early 1800s, the French clinical school analyzed pathological phenomena by comparing the course of disease observed at the bedside with autopsy observations. René Théophile Hyacinthe Laennec, a leading physician of this school, postulated the theory that all tubercular phenomena, including phthisis, scrofula, and miliary tubercles, in fact constituted a single disease.

German physicians of the "physiological" school, who opposed the "ontological" view of diseases, which posits clearly definable entities for which distinct species can be established, vigorously attacked Laennec's theory of tuberculosis. A leading theoretician of German "physiological medicine," Karl Wunderlich, asserted that it was impossible to draw

a distinct line between, for example, dysentery and enteric diarrhea. Wunderlich thought of disease names only as conveniences, not as linguistic symbols for specific entities. In his views of tuberculosis, Wunderlich echoed the ideas of his contemporary, Rudolph Virchow. Virchow, in many respects one of the greatest medical theoreticians of the nineteenth century, also repudiated the ontological theory of diseases, including Laennec's idea that all tubercular phenomena manifested a single, specific disease. Rather, he divided tubercular manifestations into the two separate categories of inflammatory and neoplastic phenomena, and thought that some forms fundamentally resembled cancer. Virchow considered the important difference between diseases not to be one of cause but of pathological processes within individual cells.

Despite Virchow's views, however, the tradition of combining clinical and pathological investigations continued in France, most notably in the work of Jean-Antoine Villemin, who followed Laennec in saying that tuberculosis was a specific disease caused by a specific agent, but went one step beyond him by demonstrating in practice what Laennec had postulated in theory. In 1865 Villemin caused tuberculosis in rabbits by injecting them with matter from human tubercles. Although this work had a negligible impact on German ideas concerning tuberculosis, the notion that it was a specific disease was provided an unshakable scientific foundation in the work of the Prussian bacteriologist Robert Koch.

Using the clearly defined bacteriologic methods he had developed, Koch proved in 1882 that it was possible to give animals tuberculosis by inoculating them with bacteria – and not simply tubercular matter – that he had isolated from human tubercles. Although a number of problems in the identification of tuberculosis remained (such as the identity of scrofula, which some still maintained was a separate disease), the discovery of the tubercle bacillus finally established tuberculosis as a single disease clearly distinguishable by a single cause. It is true that for several more years, some circles, particularly the group led by Virchow, disputed Koch's methods and conclusions. Nonetheless his discovery of the tubercle bacillus changed the way not only members of the medical profession thought about tuberculosis but also how most people viewed the disease: No longer was it the result of an inherent susceptibility but, rather, something that one "had."

Early Attempts at Prevention. Koch's discovery had little effect on attempts to treat tuberculosis, but it

had important implications for prophylaxis. Observers attempting to establish the most important routes of infection concluded that dry tubercle bacilli in dried sputum presented the greatest threat. To prevent the disease, they recommended the general removal of dust from all public and private places, restrictions on spitting and the use of spittoons in all places, and the disinfection or destruction of the belongings and surroundings of tuberculosis victims. In some places, such procedures were already "on the books," because many national and local governments had passed laws specifying some or all of them. It was not until the 1930s that researchers demonstrated that, in most cases, infection was the result of airborne infection and that dried sputum or other forms of contact with the bacillus played little role in the transmission of the disease.

Early Treatment. The primary interest of most practicing physicians at this time, however, was not in ascertaining the etiology of tuberculosis but, rather, in treating the disease. The many hundreds of thousands of tuberculosis victims worldwide were desperate to be cured, and created an unbounded demand for remedies, making equally large opportunities for both physicians and quacks – although by today's standards it is often difficult to separate the two. Some of the most popular cures for tuberculosis that physicians advocated during the nineteenth century included creosote, carbolic acid solutions, gold, iodoform, arsenic, and menthol oil; at various times all were administered orally, inhaled, or injected directly into the lungs. More unusual treatments ranged from drinking papaya juice to enemas of sulfur gases. Starting during the late nineteenth century and continuing well into the twentieth, physicians practiced surgical therapies, including pneumothorax, or collapsed-lung treatments, and the surgical removal of ribs with the objective of reducing the size of the thoracic cavity.

Advances in Diagnosis. It was the search for a remedy, rather than his discovery of the tubercle bacillus, that brought Koch international fame. In 1890, at the strong urging of Kaiser Wilhelm II's government, he announced that he had discovered a cure for tuberculosis, which attracted hundreds of scientists and thousands of the afflicted to his laboratory in Berlin. Within a year, however, many were questioning the efficacy of "Koch's lymph" (a glycerol-based extract from the tubercle bacillus). As a cure it was not effective; in fact, it proved harmful in advanced cases. On the other hand, it soon became the extremely important diagnostic tool better known as *tuberculin* and the primary means of determining infection by the tubercle bacillus.

Along with the discoveries of the tubercle bacillus and tuberculin, the X-ray, discovered in 1895, helped change the way in which both physicians and laypersons thought about tuberculosis. It made visible to the eye lesions in the lungs and other parts of the body caused by the disease long before its symptoms became noticeable, allowing physicians to start treatment at a much earlier stage in the disease. Although they did not become a dependable diagnostic tool until the end of the second decade of the twentieth century, X-ray photographs together with tuberculin became the basic tools of the mass screening programs that governments and antituberculosis associations implemented from the 1920s to the 1950s.

Later Therapies and Prevention. As diagnostic techniques improved but medicinal cures remained ineffective, therapies based on climate and regimen became increasingly popular. Hippocrates had first recommended a change of climate as a treatment for phthisis, and from the seventeenth century onward physicians in both the West and the East continued to recommend healthful climates and life-styles as consumption cures. From the mid-nineteenth century, open-air and rest therapies became increasingly popular throughout Europe and the United States, and as an extension of rest therapy, pneumothorax, or the collapsing of a heavily diseased lung so that it could "rest," became popular in the late 1800s and remained common in many countries until the 1940s. The systematic integration of these therapies with other forms of treatment culminated in the sanitorium. From the 1880s, luxury sanitoria for the wealthy, like the one in Davos, Switzerland (immortalized in Thomas Mann's *The Magic Mountain*), drew patients from around the world. And about 1900, state-sponsored sanitoria began to appear throughout western Europe, North America, and Japan.

Where sanitoria were not feasible, such as in inner cities, public health bureaucrats and physicians developed alternatives that offered open-air treatment for the diseased as well as preventive regimens for those who seemed susceptible.

Many sanitoria and prevention programs were sponsored or managed by private or semiprivate antituberculosis organizations. These had been established in most of western Europe and North America from the 1890s, and in much of the rest of the world during the first two decades of the twenti-

eth century. Such organizations also supported educational programs, which became a mainstay of tuberculosis control movements. Their purpose was to inform the public of the ways in which the disease was transmitted and developed, and to encourage people to secure frequent checkups and early treatment if they were infected. The most commonly afflicted groups, however – factory laborers, other industrial workers, and the urban poor – rarely had the necessary resources to secure treatment for the disease even if they received an early diagnosis.

Mortality and Incidence. Understandably, medical scientists, public health bureaucrats, and workers in such prevention movements where rates of mortality from tuberculosis declined dramatically from the late nineteenth century onward concluded that the decline was the direct result of their efforts. This was especially the case in Great Britain, Germany, and the United States. Yet the experience of others contradicted such claims. During the first four decades of the twentieth century, the Japanese, for example, implemented almost all the tuberculosis control measures that Western countries had developed, including extensive legislation aimed at the control of tuberculosis, state-sponsored sanitoria in the major urban centers, intensive education programs, and government-administered mass screenings and BCG immunizations. Throughout the first three decades of this period, however, Japan's rates of mortality from tuberculosis hovered at around 200 per 100,000, and then actually increased from the early 1930s. It was not until the late 1940s that the rates of tuberculosis mortality began a sustained fall. In the case of Japan, the prevention movement was much less important than later improvements in living standards and working conditions and even later government intervention with nationwide treatment programs using streptomycin, PAS, and, after 1952, isoniazid.

Since the 1950s, the countries with the highest tuberculosis mortality rates have been those with low standards of living, poor working conditions, and inadequate treatment programs. Medicine has learned that the mere availability of specifics against tuberculosis is not enough to stem the disease; their administration must be coordinated with reforms that raise living standards and improve working conditions, or the incidence of the disease will remain inordinately high. During the early 1970s, over 20 nations worldwide – all of them developing countries – had new case rates for tuberculosis of over 150 per 100,000 per year; Macau (in 1973),

Swaziland (in 1970), and Bolivia (in 1972) all had incidence rates of over 400.

Thus although the leaders of antituberculosis movements long spoke of eradicating the disease, it remains a major health problem in many countries, and serves as an index of social conditions worldwide. Even in developed, industrial countries, when social conditions deteriorate, the incidence of tuberculosis rises quickly. Clearly, the disease remains far from eradicated in the developing world. But even in the developed world, tuberculosis retains the potential of becoming a significant health problem during times of economic depression, war, and social unrest.

Tularemia

Tularemia is primarily a specific, infectious disease of rodents and lagomorphs. The causative organism, however, has been isolated from over 100 species of mammals, 9 species of domestic animals, 25 species of birds, 70 species of insects, and several species of fish and amphibians. Humans can become infected by being bitten by infected blood-sucking insects, by handling infected animal carcasses, and by ingesting contaminated water or poorly cooked meat. In humankind, tularemia is an acute, infectious, moderately severe, febrile disease, which has a mortality rate of approximately 7 percent in untreated cases. The causative agent, *Francisella (Pasteurella) tularensis,* is a tiny gram-negative, pleomorphic coccobacillus requiring special media for isolation and growth. Tularemia is also know as deer-fly fever, Pahvant Valley plague, rabbit fever, Ohara's disease, yatobyo, and lemming fever.

Etiology and Epidemiology

Two variants (biovars) of the causative organism are recognized. *F. tularensis* biovar *tularensis* (type A) has been isolated in nature only in North America and is the most virulent in human beings. The second is designated *F. tularensis* biovar *palaearctica* (type B) and is found in all areas where tularemia is endemic in the Northern Hemisphere.

Tularemia is unique in the number of ways in which humans can become infected, and the clinical picture of the disease depends upon the infection route. The most common route is via the skin, either by insect bite or by direct passage through intact skin by contact with infected carcasses or a scratch from an infected animal. Of the numerous insects that transmit the disease, the tick is the most important. The wood tick (*Dermacentor andersoni*) and three species of rabbit tick are especially important in the United States. Biting insects such as the deer fly (*Chrysops discalis*) and the stable fly (*Stomoxys calcitrans*) also carry the disease to humans. Of the several species of mosquitoes shown to harbor the disease organism, only two species act as vectors to humans: *Aedes cinereus* and *Aedes excrucians* in Sweden and the former Soviet Union. Infection of the intestinal canal follows ingestion of contaminated water and undercooked meat. Humans can also contract infection via the respiratory route by

inhaling the organism from such sources as contaminated hay and wool.

Susceptibility to tularemia is independent of age, sex, race, and health status. That men are more often infected is related to their intrusion into the transmission cycle through hunting and handling of infected, fur-bearing animals. Human-to-human transmission is extremely rare, and the disease is largely confined to rural areas. The disease may occur in any season but is least prevalent in winter when insect vectors are least abundant and small animals are not much hunted.

The fatality rate in North America, prior to the widespread use of streptomycin in the late 1940s, ranged from 5 to 9 percent. Today that figure has been reduced to less than 1 percent. In Europe, the mortality rate has always been much lower, in the realm of 1 percent owing, probably, to the lower virulence of *F. tularensis* strain. An attack confers relatively solid lifelong immunity. A live attenuated vaccine is now available that reduces the severity of the ulceroglandular infection and reduces the incidence of typhoid-type tularemia. However, the vaccine is still being investigated and used primarily for laboratory workers who are always at high risk in working with the tularemia organism.

Distribution and Incidence

Tularemia, in humans, is confined to the Northern Hemisphere with three main areas of epidemicity: North America, Europe, especially eastern Europe and Russia, and to a lesser extent Japan. It is not found in nature in the British Isles. Tularemia has been reported everywhere in the United States except Hawaii. In Canada, the disease is endemic in the central and western provinces, as well as the Northwest Territories, but seldom is reported from the eastern provinces. Other countries that have reported the disease include Mexico, Norway, Sweden, Belgium, France, Germany, Poland, Czechoslovakia, Austria, Yugoslavia, Turkey, and Tunisia. Sporadic cases have been reported from northern South America including Venezuela, Ecuador, and Colombia, but these have not been confirmed.

In the United States, tularemia became a reportable disease in 1927 and rose to a peak incidence in 1939 with 2,291 cases reported (17.5 per million population). Since the 1950s, the disease has undergone a dramatic decline. In 1984 in the United States only 291 cases were reported (1.2 per million). Since 1931 in Canada nearly 400 cases have been reported but with a steady decline over the years. In Russia a similar decrease has been ob-

served. In the mid-1940s, 100,000 cases per year were reported; yet these were reduced to a few hundred cases per year by the mid-1960s. The reasons for this worldwide decline are controversial. The reasons advanced range from ecologically induced selection against the more virulent strains of *F. tularensis* and reduction of the organism circulating in wild reservoirs, to an increased awareness of the disease through mass education, to a failure to detect and report cases.

Clinical Manifestations and Pathology

Tularemia may manifest an extremely variable clinical picture depending upon the site of inoculation and the extent of its spread. In general, the incubation period averages about 3 days, varying from 1 to 9. The disease begins with headache, chills, vomiting, fever, with generalized aches and pains. An ulcer develops at the site of initial entry, while associated lymph nodes become enlarged and tender. The disease lasts 3 to 4 weeks, with sweating, weight loss, and general debility. Convalescence requires 2 to 3 months.

Several clinical types of the disease have been described:

1. The cutaneous (ulceroglandular) type in which an inflamed papule develops at the site of inoculation, which soon breaks down, leaving a punched-out ulcer. There is painful enlargement of associated lymph nodes, which may last 2 to 3 months. The usual signs of infection, fever, and prostration are common.
2. The ophthalmic (oculoglandular) type, which occurs when the bacterium enters via the conjunctival sac. Local inflammation occurs with enlargement of the lymph nodes of the neck. Permanent impairment of vision may occur.
3. The pleuropulmonary type, which develops secondary to the other forms. Milder forms resemble atypical pneumonia and may include shortness of breath, malaise, chills, and pleuritic pain.
4. The gastrointestinal (oropharyngeal) form that is contracted from the ingestion of contaminated food and water and may be accompanied by acute abdominal symptoms such as pain, vomiting, and diarrhea with ulcerative lesions in the intestinal mucosa.
5. The glandular form, which develops without a primary lesion but with enlargement of regional lymph nodes.
6. The typhoidal (septicemic) form that also develops without a primary lesion and without enlarge-

ment of the regional nodes. Infection arises via the respiratory route or is the late result of local infection.

7. The meningitic type, which is rare in North America but not infrequent in Asia, under certain conditions of insect transmission.

In all these types, subclinical infections may be more common than previously supposed. A recent study in Sweden showed that about 23 percent of the population had been infected, but 32 percent of these were subclinical cases.

History and Geography

Tularemia enjoys a unique place in medical history as it is the first disease to be identified and entirely described by American investigators. In 1910 G. W. McCoy of the U.S. Public Health Service, while studying plague in California ground squirrels, reported a "plague-like disease of rodents" in these animals. The following year, he and C. W. Chapin, using a special nutrient medium, succeeded in culturing the causative organism and named it *Bacterium tularense* after Tulare County, California, where infected squirrels were first discovered. W. B. Wherry and B. H. Lamb were the first to diagnose bacteriologically a human case of the disease in 1914. The infected patient, an Ohio meat cutter, showed ulcerative conjunctivitis and lymphadenitis.

Earlier, in 1911, R. A. Pearse had described several cases of deer-fly fever in humans from Utah and suggested that the disease was caused by the bite of *Chrysops discalis,* the common deer fly. It was left to Edward Francis, a surgeon with the U.S. Public Health Service, to piece together the complicated etiologic connection among deer-fly fever in humans, the plaguelike disease of rodents in California, and similar illnesses in small mammals of Utah and Indiana. Francis isolated the organism in 1921 and proved that it was indeed spread by the bite of the deer fly as well as by direct contact with infected meat. The role of the tick in the spread of tularemia was determined in 1924 by R. R. Parker, R. R. Spencer, and Francis. It was also Francis who coined the term "tularemia" after finding the organism in the blood of infected individuals. In the late 1950s the genus name of the organism was changed to *Pasteurella* because of a supposed relationship to the causative organism of plague. In 1974, upon recommendation of microbiologists in the Soviet Union and the United States, the genus name was changed to *Francisella* to honor Francis who, through more than 30 years of investigation into tularemia, was

the man most responsible for sorting out its complexities and many manifestations.

In 1925, Hachiro Ohara, a Japanese scientist, published a paper entitled "Concerning an Acute Febrile Disease Transmitted by Wild Rabbits," followed shortly by a second paper describing how an illness that would become known as *Ohara's disease* was successfully transmitted to humans. Other papers by Japanese scientists soon followed, but none made reference to American investigations of tularemia.

Francis and a colleague, recognizing that Ohara's disease seemed similar to tularemia in every way, requested serums from convalescent Japanese patients. Examination of the sera quickly confirmed that Ohara's disease and tularemia were actually the same illness.

The first isolation of *F. tularensis* outside North America and Japan occurred in the Soviet Union in 1926, and by 1928 almost 800 cases were reported, rising to a peak incidence in 1941–2 of approximately 100,000 cases, but, as in North America, there has subsequently been a dramatic delcine in cases.

Although tularemia is often described as a "new disease," it is perhaps best to consider it new only in terms of its discovery. Medical historians believe there is good evidence that tularemia was endemic in the United States, Scandinavia, and the Soviet Union in the eighteenth and nineteenth centuries. Many travelers in Russia as early as 1741 noted a disease with all the characteristics of tularemia and termed "Siberian ulcer."

In the United States at least three written records survive describing the disease, including one from California in 1904 and another from Arizona in 1907. In fact, the wide distribution of the disease and its adaptation to a wide variety of animals suggest that the disease is ancient in nature, perhaps dating to the latter end of the Miocene or early Pliocene periods.

Despite the dramatic decline in the incidence of tularemia since the 1950s, it would appear that tularemia will remain a hazard to humans for many years to come. In spite of the great amount of research over the past 70 years, numerous questions remain unanswered because of the very complex interactions among hosts, vectors, and varied environments. Because of these complex ecological interactions, eradication of tularemia seems unlikely.

Typhoid Fever

Typhoid fever is a systemic infection caused by the bacterium *Salmonella typhi,* usually manifested by the slow onset of a sustained fever and a variety of other symptoms including headache, cough, digestive disturbances, abdominal pain, and profound weakness. In a minority of sufferers, findings more specific for typhoid fever may be present, such as enlargement of the spleen or liver, or a characteristic "rose spot" rash. Untreated, the illness lasts 3 to 4 weeks; it claims the lives of about 10 percent of those affected and leaves about 2 percent as permanent carriers of the organism. Three-quarters of the world's population live in areas where typhoid is endemic, and 1 out of every 300 of the world's population contracts the disease each year. One million persons die of it annually, mostly children.

A variant illness, called paratyphoid fever, has many of the same features as typhoid fever, but is caused by members of the *Salmonella* bacterial family other than *S. typhi.* Typhoid and paratyphoid fevers are sometimes lumped together under the term *enteric fever.*

Etiology

The microorganism responsible for typhoid fever is a member of one of the largest and most widespread families of bacteria on Earth with over 1,700 serotypes recognized. The salmonellae are rod-shaped bacteria that have a cell wall and flagella, which give the bacterium motility.

