In 1896 plague broke out in Bombay, and its diagnosis was confirmed by W. M. Haffkine (Nathan 1898) in October of that year. The mortality rate in Jains at that time was significant, reaching a peak of over 100,000 persons. A Plague Research Commission was formed in Bombay in 1905, which worked under an advisory committee that was constituted in India and included representation of the Royal Society, the Lister Institute, and the India Office. This commission continued to work until 1913, and their studies have formed the basis of our present knowledge of the epidemiology of bubonic plague.

Malaria

Malaria is a parasitic disease that probably tormented primates long before humankind walked the Earth. The Indian art and medical classics make it clear that malaria had a long history on the subcontinent area, a history that has been illuminated at various points in the classical medical texts of ancient Hindu medicine. Susruta established a vague relationship between malaria and mosquito bites. This mythical savant classified the relevant types of fevers, and linked these with specific types of mosquitoes. As in Egypt and Mesopotamia, in the tropical dampness of the Indian river valleys, malaria reaped a deadly harvest, as it had probably done for millennia (1.4 million deaths in British India in 1939 alone) (Thorwald 1963).

The existence of a great many diseases in ancient South Asia is reflected in the Vedic books. As might be expected, fevers predominate because India is still probably the most malarial country on Earth, as well as the breeding ground for plague and cholera. But no clear statistics on the early history of malaria are available.

The nineteenth-century British medical statistics give some clear indications of the intensity of the infection. In Bengal, Bombay, and Madras, over the periods 1847–54 and 1860–75, of 1,110,820 British soldiers, 457,088 (or 41.1 percent) were reported as malarial cases (McGrew and McGrew 1985). Two other nineteenth-century investigations are worthy of mention: (1) In 1845, a surgeon major introduced the spleen rate as a measure of malarial endemicity and used it to map out the incidence of malaria in villages in the Punjab lying along the course of the old Jammu canal. (2) A great advance in malaria therapy was made in 1877 when a method of manufacturing pure quinine sulfate was discovered at the government's Sikkim plantation, which resulted in

a great reduction in the cost of quinine production all over the world.

Kala-Azar or Visceral Leishmaniasis

In India kala-azar has been recognized as a distinct clinical entity for over 150 years. A number of epidemics occurred in Bengal in the mid-nineteenth century, and, although it was undoubtedly confused with malaria, the high treatment failure and mortality rates made the physicians of those days realize that they were dealing with a different illness. More attention was paid to the disease when in 1875 it began to invade Assam; kala-azar swept up the Brahmaputra Valley in three distinct epidemic waves between 1875 and 1917. The nature of the disease was clarified in 1903 when the causal organism now classified as *Leishmania donovani* was discovered by William Leishman in the spleen of a soldier who died in England from kala-azar, which he had contracted at Dum Dum, a military post just outside Calcutta.

Cutaneous leishmaniasis – or "oriental sore" or Delhi boil – is prevalent in the northern and western parts of India, especially in the United Provinces and the Punjab. It is caused by *Leishmania tropica,* which is transmitted by *Phlebotomus papatasii* in the subcontinent.

Other Diseases

Typhoid, influenza, dysentery, hepatitis, tuberculosis, as well as illnesses associated with malnutrition, are comparatively new diseases in South Asia in the sense that they are newly identified. However, leprosy and the venereal diseases are quite old, and ancient Vedic texts include descriptions of these diseases although they are not well sorted out from other diseases of the same classes.

VI.12
Diseases of the Modern Period in South Asia

The history of disease in modern South Asia has been dominated by epidemic diseases. Smallpox, cholera, and malaria, along with plague and influenza, figured prominently among the leading causes of sickness and mortality in the region for much of the period from the eighteenth to the mid-twentieth centuries. The recent decline or disappearance of several of these diseases has correspondingly resulted in a marked fall in overall levels of mortality.

Although the statistics are unreliable in detail (with perhaps a quarter or more of all deaths passing unrecorded), the broad trend is clear. From a peak mortality of nearly 50 deaths per 1,000 inhabitants in British India in the late nineteenth and early twentieth centuries, mortality rates were roughly halved by the 1950s, declining from 42.6 per 1,000 in 1901–10 and 48.6 in 1911–20, to 36.3 in 1921–30, 31.2 in 1931–40, and 27.4 in 1941–50 and 22.8 in 1951–60. In 1966–70, the figure was 15.3 per 1,000. The fall in infant mortality over the same period further confirms this trend. From an annual average of 212 deaths per 1,000 live births between 1911 and 1920, infant mortality in India fell to 176 in 1921–30, 168 in 1931–40, 148 in 1941–50, and 113 in 1966–70 (Davis 1951; Chandrasekhar 1972).

Mortality Levels
The reasons underlying this fall in mortality (and the earlier high levels of mortality) have been much debated. Kingsley Davis (1951) argued that India became "the home of great epidemics" only during the period of British rule (1757–1947), when it was "exposed to foreign contact for the first time on such a great scale." India's "medieval stagnation" was broken down later than that of Europe and so the region fell prey to pathogenic invasions, such as plague, at a later date. But, as in Europe earlier, India's population gradually developed an immunity to these diseases. Thus, Davis argued, even without medical and sanitary intervention, India's epidemic diseases began to lose much of their initial virulence. However, as Ira Klein (1973) has pointed out, some of the most destructive epidemics of the colonial period were not exotics but rather diseases long established in the region. Although India suffered very severely from invasions of plague and influenza between 1896 and

1918, diseases native to the region (notably smallpox, cholera, and malaria) also contributed substantially to the period's heavy mortality.