Salmonellae can colonize the gastrointestinal tract of a broad range of animal hosts including mammals, birds, reptiles, amphibians, fish, and insects. Some types of salmonellae are highly adapted to specific animals; others have a wide range of hosts. Because of this versatility and the enormous consequent animal reservoir, the eradication of all salmonellosis would be essentially impossible.

Salmonellosis is generally a mild disease in humans, characterized by a few hours or days of vomiting and diarrhea (gastroenteritis), followed by weeks to months during which the organism is shed asymptomatically in the feces. The disease is usually acquired by ingestion of foods that are contaminated with the organism, but other routes – person-to-person, animal-to-person – may sometimes play a role. In the 1970s in the United States, more than 10 percent of the nation's salmonellosis was acquired from baby turtles, a favored pet of children in those days.

Almost unique among the salmonellae, the typhoid bacillus is adapted to human beings alone. *S. typhi* also possesses a protective envelope, called the "virulence antigen" or *Vi antigen,* which appears to help the organism resist the immunologic defenses of the host. The exclusive adaptation of *S. typhi* to human beings makes control possible through public health measures.

Epidemiology

Typhoid fever is spread by the fecal–oral route: Bacteria shed in the stool by infected persons can be ingested by someone else, usually through contaminated food or water.

Control of typhoid fever depends on maintaining a separation between sewage and drinking water. In certain areas of the world, as many as 3 percent of adults may be shedding *S. typhi.* Thus with poor sanitation, the population is continuously exposed, and the disease is constantly present. Such areas are termed *endemic.* Many of the least developed regions of the world are highly endemic for typhoid fever.

In contrast, where effective sanitation barriers are suddenly breached, transmission follows an epidemic pattern with a sudden rise in the incidence of a disease within a limited geographic area. For example, typhoid fever is almost unknown in Switzerland; yet contamination of Zermatt's water supply in 1963 resulted in 280 cases in a brief period of time. Ten years later, a similar compromise of the water supply of a migrant laborers' camp in Florida permitted an outbreak of 222 cases, with a single carrier as the apparent origin.

The other main vehicle for typhoid transmission is

food. Though denied another animal host, *S. typhi* can grow well on many types of food, and contaminated foods have been responsible for large-scale outbreaks. Five hundred cases of typhoid fever in Aberdeen, Scotland, in 1964 were traced to imported canned beef which, after processing under sterile conditions in Argentina, had been cooled in a sewage-laden river where microscopic cracks in the seams of the cans permitted contamination.

Foodborne transmission may be important in maintaining high levels of endemicity in areas where drinking water is pure. In Santiago, Chile, 10 percent of water samples from the irrigation canals are positive for *S. typhi*, and contamination of produce, rather than drinking water, appears to be an important factor in the city's typhoid problem.

In fact, even when food is initially free of *S. typhi*, handling by persons who shed the bacillus can be enough to produce disease in those who eat it, particularly where refrigeration is absent and basic standards of hygiene are not maintained.

Minor roles in *S. typhi* transmission are also played by shellfish harvested from contaminated waters and flies lighting first on excrement and then on food. Transmission may also occur accidentally in the microbiology laboratory while workers are handling infected human specimens.

The percentage of persons who develop typhoid fever after exposure to the bacillus depends upon a number of factors, among them the virulence and number of organisms ingested, and the host's health and immune status.

Experiments conducted with adult volunteers demonstrate that the attack rate of typhoid fever depends directly on the number of organisms ingested. Illness was produced in about 25 percent of volunteers each ingesting 100,000 bacilli; ingestion of 10 million bacilli resulted in illness in 50 percent; and ingestion of 1 billion organisms virtually guaranteed the development of typhoid fever. The incubation period varied inversely: The larger the dose, the shorter the incubation period. Some strains, however, are able to produce disease at very low numbers: Only 10 organisms of the type involved in the 1963 Zermatt epidemic were needed to make half of volunteers ill. Attack rates of epidemics in the developed world suggest that most such outbreaks are initiated by exposure to only a few hundred or thousand organisms.

With typhoid, whatever the degree of community exposure, maintaining personal hygiene, boiling drinking water, and cooking food just before eating it play an important role in preventing typhoid fe-

ver. Predisposing factors for the development of all *Salmonella* infections include red cell breakdown diseases (e.g., sickle-cell disease, malaria), immunodeficiency (e.g., AIDS), malignancy, or dysfunction of various organs such as stomach, liver, or kidney. Other conditions such as gastric hypoacidity and the use of antibiotics that inhibit normal gut bacterial flora are risk factors that favor *Salmonella* infections. Adults in endemic areas are more resistant to typhoid than are children in the same area or previously unexposed persons from other areas.

A distinctive feature of the epidemiology of typhoid is the existence of a large number of asymptomatic carriers: persons who excrete *S. typhi* yet manifest no signs of illness.

In the normal course of typhoid fever, fecal excretion of the organism persists for a few weeks, but about 2 percent of infected persons will never clear the bacillus from their stools. In such persons, the organism appears to colonize the biliary tract – that is, the tubules that conduct bile from the liver and the gallbladder. Persons with preexisting disease of the biliary tract – for example, inflammation or gallstones – are at risk for becoming carriers. *S. typhi* appears to have a particular affinity for bile and gallstones. It grows best on media enriched with bile by-products. Once a stone is infected, it forms a focus of infection sheltered from antibiotics and the host's immune system.

The likelihood of becoming a carrier increases with age and peaks at 55 years of age, with women carriers outnumbering their male counterparts 3 to 1 – a pattern similar to that seen in biliary disease, but contrasting sharply with acute typhoid fever, which is a disease of the young and which affects both sexes equally. In Chile, where the incidence of both biliary disease and typhoid fever is high, there is an estimated 1 carrier per 150 persons. The lack of symptoms often makes the carrier difficult to identify, and sequestration of the bacillus on gallstones makes its eradication difficult or impossible.

Distribution and Incidence

Since the beginning of the twentieth century, typhoid fever has been largely a disease of the developing world, and the same factors that interfere with the provision of health care in these regions also interfere with the gathering of health statistics.

For northern Europe, North America, Japan, and Australia, the annual incidence of typhoid fever is less than 1 case per 100,000 persons, and half of these cases are acquired by foreign travel rather than by indigenous exposure. The annual incidence

in southern and eastern Europe averages about 10 per 100,000, whereas in the developing world it is 40 in Egypt, 100 in Chile, 850 in rural South Africa, and ranges from 500 to 1,000 for some areas of South and Southeast Asia.

These crude estimates in turn suggest that the global incidence averages 300 cases of typhoid fever per 100,000 persons per year or 15 million cases of typhoid fever each year.

Regarding age, sex, and race, the following generalizations can be made: In endemic areas, 75 percent of cases of typhoid fever occur in persons 3 to 18 years old. Typhoid is only rarely described in children younger than 2 years, although studies in Chile indicate that typhoid fever may be unsuspected clinically because the characteristic features of the disease are blurred in this age group. For acute typhoid fever, the ratio of the sexes is equal, but three-quarters of carriers are women; no susceptibility to typhoid fever has been identified by race.

Poverty is usually associated with poor sanitation and poor health care, and thus constitutes a risk factor for acquisition of typhoid. Blacks in South Africa have four times the incidence of typhoid, with eight times the mortality rate of whites. In Israel, the rate for the Jewish population is similar to that for Europe; for the non-Jewish population, it is similar to that for the Middle East.

In endemic areas, typhoid tends to peak in the summer months. Whether this pattern is due to greater consumption of water or enhanced proliferation of the bacteria in food is unknown. In the developed world, to judge by the United States, seasonality reflects foreign travel patterns, with peaks in January and February and again in the summer months.

Pathology

Most ingested typhoid bacilli are killed by stomach acid. Factors that reduce stomach acid (antacids) and speed transit time through the stomach (infancy, surgery, water rather than food as a bacterial vehicle) enhance the chances of infection.

Once in the small intestine, the bacilli penetrate the mucosal lining and are ingested by white cells located in gut lymph nodes. Perhaps because of its protective envelope (Vi antigen), *S. typhi* resists intracellular digestion and proceeds to multiply within the cells that normally destroy bacteria. Bacteria multiply and pass into the bloodstream. Initially, they are cleared from the blood by white cells located in the liver and spleen, but there, too, the bacilli multiply intracellularly, and reenter the bloodstream. It is during this second period of bacteremia that the clinical symptoms of typhoid begin.

Lymph nodes in the small intestine become particularly laden with bacilli, occasionally to such an extent that they and the surrounding tissues die, leading to intestinal hemorrhage or perforation – the major causes of mortality in typhoid. The biliary tract is infected, and the patient may begin shedding *S. typhi* in the stool. Delirium, inflammation of the heart, and shock may occur and are caused not by direct infection but, rather, by toxins released either by the bacilli or by the white cells. Over a period of weeks, the body's intracellular immune system recognizes the typhoid bacillus, permitting the host to destroy the invader.

Clinical Manifestations

Typhoid fever is an illness characterized by fever and headache. Other early symptoms that may occur are abdominal distension or tenderness, constipation and a few loose bowel movements, cough or bronchitis, and "rose spots" – a transient rash that usually begins on the abdomen. As the illness progresses, the headache may be more severe and be associated with mental confusion or stupor, the liver and spleen usually become enlarged, and complications such as intestinal hemorrhage, intestinal perforation, and pneumonia may occur.

If the disease is untreated, mortality ranges between 10 and 20 percent; 1 in 5 persons experiences gastrointestinal hemorrhage, and 1 in 50 suffers from perforation of the gut. Relapse occurs in about 10 percent of patients, usually after a week free of illness, but the symptoms are frequently milder and the duration shorter than during the original attack.

With early effective antibiotic treatment and supportive care, the course of the disease is markedly changed: Fever is usually gone within 3 days, and mortality is cut to less than 1 percent.

Diagnosis

Signs and symptoms so distinctive of typhoid as to render a clinical diagnosis secure are present only in a minority of patients. Particularly at the onset where fever may be the only complaint, typhoid is easily confused with a host of other diseases that share its geographic patterns: malaria, hepatitis, tuberculosis, brucellosis, and typhus, to name a few.

The usual method of diagnosis is the culture of *S. typhi* from some part of the body. In persons with typhoid fever, culture of bone marrow is positive in 80 to 90 percent, and blood cultures are positive in

70 percent. Cultures of duodenal fluid are positive in 50 percent. Stool and urine cultures have positivity rates of only 30 and 10 percent, respectively.

In 1896, Fernand Widal determined that most persons infected with *S. typhi* develop antibodies to its cell wall (O antigen) and flagellae (H antigen). Since that time, the Widal test for O and H antibodies in the blood has been used extensively to diagnose typhoid fever. But although the test uses inexpensive materials and is rapid, it is not always reliable. Persons with typhoid fever may never show a rise in antibody levels, and past exposure to *S. typhi* (such as is common among adults in endemic areas) can mean a positive Widal test, whatever the patient's current ailment. In unimmunized children in endemic areas, however, the Widal test may be of value.

Treatment

Until 1948, little other than supportive measures could be offered the typhoid patient, but with the discovery of the antibiotic chloramphenicol, mortality was markedly reduced. For 20 years chloramphenicol was an entirely effective treatment, but resistance to it emerged in the early 1970s almost simultaneously in Mexico and Vietnam. Within a few years, 75 percent of all isolates of *S. typhi* in Vietnam were resistant. In developed areas, where infections were less frequent and antibiotic use was more tightly controlled, the percentage of resistant strains remained below 5 percent. Antibiotics such as trimethoprim, sulfamethoxazole, ampicillin, and others are now the drugs of choice for typhoid fever.

Control

Strategies for control of typhoid are divided into three categories:

Elimination of the Reservoir

Identification of carriers in an endemic population is difficult, and eradication of the carrier state costly. This option appears impractical.

Interruption of Transmission

Where pure water and food can be assured, typhoid transmission is minimal. Solely by improvement of sanitary conditions in the past century in developed countries, the incidence of typhoid fever has declined from 1 in 200 to 1 in 250,000. Mathematical models suggest that the building of privies in endemic areas would be among the least costly methods of reducing typhoid prevalence. Unfortunately, the pace of progress in making such sanitary improvements is slow.

Immunization

Exposure to the typhoid bacillus appears to confer some degree of protection against subsequent infection. Volunteer trials in the twentieth century verified this, and the extent of protection was quantified at 75 percent. However, the immunity was relative; it seemed to decay after a number of years, and could be overcome, at any stage, by the administration of a sufficient number of bacilli. Nevertheless, a relative immunity was better than none, and attempts to induce it artificially began almost as soon as the bacillus was isolated in the last decades of the nineteenth century. Since that time, most clinical vaccine trials indicate a protective effect of about 75 percent. At present, three major formulations exist:

Injection of Killed S. typhi *Bacilli.* This version contributed to the elimination of typhoid from the British and American armies during World War I, and, when administered to Thai schoolchildren in the 1970s, it was apparently instrumental in decreasing endemic typhoid fever. It is cheap and easy to produce, but there is a high rate of adverse reactions (fever, pain at the site of injection), as well as the need for refrigeration, sterile administration, and one to two boosters.

Injection of Vi Antigen. Vi Antigen (the protective polysaccharide envelope of *S. typhi*) provides, for persons in endemic areas, a degree of protection that is similar to that of the killed vaccine. The efficacy of this vaccine in Western travelers is not known. Only one dose is required, no refrigeration is needed, and no adverse effects have been noted. It requires sterile administration and is relatively expensive.

Oral Vaccine. This vaccine consists of a mutant strain of *S. typhi* incapable of causing typhoid fever. Studies in Egypt and Chile have documented its efficacy, with no adverse reactions observed. Refrigeration, but not sterile administration, is required. Disadvantages include the problems of storage and administration of a live vaccine, the need for at least three doses, and the higher cost.

Although control of typhoid fever is best accomplished with improvement of sanitary conditions, immunization with the more acceptable oral and polysaccharide vaccines may play an important public health role in developing countries.

History

Antiquity Through The Seventeenth Century

Typhoid fever has surely been a disease of human beings since prehistory, but for ancient physicians its nonspecific symptoms did not make it distinct from other illnesses. Hippocrates described a case of what appears to have been typhoid, and Caesar Augustus was cured of a fever with the characteristics of typhoid by the use of cold baths, a remedy that persisted well into the twentieth century.

Although meaningful reports from ancient and medieval times are lacking, the early mercantile and colonial enterprises of European expansion were clearly affected by typhoid epidemics. In the early seventeenth century, 6,500 out of 7,500 colonists at Jamestown, Virginia, died most likely from typhoid fever.

At about the same time this epidemic was occurring, the Belgian anatomist Adriaan van den Spieghel (Spigelius) described lesions in the lymphoid tissue of the small intestine of a patient who had died of a protracted fever, the first report of the characteristic pathological findings of typhoid. Later in the century, a British physician, Thomas Willis, cataloged the symptoms, signs, and course of a disease he called "putrid malignant fever," which was clearly typhoid.

Eighteenth Through Nineteenth Century

In the mid-eighteenth century, the Frenchman François Boissier de Sauvages consolidated a variety of ailments, including what Willis had called putrid malignant fever, into the term "typhus." In the 1830s, Pierre Louis, dissatisfied with the heterogeneity of the concept of typhus, proposed isolating a particular constellation of symptoms under the name "typhoid fever," or typhus-like fever. Later the American William W. Gerhard, studying an epidemic in Philadelphia, established typhoid fever as an entity independent of typhus, a term that now refers only to diseases caused by the rickettsial family of bacteria.

Though the illness now had a clinical definition, its mode of transmission was still in dispute. Somewhat earlier in the century, Pierre Bretonneau had argued that typhoid was contagious and that an attack conferred immunity. In the 1840s, the Englishman William Budd virtually inaugurated the science of epidemiology by his demonstration that typhoid was spread from infected individuals to new hosts by means of water and food. Budd's position

was actively opposed by those who believed in spontaneous generation, and little was done to implement his recommendations of public health measures. As a result, the annual incidence in Europe at that time remained as high as 1 per 200 people.

Finally, in 1875 Budd's warnings were heeded, and the British Public Health Act was passed, radically improving sanitary practices. Within a decade, typhoid mortality was cut in half. This lesson was not lost on other developed nations who enacted sanitary laws of their own. Since that time, the incidence of typhoid in the developed world has steadily declined to its current annual rate of 1 case per 250,000 individuals.

This profound revolution in public health had begun before the microbial etiology of typhoid, or any other infection, had been established. Yet just 2 years after the Public Health Act was passed in England, the German Robert Koch demonstrated that a microorganism was the cause of anthrax; 3 years later his countrymen Carl Eberth and Edwin Klebs identified the typhoid bacillus in intestinal lymph nodes, making typhoid one of the earliest diseases for which a bacterial agent was known.

The next 2 decades saw an explosion of knowledge about the organism which was then called *Eberthella typhosa* in honor of its discoverer. In 1884 Georg Gaffky succeeded in culturing the bacillus from lymph nodes, and shortly thereafter it was isolated from blood and stool.

Despite these rapid advances, therapeutic interventions against typhoid were lacking. During the Spanish-American War of 1898, one-fifth of the American army fell ill from typhoid fever, with a mortality six times the number of those who died of wounds. At about this time in England, Almroth Wright developed a vaccine of heat-killed bacilli, which reduced the attack rate among soldiers in India by 75 percent. Despite these impressive results, the vaccine was little used 2 years later in the South African (Boer) War, and the disastrous experience of the American army in the war against Spain was virtually repeated among British troops in South Africa.

Twentieth Century

Early in this century, both the British and American commands ordered mandatory typhoid immunization and better military sanitation. The effect a decade later was dramatic: During World War I, the typhoid attack rate was reduced from 1 in 5, to 1 in 2,000, and since then, perhaps for the first time in

human history, typhoid has not played a major role in armed conflicts.

In 1906 George Soper, then a sanitary engineer for the New York Department of Health, was called upon to investigate an outbreak of typhoid. It had occurred in a summer home in Oyster Bay, a well-to-do town where the disease was unknown. Yet 6 of 11 people in the house had become ill. Soper determined that 3 weeks before the outbreak a new cook had been hired but had left after the first persons began falling ill. The cook's name was Mary Mallon, and she was destined to become inextricably linked with typhoid fever.

Four years earlier, Koch had proposed that a person might chronically shed the typhoid bacillus and thus infect others, yet remain healthy and unaffected by the disease. His carrier hypothesis lacked adequate supporting evidence and was doubted by many. It occurred to Soper, however, that the perplexing cluster of typhoid cases in Oyster Bay might be explained if the cook were a carrier.

Soper's investigations showed that over the previous 10 years inexplicable typhoid outbreaks had occurred in seven of the eight families for which Mary Mallon had worked. A year later, Soper located her working once again in a home where typhoid fever had just broken out. She was removed against her will to a hospital where culture of her stool proved that she was indeed shedding *S. typhi* in great numbers. After a 3-year detention on North Brother Island in Long Island Sound (a detention that raised many civil liberty questions), she was released on the promise that she would never again handle food. Five years later, however, she was found to be the source of an epidemic of 25 cases of typhoid that occurred at Women's Hospital in Manhattan. She was arrested and spent the rest of her life on North Brother Island. "Typhoid Mary" had established beyond scientific doubt that a carrier state existed in typhoid.

In 1933 *Eberthella typhosa* became *Salmonella typhi,* thereby joining a family of bacilli named after D. E. Salmon, who in the 1880s had discovered an organism (*Salmonella cholerasuis*) responsible for bacteremia in humans and diarrhea in swine. The discovery in 1948 of antibiotics active against *S. typhi* converted typhoid in the developed world from a rare but dread disease to just a rare one, acquired mainly by travel abroad.

On a global scale, however, there has been little evidence that typhoid is fading into obscurity. Although inexpensive vaccines place typhoid control within reach of those nations with limited health resources, the huge worldwide reservoir of carriers and the continuation of poor sanitation in endemic areas suggest that it will be some time before the developing nations can significantly reduce the incidence of typhoid fever.