Davis probably exaggerates India's precolonial isolation. He also neglects its importance as a disseminator as well as a recipient of epidemic disease. The five pandemics of "Asiatic cholera" that raged between 1817 and 1923 all had their sources in India, as did the smallpox epidemics that caused such devastation at the Cape of Good Hope in the eighteenth century. Through extensive trading links developed long before the advent of British rule, as later through the exodus of its laborers and soldiers, South Asia acted as a source of several major diseases. Ancient ties of commerce and conquest with the rest of the Eurasian landmass saved the Indian subcontinent from many of the "virgin soil epidemics" that wrought such human havoc in the Americas and Oceania: Even plague had visited India several times before 1896. The critical factor was thus not so much the arrival of Europeans or the establishment of British rule as the greater degree of external contact that resulted from expanding trade and improved communications during the nineteenth and early twentieth centuries and the consequent social, economic, and environmental changes that facilitated the spread of epidemic diseases, whether exotic or indigenous in origin, throughout the region.

A second explanation for the twentieth-century decline in epidemic mortality focuses on the role of medical and sanitary intervention. Measures to protect South Asia from epidemic disease began early in the colonial period with the introduction of smallpox vaccination in 1802, and it has been claimed that this dramatically reduced the incidence of what had formerly been one of the region's greatest afflictions. Later measures against cholera, plague, and malaria – from mass immunization to chemical spraying – have likewise been identified as decisive factors in the eradication or control of these diseases. Davis (1956) claimed that by the mid-twentieth century, medical technology had the capacity to reduce mortality without waiting for supporting advances in socioeconomic conditions. But the limits of therapeutic intervention have since become apparent (especially with the resurgence of malaria since the 1960s), and recent writers are more skeptical about its effectiveness as an explanation for earlier falls in mortality. The low level of colonial (and postcolonial) expenditure on medicine and public health; the paucity of doctors, hospitals, and medical supplies relative to the size of the population; and

the enormous technical, social, and cultural obstacles in the way of effective medical action – all have been cited as evidence of the limited human capacity to master epidemic disease in South Asia.

A third hypothesis draws close parallels with the European experience. It has been argued that the fall in mortality in eighteenth- and nineteenth-century England owed little to medical advances (apart, latterly, from vaccination) and derived instead from improved living conditions and diet. A comparable development has been suggested for South Asia, albeit at a somewhat later date. Despite massive famines that resulted in some 20 million deaths in British India during the second half of the nineteenth century, it is claimed that there was a significant improvement in economic conditions by 1900. The food supply became more dependable, helped by the construction of an extensive rail network and the expansion of irrigated agriculture; famine relief grew more effective in saving lives, and there was a rise in rural incomes through the stimulus of an expanding market economy. Those epidemic diseases most closely associated with famine – smallpox and cholera – declined with the disappearance of severe famines from India after 1908 (apart from the Bengal famine of 1943–4, which significantly saw a marked recurrence of epidemic mortality). The high death rate was sustained into the 1920s only by epidemics of plague and influenza, diseases that (it is claimed) had little connection with rural poverty and hunger (McAlpin 1983).

This argument has the virtue of singling out famine as a critical determinant of mortality trends in South Asia and hence provides a nonmedical explanation for the decline of two of the greatest killer diseases, smallpox and cholera. But although famine as such may have disappeared from most of the region after 1908, South Asia remained (and remains) afflicted by chronic poverty, with half the population below the poverty line. Malnutrition and overcrowded and unsanitary living conditions have remained fertile ground for disease and have kept mortality and morbidity at levels far above the norm in Western countries. Economic gains have failed to reach most of the people, and per capita foodgrain availability may even have fallen during the course of the twentieth century. There thus seems little basis for claiming that socioeconomic change has resulted in a healthier population. It would be more realistic to argue instead that although the cessation of major famines and the medical targeting of specific diseases like smallpox and cholera have been responsible for reducing or eliminating some of the earlier and most conspicuous causes of high mortality, other "competing" causes of debility and death have taken over or have remained largely unaffected. Mortality has declined since 1900, but sickness and death remain all too common.

Diseases

In view of the diverse characteristics of the main diseases of South Asia and of the various factors affecting them, it will be helpful to consider the recent history of the most important of them in turn.

Smallpox

Smallpox was held by nineteenth-century medical opinion to be "the scourge of India," responsible for more deaths than all other diseases combined. Endemic throughout much of the region, smallpox returned in epidemic strength every 5 to 7 years. So prevalent was the disease between February and May that it was known in eastern India as *basanta roga,* the "spring disease." With the onset of the monsoon season, however, smallpox abated, reaching its lowest ebb in October and November. Climate might provide a partial explanation for this marked seasonality, but social and cultural factors were influential, too. In India the dry spring months, a slack period in the agricultural year, were traditionally a time for congregation and travel, for religious fairs, pilgrimages, and marriages, all activities that provided the close social contact needed for transmission of the *Variola* virus.

In driving large numbers of destitute and undernourished villagers to seek food in relief camps and cities, famines also created conditions favorable to the dissemination of the disease. So, too, did the dislocation caused by warfare. Just as Maratha invasions may have contributed to an upsurge in smallpox mortality in eighteenth-century Bengal, so did the displacement of millions of refugees in the same area during Partition in 1947. Bangladesh's war of independence in 1971–2 also occasioned major outbreaks of the disease (Chen 1973).