Typhomalarial Fever

Typhomalarial fever as a specific disease is not recognized by medical authorities today, but for the last half of the nineteenth century it was a frequently useful diagnostic category of diverse and often imprecise meaning. Joseph J. Woodward, a U.S. Army surgeon, defined the term during the American Civil War for those camp diseases "in which the malarial and typhoid elements are variously combined with each other and with the scorbutic taint." Woodward considered the disease "a new hybrid of old and well known pathological conditions," but one that was distinct, both clinically and at postmortem, from malarial and typhoid fevers.

Distribution and Incidence

William Osler once wrote that typhomalarial fever existed "in the minds of doctors but not in the bodies of patients." If so, it existed in the minds of many American doctors in the South, Midwest, and western regions of the country as well as in the minds of military and other European physicians practicing in the unsanitary, malarious regions of the globe, particularly the Mediterranean, British India, and some areas of China. It was primarily an Anglo-American phenomenon, although there are a few reports from southern Europe, which indicate that the possibility of the diagnosis was at least considered.

Etiology and Epidemiology

Typhomalarial fever was generally regarded as a noncontagious, infectious disease that resulted from exposure to the atmospheric or environmental infections or toxins that caused malarial fevers and typhoid fevers. Most commonly, patients were previously debilitated, or their vital powers were depressed in some way. In Woodward's classic formulation, this was the result of the depression produced by army camp life and malnutrition – particularly incipient scurvy. The disease required an area of endemic malarial fever, frequently a marsh, into which the animal causes of typhoid fever – crowding and improper sanitation – intruded. The debilitated individual in such an environment was almost sure to contract typhomalarial fever.

Clinical Manifestations and Pathology

The clinical course of the disease was extremely varied, depending on whether the malarial or typhoid elements predominated. When the malarial element was dominant, the symptoms were those of periodic fever – usually of the remittent rather than the intermittent variety. It was frequently quotidian but could be tertian, quartan, or irregularly remittent. However, the patient was more than usually depressed; there were frequent central nervous system symptoms, commonly stupor or coma, as well as gastrointestinal complaints, most commonly diarrhea. The disease was of more rapid onset than classic typhoid fever, but if the typhoid elements dominated, the disease would clinically resemble typhoid fever except for a definite periodicity, frequent hepatic tenderness, and a greater degree of splenomegaly, often with pain on palpitation. The convalescence would be more rapid than typical typhoid fever.

At postmortem there was a "greater tendency to the deposit of black pigment in the enlarged follicles" of the small bowel in typhomalarial than in typhoid fever. Furthermore, there were, in Woodward's (1863) formulation, some differences in the enlargement of the intestinal glands, the glands rising more gradually from the surrounding tissue in typhomalarial fever cases than in typhoid. By 1876, however, Woodward denied the significance of this supposed difference.

History and Geography

Woodward's concept was born of the frustrations of mid-nineteenth-century medicine, particularly in America.

1800–50

At the beginning of the nineteenth century, diagnosis was based almost entirely upon patient descriptions of their complaints – that is, the perceived func-

tional derangements that resulted in a consultation with the physician. The physicians placed these complaints in the context of their own experience and knowledge, made a diagnosis, and offered the patient their professional advice. Diseases were collections of symptoms appearing in known orders in particular locations; adjectives were frequently part of a diagnosis, providing further refinement to a relatively limited array of disease nouns. The most common disease was "fever," of which fever was the chief symptom. The symptom fever was essentially the subjective sensation of chill and heat and was related by the medical profession to a quickened pulse. Elevated body temperature was related to fever but was not objectively measured by most physicians until the last third of the nineteenth century. If there was an observed cause of the fever, particularly an inflammation, then the fever was symptomatic. Both pneumonia and erysipelas had symptomatic fevers associated with them. If there was not an observed cause of the fever, then the fever was *essential* – that is, a disease itself. The essential fevers were categorized by symptom variation, severity, location, pathological associations, and so forth.

The two main categories were *periodic* and *contin-ued* fever, but they were also categorized by such terms as malignant, pernicious, epidemic, putrid, spotted, and bilious, based upon the understandings of the physician observing a particular case. Periodic fevers – intermittent and remittent fevers, which had a classic periodicity – were believed to be caused by the atmospheric contamination of vegetable decomposition associated with marshes and other well-recognized areas of periodic-fever endemicity. During the nineteenth century, this poison came to be called "malaria," and the fevers it caused were "malarial" fevers. The continued fevers were more variable: Some were of short duration and only an inconvenience to the patient, whereas others were long and grave of prognosis. Those continued fevers with coma or stupor and of severe aspect were frequently called typhus by the Anglo-American medical world of the late eighteenth century. The adjective "typhoid" was applied to fevers that were typhus-like but not true typhus.

During the first half of the nineteenth century, a group of research-oriented, urban hospital-based physicians began to define disease on the basis of the postmortem findings as correlated with the clinical course. This hospital-based medicine was most strongly associated with the hospitals and pathologists of Paris, particularly René Laennec, Jean Corvisart, and Pierre Louis. In Great Britain, the

Irish clinicians William Stokes and Robert Graves and the London hospital physicians Richard Bright, Thomas Addison, and Thomas Hodgkins were part of the same movement. This approach to medicine spread through the world but did not fully replace the purely clinical approach, particularly among those whose chief interests were in medical practice. In 1829 Louis described a specific fever with lesions of Peyer's patches of the small bowel and named it "typhoid" because he thought it was the disease British authorities of the previous generation had called "typhus." This is, of course, the disease known today as typhoid fever.

All of this nosographic confusion was reflected in the American medical literature. Daniel Drake, the great medical geographer of the interior valley of North America, wrote about the typhoid stage of autumnal fever, by which he probably meant what we might call pernicious malaria. Louis's American students brought his view of typhoid to America, and one of them, James Jackson, Jr., demonstrated that what was commonly called autumnal fever in New England was the same disease Louis called typhoid. Another student of Louis, William Gerhard of Philadelphia, proved that the disease his mentor had termed typhoid was distinct from the disease usually called autumnal fever in Philadelphia.

Based largely on his New England practice and experience, Elisha Bartlett described typhoid fever as the most common disease in the United States. By 1847, however, he realized that malarial fevers were the dominant concern of physicians in the South and Midwest, but not enough people learned of the revised opinion. Support for almost any interpretation could be found in the medical literature of the period.

1850s–1870s

In the 1850s, as the American South became increasingly isolated culturally, there arose a campaign for a distinctively southern medicine. In part, this desire reflected real geographic differences in disease, but in part it was a result of the increasingly strident southern nationalism that led to the Civil War. As a result of this campaign and the preexisting nosological confusion, there was, by 1860, a belief in a southern typhoid fever that was occasionally periodic and frequently cured by quinine therapy.

Etiologic theories of the mid-nineteenth century also contributed to the confusion. Urban diseases, like typhus and typhoid, were believed to be the result of the unsanitary conditions of life in the early industrial city. Crowding, a general lack of cleanli-

ness, and a combination of animal and human waste, gave rise to a distinct and unpleasant odor in the cities. Where the smell was worst was also frequently the area of greatest morbidity, and it was believed that there were animal miasmas that caused urban fevers, much like the marsh miasmas (malaria) that caused rural fevers. If the two causes were simultaneously present, a combined or composite disease state should be expected. In the camps of the Civil War, that is exactly what was experienced, and typhomalarial fever was the name officially sanctioned for the camp disease that was not obviously a malarial or typhoid fever.

During and immediately after the war, an era when disease theory was changing and the diagnostic precision of the profession was limited, physicians found the concept of typhomalarial fever to be very useful and flexible in diagnosis. There were, however, serious doubts on the part of leading medical theorists concerning the specific nature of typhomalarial fever. In the 1870s, these doubts increased, but so did the utilization of the diagnosis. By the late 1870s, the specificity, in pathological terms, of typhomalarial fever was an idea of the past, but the clinical reality remained, and the name seemed to explain the etiology of the symptom complexities so described.

For the same reasons physicians in other parts of the world began seriously to consider the American diagnosis in the 1870s. In the 1860s, British army surgeons stationed on Malta had identified a new disease originally called gastric remittent fever and later Malta fever. We know it today as brucellosis. In 1875 W. C. Maclean, professor of military medicine at the Army Medical School at Netley, suggested that Malta fever might be typhomalarial fever. James Donaldson, on the other hand, suggested the name "faeco-malarial fever" to reflect more accurately the current understanding of dual causes. By the 1870s, the special role of human fecal matter in the propagation of typhoid fever was becoming accepted in Great Britain, largely as a result of the work of Charles Murchison and William Budd. Similar new diseases reported by the British doctors in the Indian Medical Service and the Chinese Imperial Customs Medical Service were also considered as typhomalarial fever by some authorities.

The primary interest of these physicians was in disease prevention, and the name "typhomalarial" lent force to their campaign for cleanliness. J. Lane Notter explained:

The cause then of this disease is, I maintain, a preventable one. It essentially consists in defective drainage, in having

to sleep in houses and breathe air impregnated with faecal organic vapours given off from saturated subsoil or filthy waterclosets, aided by climatic conditions which make enteric fever in Malta assume a malarial type, and which would, under similar conditions in England, simply produce typhoid fever.

1880s

In the 1880s the miasmatic etiologic speculations began to give way to the new germ theory of disease based in medical microbiology. Alphonse Laveran observed the malaria plasmodium; Georg Gaffky isolated *Salmonella typhi*. David Bruce discovered an organism that caused Malta fever; he called it *Micrococcus melitensis,* but the genus was subsequently named *Brucella*. However, the germ theory and medical microbiology were not immediately accepted by all or even most practitioners. Debate on typhomalaria remained lively, particularly in the American medical literature. Leading physicians saw etiologic research and eventual etiologic definition of disease as the way to resolve the clinical difficulties, but microbiological techniques remained largely in the realm of experimental pathology, not yet overly useful to practitioners. The possibility of specific diseases similar to typhoid and malaria yet etiologically unique remained viable, but the profession was divided on how prevalent such diseases might be. Periodic typhoid and severe malaria were clinically real and needed names. Debate continued, but the terms were changing.

1890s–1900s

In the 1890s, progress in medical microbiology and the development of serum diagnostic tests for typhoid and Malta fevers made etiologic definitions of disease more useful to practitioners, and doubts increased about the utility of typhomalarial fever as a diagnosis.

When America mobilized volunteers for the war with Spain in 1898, the sanitation in the camps was very bad. Disease was widespread and Army Surgeon General George Miller Sternberg appointed a commission of experts composed of Walter Reed, Victor Vaughan, and E. O. Shakespeare to investigate. Using modern techniques – blood smear examinations and Fernand Widal's serodiagnostic test – the commission proved that most of the cases diagnosed as typhomalarial fever were typhoid. Because the conditions, particularly in camps in the Deep South, approximated those under which Woodward had originally postulated the existence of typhomalarial fever, these results were particularly significant. By

the early twentieth century, the diagnosis of typho-malarial fever was widely regarded as an admission of diagnostic failure, and slowly it vanished from the medical literature.

Typhus, Epidemic

Epidemic typhus fever is an acute rickettsial disease transmitted among victims by the human body louse, *Pediculus humanus corporis*. Its characteristic symptoms include high fever, prostration, headache and body aches, and a widespread rash that covers the trunk and limbs of the body. Mortality rates in untreated cases vary widely. Broad-spectrum antibiotics provide an effective therapy for the disease.

Because of its association with conditions of human misery, typhus has been known by many names. *Jail distemper* and its variations – *morbus carcerum*, gaol fever, and jayl fever – indicate the prevalence of typhus in detention facilities. Ship fever, camp fever, and famine fever reflect the poor hygiene characteristic of travel, of military expeditions, and of refugee populations. The characteristic rash of typhus has elicited other descriptive names, including spotted fever in English, *Fleckfieber* and *typhus exanthematicus* in German, *typhus exanthé-*

matique in French, *tifo exantemático* and *tabardillo* in Spanish (the latter meaning "red cloak"), and *typhus-esantematico* in Italian. Although Hippocrates applied the word *typhus*, from the Greek word meaning smoky or hazy, to confused or stuporous states of mind frequently associated with high fevers, the word was not associated with the disease as it is currently known until the eighteenth century. After murine typhus was identified, the appellation *typhus historique* was sometimes applied to the classic, epidemic disease.

Etiology and Epidemiology

Occurring as a natural infection only in humans, epidemic typhus is caused by *Rickettsia prowazekii*. It is spread from host to host by the human body louse, *P. humanus corporis*, and less often by the human head louse, *Pediculus humanus capitis*. The body louse spends its entire existence in the clothes of humans. Eggs laid in the seams of the undergarments hatch after about 8 days, and the nymphs become adults in about 2 weeks, going through three molts. Each louse takes four to six blood meals a day from its host under natural conditions. Human blood constitutes its only food.

Once typhus organisms in infected human blood are ingested by a louse, they multiply rapidly in the cells lining the louse's intestines and are secreted in the feces of infected lice. Since rickettsiae are not found in other tissues (such as the salivary glands) of the louse, they are transmitted to new human hosts mechanically. This is usually accomplished by contact of infected louse feces with a small abrasion of the skin incurred when the human scratches the unpleasant itch caused by feeding lice. The disease spreads when lice leave feverish or dead victims for new hosts with normal temperatures. Unlike other rickettsial organisms, *R. prowazekii* is not passed from generation to generation in the eggs of its host arthropod. In fact, as Hans Zinsser of Harvard Medical School pointed out in his 1935 history of typhus fever, humans constitute a great threat to the health and happiness of these small creatures, for humans usually recover from typhus fever, whereas the disease is inevitably deadly for infected lice.

Typhus is widely known as a disease of cold climates, appearing in epidemics that usually reach their peaks in late winter and taper off in the spring. This pattern is clearly related to the ideal conditions for multiplication of lice and their rapid transmission to new hosts. Typhus flourishes when people are crowded together in unsanitary surroundings and

lack fuel, circumstances that predispose them to wear the same garments day and night for months at a time.

Persons of all ages are susceptible to typhus. Mortality rates in untreated typhus fever vary between 5 and 25 percent, occasionally reaching 40 percent. In children under 15 years of age, however, the disease is generally mild. As age increases, so does mortality.

Clinical Manifestations and Pathology

After an incubation period that may vary from 5 to 15 days, the onset of typhus is abrupt. Many patients are able to state the exact hour at which they noted the beginning of their illness. Headache, loss of appetite, and general malaise are followed by a rapidly rising fever. Bouts of chills, nausea, and prostration characterize the first week of illness. The most characteristic symptom of typhus is a widespread rash that appears about the fourth to sixth day after onset. Dark, reddish, discrete spots 2 to 5 millimeters in diameter appear scattered over the body and limbs. These lesions at first are bright red, but they rapidly become darker in color and more petechial in character. After recovery, the rash usually fades, but in rare cases it may leave a brownish stain that persists for several months.

During the first 2 or 3 days, the fever reaches its maximum, between 102° to 105°F, and is sustained for another 5 days, after which it falls rapidly if the outcome is favorable. In fatal cases, however, prostration becomes more progressive, with neurological symptoms increasing. These may include deafness, stupor, delirium, and eventually coma preceding death. Since 1948, however, when chloramphenicol and the tetracyclines (known collectively as broad-spectrum antibiotics) were introduced, no one need die of typhus if diagnosis is made in a timely manner.

Immunology

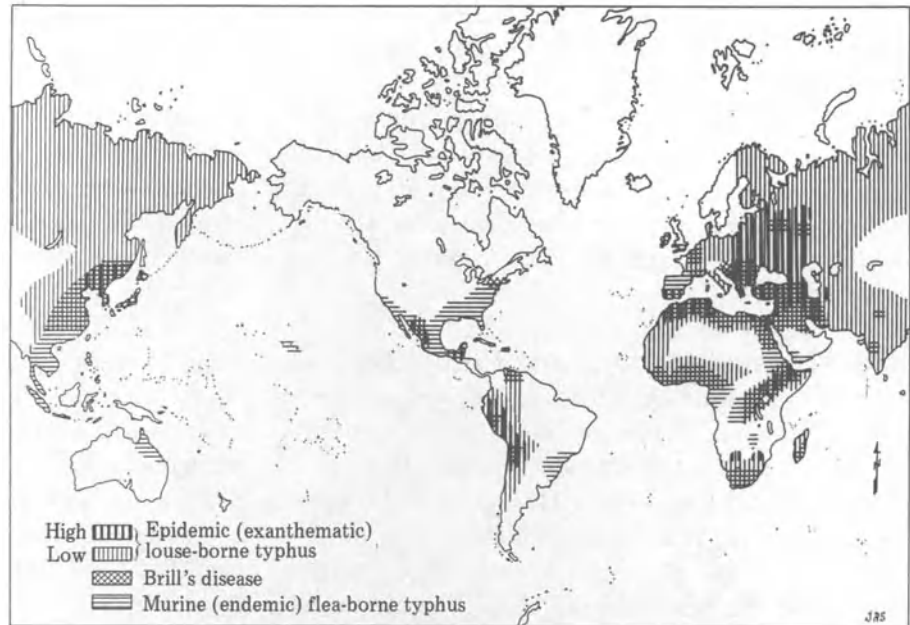
An attack of typhus confers long immunity. Many children in regions where typhus is frequent may contract subclinical or mild cases that protect them somewhat from a later, more severe infection. Because R. prowazekii persists in the tissues of its victims even after recovery from the disease, however, symptoms of the disease may reappear years later, especially under conditions of stress when a victim's immune system is depressed. This phenomenon was noted but not recognized in 1898, when New York physician Nathan Brill described a disease frequently diagnosed as typhoid but having symptoms more closely related to typhus. In 1910 Brill published an exhaustive study of 221 cases, and his thoroughness led to the designation of "Brill's disease" as a catchall for unknown, typhus-like symptoms. Two years later, U.S. Public Health Service investigators John F. Anderson and Joseph Goldberger demonstrated reciprocal cross-immunity in monkeys between Brill's disease and epidemic typhus.

For the next two decades, moreover, because of ignorance surrounding many other rickettsial diseases, illnesses exhibiting typhuslike symptoms anywhere in the world were often classified as Brill's disease. In 1934 Zinsser correctly hypothesized from epidemiological data that Brill's disease was a recrudescence of epidemic typhus in persons who had earlier suffered an attack of the classic disease. During the 1950s, laboratory investigations confirmed his hypothesis, and the disease was renamed Brill–Zinsser disease.

The first laboratory diagnostic test for typhus grew out of a chance observation in 1916 by Viennese physician Edmund Weil and his English colleague Arthur Felix that a strain of Bacillus proteus was agglutinated by the sera of typhus patients. Later studies revealed that the phenomenon was a chance antigenic "fit," but the Weil–Felix reaction, as it came to be called, provided a laboratory tool that became useful in several rickettsial diseases. In 1941 a more specific complement-fixation test was developed, and during the 1970s a variety of new techniques have improved the sensitivity and accuracy of laboratory diagnosis.

Distribution and Incidence

In all areas of the world where public health and sanitation measures have been rigorously enforced, the incidence of typhus has declined dramatically. Cases may erupt in urban slums, and the disease remains a threat to many isolated rural regions. Reporting of cases is poor in many regions of the world where typhus is most prevalent. Map VIII.151.1 shows the worldwide distribution of epidemic typhus during World War II. A recent study indicates that the major areas where typhus-infected lice are widespread have been reduced to three: the Himalayan region of Asia, the Andean regions of South America, and the horn of Africa, especially famine-ridden Ethiopia. In November 1984, for example, 68 cases were serologically confirmed in one Ethiopian refugee camp. Following treatment with tetracycline antibiotics, however, only three people died. Thus typhus, although causing considerable morbidity, is not at present as great a killer as in past centuries.