In the absence of reliable statistics it is impossible to gauge the full extent of smallpox mortality before the late nineteenth century. One demonstration of the disease's long-standing importance was the reverence paid throughout South Asia to the Hindu goddess Sitala (or her counterparts) as the deity credited with the power to either cause or withhold the disease. A nineteenth-century writer further attested to the prevalence of smallpox when he speculated that as many as 95 percent of the 9 million inhabitants of the north Indian Doab had experienced the disease. So common was it, he claimed,

that "it has become quite a saying among the agricultural and even wealthier classes never to count children as permanent members of the family . . . until they have been attacked with and recovered from smallpox" (Pringle 1869).

As these remarks suggest, smallpox was mainly a childhood disease, the chronology of smallpox epidemics being largely determined by the creation of a pool of susceptible infants born since the previous outbreak. Between 60 and 70 percent of fatalities occurred among children under 10 years of age, and of these half died before they were even one year old, although one of the consequences of the spread of childhood vaccination was to increase the proportion of adult victims.

Smallpox mortality probably reached a peak in British India in the middle and later decades of the nineteenth century before entering a period of sustained decline. From 1.4 million deaths recorded for the decade 1868–77, and 1.5 million for 1878–87, smallpox mortality fell to barely 1 million in 1888–97 and 800,000 in 1898–1907. From 0.8 smallpox deaths per 1,000 inhabitants in 1878–87, the ratio fell to 0.4 in 1908–17 and down to 0.2 in 1937–43, before the Bengal famine and Partition fueled a partial resurgence. Although in epidemic years in the 1870s the number of smallpox deaths soared as high as 2 per 1,000, by the 1930s there were fewer than 0.5 fatalities per 1,000 of the population (James 1909; Hopkins 1983).

Significantly, smallpox mortality began to decline even before the worst famines of the period were over, and exactly when medical intervention began to have an effect on smallpox mortality is unclear. In Sri Lanka, an island with a small population, vaccination may have eliminated endemic smallpox early in the nineteenth century; but because of constant reinfection from India, the disease was not finally eradicated until 1972.

Although vaccination was introduced into India in 1802–3, its impact there at first was slight. Imported lymph was unreliable, and local sources of supply were not adequately developed until late in the century. The arm-to-arm method of vaccination was extremely unpopular, and the bovine origin of vaccinia provoked strong Hindu hostility. Vaccination had, moreover, a popular and well-established rival in variolation (smallpox inoculation), which was considered more effective and culturally acceptable. Faced with such opposition, the colonial regime was disinclined to commit substantial resources to vaccination, and during the nineteenth century it was practiced mainly among Europeans and those

Indians, especially of the middle classes, most closely associated with them. Compulsory vaccination and the outlawing of variolation began in Bombay city in 1877 and was followed by the Government of India's Vaccination Act in 1880. However, the implementation of the acts was piecemeal and deficient. As late as 1945, primary vaccination was compulsory in only 83 percent of towns in British India and a mere 47 percent of rural circles. Compulsory revaccination was even rarer (Arnold 1988). Nevertheless, the evidence suggests that vaccination did contribute to the relatively low levels of smallpox mortality achieved by the early twentieth century. The number of vaccinations in India rose from approximately 4.5 million a year in the 1870s to twice that number in the 1900s and exceeded 40 million (nearly three-quarters of them revaccinations) by 1950. Given the heavy death toll smallpox had formerly levied among those under 10 years of age, vaccination significantly reduced mortality among infants and children.

Existing methods of smallpox control were, however, inadequate to secure the final eradication of the disease. In 1962, the year in which India launched its eradication program, the country reported 55,595 cases of smallpox and 15,048 deaths from the disease. There were a further 4,094 cases and 1,189 deaths in Pakistan (mainly East Pakistan). Five years later, the World Health Organization began its own eradication campaign, which concentrated upon early recognition and reporting of the disease, the isolation of cases, and the vaccination of contacts. The Bangladesh war of 1971–2 delayed eradication and enabled a fresh epidemic to flare up. In 1974 India again suffered a severe outbreak (showing that *Variola major* had lost none of its former destructiveness), with 188,003 cases and 31,262 deaths. South Asia was finally freed of smallpox in 1975.

Cholera

Like smallpox, cholera has had a long history in South Asia. Reliable accounts of the disease date back to at least the sixteenth century, and it was reported from several parts of India during the late eighteenth century (MacPherson 1872). But the cholera epidemic that erupted in the Jessore district of Bengal in August of 1817 assumed an unprecedented malevolence and in barely 2 years it penetrated to almost every part of the subcontinent, including Sri Lanka, before setting out shortly afterward on the first of its "global peregrinations." Epidemics of cholera repeatedly swept through South Asia during the

nineteenth century, and the disease was undoubtedly a leading cause of high mortality and (relatively) low population growth in India before 1914. Perhaps from the absence of any existing immunity, mortality rates were particularly high during the 1817–19 epidemic (though not as high as an alarmed Europe was willing to believe).

The incidence of epidemic cholera in India can be related to a number of factors: The emergence of Calcutta, the most populous city of British India and an important regional center for trade and administration, during the eighteenth and nineteenth centuries favored the wide dissemination of the disease from its endemic home in the Ganges–Brahmaputra delta. As elsewhere in the world, cholera often moved in the wake of advancing armies. Soldiers unwittingly helped spread the disease in northern and central India in 1817–18 and again during the Mutiny campaigns of 1857–8. The seasonal migration of laborers and plantation workers may also have had a comparable effect. They passed through endemic areas, lived in primitive accommodation at the site of their employment, and drew water from contaminated sources.

Of even greater significance was the close association, much remarked upon during the nineteenth century, between epidemic cholera and Hindu pilgrimage. Pilgrims traveled long distances, mainly on foot (before the railway age); they were ill-clothed and ill-fed, and crowded in their thousands into insanitary towns or into makeshift camps at the main fairs and festivals. Cholera not only spread easily and rapidly among the pilgrims themselves but also was carried far afield as they dispersed to their homes. Several of the largest epidemics of the nineteenth century were traced to the festival of Rath Jatra, held annually at Puri in Orissa, close to the Bengal cholera zone, and the 12 yearly bathing festivals, the Kumbh melas at Hardwar and Allahabad on the Ganges (Pollitzer 1959).

As a mainly waterborne disease, cholera was endemic in low-lying areas, such as lower Bengal, where the cholera vibrio flourished in village reservoirs ("tanks") and irrigation channels that were also used for drinking water. But epidemic cholera occurred, too, in conjunction with famine. Although major epidemics could occur (as in 1817–19) in the absence of famine conditions, the scale of cholera morbidity and mortality was greatly magnified by the migrations of the famine-struck, by their lack of physical resistance to the disease, and by their dependence upon scant sources of water and food that quickly became contaminated.

Whereas in times of good harvests cholera tended to retreat to the low-lying areas where it was endemic, many of the worst epidemics between the 1860s and the early 1900s bore some relation with concurrent famine. The disease thus exhibited even more violent fluctuations than smallpox, dying away in some years, only to return in devastating strength once or twice in a decade. In 1874, for example, cholera mortality in India sank to 0.16 per 1,000 of the population; only 3 years later (with famine widespread), it reached 3.39 per thousand, before ebbing away again to 0.64 in 1880.

In 1900 cholera soared to its highest recorded peak with 797,222 deaths in British India, a ratio of 3.70 per 1,000: In this year of sickness and starvation, cholera accounted for a tenth of all mortality (Rogers 1928). But, having hovered at around 4 million deaths each decade between 1889 and 1919, cholera mortality finally began to fall, dropping to 2.2 million in 1920–9, and 1.7 million in 1930–9, although there was a partial resurgence during the 1940s (the decade of the Bengal famine and Partition) to just over 2 million deaths with 500,000 cholera deaths in 1943 alone, nearly 50 percent of them in Bengal. From a death rate of 0.74 per 1,000 in 1925–47, and 0.17 in 1948–63, the ratio continued to fall to 0.0017 in 1964–8. Epidemic cholera did not disappear entirely, however. In 1974, for instance, there were 30,997 reported cases in India with 2,189 deaths. In the same year Bangladesh suffered 5,614 cases and 177 deaths, while Sri Lanka, long the recipient of epidemics originating on the Indian mainland, had 4,578 cases and 343 deaths.

Although various theories were advanced during the nineteenth century to explain cholera's origins and spread, it was only in 1883 that Robert Koch finally identified cholera vibrios in a Calcutta tank. Even without this knowledge, sanitary measures (as taken in Europe and North America) had had some earlier effect, helping in particular to reduce mortality among European soldiers who, until the 1870s, suffered a high proportion of casualties from the disease. Improved sewers and filtered water lessened cholera mortality in several major cities (including Calcutta from 1869); the long-term decline in the disease has also been identified with the creation of public health departments in the provinces from the early 1920s. But the latter were poorly funded, and in India, with a predominantly rural society and a large and growing slum population, sanitary reform had a more limited impact than in the West.

Cholera inoculation proved a less effective form of

prophylaxis than smallpox vaccination, and the connection between cholera and Hindu India's pilgrimages and sacred sites made the colonial authorities wary for a long time of provoking a religious backlash. But, for all this, anticholera inoculation is likely to have had some success in curbing the explosions of mortality formerly associated with pilgrimages and melas. For many years a voluntary practice, inoculation for pilgrims became compulsory in 1954 in time for the Allahabad Kumbh mela, when nearly a quarter of a million pilgrims were inoculated. Combined with intensive medical surveillance and prompt reporting, inoculation contributed to the decline of epidemic mortality, although, again, the absence of major famines after 1908 (apart from that of 1943–4 in Bengal) must also have been a contributory factor.

In addition, the virulence of the disease may have been on the wane by 1914 (or human resistance may have been increasing). The El Tor biotype, which invaded the region from Southeast Asia in 1964–5, proved less fatal than the "classical" form it largely displaced. Immunity acquired early in life, rather than inoculation or improved sanitation, possibly contributed most to cholera's long-term decline. But, despite this, cholera remains a recurrent threat to human health in South Asia.

Other Enteric Diseases

The reasons for the persistence of cholera – insanitary living conditions and contaminated water supplies – are also reasons for the continuing importance of other enteric diseases. *Dysentery* and *diarrhea* have long been significant among the major causes of sickness and death in South Asia, and, like cholera, greatly swelled mortality during times of famine. Alexander Porter (1889), in his pioneering study, reckoned dysentery and diarrhea the chief cause of death among famine sufferers in Madras in 1877–8. In the high wave of mortality at the turn of the century, one death in every seven in British India was attributed to dysentery and diarrhea, placing these diseases in third place behind malaria and plague as major killers. But they also accounted for a great deal of the mortality even in nonfamine times, particularly among children. In 1962 in India they were responsible for 179,714 deaths (equivalent to 0.4 per 1,000 population). In 1974, along with 846,858 cases of gastroenteritis and 333,687 of typhoid (with 3,623 and 924 deaths, respectively), dysentery, with 4.5 million cases and 2,182 deaths, stood high among the most commonly reported illnesses.