Map VIII.151.1. Outline map of the world (c. World War II), showing the approximate geographic distribution of epidemic (exanthematic) louse-borne typhus, murine (endemic) flea-borne typhus, and Brill's disease. (From Stanhope Bayne-Jones, in U.S. Army Medical Department 1964, 177.)


History and Geography

Antiquity Through The Sixteenth Century

As a disease having a human reservoir, epidemic typhus has undoubtedly existed for centuries. Although it has been speculated that certain ancient plagues were probably typhus, the first contemporary accounts of a disease that may well have been typhus appeared near the end of the fifteenth century. In 1489–90 during the civil wars of Granada, Spanish physicians described a typhus-like disease that killed 17,000 Spanish soldiers – six times the number killed in combat with the Moors.

In the early sixteenth century, a similar malady appeared in Italy. During the French siege of Naples in 1528, an apparent typhus epidemic may have altered the subsequent course of European history. The French were at the point of decisive victory over the forces of Charles V when the disease appeared and struck down 30,000 French soldiers, forcing the remnants of the army to withdraw. In 1546 Girolamo Fracastoro (Fracastorius), who had observed the epidemics in Italy, published the first clear description of what he termed a "lenticular or punctate or petechial" fever also characterized by headache and general malaise.

In the Balkan regions, where German, Italian, and French troops assembled to combat the Turks, many soldiers were struck by typhus even before they reached the battlefield. As it was disseminated across Europe by forces returning from Hungary, typhus became known as *morbus hungaricus*. Toward the end of the sixteenth century, typhus was also recorded in the Mexican highlands, where it killed more than 2 million Amerindians. It remains unclear, however, whether the disease was brought to the New World by Spanish explorers or, as some evidence indicates, was known to the Aztecs and some pre-Columbian Indians in Mexico.

Early to Mid-Nineteenth Century

Typhus increased dramatically in the early nineteenth century. In 1812 Napoleon's catastrophic expedition to Russia was plagued by typhus. Between 1816 and 1819, moreover, a great epidemic of the disease struck 700,000 people in Ireland, whose population was only 6 million. For several decades, however, confusion characterized medical understanding of the disease. By the late eighteenth century, the medical nosologist Boissier de Sauvages had begun using the word *typhus* to describe the neurological symptoms of typhus, but few attempts were made to distinguish pathologically between typhus and typhoid fever, which also produced a red rash. Even into the twentieth century, confusion between typhoid and typhus was perpetuated in the nomenclature. In many European countries, the former was known as *typhus abdominalis* and the latter as *typhus exanthematicus*.

In 1837 Philadelphia physician William Wood Gerhard, who had studied the distinctive intestinal lesions of typhoid as a student of Pierre Louis in Paris, noted their absence in victims of typhus fever, which had been epidemic in Philadelphia the previous year. Gerhard's work, however, was not immediately embraced by physicians who clung to older theories of the unity of fevers. It was not until mid-century

that additional pathological and epidemiological re-search, especially by William Jenner and Austin Flint, convinced most American physicians that ty-phus and typhoid were distinct disease entities.

The European revolutions of 1848 spawned typhus epidemics in eastern Europe, as did warfare in Ethio-pia. During a particularly severe typhus epidemic in Upper Silesia, the German physician and politician Rudolph Virchow published a radical assessment of the epidemic that subsequently cost him his govern-ment post. Observing that the disease afflicted the poor, the uneducated, and the unclean, Virchow called for democracy, education, and public health measures as the proper "treatment" of the epidemic.

Late Nineteenth Century Through World War I
Although typhus itself subsided during the latter half of the nineteenth century, the advent of the germ theory of disease during the 1870s spurred bacteriologists to search for a microbial cause for the classic scourge. In 1909, exploiting recent discover-ies about the role of insect and other arthropod vec-tors of microorganisms, Charles Nicolle, director of the Institut Pasteur in Tunis, North Africa, demon-strated that the body louse was the vector of typhus. The following year, Howard Taylor Ricketts, who was investigating typhus in Mexico City, described small bacteria he found in the blood of typhus vic-tims, in infected lice, and in lice feces. Before Rick-etts could confirm his observations, he contracted typhus and died. In 1916 the Brazilian Henrique da Rocha Lima described similar organisms, which he named *Rickettsia prowazekii*, the genus name after Ricketts and the species name after Polish re-searcher Stanislaus von Prowazek, who had also died from a laboratory-acquired typhus infection.

During World War I, military forces on both sides of the conflict acted on Nicolle's discovery, institut-ing delousing procedures to combat typhus. These included bathing and steam-treating clothing to kill lice. Among poor civilian populations in war-torn eastern Europe, where such preventive measures were not enforced, the disease continued to exact a high rate of mortality. In 1915 Serbia was particu-larly hard hit, and typhus settled with a vengeance on Russia and Poland after 1918. Typhus research in Poland after World War I, sponsored by the League of Red Cross Societies, confirmed Rocha Lima's asser-tion that *R. prowazekii* was the cause of typhus. Even so, because rickettsiae could not be cultured on lifeless media like ordinary bacteria, their etiologic relationship to typhus and other rickettsial diseases was not firmly established until the late 1930s.

Postwar Period Through World War II
During the 1920s and 1930s, empirical research on a vaccine against typhus was hampered because the organisms could not be grown in necessary quanti-ties outside of living cells. Displaying ingenuity in the face of this limitation, researchers prepared vac-cines from infected lice intestines, from lice feces, and from the typhus-infected lungs of rats. Then in 1937 U.S. Public Health Service investigator Herald R. Cox discovered that rickettsiae grew luxuriously in the yolksacs of fertile hens' eggs. This method simplified vaccine production and made it commer-cially feasible just as the onset of World War II again raised concern about large-scale typhus epidemics.

The threat of typhus was a key factor in Allied military plans during World War II, and in 1942 Presi-dent Franklin D. Roosevelt created an extraordinary body, the U.S.A. Typhus Commission, to combat ty-phus wherever it might threaten the U.S. military efforts. The so-called Cox vaccine was administered to all Allied military personnel, and although experi-ence during the hostilities indicated that it did not actually prevent the disease, it clearly ameliorated its course. Intensive research on antilouse agents by government and private groups, moreover, demon-strated that lice could be effectively controlled by dichlorodiphenyl-trichloroethane, more commonly called DDT. This powder could be applied with a "blowing machine" to puff it under clothes without their owners having to remove them. The method was not only faster, it was also accepted by even the most modest civilians. DDT also proved to be highly effec-tive in the typhus epidemic that occurred during the winter of 1943–4 in Naples, Italy. With astonishing rapidity, the nascent epidemic collapsed. Within two decades, however, the ability of lice to become resis-tant to DDT had been documented. In addition, the chemical's ecological hazards were found unaccept-able, and it is no longer widely used to prevent typhus.

Prophylaxis and control of typhus with the Cox vaccine and with DDT during World War II reduced typhus from a major threat to a mere nuisance among Allied troops. Only 104 cases occurred among U.S. military personnel, with no deaths. In contrast, severe epidemics occurred among civilians in North Africa, Yugoslavia, the German concentra-tion camps, Japan, and Korea.

Mid-Twentieth Century to Present
In 1948 the tetracyclines and chloramphenicol, known together as broad-spectrum antibiotics, were discovered to be effective treatments for rickettsial

diseases. Since the late 1940s, efforts to combat typhus have depended almost exclusively on these antibiotics. In 1980 concern about the limited efficacy and side effects of the Cox vaccine halted its production, and at the present writing, no typhus vaccine is commercially available. Recent research, moreover, has indicated that the humoral immunity stimulated by all existing rickettsial vaccines is less important than is cell-mediated immunity. At present, genetic engineering techniques are being employed in research on a more effective vaccine.

Since 1950, typhus has been reported most frequently from the horn of Africa, from the high plains of the Andes in South America, and from the Himalayan regions of Asia – all areas characterized by rural poverty and cold weather. In one survey of Bolivian army recruits, for example, 80 percent had antibodies against the disease. Another study in a Bolivian village near the Peruvian border found mild typhus in children often confused with measles. Typically, the disease was more severe in afflicted adults than in children.

In Ethiopia, with its frequent famines, thousands of cases of typhus have been documented in recent years, especially in refugee camps. Similar ecological and sociological conditions in neighboring countries suggest that the disease may also be widespread in them but masked by poor reporting. Reliable statistics are also virtually impossible to obtain from the Himalayan regions of Asia.

Since Nicolle's identification of the body louse as the vector of typhus, the slogan "no lice, no typhus" has been the watchword of public health efforts against this disease. But as Hans Zinsser noted in 1935, typhus will always remain a smoldering threat, ready to break out at any time that war, famine, or other catastrophes remove the public health barriers against it.

VIII.152
Typhus, Murine

Murine typhus is an acute illness characterized by symptoms similar to those of epidemic typhus but milder in character. Unlike its epidemic relative, it is a natural infection of the rat and transmitted sporadically to humans by the rat flea, *Xenopsylla cheopis*. Its relation to the rat is reflected in the name *murine* typhus. The etiologic agent is *Rickettsia typhi*.

Clinical Manifestations

Symptoms and the course of illness in murine typhus are similar to those in epidemic, louse-borne typhus. For this reason, distinguishing between the two diseases has been difficult. The flea-borne illness, however, is almost never fatal, with about a 2 percent mortality in persons over age 50.

Etiology and Epidemiology

Murine typhus is found worldwide and is infectious for persons of all ages (see previous chapter, Map VIII.151.1). Those living or working in areas where rats are abundant are most susceptible. Like epidemic typhus, murine typhus is transmitted mechanically, through rubbing infected feces of the flea *Xenopsylla cheopis* into a skin abrasion, through the eye, or through mucous membranes of the respiratory tract. In the years following World War II, active campaigns against rats and their fleas with DDT and rodenticides sharply reduced the incidence of murine typhus in the United States.

The causative agent of epidemic typhus is known as *R. typhi*, although some investigators prefer to call it *Rickettsia mooseri* in honor of Herman Mooser, a Swiss pathologist who, working in Mexico, differentiated between this organism and *Rickettsia prowazekii*. In guinea pigs, *R. typhi* causes a characteristic reaction in scrotal cells useful for distinguishing between murine and epidemic typhus. First noticed in 1917 by U.S. Public Health Service investigator Mather H. Neill and confirmed nearly two decades later by Mooser, the reaction became known as the Neill–Mooser phenomenon.

History and Geography

Although murine typhus was identified only during the twentieth century, it may be an even older disease than classic, epidemic typhus. Neither of the two hosts of *R. typhi*, the rat and the rat flea, suffer ill effects from their infection with the organism, whereas *R. prowazekii* inevitably kills its vector louse and causes a serious illness in its human host.

Sporadic cases of typhuslike fevers in areas free from lice were reported early in the twentieth century in the United States, Malaya, and Australia. Often these infections were designated by local names, such as "urban" or "shop" typhus. It was not until 1926, however, that the distinctiveness of this disease was recognized. During an epidemiological investigation of such cases in the southeastern United States, U.S. Public Health Service investigator Kenneth F. Maxcy described an *endemic* form of typhus fever and postulated that some ectoparasite of the rat might be its vector. By 1931, infected fleas had been found in nature, confirming Maxcy's hypothesis. Although the name "endemic typhus" was used for some time, it was shortly observed that the disease could occur in epidemics as well as sporadically. In 1932 Mooser proposed that the disease be called "murine typhus" instead to indicate its relationship to rats.

Although broad-spectrum antibiotics provide effective treatment against this disease, its mild course and low fatality rate make these measures almost unnecessary. By the time the disease is diagnosed, the patient is usually in convalescence.

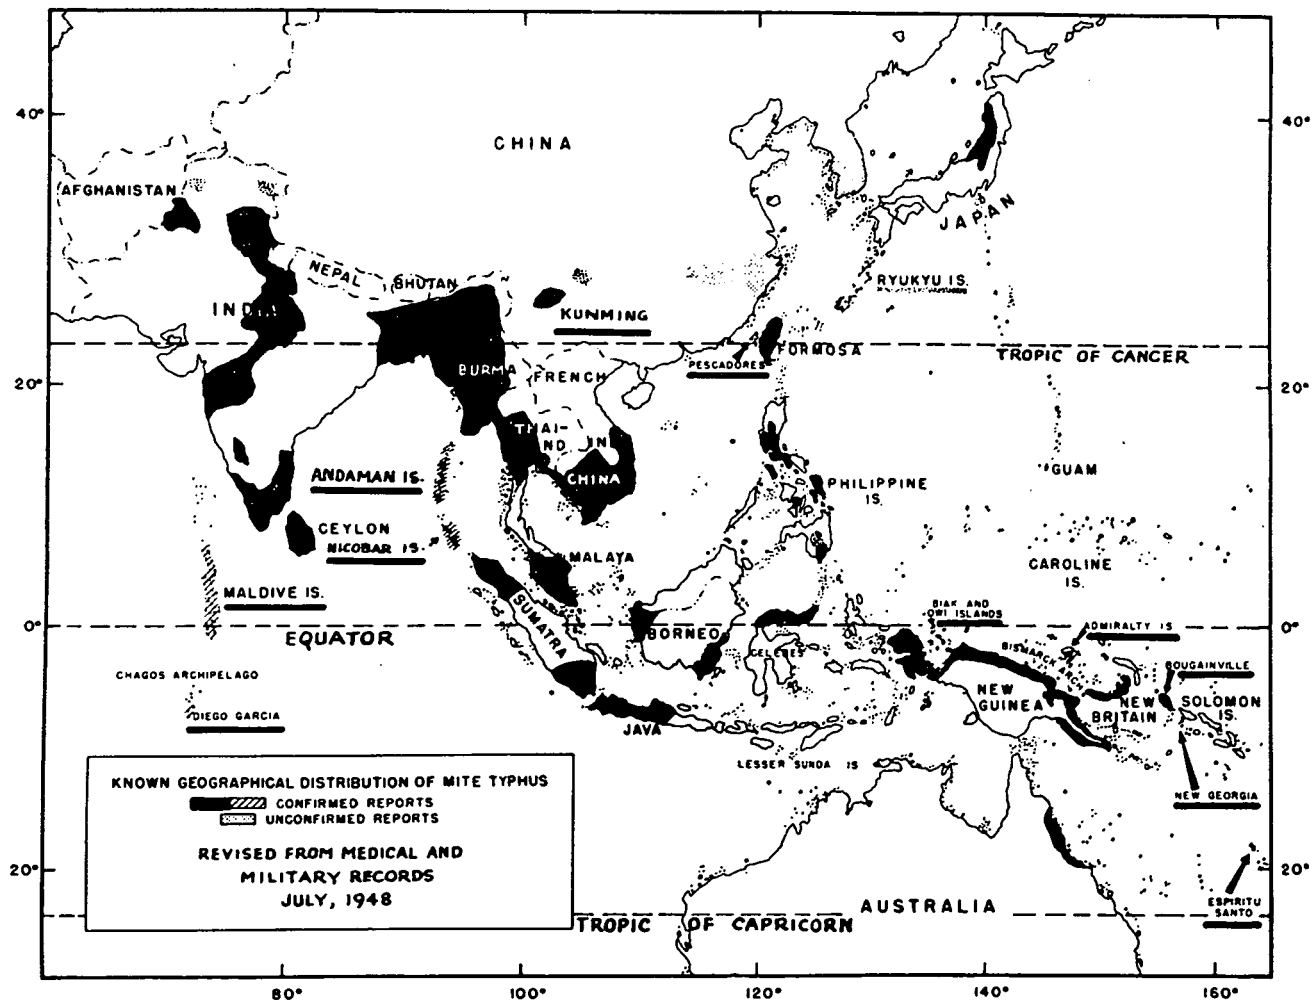
VIII.153
Typhus, Scrub
(Tsutsugamushi)

Tsutsugamushi, like epidemic typhus, has been known in the Orient for centuries. In 1810 the Japanese Hakuju Hashimoto described a *tsutsuga* (disease) along the tributaries of the Shinano River. A similar disease, thought to be carried by mites, or *mushi* in Japanese, had also been known at least since the sixteenth century in southern China. Sometimes called Japanese flood fever, tsutsugamushi is more commonly known in the United States as scrub typhus – a name used widely by English-speaking troops during World War II. The disease exhibits characteristic typhuslike symptoms of high fever, headache, duration of 2 weeks, and a widespread rash.

Distribution and Incidence

The geographic boundaries of this malady are defined by the range of its vectors, primarily the trombiculid mites, *Lentotrombidium akamushi* and *Leototrombidium deliensis,* and their vertebrate hosts. They extend from India and Pakistan in the West, to Japan and the northern portions of Australia, including all the countries of Southeast Asia, southern China, Korea, the Philippines, and Indonesia, as well as additional islands in the Pacific Ocean (see Map VIII.153.1). During World War II, the incidence of scrub typhus rose dramatically among military troops, reaching 900 per 1,000 personnel in some areas. It continues to remain a problem in isolated, rural areas.

Etiology and Epidemiology

The etiologic agent of scrub typhus, *Rickettsia tsutsugamushi,* is a natural infection of several trombiculid mites, most commonly *L. deliensis*. Maintained in


Map VIII.153.1. Known geographic distribution of mite (scrub) typhus in Asia, July 1948.

nature by generational transmission through the eggs of the female, the disease is communicated to humans only during the larval stage of the mite's life cycle. At this time, the six-legged larval mite, often called a "chigger," seeks an animal on which to find a meal of tissue juices, or lymph. Usually they feed on field mice, rats, tree-shrews, and other small mammals, but humans are satisfactory if they happen into the mite's environment. Ground-frequenting birds may also become infected and transport infected mites to a new location. In later stages of their lives, the mites live in the soil and not in animals.

Because of the wide geographic area across which tsutsugamushi is spread, its epidemiological pattern varies. In the Niigata region of Japan, for example, the disease is most common during the summer months, associated with increased incidence of the mite *L. akamushi,* whereas in the Chiba and the Kanagawa prefectures and the Izu Schichito Islands, it occurs in mild form throughout autumn and winter. In Malaya, a hot, tropical climate supports the disease throughout the year, and near the India–Burma border it is usually associated with the monsoon season.

Similarly, a variety of terrains may support the development of the vector mites, including grassy fields, river banks, neglected or abandoned rice fields, overgrown clearings, forests, jungles, and border areas between field and forest. The key requirements in any area include a suitable rodent population and sufficient ground moisture to support the mites. The "islands of infection" in which scrub typhus typically occurs apparently represent favorable ecological conditions for the mites.

Clinical Manifestations

Scrub typhus incubates in human hosts for about 10 to 12 days, after which it manifests itself suddenly, with chills and fever, headache, and other typical typhuslike symptoms. In most Caucasians and, less frequently, in Asians, an *eschar* or initial lesion from the mite bite occurs and causes lymph-gland swelling. During the first week of the disease, the fever increases to 104° or 105°F. Between the fifth and the eighth day, a red macular rash appears on the trunk of the body, and it may extend to the arms and the legs. During the second week, the pulse rate may increase to 120 or 140, blood pressure falls, and neurological symptoms such as deafness, stupor, delirium, and muscle twitching may appear in untreated patients. Pneumonia and signs of circulatory failure may also occur, but by the beginning of the third week, those untreated individuals who recover begin to experience a reduction in fever and other symptoms. Those who die usually do so by the end of the second week from circulatory failure or from secondary pneumonia or encephalitis. Even in recovered patients, however, neurological effects may continue, and convalescence is usually long. Fortunately, the broad-spectrum antibiotics have reduced the mortality in treated patients to nearly zero.

Unfortunately, the immunity conferred by this infection is specific to the scrub typhus strain only. Current infections may occur when the individual is infected by other strains.

History and Geography

Reports of tsutsugamushi reach back to at least the sixteenth century in the Orient. Bacteriologic investigations of the disease began in Japan in the early 1890s when it captured the attention of Shibasaburo Kitasato, who had returned from his work with Robert Koch in Germany to found the Institute for Infectious Diseases in Tokyo. Various other researchers, principally Japanese, continued to study the disease through the first three decades of the twentieth century, identifying its causative microbe as a rickettsiae.