Malaria

Although malaria has undoubtedly been present in South Asia for a very long time, it was not recorded separately from other "fevers" until late in the nineteenth century and so is even more difficult than are smallpox and cholera to trace in recent times. But, once identified as a distinct disease, malaria was soon recognized as a primary cause of much ill health and death. Almost a fifth of the mortality that occurred between the 1890s and the 1920s (amounting to some 20 million deaths) was attributed to malaria. As plague, smallpox, and cholera abated, so malaria gained prominence as the greatest single threat to health in South Asia. J. A. Sinton estimated in the 1930s that malaria was responsbile for 3 or 4 times as many deaths as the 3 other diseases combined. Of 6.3 million deaths in British India between 1924 and 1933, at least 1 million, he believed, were directly attributable to malaria, while millions more, weakened by the disease, fell ready prey to other ailments and afflictions. In addition, the disease was a frequent cause of abortions and stillbirths.

As elsewhere, malaria in South Asia has had a close relationship with the environment and with environmental change. During the nineteenth century, the expansion of irrigation canals and the building of railway embankments and other major construction works that interfered with the natural lines of drainage or left patches of stagnant water created human-made environments in which malaria-bearing *Anopheles* mosquitoes could breed (Klein 1972). South Asia thus failed to experience the beneficial side-effects of the draining of marshlands and swamps that contributed so significantly to malaria's decline in Europe. The extension of irrigated cultivation and the dense settlement it commonly sustained in South Asia, combined with the development of new networks of labor migration and mobility, have also tended to create conditions favorable for human transmission of the disease.

Until recently, malaria infestation largely prevented agricultural colonization of areas like the Terai in the Himalayan foothills and the hill tracts along the Andhra–Orissa border. The partial eradication of malaria in the 1950s and 1960s facilitated the penetration and settlement of these areas, but its return severely affected immigrant farmers (e.g., in the Chittagong Hill tracts of Bangladesh) with no inherited or acquired immunity to the disease.

Like the other diseases so far discussed, malaria has some connections with human hunger. S. R. Christophers (1911) showed a close correlation between

peaks of malaria mortality and morbidity in the Punjab between 1869 and 1908, and periods of high food prices, a basic index of widespread poverty and incipient famine. But in this instance the decline of famine was apparently not matched by any corresponding downturn in malaria morbidity and death.

Around 1950 malaria was still killing 500 out of every 100,000 of the population in South Asia, with India alone suffering 800,000 deaths a year. Although quinine prophylaxis and the mosquito nets and screens have provided limited protection to a small minority (mainly Europeans), the advent of DDT from the end of World War II made a comprehensive assault on malaria possible for the first time. India launched a National Malaria Eradication Campaign in 1958, and such was the apparent success of DDT spraying there and in Sri Lanka that Davis (1956) was prompted to write of the "amazing decline" in Third World mortality modern medicine made possible. But the triumph soon proved short-lived. Increasing anopheline resistance to DDT and the diminishing effectiveness of the drug chloroquine resulted in a startling recrudescence of malaria during the 1960s and 1970s. From a low point of 50,000 cases in India in 1961, the number rose to 1.4 million in 1972 and 1.9 million in 1973. It then shot up to 3.2 million in 1974 and 5.2 million in 1975. Two years later, in 1977, an estimated 30 million people in India were suffering from malaria.

Plague

Although not unknown to the subcontinent in previous centuries, plague arrived in epidemic force in 1896, when the disease broke out in Bombay city and then gradually spread to other parts of western and northern India. By 1907 close to 2 million plague deaths had been recorded, and at its peak in 1904–5 the number of deaths reached 1.3 million in a single year. By 1907–8 plague accounted for more than 14 percent of all mortality in British India, and its heavy toll swelled India's great mortality between the 1890s and the 1920s. In this third plague pandemic, India was exceptionally hard-hit. Of 13.2 million deaths recorded worldwide between 1894 and 1938, 12.5 million occurred in India: Nearly half of the deaths in India fell in the period from 1898 to 1908, with a further third between 1909 and 1918 (Hirst 1953). At first mainly a disease of the cities, plague moved steadily into the countryside. The Punjab was worst affected, with nearly 3 million fatalities between 1901 and 1921; in 1906–7 alone there were 675,307 deaths in the province, equivalent to 27.3 per 1,000 inhabitants.

But for all the severity of the disease, plague in modern India never took as heavy a toll of human life as in Europe during the Black Death of 1347–9, partly because the deadly pneumonic form of the disease was absent. Several areas escaped largely unscathed. Northern and western India bore the brunt of the epidemic, whereas Bengal, the south, and Sri Lanka were far less affected. One possible explanation for this, favored by L. Fabian Hirst, was that the type of flea found on the rats in western and northern areas, *Xenopsylla cheopis*, was a more efficient vector of the plague bacillus than *Xenopsylla astia*, which was more common in southern regions.

At the start of the epidemic, in part responding to international pressure and the threat of commercial sanctions by other European powers, the British adopted measures of far greater severity than previously employed against cholera and smallpox. Suspects and victims of the disease were hospitalized or put in segregation camps; house searches were made to discover concealed cases and corpses; many thousands of travelers were examined, and walls and roofs pulled down to allow sunlight and fresh air into dark interiors. At this early stage the role of rat fleas in the transmission of the bacillus was not understood, and the assumption was that plague was a disease of "filth" or an "acute infectious fever" spread through close human contact.

But medical intervention on such a scale proved singularly ineffective. It failed to extirpate the disease, which continued to spread (in part through people fleeing from such drastic measures), and it led to evasion and even open defiance in several cities. In consequence, the British administration soon settled for a less interventionist policy, turning down W. M. Haffkine's suggestion of compulsory inoculation with the antiplague serum he had recently developed. Reliance was placed instead upon voluntary segregation and hospitalization, greater use of indigenous medical practitioners, and latterly (once the rat flea connection had been established) on the trapping and poisoning of rats.

These measures may have contributed to the decline of the disease, already marked by 1917; so also may the extensive use made of voluntary inoculation (in the long term). It is possible that just as the prevalence of famine in the early years of the epidemic aided the spread of plague, so the later absence of famine contributed indirectly to its decline. The bulk movement of grain (and with it *X. cheopis*) in times of food shortages may have facilitated the spread of the disease: There is some evidence for this connection in its partial resurgence as a result of the

massive movements of grain triggered by the Bengal famine of 1943–4. Another possibility is that whereas human susceptibility remained unchanged, rats developed a growing immunity to the plague bacillus. For whatever reason, plague was in decline in India from the early 1920s and, since 1950, has been rare, confined to a few isolated pockets, mainly in the southern Deccan.

Influenza

Influenza had a much shorter but more devastating career than did plague. As with plague, India was one of the areas of the globe hardest hit by the influenza pandemic of 1918–19. In the space of barely 3 months it lost between 12 million and 20 million lives, equivalent to nearly 5 percent of the total population of British India, and up to twice as many as had fallen victim to plague during the whole of the previous decade. As with plague, influenza entered India through international ports like Bombay, but then moved with lightning speed from one city to the next along the main lines of transport and communication. Southern and eastern India were again the areas least affected (Davis 1951; Mills 1986).

The greatest number of deaths occurred during October, November, and December 1918, with the major casualties being young adults between the ages of 20 and 40. Connections between influenza and famine have often been denied, but because the epidemic struck at a time of high prices and food shortages in several parts of India and caused disproportionate mortality among the poorer classes, grounds exist for arguing that one reason why India suffered so severely from the epidemic was precisely because so large a part of its population was at the time hungry or malnourished (Klein 1973; Mills 1986). As elsewhere influenza died away almost as quickly as it had come, and though influenza has remained a common affliction in the region, it has been responsible for few deaths. In 1974, for example, 1,700,000 cases of influenza were reported for India, but there were only 87 deaths.

Tuberculosis

Tuberculosis was not a disease that attracted much medical attention before 1945, but it has increased in importance as other diseases have declined and as the crowded, especially slum, conditions in South Asian cities have grown. Already at the start of the century, TB and the other respiratory diseases accounted for at least one-seventh of all deaths. Fully 342,391 deaths from the disease were reported in

India in 1961–2 (equivalent to 0.85 per 1,000), and between 100 and 150 out of every 100,000 city-dwellers died from this cause. By 1981 an estimated 1.5 percent of the total population of India was affected, placing TB among the leaders of India's many competing causes of death.

Miscellaneous

Several other diseases warrant mention, however briefly. *Tetanus* in India has been particularly associated with childbirth through the use of unsterilized implements to cut the umbilical cord. Cases numbered 32,825 in India in 1974, with 4,400 reported deaths. *Hepatitis* was widespread, too, with 126,071 cases and just over 1,000 deaths in 1974. In that year there were also 206,386 cases of *whooping cough* (300 deaths) and 333,697 (924 deaths) from *typhoid,* making these, along with malaria, dysentery, gastroenteritis, and influenza, two of the main identifiable causes of morbidity.

Leprosy remains strongly entrenched in South Asia. Whereas the census of 1881 counted only 131,618 lepers in British India (surely a gross undernumeration), the census of India 90 years later, in 1971, put the figure at 3.2 million. Some experts, however, estimate at least 4 million cases of leprosy in the country. Not only is this a high figure in national terms, with 5 to 6 per 10,000 of the population affected, but it also makes India home to one-third of the world's leper population. Despite the availability of modern drug therapies, the socioeconomic conditions in which leprosy is transmitted (and perpetuated) have so far prevented its effective eradication.

Conclusions

Several major epidemic diseases of the recent past have been brought under control (or have largely disappeared through reasons that may have little to do with human intervention). But, so long as poverty remains endemic in the region and levels of public health expenditure and provisioning remain low even by Third World standards, there seems little likelihood that the high levels of morbidity and mortality that continue to afflict the region will effectively disappear.

VI.13
Diseases of Antiquity and the Premodern Period in Southeast Asia

In the imaginations of commentators, both Asian and European alike, disease and Southeast Asia have long held a close association. For Chinese officials posted to the southernmost regions of the T'ang empire, it was a fearful place of miasmas and malarial fevers. To many Europeans, Southeast Asia was, like tropical Africa, a "white man's grave." In the chronicles of the inhabitants of the region, the reality of disease merged with that of other calamities, in a world populated with spirits that held sway over human life. Aside from biomedical considerations, there are clearly important political and cultural dimensions to these links between region and disease. This essay will examine some of the factors that have given disease such a prominent place in Southeast Asian history.

The Region

Following Anthony Reid (1988), Southeast Asia will here be taken to refer to the area of Asia lying between the southern regions of China and the northwestern extremities of New Guinea. This region encompasses both the land areas of mainland Asia draining the eastern Himalayas, characterized by large rivers and plains, and the many volcanic islands lying between the Pacific and Indian oceans. A feature of the region is its high temperatures and monsoonal rainfalls, which, prior to recent times, supported an abundant flora and fauna.