Renewed investigation by Western scientists was stimulated by severe outbreaks of scrub typhus in the Pacific and the China–Burma–India theaters during World War II. With the Allied countermove to stem the rapid Japanese advance in the Pacific, the occupation of islands often took place in haste, and groups of soldiers would shortly become very ill. Between January 1943 and August 1945, scrub typhus disabled some 18,000 Allied troops, including 6,685 American servicemen. Fatality rates varied from a low of 0.6 percent in some regions to as high as 35 percent in others; there were 234 deaths among U.S. troops.

Throughout the 1920s and 1930s, British researchers and their colleagues at the Institute of Medical Research in Kuala Lumpur, Federated Malay States, had observed that tsutsugamushi was distinguished from other typhuslike diseases by its reaction to a particular strain of bacteria used in the Weil–Felix test. When the U.S. Typhus Commission began to study scrub typhus ("because of its last name" as Commission Director Stanhope Bayne-Jones noted) the Weil–Felix diagnostic test was virtually the only laboratory tool available. Numerous experts in medicine, epidemiology, and entomology were called upon to examine the problem, and, by the end of the war, two major lines of defense against the disease had been developed.

The first was prevention. The army launched education efforts, including posters describing the mite, where it was likely to be found, and how soldiers should prepare their campsites to avoid it. In addition, chemicals were developed to impregnate clothing that would repel the tsutsugamushi mite. Benzyl benzoate proved to be effective and lasted 2 weeks before reapplication was necessary. The second line of defense focused on intensive research to develop an antiserum or a vaccine against tsutsugamushi. World War II ended, however, before either could be made practical. In 1948, the broad-spectrum antibiotic chloramphenicol was tested at the Institute of Medical Research in Kuala Lumpur and found to be highly effective as treatment for the disease.

VIII.154

Urolithiasis (Renal and Urinary Bladder Stone Disease)

The major forms of urolithiasis consist of either upper tract stones within the kidneys or ureters (renal stones) or lower tract stones formed within the bladder. These two forms of urolithiasis have distinct differences in etiology, chemical composition, and epidemiological features, and should therefore be considered two separate diseases.

Historical evidence has shown a striking increase in incidence of renal stone disease in more developed countries over the past 100 years. There has been a simultaneous decrease in bladder stone incidence, demonstrating an inverse relationship between the two disorders. Changes in the environment have a profound effect on the epidemiology of human diseases. An unusual example of this interplay is the role of dietary change in the shifting epidemiological pattern from bladder stone to renal stone disease.

Etiology

The large majority of bladder stones occur in young boys from rural or impoverished areas. In these regions, the disorder is known as endemic bladder stone disease. Information from both historical and experimental sources points to a nutritional deficiency during infancy or possibly in utero as the major factor in endemic bladder stone formation. Other less common causes of bladder stone are schistosomiasis (producing bladder wall thickening, stricture, and outlet obstruction) as well as obstruction in elderly males from benign prostatic hypertrophy.

Although deficiencies of vitamin A, vitamin B$_6$, or magnesium have been suggested in endemic bladder stone disease, low intake of animal protein in combination with high intake of grain carbohydrate is more important. Indeed, it seems that whereas low animal protein intake in infancy may cause bladder stone, a high animal protein diet provokes renal stones (Robertson 1978). This probably explains the epidemiological enigma of the disappearance of endemic bladder stone as areas improved economically, with a concomitant increasing incidence of renal stone (Table VIII.154.1).

Low intake of animal protein and high intake of grain carbohydrate produce more acidic urine and decreased urinary phosphate excretion. These in turn

Table VIII.154.1. *Major features differentiating bladder and renal stone disease*

Features	Bladder stone	Renal stone
Age	Young children	Adults
M/F ratio	12:1	1.2:1
Socioeconomic class	Poor, usually rural areas	All classes affected in more developed countries
Diet	Almost strictly vegetarian; animal protein intake <10 g; high grain intake	Increased meat consumption; animal protein >40 g; high intake of refined sugar
Chemical composition	Ammonium acid urate, uric acid, calcium oxalate	Calcium phosphate, calcium oxalate, other
Recurrence	Rare	Frequent

decrease the solubility of calcium oxalate and uric acid leading to bladder stone formation. Conversely, greater animal protein intake produces more urinary phosphate. An increased intake of refined sugar plus a decreased intake of fiber increase the intestinal absorption of calcium. Increased protein and sucrose intake cause increased urinary calcium excretion, possibly secondary to a distal renal tubular acidosis. This sets the stage for calcium phosphate or calcium oxalate stone formation in the kidneys.

Other less common types of renal stones have specific etiologies. For example, cysteine stones are created by a genetic defect in renal tubule reabsorption of certain amino acids. Repeated urinary infections can result in magnesium ammonium phosphate stones. A number of systemic diseases can cause hypercalcemia with subsequent calcium stone formation. These include hyperparathyroidism and Cushing's syndrome.

Finally, a multitude of other factors also operate in renal stone formation or prevention. Substances known as stone inhibitors are normally present in the urine. Dehydration, by producing relative stasis and more concentrated urine, is an added factor in stone formation and partially explains the increased incidence in hot and arid climates and seasonal increases during summer months.

Epidemiology and Geographic Distribution

Bladder Stone Disease

Among early authors, Galen during the second century in Rome and Albucasis during the eleventh century in Spain observed the frequent occurrence of bladder stone in young boys. Bladder stone still primarily affects boys under 10 years of age. Among approximately 7,000 cases from Thailand, the median age at operation was 4.5 years. Almost 95 percent of all patients were male (Halstead 1961). Numerous clinical studies of the disease in other regions confirm the occurrence at an early age and a marked predominance of male patients (Thomson 1921; Racic 1935; Brown and Brown 1941; Eckstein 1961).

Anatomic differences in the urethra of males and females probably account for the infrequency of bladder stone in females. The female urethra is short, wide, and straight, allowing stronger flow of urine and passage of gravel before large stones are formed.

Bladder stone disease occurs in agricultural regions, particularly in the lower economic classes. Fifty years ago, bladder stone commonly occurred in the inland districts of the Balkans, where living conditions were very primitive. At the same time, the disease was rare along the Adriatic coast, where better living conditions prevailed (Anderson 1972). Bladder stone was quite common in the economically depressed rural areas of Norfolk, England, during the eighteenth and nineteenth centuries, whereas the disease was rare among the more affluent people living in the adjacent urban centers (Thomas 1949; Batty Shaw 1970). A similar disparity is seen today between the rural farmers and city dwellers of Thailand and northern India (Halstead 1961; Anderson 1969, 1972).

Accurate figures on the prevalence of bladder stone disease come from northeast Thailand, where over 20,000 people were interviewed. A history of past or present bladder stone was obtained in 3.8 percent. A small group (0.33 percent) had required surgical removal of the bladder stone (Halstead and Valyasevi 1967). Contrary to this low number, nearly 2 percent of all admissions to the Norfolk and Norwich Hospital during the period 1772–1816 were for removal of bladder stone (Batty Shaw 1970).

Historical accounts from the 1500s to the mid-1800s document the prevalence of the disease throughout Europe, Asia, and America (Anderson 1962; Lonsdale and Mason 1966; Batty Shaw 1970; Prien 1971). Bladder stone remains quite common in Egypt, northwest India, southern China, Thailand, Afghanistan, Iraq, Turkey, and Madagascar. Prior to 1940, bladder stone was also common in portions of Iceland, Russia, Hungary, Indonesia, Tunisia, and Sicily.

Renal Stone Disease

Renal stone disease has mainly been an affliction of the more industrialized and affluent countries of Europe, North America, and Japan and has been uncommon or unknown in impoverished regions and primitive societies. However, people in these areas have developed a similar prevalence with improvement in living conditions and subsequent dietary changes (Modlin 1967).

Population studies in both America and Europe reveal prevalence rates for renal stone ranging from 3 to 13 percent. Nearly 75 percent of these people with so-called idiopathic calcium stone disease have one or more recurrences, implying a continuous exposure to risk factors such as diet. The incidence of the disease has risen continuously since the turn of the century except for brief declines during both world wars – again pointing to dietary changes as an important factor.

Unlike bladder stone disease, renal stones occur predominantly in adults. Men are affected slightly more often than women.

History and Paleopathology

Epidemiological studies have shown that bladder stone is a disease of communities where the diet is high in grain or rice and low in animal protein. With dietary changes resulting from improved technology, migration, or cultural shift, bladder stone disease is replaced by renal stone disease. This is well demonstrated over the past two centuries in parts of Britain, France and other European countries, Russia, China, and Turkey. It is therefore not surprising that ancient references to stone disease deal almost entirely with bladder stone, with rare mention of the renal colic characteristic of upper tract stones.

Bladder stone was common in ancient Persia (600–300 B.C.), particularly in infants, and was considered a result of ingesting sour milk, fruits, or acidic drinks. The Babylonian *Talmud* contains references to bladder stone disease and includes the ingenious suggestion that patients should urinate on the doorstep in order to see the stone.

In India, the *Rig Veda* and *Atharva Veda,* inscribed around 1500 B.C., consist of incantations against disease, including bladder stone. The *Ayur Veda,* published much later, around the first century A.D., described suprapubic incision for removing bladder stones. In the second century A.D., Charaka described four types of stones, almost certainly originating in the bladder. The first was white and as large as a hen's egg; the second was rough and covered with spines; the third was of a dark color; and the fourth was composed of sperm. The first three stones were probably urate and calcium oxalate bladder stones typical of endemic disease.

Early Chinese literature contains few references to any recognizable disease. However, detailed case histories of 25 patients treated by Shunyü I in the second century B.C. have been preserved. They include a palace superintendent afflicted with hematuria, urinary retention, and bladder stones. This may represent a case of either schistosomiasis or endemic stone disease (Lu and Needham 1967).

In Greece, Hippocrates had earlier recognized both renal and bladder stone and recommended diuretics and ingestion of large quantities of water for their removal. He considered wounds of the bladder wall as invariably fatal and therefore specifically forbade his followers to cut for the stone.

The Assyrian *Book of Medicine,* probably written around 300 B.C., includes much of the work of Hippocrates. Among the numerous prescriptions for various maladies are two elaborate potions for flushing out or dissolving renal stones. The latter recipe contains 50 substances with particular emphasis on camphor and vinegar. Other Assyrian works contain directions for infusing various preparations into the bladder through a bronze tube to dissolve bladder stones (Thompson 1934).

In Alexandria around 100 B.C., Ammonios developed an instrument for crushing stones within the bladder. In the first century A.D. in Alexandria, Rufus of Ephesus gave detailed instructions for removing bladder stones through a transverse perineal incision.

In Rome during the same century, Celsus performed numerous operations for bladder stone in boys 9 to 14 years of age. His eight-volume *De Medicina* contains a precise description of transverse perineal lithotomy followed almost without modification until the sixteenth century. Galen described the lateral perineal lithotomy, but, more importantly, noted the frequent occurrence of bladder stone in young boys. He also tried giving stone solvents (lithotryptics) in an effort to dissolve the stones.

In Arabic medicine, Rhazes at about the turn of the tenth century described both renal and bladder stones, and he implicated increased salt intake and hot weather as factors in renal stone formation. Around a century later, Avicenna thought that bladder stones formed when the urine contained an excess of matter (Bitschai 1952).

By the eighteenth century, more and more sur-

geons were attempting the dangerous lateral peri-neal lithotomy. Special hospitals for bladder stone patients were opened in England, France, Holland, and elsewhere. In 1753, Frère Come opened such a hospital in Paris and operated on over 1,000 patients. The Norfolk and Norwich Hospital was founded in 1771, and one of every 55 admissions in this endemic region was for removal of bladder stone.

Through paleopathology and careful archaeological technique, actual specimens of ancient renal and bladder stones have been recovered from skeletal and mummified remains. This material has been extensively reviewed elsewhere and is summarized in Table VIII.154.2 (Steinbock 1985).

Varicella Zoster

Varicella (chickenpox) is an acute infection of short duration caused by *Varicella–Zoster virus* (VZV), which is spread in the early stages of disease by droplets of secretions from the nasopharynx. It is followed by lifetime latency that may be broken in occasional patients by reactivation of virus in sensory ganglia manifested as *herpes zoster* (shingles).

Epidemiology and Incidence

Chickenpox is endemic worldwide, is highly communicable, and commonly appears as epidemics among children who are usually attacked between 2 and 8 years of age. (Infants are protected by transplacental maternal antibodies.) Few escape infection until adult life, and these usually live in isolated rural communities. Probably most of those who have seemed to escape the disease had subclinical infections. (The annual *Report of Morbidity and Mortality in the United States* shows, for 1984, 221,983 cases of varicella reported from 33 states, an incidence of 138 cases per 100,000 population. The age was known in 28 percent; 56 percent of these cases appeared in the 5- to 9-year age group, less than 6 percent were 15 years of age or older.)

The sporadic reactivation of the virus as shingles is unrelated to exposure to exogenous infection and, in general, is uncommon even in populations in which practically all have had chickenpox. Its peak incidence is after age 50. Of those who develop shingles, only 1 percent have two attacks. Patients with impaired cellular immunity are at risk, and herpes

zoster is not uncommon in those suffering from malignant disease.

Immunology

A viremia develops promptly after infection with VZV of which there is only one serotype. Circulating antibody is demonstrable within 1 to 4 days after the appearance of the rash. Although immunity is lifelong, it has been suggested that a waning of immunity in older age explains shingles, and viremia would seem to account for a varicella-like rash in some instances. Reactivation of humoral and cellular antibodies might then account for the termination of a bout with herpes zoster. Patients receiving cancericidal drugs or adrenocortical steroids are at high risk for serious complications from VZV infection.

Clinical Manifestations and Pathology

Presumably the virus enters and replicates briefly in the cells of the respiratory mucosa followed by an intermittent viremia. The histopathology is identical with that described for herpes simplex infection. The virus is present in the vesicles. During viremia the virus travels from cutaneous sensory nerve endings to the posterior ganglia where it remains latent to be reactivated in some patients as herpes zoster. Then the dorsal ganglia show intense inflammation even with hemorrhagic necrosis, leptomeningitis, and myelitis of the posterior spinal columns. Although VZV has been isolated from ganglia during active disease, it has not been found during quiescent periods.

After an incubation period of 10 to 20 days and some 24 hours before the rash of varicella appears, the prodromes of mild headache, malaise, and moderate fever appear. Because these are commonly unrecognized in young children, the rash seemingly is the initial evidence of disease. It appears as a cutaneous blush, with the development of successive crops of macules, papules, and superficial vesicles surrounded by a red areola, which go on to crusting within 24 hours. The acute phase lasts about a week.

Although the rash may be generalized, it usually involves the trunk and face, with fewer lesions on the extremities. Vesicles may appear in the mouth, and laryngeal involvement may cause dyspnea. Chickenpox is a benign disease in children unless they suffer from leukemia or are taking corticosteroids. Other than acute encephalitis, an occasional circumstance late in the disease, complications have been reported very rarely in almost all the body systems. In adults varicella tends to be less benign, and commonly the X-ray reveals pulmonary infiltrates.

An attack of herpes zoster may be ushered in with 1 or 2 days of fever, chills, malaise, and gastrointestinal symptoms before symptoms of local disease appear. Either with or without prodromal symptoms the patient becomes aware of some pain, at times with itching, in the area of the affected segmental nerves. After several days, crops of vesicles on an erythematous base appear in the distribution of the nerves of one or several posterior root ganglia, usually accompanied by hyperesthesia and pain. The vesicles dry and become crusted in about a week, although the course may be slower in aged persons. Hyperesthesia or pain may last for weeks and months especially in those patients with malignant disease. In an occasional aged patient, these residua never disappear. Herpes of the ophthalmic branch of the trigeminal nerve is not uncommon and may be accompanied by keratoconjunctivitis, which may be followed by serious corneal scarring and glaucoma. Zoster of the geniculate ganglion produces Ramsey Hunt's syndrome. The characteristic pain syndrome of zoster may run its course without skin eruption, contrary to the clinician's initial prediction.

History and Geography

Both J. E. Schmidt (1959) and F. H. Garrison (1960) credit Giovanni Filippo Ingrassia, an Italian physician, with differentiating chickenpox from scarlet fever in 1553, and state that the English physician William Heberden (1785) gave the earliest clear description of varicella and distinguished it from smallpox in 1768. Jean Alibert (1832) included varicella in his group II category of exanthematous dermatoses – acute febrile contagous diseases. E. E. Tyzzer (1905), an American pathologist, described cellular inclusion bodies, and T. M. Rivers and W. S. Tillett (1924) reported isolation of the virus.

P. A. Rayer, in his 1845 treatise on diseases of the skin, described the microscopic contents of zoster vesicles and of the underlying skin. F. von Bärensprung (1861–3) concluded that zoster was due to disease of the posterior roots. In the following years, several case reports of herpes zoster in which there were postmortem findings of inflammation of the posterior root ganglia appeared. Bärensprung's suspicion that the Gasserian ganglion was affected in herpes zoster of the face was confirmed by O. Wyss (1872). A. W. Campbell and Henry Head (1900) established that herpes zoster results from a hemorrhagic inflammation of the posterior nerve roots and the homologous cranial ganglia. In 1925, Karl Kundratitz described the inoculation of susceptible children with zoster vesicle fluid resulting in varicella.

Whooping Cough

Whooping cough, otherwise known as pertussis, after the causative bacillus *Bordetella pertussis,* is an acute infectious disease of childhood. Affecting the respiratory tract, it is characterized by paroxysms of coughing, culminating in the prolonged inspiration which gives the disease its name. Before the present century, the popular name was generally spelled without the initial "w," and did not come into general use until the end of the eighteenth century. Until the early nineteenth century, the commonest appellation was *chincough.* The term *pertussis* was first used by Thomas Sydenham in the latter part of the seventeenth century.

Distribution and Incidence

The distribution of whooping cough is now worldwide. It is generally an endemic disease that erupts in sporadic epidemics, but in most developed countries it has been controlled by immunization programs. Of clinical cases, 80 percent occur in the under-10 age group, and unlike most other communicable diseases, whooping cough develops more often in females than in males.

Etiology and Epidemiology

Although included among the more important diseases of childhood, whooping cough has been relatively neglected, and various aspects of its epidemiology are not yet fully understood. Transmission seems to be mainly airborne, apparently by droplet infection. Human beings are the only reservoir of the disease; *B. pertussis* cannot survive long outside the host, and quickly succumbs to drying, ultraviolet light, and temperatures above 120° to 130°F. It spreads primarily through household and schoolroom contact, although mild subclinical cases, perhaps in adolescents and adults, may play a further (undemonstrated) role in transmission. One attack confers immunity, and rare second attacks are probably explained by infection with the much milder, and less common, *Bordetella parapertussis.*

Clinical Manifestations

An incubation period of 7 to 10 days is followed by an initial catarrhal stage, lasting 1 to 2 weeks. During this phase the disease is highly communicable, but the symptoms are nonspecific and resemble those of many other infectious diseases, and of minor respira-

tory ailments. An increasingly persistent cough develops, which in the third stage becomes more severe and spasmodic, terminating in the characteristic whoop. In acute cases, paroxysms may occur 40 or 50 times in 24 hours. The whoop is frequently followed by vomiting. In young infants, who are unable to produce the whoop and resume effective breathing quickly, episodes of cyanosis follow the paroxysm. The acute stage lasts up to 4 weeks, but paroxysms may continue for 3 months or longer. The patient is considered convalescent when vomiting ceases, and the severity of the paroxysms diminishes. Complications include collapsed lungs, anoxic convulsions, and exhaustion; secondary bacterial infections may cause otitis media or pneumonia. Bronchiectasis has become rare since the introduction of antimicrobial agents.

History and Geography

The history of whooping cough before the twentieth century is obscure. It cannot with certainty be traced back further than the mid-sixteenth century and it was almost certainly unknown to the ancient world. Although the term "chincough" was current in the early sixteenth century, the first medical description of the disease dates from 1578, when Guillaume Baillou observed a severe epidemic in Paris. He wrote of it as a familiar affliction, for which there seemed to be several names already. Moreover, it was apparently the subject of medical discussions.

Nonetheless, the prevalence of the disease remains largely obscure until the mid-eighteenth century. August Hirsch in 1886 suggested that the native habitat of the disease was originally northern Europe. But the existence of a widespread folklore with regard to its treatment may indicate a more ancient existence in such places as southern India and Malabar.

Thomas Willis in 1675 described the chincough as an epidemic disease of infants and children, usually occurring during the summer and autumn. In his view, the cough, although difficult to cure, was rarely fatal or very dangerous.

By contrast, his contemporary, Sydenham, thought it so formidable as to require the most rigorous treatment. The earliest statistics regarded as in any way reliable come from mid-eighteenth-century Sweden, where Nils Rósen von Rosenstein described it as a familiar epidemic disease of variable fatality. The terms "whooping cough" and "chincough" first appear as causes of death in the London Bills of Mortality in 1701, and an increasing number of deaths were attributed to them. Indeed, the toll rose from 119, in

the 15-year period 1702–17, to 4,252 in the period 1762–77. With the introduction of the civil registration of deaths in 1838, English mortality figures became more reliable. Deaths from whooping cough reached a peak of some 1,500 per million population under age 15 per annum in England and Wales in about 1870, after which the death rate from the disease began to decline. This fall was first manifest in agricultural areas, whereas in urban and industrial countries the death rates were slower to fall. During the 1880s, case fatality, so far as can be ascertained, stood at 10 percent, compared to 1.1 percent during World War II, and 0.1 percent in recent years. In underdeveloped countries today, hospital case-fatality rates are about 15 percent.

Although the infectious character of whooping cough was appreciated from at least the early eighteenth century, the nature of the clinical disease was simultaneously a matter of debate. Both Willis and Sydenham, for example, thought the disease seated chiefly in the chest, whereas William Harvey and his followers held it to be in the stomach and the alimentary canal. Not until Robert Watt of Glasgow, stimulated by the deaths of two of his children from the disease, undertook a series of dissections in 1812–13 did the involvement of the respiratory tract become clear. Medical interest in the disease during the nineteenth century was minimal, until discussion began about the possibilities of prevention in the 1880s.

In London, during the nineteenth century, the highest whooping cough mortality was experienced by the children of the working classes, and death was generally due to complications involving the respiratory organs. Whooping cough cases were not received into the Metropolitan Asylums' Board's hospitals (London) before 1910. The disease was made notifiable in the United States in 1922, but not until somewhat later in Great Britain.

Mortality and morbidity from whooping cough have declined greatly in developed countries during the twentieth century. The causative organism was first isolated by Jules Bordet and Octave Gengou in 1900, but was not grown in vitro until 1906, when its morphology and cultural characteristics were established. Vaccines against the disease were first introduced in the 1930s, and were in widespread use by the later 1940s.

But recently, there has been increasing public awareness of possible complications from whooping cough vaccine, which has been stimulated by the publicity surrounding the relatively small number of cases in which the vaccine is supposed to have

caused brain damage to children. The result was that during the 1970s rates of vaccination fell off in both Britain and Japan, where immunization is voluntary. In both countries the disease subsequently began to increase in prevalence, and epidemic outbreaks in 1978 and 1982 were similar in scale to those of the 1950s, when the immunization program was new. Another large outbreak was anticipated in 1986, but was aborted by intensive publicity concerning the benefits of vaccination, which caused immunization rates to rise.

Yaws

This disease has suffered from variable and confusing descriptions. It is now generally called yaws, although the term *framboesia* is also still in common use. Although primary, secondary, and tertiary stages of the condition are recognized, further subdivisions have been made that are associated with various alternative terminology.

Yaws is generally considered to be a highly contagious disease in tropical areas of the world, and in populations with limited hygiene. It is characterized in the early stages by variable cutaneous changes, and eventually affects joints and bones. The causal organism is considered to be *Treponema pertenue,* although the taxonomy of the pathogenic treponemes is in some doubt, and some reclassification may well take place in the near future. An incubation period of up to 28 days is followed by the appearance of the primary lesion, 2 to 5 centimeters in diameter, which develops into granular excrescences at times with lymph node enlargement. Further eruptions take place, which can be characterized by a "waxing and waning" of successive lesions. Single

or multiple lesions can eventually develop on the feet ("crab yaws," "ulcerative plantar papules") and are some of the most painful and disabling lesions of all. Eventually, in what some would see as a tertiary stage, there can be patchy depigmentation, deep destruction and remodeling of bones, and gangosa (changes to nasopharyngeal structures). The internal organs are not normally involved, and in this respect it contrasts markedly with the sister treponematosis venereal syphilis.

Distribution and Incidence
As a result of the intensive campaign against yaws that was carried out in the 1950s by the World Health Organization, the disease is no longer present in many populations where previously it was a serious health threat. Nevertheless, some comment on its previous geography and ecology is worthwhile, particularly as this may tell us something about its adaptive evolution. Indeed, it would seem true to say that of the treponematoses, yaws is the one that appears to be adapted to infecting human populations in tropical or subtropical climates (so there are the combined factors of heat, humidity, poor living conditions and hygiene, and limited clothing worn). Thus although it has been estimated that 80 percent of the yaws-afflicted populations lived within the mean annual isotherm of 80°F, it has to be recognized that various environmental and social factors must be taken into account in order to understand the variable incidences of this disease.

Exceptions to the geographic rules that might be seen to govern this condition are not difficult to find. For instance, in the case of mean annual rainfall, yaws was usually found in areas where there is 50 to 75 inches of rain a year, but it has occurred in drier climates as represented by parts of Madagascar, India, and Bolivia. In all, there were probably some 50 million yaws cases in the world half a century ago.

In the 1940s and early 1950s, estimates of yaws prevalence were made in various areas of the world, partly in relation to yaws eradication programs. Although regional figures have now dropped radically, it is pertinent to the history of the subject to note the extent of the previous evidence, and the variation found. In the case of most of the New World, although yaws was probably introduced by slaves centuries ago, no significant incidence has remained into this century. However, in the Caribbean area, which had been varyingly affected by the slave trade, yaws displayed some contrasts. Thus, Cuba was reported as having a low frequency of yaws, whereas in Haiti 60 to 80 percent of the rural popula-

tion were estimated to have had yaws. Similarly, Jamaica registered 70 to 80 percent frequency figures in some districts. In South America, Brazil was known to have many cases, especially in the northern regions where 350,000 cases were at one time noted. In Colombia, there was also regional variation, with the Pacific coast regions reporting 80,000 cases (with a general rate of 43.5 per 100,000). In contrast to these two countries, yaws appears to have been only a very modest health problem in Peru and Venezuela.

In the Old World, the disease was endemic in parts of Africa, Asia, and the Pacific. In Africa, quite high frequencies were found in some areas, although possibly the highest incidences occurred in Asia and the Pacific. In 1945, in the area then designated the Belgian Congo, there were 325,994 cases; and, in the same year, Tanganyika recorded 69,000 cases. Also about this time, frequencies in French West Africa varied from 0.02 percent (Niger) to 6.3 percent (Ivory Coast). French Equatorial Africa similarly had frequencies ranging from 0.1 percent (Chad) to 4.3 percent (Gabon), and the regional incidences in Uganda varied from 2 percent to 17.5 percent.

Yaws was also an important disease in the more tropical areas of Asia. In the Indian territory of Madhya Pradesh, 5.6 percent of the population was recorded as having yaws. Indonesia may have had as many as 10 million yaws cases before its anti-yaws campaign had any effect, and in some areas possibly 60 percent of the population had some experience of the disease. Thailand may also have had some 1.4 million cases prior to its current reduction, and in Laos, too, 1 to 15 percent of the population was thought to be affected.

Territories of the Pacific area showed some surprising frequencies, and clearly the relatively small populations of most of the islands did not prevent the spread of this disease. It was frequent on Guam, and, in 1953, on Simbo Island 20 percent of the general population had experienced yaws (and 78 percent of the children had been affected at some time). Also in the early 1950s, it was recorded that 17 percent of the population of Wallis Island and 18 percent of 80,000 Western Samoans had yaws.

This evidence of yaws in various parts of the world just prior to the antibiotic campaigns for its eradication helps to emphasize points of historical interest. One is that yaws probably had a relatively limited distribution in the New World. In some areas where notable frequencies have been attained, the phenomenon was probably linked to the history of the arrival of yaws-affected African slaves on the one hand, and environmental and social variable conducive to the survival and expansion of yaws on the other. A second point of historical interest is that in the Old World it is clear that yaws affects widely divergent ethnic groups distributed from Africa to the Pacific and that the history of the disease in these areas is likely to be hundreds if not thousands of years old.

Etiology and Epidemiology

Yaws is one of the four chronic infectious treponemal diseases that affect humans, and, in contrast to pinta, endemic syphilis, and venereal syphilis, it appears to be especially adapted to hot and humid tropical and subtropical environments. Rural populations were probably more affected than urban groups. The causal organism has been given separate species status, *Treponeme pertenue*, but the taxonomy of the treponematoses deserves reevaluation. The microorganism was discovered by Aldo Castellani in 1905, and since then its morphology has been to some extent revealed, especially by electron microscopy. Differences between the pathogenic treponemes have not, however, been resolved at this level, and it now seems unlikely that significant morphological differences will appear between *T. pertenue* and *Treponeme pallidum* (which causes syphilis).

Only humans appear to be the natural hosts of all the pathogenic human treponemes. None have so far been cultivated in artificial media, and there is still much to learn about their biological characteristics. In terms of the nature of the lesions produced, the most divergent forms are yaws and venereal syphilis. There is variable cross-protection once an individual has one variety of treponeme and comes into contact with another form.

The site of entry for yaws treponemes is not usually the genitalia, but often the legs. Large numbers of treponemes are probably unnecessary to instigate the disease. Infectious yaws lesions are mainly the early-stage papillomas, the infection being spread perhaps to small abrasions by direct or hand contact (via lesions). Transmission by flies is still considered to be unimportant. The yaws organisms are known to remain infectious in serum for up to 2 hours, provided the temperature remains at about 28°C.

Like endemic syphilis, yaws characteristically develops during childhood by nonvenereal contact. Eventually, after chronic progress of the disease, over 8 months or more, individuals commonly undergo spontaneous cure, although some cases continue to a tertiary stage.

Immunology

There appears to be no significant natural resistance to infection by yaws or other pathogenic treponemes. However, there is clear evidence that some individuals can develop specific resistance or immunity following infection with these treponemes. Thus, early clinical lesions can disappear, so there can be an asymptomatic or latent period, and this may or may not be followed by later-stage symptoms. The plasma cells and lymphocytes present in treponemal lesions indicate local antibody formation and some degree of immunologic response. Sera from yaws and the other pathogenic treponemes react to the same antigens.

Clinical Manifestations and Pathology

The progress of yaws seems best described in two major stages: an early phase with initial and secondary lesions; then a late stage, which usually develops after some years.

The clinical features of early yaws can be summarized as follows. In the region of entry of the treponemes, the primary lesions develop within the first 8 weeks. It is usual to find that the legs are involved first, the lesion being in the form of a large rounded itching papule, which is usually less than 5 or 6 centimeters in size. There is the possibility that it will ulcerate or become secondarily infected. Crusting of the ulceration occurs, and eventually a raspberry-like granuloma develops beneath. Bleeding may occur, and there can be a yellowish discharge.

Within 3 to 6 weeks after the initial lesion, secondary eruptions occur, and extend all over the body. These can continue for up to 2 years. Variants of these yearly yaws lesions have been given a confusing range of names. According to the 1951 WHO nomenclature, they may be summarized as follows.

Circinate (annular or ringworm) yaws lesions tend to encircle an area of skin, which may be several centimeters in diameter. Macular eruptions may occur and can be depigmented or partly hyperpigmented (peripherally). These disappear within a few weeks or months. The papular or "lichenous" rash can be regional or cover the whole body with small papules, usually for not more than a few weeks. Plantar and palmar lesions can be ulcerative or nonulcerative. In the case of painful ulcerating soles, the individual tends to walk on the outer border of the foot in a crablike fashion ("crab yaws"). Alternatively, in the nonulcerating lesions, there may later be a worm-eaten appearance associated with thickened dry hyperkeratotic skin. In the moist parts of the body (anus, vagina, mouth, nose, axillae), raised condylomatous areas resembling the condylomata of venereal and endemic syphilis can occur.

In the later stages of yaws, usually after 5 years, further lesions may occur in individuals whose condition has not become fully latent. In particular, there can be a nodular "lupoid" involvement of the skin, with the formation of granulation tissue, ulceration, and scar formation. In this late stage, there may also be one or a few large ulcers ("gummatous ulceration") lasting for years. Disturbances in pigmentation may further occur, being usually patchy. Possibly the most significant of the late stages of yaws are those that cause significant changes in the bones, for these can clearly be searched for archaeologically and thus may provide an ancient perspective to the history of this disease. Parts of the skeleton, especially the long bones, may show a range of changes from periostitis to deep cavitation and shaft swelling. In children there can also be dactylitis, which can produce remodeling and expansion of one or more phalanges, especially of the fingers. Also, the vault of the skull may be affected, causing localized cratering or more widespread osteitis and eventual stellate scarring. Most destructive of all is gangosa (rhinopharyngitis mutilans), which is characterized by massive destruction of the nose, palate, turbinates, and vomer.

History and Geography

It is important to emphasize at the outset that the history of yaws has been, to some extent, mixed up and confused by studies of syphilis. This, of course, is understandable, in that they are closely related treponemal diseases, and even now can be confused at a clinical level. It is thus small wonder that earlier writers could mistake one condition for the other, or are vague about the actual nature of the disease. Possibly the best example of this confusion is provided by writings on the Australian aborigines, in whose tribes yaws may have been a long-term pre-European problem. Indeed, the Aranda tribe has an old established name, *irkintja,* for the condition that many observers believed was syphilis (Hackett 1936b). This does not mean that all of the earlier medical writers were wrong, and Robert Koch, in a 1900 report to the German government, perceptively wrote that in the Bismarck Archipelago he had seen places where practically all children were infected with yaws, and that framboesia was frequently mistaken for syphilis by both laypersons and medical practitioners. Koch went on to say that the alleged great epidemics of syphilis in the South Seas were in large part the result of this same misdiagnosis.

Antiquity Through the Fifteenth Century

Although it has been suggested that the biblical condition "blains" (Exodus IX) could have been yaws, and similarly that the reference by Pliny the Elder (first century A.D.) to a yawslike eruption of the face could have indicated early treponemal disease, there is really no ancient written records that can be taken seriously as good evidence. On the other hand, the archaeological record does appear to provide clear proof of the antiquity of the treponemal diseases.

Regarding the medieval period, European history provides some facts that seem relevant to a full understanding of the history and spread of yaws. In 1367 Marco Pizziani explored along the African coast, and by 1470 others had sailed south as far as the Equator. Portuguese settlements were established, linked to the slave trade, and these intimate contacts between widely different peoples and environments provided opportunities for the movement of disease as well as people. Although the estimated figure of between 300,000 and 400,000 Negro slaves arriving in Portugal by the end of the fifteenth century may well be too high, there is no doubt that we must recognize this as a significant corridor for the potential shunting of disease, including yaws, to other areas, including northern Europe. Moreover, the slaves did not simply move toward Europe and western Asia.

Sixteenth Through Eighteenth Century

At the very beginning of the sixteenth century, the first consignment of slaves from Africa arrived in Hispaniola and, following this, millions more reached the New World. It was thus that yaws became established to varying degrees, depending on social and environmental factors, in various parts of the Americas. In 1648 Willem Piso, a Leiden doctor associated with the Dutch West India Company, which occupied a part of Brazil for a few decades, wrote in his *Historia Naturalis Brasiliae* of treponematosis in that country, mentioning a condition called "bubas" which he distinguished from the "Spanish pocks."

Earlier, in 1642, Jacobus Bontius, another Leiden doctor, had written of witnessing yaws as a result of his travels in the East Indies. In the Moluccas, the frequency of yaws led Bontius to call it a "common plague."

From the middle of the seventeenth to the end of the eighteenth century, there were a series of writings that consolidated the view that yaws was a distinct disease. Some of this evidence is so skimpy as to provoke only the suspicion of yaws as, for example,

the 1720 "epidemic" in Scotland of "sibbens," with symptoms suggestive of intruded yaws.

On the other hand, John Brickell of North Carolina, writing in the 1730s, distinguished yaws and syphilis, and noted that the former condition was "brought hither by the Negroes from Guinea" and was "seldom cured by mercurials." In the West Indies physicians who attended slaves came to know the disease well. They, too, believed its origin was in Africa. As in Africa, yaws was a disease mostly of children in the Caribbean, and many plantations erected yaws houses. Edward Bancroft, an eighteenth-century physician who gained experience with yaws in Guiana, South America, concluded that it could be transmitted by flies. This view was accepted by various medical writers in the following decades.

In this closing period of the eighteenth century and the first decades of the next, the stages of yaws development were slowly being understood. Vaccination was also tried in an attempt to prevent the disease, and positive results were claimed. Somewhat more alarming in humanitarian terms, the experimental injecting of slaves was carried out, at times with "success." Of special value were experiments on humans known to have already suffered from yaws, the negative results showing that immunity to secondary infection was possible.

Nineteenth Through Twentieth Century

Gangosa, meaning nasal voice, was first mentioned in the literature by a Spanish medical committee in 1828, and by 1891 J. Numa Rat had discussed these lesions in rhinopharyngitis mutilans and viewed them as an indication of the tertiary stage of yaws. Similarly, E. C. Stirling in 1894 was the first to note "boomerang leg" (also called *sabre tibia*), which was a later-stage yaws feature he saw in Australian aborigines.

The question of the taxonomy of the pathogenic treponemes was opened up for debate in 1900, when Joseph Hutchinson agreed that, contrary to growing opinion, yaws and syphilis were simply different patterns of the same disease – an argument that was to be strongly defended later by Ellis H. Hudson (1946, 1958). But during this century, the treponemal diseases have tended to be worked on more and more in isolation. Thus, R. L. Spittel (1923) concentrated not only on yaws but specifically on *parangi,* the form with which he had had considerable experience in Ceylon. Perhaps the most versatile treponematologist has been C. J. Hackett, whose field work in the 1930s took him to

tribal communities in Australia and Africa. His contributions dealing with the bone changes in yaws and syphilis have been especially significant. These findings in turn are helping physical anthropologists to trace the history of these diseases in human skeletal materials. It is hoped that such efforts will soon produce major breakthroughs in our knowledge of the history of the treponematoses.

Yellow Fever

Yellow fever is an acute group B virus disease of short duration transmitted to humans by different genera of mosquitoes, but especially by the *Aedes aegypti* (known previously as the *Stegomyia fasciata*). It remains endemic in the tropical regions of Africa and the Americas in a sylvan or jungle form, but historically its greatest impact on humans has been in an epidemic or urban form. The disease can appear with symptoms ranging from extremely mild to malignant; in classic cases it is characterized by fever, headache, jaundice, albuminuria (high-protein content in the urine), and hemorrhage into the stomach and intestinal tract. High mortality rates were frequently recorded during epidemics (20 to 70 percent), although today we know that yellow fever mortality is actually relatively low, suggesting of course that the majority of the cases were mild and went undiagnosed. The jaundice has prompted the appellation yellow fever, and other designations such as the *mal de Siam, fièvre jaune, gelbfieber,* and *virus amaril,* whereas the hemorrhaging of black blood led to the name "black vomit" or *vomito negro.*

Known early in the New World as the "Barbados distemper," "bleeding fever," the "*maladie de Siam,*" "*el peste,*" *vomito negro,* and later yellow jack (because of the yellow quarantine flag flown by ships), the disease has been called by some 150 names. It was first termed "yellow fever" apparently by Griffin Hughes in his *Natural History of Barbados* (1750).