Human settlement also flourished in this environment from around 18,000 B.C., when the earliest hunter-gatherers are thought to have existed in the region (Higham 1989). Evidence suggests that village settlements developed from around the third or fourth millennium B.C., and more complex, centralized polities from the first century A.D. (Coedès 1975; Higham 1989). The larger "city-states" of mainland Southeast Asia developed from the sixth and seventh centuries A.D. It is from the time of the development of these complex polities that the earliest written records of Southeast Asian peoples date.

Prior to the nineteenth century, the region was, as a whole, sparsely populated, the inhabitants concentrated mainly in large trading cities and areas of wet

rice cultivation (Reid 1988). With the development of "city-states" and an increase in commerce and trade both within the region, and with China, India, and the Middle East, important changes occurred in Southeast Asia. These changes, which affected the size and distribution of Southeast Asian populations, their occupations, living conditions, and diet, were further enhanced by the contact with the West, via both Africa and the Americas, which developed from the sixteenth century. This culminated in the colonization of much of Southeast Asia by European powers, beginning with the establishment of a Portuguese colony at Malacca in 1511.

The development of the region was, however, confined to certain sections of the region and its population. Until very recently, a considerable proportion of the people of Southeast Asia lived much as they had hundreds of years ago. There remain, for example, hunter-gatherer communities in remote areas of Borneo and Northern Thailand. Even for villagers living in rural areas, and the urban poor, many aspects of thought and culture continue to reflect traditional concepts and values. For this reason it is difficult to make a general distinction between "antiquity" on the one hand, and the "premodern" and "modern" periods on the other. For the sake of convenience, however, in this essay "antiquity" will be used to refer to the period prior to the entry of Europeans into the Southeast Asian region. The period following the entry of Europeans into the region, up until the beginning of the present century, will be termed the "premodern era" of Southeast Asian history.

The peoples who inhabited the region in antiquity spoke languages representing a diversity of families, including Austronesian, Austro-Asiatic, and Tai. However, though there were considerable regional variations in their customs and rituals, a good many of the peoples of the region were unified by some basic cultural features. Thus, throughout much of Southeast Asia, transport was (until recent times) mainly by water, dwellings were of wood and bamboo, and rice and fish formed the basis of the diet. Similarly, the custom of betel chewing, and sports such as cockfighting and *takraw*, played with a rattan ball, were common to many peoples. Trade, and the ease of maritime access within the region, probably facilitated the process of acculturation (Reid 1988).

Beliefs regarding the soul and the spirit world were also widely shared throughout Southeast Asia. It was believed that if the soul, or life-force, contained within the human body were weakened or disturbed in some way, then health could be im-paired. The outside world was believed to be populated by spirits that had the potential to inflict harm on humans (Anuman 1962; Endicott 1970; Terwiel 1978). Practices performed in order to strengthen the soul, or to propitiate the spirit world, were thus common to the region as a whole (Reid 1988).

The natural wealth of Southeast Asia, together with its intermediary position between the East and West, has ensured that contact with some of the world's major civilizations has taken place over a long period of time. Early contacts with China and India were later followed by Arabs and then Europeans. Many features of these civilizations – in particular, religion and writing – were to become important in Southeast Asian life. However, at least up to the premodern period, as Reid points out, ties within the region were generally more important than those with peoples beyond it (Reid 1988).

This "distancing" from civilizations outside the region is reflected in the pattern of the adoption of cultural features. There is strong evidence to suggest that aspects of other civilizations were restated in terms of the indigenous cultures concerned (the phenomenon termed "localization" by Owen Wolters in 1982) in many of the areas where such borrowing occurred. It will be argued here that this process of adaptation was also prominent in the classification of, and response to, disease.

Disease in the Southeast Asian Past

Knowledge of disease in the Southeast Asian past is severely constrained by some of the same features that give the region its uniqueness. Human remains, and written records of disease, deteriorate rapidly in the acid soils, heat, and humidity that are characteristic of this part of the world. This lack of sources would, in itself, constitute a major difficulty in the study of the history of disease in Southeast Asia. However, the cultural diversity of the region also raises other issues fundamental to the interpretation of the past. For our purposes, paramount among these is the question of differing perceptions of disease.

Following Arthur Kleinman (1987), the term "disease" will be used here to include a wide range of explanations or perceptions of illness. Unlike plants and animals, most diseases are not so readily distinguishable by common features. Not only do peoples differ in the ways in which they group the various symptoms of illness into diseases, but there may be considerable variation in the types of bodily phenomena that constitute symptoms. Conditions such as the enlarged spleen associated with malaria may, among

some populations, be regarded as nonpathological (Ackerknecht 1946). With other peoples, much emphasis is placed on whether symptoms are located in the upper or lower part of the body and the time of their onset in relation to the phases of the moon (Ohnuki-Tierney 1981; Mulholland 1987). In some cases there may even be little distinction made between disease and the agent that causes it (Schafer 1967). As a consequence, available descriptions of illness often do not provide the type of information that is necessary for biomedical diagnoses to be made.

Information on illness in the Southeast Asian past comes in several forms: In addition to what may be regarded as indigenous classifications, there are Indic, Chinese, and early Western systems of classification. It is possible, for example, that a case of diarrhea might be seen as "internal heat," "an expansion of the heat element," "fluxes," or as a "normal" phenomenon, depending on the source of the description. Furthermore, as Norman Owen (1987) has indicated, a feature of the Southeast Asians' response to disease was their syncretism. An appropriate diagnosis and treatment was selected from among the various systems available. For this reason, a history of disease in Southeast Asia is, in part, a history of the ways in which illness has been classified in this region of the world.