Etiology and Epidemiology

Generally speaking, humans suffer most from those illnesses for which they are not the intended host. Bubonic plague, for example, is normally a disease of rodents that has, from time to time, incidentally infected humans with devastating consequences. Similarly, yellow fever is normally a disease of nonhuman primates, particularly monkeys. The disease is transmitted among them by mosquito vectors, but not mosquitoes that are ordinarily attracted to human beings. In this form the disease is called sylvan or jungle yellow fever, and is enzootic, meaning that the pattern of transmission is from nonhuman primate to mosquito to nonhuman primate.

When the disease leaves the treetops (as, for example, when a tree is felled), and when mosquitoes such as *Aedes africanus* and *Aedes simpsoni* in Africa and

Haemogogus genera in the Americas link jungle yellow fever with humans and begin a cycle of transmission from nonhuman primate to mosquito to human, the disease is often called *endemic;* when the yellow fever virus is taken in the blood of an infected human to heavily populated areas where the cycle is one of human to the female *A. aegypti* mosquito to human, the disease is termed *epidemic* or *urban* yellow fever.

The habits of the female *A. aegypti* have much to do with shaping the characteristics of an epidemic. She is a domestic mosquito that lives close to humans, depending on them for blood meals and breeding in puddles or containers of water in and around their places of dwelling. Her range is very short, generally a few hundred yards at most, which means that *A. aegypti* requires a fairly closely packed human population. Because *A. aegypti* can survive only a few days without water (although her eggs can survive for years in dehydrated form) and requires water in which to breed, adequate rainfall is a prerequisite for urban yellow fever, and indeed, many of the classic epidemics have taken place shortly after a period of extended rainfall. Warm weather is another prerequisite, for *A. aegypti* will not bite when the temperature falls below 62°F (or 17°C), and extended chilly weather will send her into hibernation.

The virus also has some distinctive requirements, especially for transmission – a process in which humans are best thought of as the site where the virus changes mosquitoes. This exchange can take place only during the first 3 to 6 days of infection of the yellow fever victim while the virus still remains in the blood (viremia); after the virus has entered the mosquito, it must incubate for another 9 to 18 days before the mosquito can infect another human being. After this period of extrinsic incubation, however, the mosquito will remain infective for the remainder of its life, which could be upward of 180 days, although generally the life-span of the female *A. aegypti* is closer to a month or two.

Although it has generally been thought that monkeys serve as the reservoir for the virus, other mammals (marsupials and armadillos) are also suspected of carrying the virus in endemic areas, and for short periods of time the mosquito populations can act as a reservoir.

Distribution and Incidence

In the Americas epidemic yellow fever has been in rapid decline during the twentieth century, essentially due to efforts aimed at eradicating *A. aegypti* from major population centers. The last outbreak of urban yellow fever took place in Trinidad in 1954.

Nonetheless the yellow fever virus remains very much alive in the monkeys that inhabit the forests of Central and South America, and consequently a small number of human cases (between 50 and 300) continue to be reported annually among individuals who work in or live in close proximity to those forests. The vast majority of the cases occur in regions of Brazil, Ecuador, Venezuela, Colombia, and Peru that are drained by river networks contributing to the Orinoco, Magdalena, and Amazon systems. A bit earlier in the century, human cases of the disease were also reported with some regularity in Central America, Bolivia, Argentina, and Paraguay.

In Africa, severe epidemics of urban yellow fever still occur from time to time; a notable recent example is the Ethiopian epidemic of 1961, which cost thousands of lives. Still more recently a major outbreak in western and southwestern Nigeria claimed thousands of lives. Isolated human cases, however, are not reported with systematic regularity despite the vast belt of endemic yellow fever that stretches across much of that continent, and despite the presence of antibodies in a great number of the inhabitants of that belt, indicating past yellow fever infection.

One mystery surrounding yellow fever is that it has never occurred in Asia, despite the presence there of the *Aedes* mosquito vector. Some think that the mosquitoes themselves in that part of the world are resistant to infection. Others suspect that a population may be able to support only so many group B arboviruses and that entrenched illnesses in this category such as dengue and Japanese encephalitis may have forestalled the advance of the yellow virus.

Immunology

An attack of yellow fever confers on the host a lifetime of immunity against reinfection. Because the disease generally reserves its most severe symptoms for young adults and (as some illnesses) treats children more gently, whole populations in endemic areas or in areas frequently visited by yellow fever can become more or less quietly immune as children experience the illness as just one more in a train of childhood ailments. Under such circumstances an epidemic is never seen, unless or until large groups of newcomers suddenly arrive, such as was so often the case with immigrants, soldiers, and sailors reaching the Americas. It was this phenomenon that gave rise to yellow fever nicknames such as "strangers' fever," the "disease of acclimation," and "patriotic fever."

On the basis of the experience of both slave and free black populations in the hemisphere, however, many came to believe that blacks possessed a special (today some would say innate) ability to resist the disease. The question remains unresolved. Some have denied this ability, by pointing to urban epidemics in Ethiopia or Sudan and western Nigeria in which thousands of blacks lost their lives. These regions are on the edge of the endemic belt where many presumably would not have been exposed regularly to yellow fever, and thus would have included many with no acquired immunity. By contrast, most of the slaves reaching the Americas originated from deep within the endemic zone, and consequently would have acquired immunity to yellow fever before they ever stepped aboard a slaving ship. Thus it is possible to explain much of blacks' refractoriness to yellow fever on the basis of acquired immunity.

On the other hand, genetic selection for yellow fever resistance as a result of prolonged exposure cannot be discounted, for many of the West African descendants of those first arrivals to the Americas lived for generations in areas untouched by yellow fever, yet, without any opportunity to acquire immunity in advance, suffered much less than whites when the disease finally did make an appearance. It has been suggested that related arboviruses or flaviviruses (dengue or Japanese encephalitis, for example) may confer some cross-protection against yellow fever, whereas others believe that certain strains of the illness may vary in mildness or severity, depending on the groups of individuals under attack. In this latter connection it may be significant that Chinese in the New World were reputed to be almost as resistant to the illness as blacks because although yellow fever has never invaded Asia, dengue and Japanese encephalitis are endemic to much of the region.

Fortunately today one need not suffer through the illness in order to ensure resistance to it. Rather immunization can be gained with a strain of living virus called 17D, and immunization projects have been in effect since the 1930s in many regions of endemic yellow fever.

Clinical Manifestations and Pathology

The onset of symptoms generally occurs 3 to 6 days after the virus is injected into the blood. In the range of moderately severe to malignant cases, the symptoms arrive suddenly with flushed features, severe chills, high fever, intense headache, and perhaps a backache and other muscular aches and pains. Quite often there is nausea. These symptoms continue throughout a restless, agitated 2 or 3 days, after which the patient characteristically experiences a remission.

From this point forward, most patients fortunately will recover, but for others, the remission will be short-lived, jaundice may set in, hallucinations frequently will take place, and internal hemorrhaging will occur, with the victim vomiting huge quantities of black vomitus. This frequently terminal signal is confirmed by convulsions, coma, and, generally from the seventh to the tenth day of the illness, death.

Early in the course of the illness the virus sets up an infection – primarily in the liver – and multiplies to the extent that just one drop of blood contains millions of virus particles. This volume of foreign matter in the blood quickly summons an antibody response, which, if the patient recovers, remains in the blood for a lifetime to ensure that he or she never will be called upon to repeat the experience. If the patient dies, pathological findings usually reveal extensive internal damage such as cardiac enlargement and kidney congestion; hemorrhages of the stomach, duodenum, bladder, and mucous membranes; and liver necrosis.

Diagnosis

Because of its wide range of symptoms, diagnosis of yellow fever has always been difficult, and in the past the disease has doubtless been confused with many other ailments that present similar symptoms. Examples of such illnesses are infectious Weil's disease, dengue, tick-borne relapsing fever, lassa fever, malaria (especially blackwater fever), scurvy, and typhoid and typhus; even illnesses such as influenza easily could have camouflaged mild yellow fever.

History and Geography

American Versus African Hypothesis of Origin

Much historical interest in yellow fever has focused on its place of origin: Africa or the Americas? Those who believe it to have been the latter have emphasized that the disease was described and epidemics were recorded in the Western Hemisphere well over a century before it was recognized in Africa, with the first recognizable epidemic striking Barbados in 1647 and then spreading during the next 2 years to Guadeloupe, St. Kitts, Cuba, and the Yucatan Peninsula. Moreover, Amerindian accounts and records of the early Spanish conquistadores make mention of diseases that could have been yellow fever, such as an epidemic of 1454 on the Mexican plateau, a 1477–

97 epidemic that raged in the Yucatan, and an outbreak of disease in Santo Domingo that assaulted the men of Columbus in 1493.

By contrast, the protagonists of the African hypothesis dismiss these outbreaks as typhus, malaria, or some other disease but not yellow fever, in large part because of immunologic evidence. Whatever the illnesses might have been they argue, the Indians were very susceptible to them; however, any endemic presence of yellow fever should have created a high degree of immunity to it. In addition, American monkeys are demonstratively susceptible to the illness, whereas West African populations of both humans and monkeys have shown themselves to be quite resistant to it, suggesting a history of long exposure.

Indeed, the West Africans' ability to resist yellow fever would explain why recognition of the disease was so slow in coming to that region. In the case of Europeans in Africa, it was difficult to distinguish among the "fevers" that fell upon them (and, in the case of portions of the British army during the early nineteenth century, were eliminating more than half of the troops annually). But judging from the extraordinarily low (by comparison) death rates of black troops serving alongside the Europeans, yellow fever must have been prominent among them, and in this connection it is worth noting that even in this century, physicians in Africa have almost routinely misdiagnosed yellow fever as malaria. Interestingly, too, J. P. Schotte, who is credited with first describing yellow fever in West Africa in 1778, did not claim that it was the first epidemic of the disease in the region. Rather, he discussed previous epidemics, in which he reported (significantly) that only the Europeans had suffered greatly.

A final piece of evidence that may point to an African cradle of yellow fever has to do with the prevalence of its A. aegypti vector. In Africa, many species of mosquitoes are more or less closely allied to the Aedes, whereas very few are thusly related in the Americas, suggesting that the vector, at least, is an import. On the other hand, it is possible (although unlikely) that the yellow fever virus was present in the monkey populations of the New World prior to the arrival of the Europeans but had to await the arrival of the vector in order to be transmitted to humans.

Certainly the timing of yellow fever's recorded appearance in the New World does nothing to detract from the case for an African origin of the vector, and probably of the virus as well, for the decade of the 1640s was one of accelerated slave trade activity to Barbados as that island was converting its economy to one of a sugar plantation system based on slave labor. The same slave ships that could have delivered the virus in black bodies doubtless did carry the mosquito in their water casks. However, whether the disease achieved endemicity by establishing itself in the monkey populations of those few Caribbean islands that contained monkeys can only be speculated upon, for so many of the serious outbreaks to follow also seem to be traceable directly back to Africa via the slave trade. It does seem, however, that the Yucatan Peninsula and the region around Vera Cruz became endemic foci.

Disease Outbreaks: Seventeenth Through Nineteenth Century

Having reached the Caribbean, the disease began making summer visits northward, striking New York in 1668, Philadelphia and Charleston in 1690, and Boston in 1691, while to the south, yellow fever became a regular visitor to the port cities of Colombia, Ecuador, and Peru. Interestingly, it disappeared from Cuba in 1655 after raging there since 1649 and, save for a visit to Santiago de Cuba in 1695, did not return until 1761, apparently because of the islands' sparse population during this century-long period.

A similar phenomenon appears in the medical literature on Brazil. There seems no doubt that the *bicha* or *molestia da terra* that struck Pernambuco in November of 1685 was yellow fever. It killed thousands in Recife and Olinda and spread into Ceará before burning out about 5 years later. As was the case in the Caribbean, the outbreak in Brazil has been attributed to a ship that arrived from the African coast. However, despite a thriving slave trade that presumably could have brought the vector and virus to Brazil in countless ships, and a monkey population that some believe already harbored the virus, the region reputedly was free of the disease for the next century and a half. It is true that many slaves reaching Brazil came from Angolan and, to a lesser extent, East African regions that were outside the endemic zone of yellow fever. But many also came from regions within that zone, which makes it so perplexing that when yellow fever was allegedly reintroduced, some say that it arrived not from Africa but from North America, in 1849, on the brig *Brazil,* whose crew had been infected either in New Orleans or Havana when the ship had put in to those ports.

Equally perplexing is the selectivity yellow fever demonstrated in seeking out victims as the disease spread from Bahia to other coastal cities, for, al-

though it fell upon European newcomers with considerable fury, it treated local blacks and whites far more gently, suggesting, of course, that the disease may have been present in the region all along – in its jungle or sylvan form – quietly immunizing the population by periodically producing mild cases in the young. Significantly, in the years immediately prior to the outbreak of the 1849 epidemic, Brazil had been the recipient of a sizable influx of European immigrants, in addition, the population of Rio de Janeiro still included a number of individuals on their way to California. Thus in this epidemic, as in the countless ones to follow, it would be the newcomers who were the chief sufferers of the illness.

Yet yellow fever did not limit its assaults on Europeans to Africa and the Americas, but rather on notable occasions sought them out in their homelands as well, apparently reaching the continent from the Caribbean. The Iberian Peninsula was the most common target, with periodic epidemics reported there throughout the eighteenth and nineteenth centuries. The coastal cities of Oporto, Lisbon, and Barcelona bore the brunt of these attacks, although the disease did penetrate to the heart of the peninsula from time to time, even reaching Madrid in 1878. Small outbreaks also occurred on occasion in France, England, and Italy.

Without doubt, however, yellow fever gained its most fearsome reputation in the Caribbean because of Europeans on hand to host it, often in the form of military personnel who provided the disease with a seemingly endless stream of nonimmunes. In 1655, of the 1,500 French soldiers sent to occupy Saint Lucia, only 89 were reported to have survived an onslaught of disease led by yellow fever. The decade of the 1690s saw yellow fever sweep much of the Caribbean, and whole populations of many islands thinned considerably. In 1693 the English attack on the French at Martinique collapsed in face of yellow fever, whereas in 1741, Admiral Edward Vernon's abortive attack on Cartagena saw the loss of close to half of an original landing force of 19,000 (including many North Americans) to yellow fever.

Prisoners sent as workmen from Vera Cruz to Havana in 1761 are credited with reintroducing yellow fever to Cuba where it proved a formidable ally of the Spaniards the following year in a nearly successful effort to deny Havana to the English. However, it was during European attempts to invade St. Domingue around the turn of the century that yellow fever deaths really peaked in the Caribbean. Over the years 1793–6 the British army in the West Indies lost some 80,000 men, with over half of the

deaths attributed to yellow fever. The disease also decimated the French soon after they began their invasion of Hispaniola in 1802 and accounted for a sizable portion of the 40,000 men lost in the first 10 months of the war. After the French retreat to the islands of Martinique and Guadeloupe, yellow fever destroyed any French notions of attempting a second assault by raging among the survivors for another 3 years. It was this tremendous loss of European life to yellow fever (and to malaria) that prompted the English to begin to fill West Indies regiments with black troops who were thought to be immune to the disease and demonstrated over and over again that, indeed, many were.

Because of Philadelphia's brisk trade with the West Indies, yellow fever found its way frequently to that port city during the eighteenth century, with epidemics recorded for the years 1741, 1747, 1762, 1793, 1794, and 1797. The epidemic of 1793 was carried to the city by French refugees from revolution-torn San Domingue. With the turn of the nineteenth century, however, as the West Indian trade was shared to a greater extent by southern ports, it was the South that began to receive most of yellow fever's attention, with New Orleans, Savannah, Mobile, and Charleston the most frequent ports of call for the disease.

During the first 6 decades of the nineteenth century, Savannah suffered from 15 epidemics, Charleston had 22, and New Orleans at least 33. The most notable of the New Orleans epidemics occurred in 1853 during which the city lost almost 8,000 individuals to the disease. Chief among the victims of this and all other epidemics were Northerners and foreigners (especially the Irish), along with white Southerners from the interior. Permanent white residents, however, seldom suffered from fatal yellow fever. Among blacks, it was reported by physicians that mulattoes were the most susceptible (to about the same degree as local whites), and until late in the antebellum period, "pure" blacks were believed to be totally immune. Yet in the decade or so before the Civil War, physicians began to notice that blacks did take the disease in a very mild form during epidemics – so mild that it had heretofore escaped notice.

In Brazil, too, blacks were reputed to be extraordinarily resistant to yellow fever, whereas the European immigrants flocking to South America in large numbers became the primary target. With the end of the slave trade in 1850, the chances of the disease entering the country from Africa were reduced. There was always the possibility that the disease would be

imported from the Caribbean or North America as supposedly occurred in 1849, but in view of the almost continual epidemic onslaught of yellow fever on Brazilian coastal cities for the remainder of the century, it seems a reasonable supposition that the disease was endemically established in the country.

Cuba, too, was the nineteenth-century destination of European laborers (from Catholic Europe and the Canary Islands), and these, as well as numerous refugees from Spanish America and numerous Spanish soldiers, assured yellow fever a plenitude of hosts on that island. Moreover, a contraband slave trade continued contact with the reservoir of yellow fever in Africa, and regular trade with Vera Cruz kept Cuba in touch with another endemic focus of the disease. Thus it is not surprising that Cuba became the yellow fever capital of the Caribbean. By contrast, the disease began to wane in most of the rest of the islands as the end of the British and French slave trades and the decline of the sugar industry turned them into economic backwaters seldom visited by outsiders.

The northern blockade of southern ports during the American Civil War, rather ironically, kept the South free of yellow fever for the duration by curtailing West Indian shipping traffic. However, the disease returned to New Orleans in 1867, assaulted inland Montgomery in 1873 and Savannah in 1876, before beginning an ascent of the Mississippi River in 1878 that left countless yellow fever dead in a wake that stretched from New Orleans to Memphis, Tennessee, where 5,000 alone went to a yellow fever grave.

This 1878 epidemic almost certainly reached the United States from Cuba, where the influx of Spanish soldiers sent since 1876 to end the Ten Years' War had provided the tinder for an epidemic that raged on that island from 1876 until 1879. Whether the Cuban epidemic also reached out to slaughter French workers arriving in Panama from 1878 onward to work on Ferdinand de Lesseps' abortive attempt to build a canal across the isthmus, or whether that outbreak came from an endemic jungle source is a matter of speculation. But like their predecessors, who between 1851 and 1855 lost thousands of their numbers to yellow fever in building the Panamanian railroad for American financiers, the French canal workers died in droves, many even bringing their own caskets with them to the isthmus.

Transmission and Control: Twentieth Century
The beginning of the end of yellow fever's seemingly endless onslaughts on the Atlantic coastal regions of the hemisphere came just 3 years after the disastrous yellow fever year of 1878, when Carlos Finlay y Barres of Cuba put forth his theory that the *A. aegypti* mosquito transmitted the disease. The theory was confirmed in 1900 through the use of human volunteers (three of whom died) by the U.S. Army Commission on Yellow Fever in Havana headed by Walter Reed. Armed with this knowledge, William Gorgas was able, by eradicating the *A. aegypti,* to rid Havana and consequently much of Cuba (which just 3 years previously had registered 6,000 yellow fever deaths) of the disease. Following this, Gorgas applied the same mosquito eradication methods in Panama, making it possible for workers on the American canal to avoid the fate of so many of their French predecessors. The measures were also quickly applied elsewhere so that the 1905 outbreak of yellow fever in New Orleans and the 1908–9 appearance of the disease in Barbados represented, respectively, the last of the disease on North American soil, and the last reported appearance in the Caribbean for decades.

Plans for eradicating the disease from the entire globe were put forth by Gorgas, and in 1915 the Rockefeller Foundation launched this effort with the creation of its Yellow Fever Commission. The commission began by concentrating on sites in Latin America, but in 1920 shifted much of its attention to Africa. In 1925 the Second Commission to West Africa established itself at Lagos, Nigeria, where, among other things, it was discovered that the rhesus monkey from India, unlike African monkeys, was susceptible to yellow fever. With that discovery, it became possible to use monkeys rather than human volunteers for yellow fever experiments. Nonetheless, yellow fever research remained a dangerous affair, and Adrian Stokes, Hideyo Noguchi, William A. Young, and Theodore B. Hayne all perished from the disease in Africa during these "heroic days" of yellow fever research, which by 1929 had demonstrated beyond doubt that yellow fever was the result of infection by a virus.

In Brazil, the knowledge gained by the Reed Commission in Havana was quickly applied by Oswaldo Cruz to a mosquito eradication campaign that freed major coastal cities from the terror of almost unremitting yellow fever assaults for the first time in over a half-century. Despite the campaign, however, the disease stubbornly refused to disappear from Brazil. Sporadic outbreaks continued with puzzling frequency in that country, and in Peru, Ecuador, and Venezuela and Colombia as well, all of which shared portions of South America's great rain forest.

In 1923 the International Health Division of the Rockefeller Foundation accepted Brazil's invitation to administer the Brazilian Yellow Fever Service and, under the direction of Fred Soper, conducted immunologic surveys which showed that many Brazilians residing close to the forest regions had hosted yellow fever in the past. In 1928 a yellow fever epidemic in Rio, which had been free from the disease for over two decades, triggered investigations revealing that yellow fever could spread in the absence of the *A. aegypti* mosquito, and that the disease was very much alive in the monkey inhabitants of the great South American rain forest. Jungle yellow fever had been discovered, and with that discovery most of the final riddles connected with yellow fever transmission were resolved.

Meanwhile, as mentioned previously, by the late 1920s workers in Africa had demonstrated that the rhesus monkey was susceptible to yellow fever; thus with an animal that could be used in laboratory experiments, efforts to isolate the yellow fever virus were begun. Shortly afterward Max Theiler discovered that the disease could also be transmitted to white mice, which were less expensive and certainly easier to handle experimental animals. Next Theiler showed that if the virus was transmitted from mouse to mouse, it became sufficiently weakened that it could be used to inoculate and immunize monkeys against yellow fever. More effort on the part of Theiler and co-workers led, by the late 1930s, to a further attenuation of the virus, called the *17D Valline strain,* which is a mutation of the virus achieved by successive passage of virus in cultures and chick embryo tissues. It is harmless to humans, but immunizes them against the disease.

The development of a vaccine against yellow fever was crucial, for with the discovery of jungle yellow fever came the realization that yellow fever could not be wiped out after all. This vaccination became the only method of yellow fever prevention in regions where mosquito eradication was not practical. The virus is always present in monkeys and perhaps other wild creatures of the forests, and consequently cannot be pinpointed.

For this reason epidemiologists are particularly alarmed at the relaxation of mosquito control measures in the Western Hemisphere, where very few have been vaccinated. In the southern portions of the United States and much of the Caribbean and Central America, *A. aegypti* has reestablished itself, and Brazil, once apparently free from the mosquito, has reimported it from North America. With modern air travel, an infected individual – or even mosquito – could easily be whisked from the South American or African forests to any number of large cities where *A. aegypti* again resides in large numbers, and stands ready to spread the disease throughout nonimmune populations. In addition, *Aedes albopictus,* a close relative of *A. aegypti,* has recently (within the last decade) been introduced to the United States from its native habitat in the Orient. Laboratory studies have revealed *A. albopictus* to be fully susceptible to the yellow fever virus and capable of transmitting it to vertebrates, and it is known to be a prominent vector of dengue as well. Its habits, feeding preferences, and general biology closely resemble those of its more famous congener, and both can inhabit the same areas. Moreover, the newcomer is more tolerant of cold weather, and it has spread widely in the United States. Its spread to the West Indies, and Central and South America is feared. As Wilbur Downs stated in a personal communication, "It could prove to be a most unwelcome contributor to yellow fever epidemiology in coming decades."

Indexes

Our approach to indexing this work was guided, in part, by the desire to make available substantive information that seemed best omitted in the text. As a consequence, the Name Index gives a brief biographical sketch, including dates of birth and death, for each (normally pre–twentieth-century) figure of prominence in the history of medicine who is mentioned by more than one of our authors.

Yet this work is less a history of medicine than it is the history (and geography) of human disease promised by the title, and it is this promise that dictates the primary focus of the Subject Index. This index first divides the globe into its major regions and then subdivides these regions geographically and chronologically so that, for example, the diseases of Japan in the premodern period are found listed alphabetically under Asia, East, Japan, premodern.

If, however, the reader is interested only in smallpox in premodern Japan, then the smallpox entry in the Subject Index may also be consulted, where a chronology of epidemics during the period in question is provided along with a listing of the outbreaks of this disease noted by our authors in every portion of the globe, from its earliest recorded appearance to the most recently reported cases.

Other areas of interest, such as the history of medicine or infant mortality or public health, can be accessed through topical entries such as medicine and medical history; mortality, infant; and public health and sanitation. In addition, in the Subject Index we have provided cross-referencing among topics covered in the text, and we have also attempted to include, whenever possible, synonyms that have been used historically for modern diseases.

Name Index

Boerhaave, Hermann (1668–1738): A Dutch physician, Boerhaave was enormously influential during his lifetime as a professor of botany, medicine, and chemistry at Leyden. He apparently was the first to describe the sweat glands and to establish that smallpox is spread by contact alone. 16, 49, 85, 86, 636, 693–4, 1004

Bondy, Gustav, 869

Bonland, A., 929

Bontius, Jacobus (1592–1631 or 1632): A physician and naturalist in the service of the Dutch East India Company, Bontius is regarded as one of the founders of tropical medicine as a separate branch of medical science. He wrote the first Dutch work on the subject in which he provided the first modern description of beriberi and cholera. 645, 1099

Book, J. A., 686

Borah, Woodrow W., 40, 498

Bordet, Jules Jean Baptiste Vincent (1876–1961): Bordet wrote extensively on the properties of sera in immunized animals on bacterial hemolysis, and the Bordet-Gengou Complement fixation reaction constitutes the basis of many tests for infection. Bordet is credited for discovering the causitive agent of whooping cough in 1906. In 1919, he was awarded the Nobel Prize. 129, 1095

Bordeu, Théophile de, 86

Borelli, Giovanni A., 15

Borovsky, Peter Foritsch, 833

Boswell, James, 63, 760

Botallo, Leonardo, 1030

Botstein, D., 124

Bouchardat, Apollinaire, 665

Bouchut, Eugène (1818–91): A French physician, Bouchut has been credited with penning the first important work on neurasthenia (1860) and with describing "false croup" (1852). 585, 656

Bouillaud, Jean Baptiste (1796–1881): A French physician, Bouillard was the first to identify the anterior lobes as the speech center. He also studied cirrhosis, helped establish the connection between rheumatic fever and heart disease, and recognized the value of digitalis. 940, 970

Findlay, L., 978

Finlay, Roger, 284

Finlay y Barres, Carlos Juan (1833–1915): A Cuban physician, Finlay was the first to suggest that yellow fever was transmitted to humans by mosquitoes. His hypothesis was tested by the Reed Commission in Cuba and, following this, yellow fever was quickly brought under control in the Western Hemisphere. 502, 1105

Fischer, J. N., 902

Fiset, P., 961

Fisher, J. W., 792

Flatz, G., 813, 816

Fleck, Ludwik, 1029, 1032

Fleming, Sir Alexander (1881–1955): A British bacteriologist, Fleming spent his career studying the body's defenses against bacterial infections. He discovered penicillin (1928), ushering in the era of antibiotics. He was knighted in 1944 and received (with E. B. Chain and H. W. Florey) the Nobel Prize in medicine (1945). 127

Flexner, Simon (1863–1946): An American pathologist and bacteriologist, Flexner developed Flexner's serum for cerebral meningitis (1907), directed research that led to identification of the virus causing poliomyelitis, and discovered the dysentery bacillus, which is named for him. 777

Flinn, Michael W., 280, 288

Flint, Austin, Sr. (1812–86): Flint was an outstanding American clinician whose research ranged from heart murmur ("Austin Flint Murmur") to anemia. His research was also important in helping American physicians to differentiate between typhoid and typhus. 572, 1083

Floyer, Sir John (1649–1734): A British physician, Floyer was the first to describe changes in lungs caused by emphysema, and made the first observations of the pulse rate using a pulse watch, which was his invention. Floyer also wrote the first book on geriatrics, *Medicina Gerocomica* (1724). 92, 707

Fowler, W. M., 640

Fracastoro (Fracastorius), Girolamo (c. 1480–c. 1553): An Italian physician, Fracastoro has been called the father of scientific epidemiology and was the first to present a consistent theory of contagious disease. Fracastoro attributed the spread of epidemics to small germs, which carried the disease. Today, however, he is best known for a poem he wrote, which remains the most famous of all medical poems, and from which the name syphilis was derived. 18, 964, 1030, 1063, 1082

Fraikor, A. L., 1039, 1040

Head, Henry, 1093

Heagerty, J. J., 524

Heberden, William (1710–1801): An English physician, Heberden differentiated chickenpox from smallpox (1764), and presented a classic description of angina pectoris, while also coining the term. In addition, he described a form of rheumatic gout in which bony nodules (Heberden's nodes) develop in the fingers. 91, 92, 601, 906, 1093

Hecker, Ewald, 75

Hecker, Justus Friedrich Karl (1795–1850): A German historical epidiomologist, Hecker wrote of the Black Death, the dancing mania, and the English sweating sickness. 275, 1023

Heidelberger, Michael (1888–1991): An American chemist, Heidelberger is considered the founder of immunochemistry. He also conducted research in organic chemistry, sodium–uranium compounds, and chemotherapy for which he received numerous awards, including the Pasteur Medal from the Swedish Medical Society (1960). 133, 941

Heine, Jacob von, 942

Heiple, K., 308

Helgason, T., 667

Helmholtz, Hermann Ludwig Ferdinand von, 17, 18

Helmont, Jean Baptiste van (1577–1644): Helmont was instrumental in describing the digestive process. He also discovered carbon dioxide and invented the word "gas." 15, 47, 48

Helwich, Christianus, 694

Hench, Philip S., 765, 769

Henderson, Donald A., 1012

Henle, Friedrich Gustav Jakob (1809–85): A German pathologist and anatomist, Henle is considered the founder of histology, the science of microscopic study of tissues. He studied the anatomic structure of hair, blood vessels, nails, and the nervous system, and also discovered the looped portion of the kidney tubule (Henle's loop). 17, 18–19, 648

Hippocrates of Cos (c. 460–375 B.C.): A Greek physician, Hippocrates is generally considered to be the "father of medicine." Although we know little about him, he is reputed to have been a fine clinician, as well as the founder of a medical school and the author of a number of books, though most of the works attributed to him were written by other members of the Hippocratic school. These works are collectively know as the *Corpus Hippocraticum*, which summarized much that was known about disease in the ancient world. 11, 18, 29, 47, 102, 115, 116, 140, 187, 262, 263–9, 335, 413, 585, 615, 635, 648, 656, 679, 692, 697, 720, 739, 740, 744, 759, 776, 786, 795, 803, 838, 861, 868, 873, 888, 908, 916, 940, 969, 1001, 1004, 1044, 1048, 1065, 1075, 1080, 1090

Hiro, Y., 988

Hirsch, August (1817–94): A German medical historian, Hirsch was the author of the classic *Handbuch der historisch-geographischen Pathologie* (1860–4). A revised addition was translated into English by Charles Creighton and published by the English New Sydenham Society in 1883–6. 1, 2, 7, 94, 144, 275, 296, 500, 609–10, 719, 752, 873, 874, 888, 939, 940, 1050, 1095

Hoerlin, M., 121

Hoffman, Erich, 1032

Hoffman, Frederick, L., 190, 673

Hoffmann, Friedrich (Frederick of Halle) (1660–1742): A German physician and chemist, Hoffmann elaborated a mechanist theory that viewed the body as a sort of hydraulic machine. He also left behind clinical descriptions of many diseases including rubella, called "Ger-

man measles" because of his description. 16, 48, 85, 190, 639, 693, 694, 695

Högberg, Ulf, 216

Hogikyan, N. D., 1038

Hohenheim, Phillipus von, *see* Paracelsus

Holladay, A. J., 935, 936

Holmes, Oliver Wendell (1809–94): An American physician and author, Holmes received his medical degree from Harvard (1836). In an article entitled "The Contagiousness of Puerperal Fever" (1842–43), he argued correctly that the disease was contagious and could be carried by physicians from one patient to another. He also experimented with the use of ether and suggested the name "anesthesia." 165, 720, 956, 1014–15

Holst, Axel, 1005

Holzel, A., 813

Home, Francis (1719–1813): A Scottish physician, Home was the first to discover that yeast ferments sugar in diabetic urine. He also vaccinated with material from measles, obtaining some immunity. His *Inquiry into the Nature, Cause and Cure of the Croup* (1765) contains the first clear systematic description of diphtheria. 656, 873

Homer, 262, 264, 656, 1063

Hong, Lysa, 433

Hood, Lou, 136

Hooke, Robert (1635–1703): An English scientist and natural philosopher, Hooke studied at Oxford, where he became an assistant to Robert Boyle. Hooke was an early microscopist who gave the name "cell" to formations in plants that were revealed by the microscope. 15, 103

Hooker, Edna, 936

Hooper, David, 930

Hope, James (1801–41): An English physician, Hope helped prove the value of ausculation, showed how myocardial failure results in dyspnea, and generally did much to advance the field of cardiology. Hope's murmur is named for him. 694, 970

Nicholson, Marjorie, 286

Nicolaier (Nikolaier), Arthur (1862–1942): A German physician, Nicolaier has been credited with the discovery of the tetanus bacillus in 1884 although he did not isolate the organism in a pure culture. 1044, 1049

Nicolle, Charles Jules Henri (1866–1936): A French physician and epidemiologist, Nicolle is best known for his demonstration in 1909 that typhus was transmitted by lice that also carry relapsing fever and trench fever. He was awarded the Nobel Prize in 1928. 969, 1083

Nicot, Jean, 177

Niemann, Albert, 173

Ninsho, 382

Nitze, Max, 18

Noe, G., 729

Noguchi Hideyo (1876–1928): A Japanese-born bacteriologist and pathologist, Noguchi studied medicine in Japan, served in China as a quarantine doctor during an epidemic of bubonic plague, and later settled permanently in the United States. He developed the first pure cultures of *Treponema pallidum* as well as a number of other cultures, and studied Oroya fever and the *verruga peruana* of Peru and Ecuador, demonstrating that they were caused by the same organism. Noguchi became a part of the Rockefeller-led effort to discover the causes of yellow fever and eradicate it. He died of the disease in Africa. 79, 635, 842, 1032, 1105

Oribasius (325–403): One of the last of the great Greek compilers, Oribasius preserved the writings of countless Greek physicians. His *Synagoge* is a 70-volume compilation of medical knowledge from Hippocrates to his own times. 12, 264–5, 267

Orta (Horta), Garcia da (c. 1490–1570): A Portuguese physician, Orta studied medicine at the universities of Salamanca and Acala de Henares and practiced briefly in Portugal before leaving for Portuguese territories in the Far East. He was the first European to describe cholera in modern times and, according to H. Harold Scott, the first European to leave behind works in tropical medicine. The Portuguese regard Orta as the father of tropical medicine. 415, 643, 645

Ortner, Donald J., 251, 252, 309, 602

O'Shaughnessy, W. B., 649

Osler, Sir William (1849–1919): A Canadian-born physician and medical historian, Osler was an authority on the heart but was also responsible for advances in numerous other areas of medicine. His textbook on *The Principles and Practice of Medicine* (1892) was considered the best work in English on medicine at the time. Osler was successively professor of medicine at McGill University, the University of Pennsylvania, Johns Hopkins University, and Oxford University. He became a Fellow of the Royal Society in 1898. 179, 639, 712, 939, 1019, 1028, 1044, 1077

Woodward, Joseph J. (1833–84): An American military physician, Woodward wrote *Diarrhea and Dysentary,* which has been called the greatest single monograph on the subject. 178, 1077, 1079

Wright, Sir Almroth Edward (1861–1947): An English physician and pathologist, Wright conducted research on parasitic diseases and immunology and introduced vaccines for enteric tuberculosis and pneumonia. He is best known for making the first active innoculation against typhoid fever in 1896. 127, 941, 1075

Wright, James Homer, 833

Wright, Sewall (1889–1988): An American geneticist, Wright's studies led to the formulation of rules for inbreeding, crossbreeding, and selection in livestock improvement. He was the discoverer of genetic drift, a process called the "Sewall Wright effect" that can lead to new species. 114, 1040

Wright, Thomas, 62

Wrigley, E. A., 209

Wucherer, Otto Eduard Heinrich (1820–73): A German born in Portugal who spent most of his career in Brazil, Wucherer was a member of the trio (Wucherer, J. F. da Silva Lima, and C. C. Patterson) that has been called the Bahian school of tropical medicine, with their chief organ the *Gazeta Médica da Bahia.* He reported on many tropical illnesses but is best remembered for his confirmation of W. Griesinger's conclusion that tropical anemia was caused by the hookworm and most especially for his spying the embryo form of the filarial worm, which now bears the name *Wucheria bancrofti.* 727–8

Zinke, Georg Gottfried, 965

Zinsser, Hans (1878–1949): An American bacteriologist and medical historian, Zinsser did much research on typhus, and advanced the notion that Brill's disease was a recrudescence of epidemic typhus contracted much earlier. The disease was subsequently renamed "Brill-Zinsser disease." Most medical historians are familiar with Zinsser because of his marvelous study *Rats, Lice and History* (1935). 285, 323, 935, 1024, 1080, 1081, 1084

"The last definitive history of disease was published over 100 years ago. Now Kenneth F. Kiple, in *The Cambridge World History of Human Disease*, has accomplished this feat again."

– *American Libraries*

"*The Cambridge World History of Human Disease* is probably the single most valuable reference work for any scholar of human health and medicine. . . . [T]his work covers an enormous range of biology, history, anthropology, and epidemiology with impressive depth."

– Lawrence M. Schell et al.,
American Journal of Human Biology

"A virtual army of one hundred sixty scholars prepared more than two hundred entries covering the rich panorama of disease in human history, in its many varied geographical expressions. The Napoleonic figure marshaling this assault on the bastions of ignorance and neglect – the one with the vision to see the whole – is editor Kiple, flanked by teams of executive, associate, and assistant editors. . . . There are gemlike discoveries to be made everywhere."

– John M. Hunter, *Geographical Review*

"More than merely a work of reference, this is a fascinating collection of interdisciplinary essays that constitutes a universal history of human disease. The editor has succeeded in imposing a remarkable degree of thematic and stylistic uniformity on a disparate mass of historical and statistical data."

– Gary B. Ferngren,
New England Journal of Medicine

"Every individual and institution interested in and involved with the history of human diseases will find this an important reference work. Kiple and the Cambridge University Press set out to portray the history of human diseases from many angles and in substantial detail, to provide a starting place for researchers, and to 'encapsulate' what this generation knows about the field. They have achieved their goals."

– William K. Beatty,
Journal of the American Medical Association