This is not to say that biomedical interpretations are not possible. In past accounts one can recognize many of the diseases that were known in the region until quite recent times and, in a large number of cases, are still prevalent in the region today. Malaria, smallpox, dysentery, cholera, typhoid, typhus, plague, leprosy, beriberi, goiter, trachoma, respiratory diseases, tuberculosis, and parasitic and helminthic infestations are but a few examples. However, although it is often possible to interpret accounts of illness in terms of our modern understanding of pathology, this approach reveals only one aspect of the history of disease in Southeast Asia. Neglected is the place of disease in the context of extra- and intraregional dynamics involving trade, warfare, politics, and culture. In short, biomedical interpretations do not show how Southeast Asians perceived disease and what it meant to them.

Another difficulty in treating the history of diseases in Southeast Asia as a whole is posed by the number of different ethnic groups and languages in the region. This problem is further exacerbated by the diversity of languages and methodologies of the available secondary sources on the subject. For this reason, although the general features described will relate, in the main, to the history of diseases in the whole of Southeast Asia, the specific illustrations given in this essay will be taken mainly from mainland Southeast Asia. In particular, a good many examples will be drawn from the Thai peoples.

There are several reasons for this narrow focus. In part it reflects this writer's own area of specialization, a situation that is unavoidable in approaching such a topic. In addition, however, the history of disease among the Thai peoples is an appropriate focal point for a study of the disease in Southeast Asia. The region of mainland Southeast Asia where the Thai kingdoms developed in many ways represented a meeting place for the major civilizations of Asia, lying between China to the north, India to the west, and the Austronesian peoples to the south and east. Originating in the north, the Thai, who were "syncretizers" par excellence, moved into a region already occupied by Mon and Khmer peoples. Furthermore, although the kingdom of Siam came to dominate the other Thai "city-states," it was alone among Southeast Asian countries in remaining uncolonized by Europeans. On the other hand, it may be argued that, though not directly colonized, Siam was a de facto colony, in that its development during the late nineteenth and early twentieth centuries was mainly in the hands of European and American advisors.

Previous historical studies have not, in general, taken advantage of the opportunities that mainland Southeast Asia presents for the examination of disease. The processes of adaptation, perception, and response to illness have, for the most part, been examined in the context of the colonized regions of insular Southeast Asia. This is to be expected, in view of the ready availability of information on disease, and the size of the populations in these areas, with their concomitant health problems. But in using illustrations from uncolonized mainland Southeast Asia, this chapter seeks to redirect some of the emphasis in the study of the history of disease.

Diseases in the Prehistoric Period

Our knowledge of the types of diseases suffered by the prehistoric inhabitants of Southeast Asia is, of necessity, based on the examination of a very limited range of human remains unearthed in a few sites in present-day Thailand, the Malay Peninsula, and Sulawesi. The remains represent only the most durable of the body's hard tissues, primarily the skull, mandible, and teeth. Despite such limitations, however, they nevertheless reveal a good deal of information regarding the diseases suffered by the ancient inhabitants of the region.

Skeletal remains, for example, recovered from sites at Ban Chiang, Non Nok Tha, and Ban Na Di in northeastern Thailand suggest that the prehistoric inhabitants of these villages suffered many of the same diseases found in these areas today. As might be expected from the nature of the source materials, these included a range of diseases primarily affecting the skeleton, such as osteoarthritis (or degenerative joint diseases), and bone infections, possibly including osteomyelitis and tuberculosis of the spine.

There is also evidence for a range of dental pathology, including caries, periodontal disease, abscesses (periapical and alveolar), and excessive tooth wear, sometimes with pulpal involvement (Pietrusewsky 1974, 1982, 1982–3; Houghton and Warrachai 1984). Evidence for caries, periodontal disease, and abscesses has also been found in human remains from sites at Talaud Island in North Sulawesi, and Gua Cha in the Central Malay Peninsula (Bulbeck 1982).

In addition, examination of skeletal remains provides evidence of diseases affecting other organs of the body. These include tumors, or tumorlike defects (in a child's cranium from Ban Chiang), and blood disorders. Evidence for the latter comes from a number of skeletons found in northeastern Thailand, which, it has been argued, may indicate thalassemia or elevated hemoglobin B levels (Pietrusewsky 1982, 1982–3).

These conditions, both of which are widespread in the region today, may be associated with resistance to malaria, which is common in the area. Indeed the evidence from the pathology observed in skeletal remains has thus been used to argue for the antiquity of malaria (Pietrusewsky 1982). More recently, however, iron deficiency anemia has been put forward as an alternative explanation (Houghton and Warrachai 1984). This explanation is consistent with the effects of parasitic infestations of the body, which are also prevalent today in this region of Southeast Asia.

Diseases in Antiquity

Apart from evidence derived from archeological research, the earliest available sources of information on disease in Southeast Asia are references in inscriptions and accounts appearing in traditional texts. Khmer inscriptions of the seventh and eighth centuries A.D., for example, make reference to lice, eye impairments, and "dermatitis" or "ringworm" (Jenner 1981). It is difficult to date some of these sources, especially texts, but it is clear that by the time of their appearance there had already been considerable contact between Southeast Asia and civilizations in other parts of Asia. Much of the language used, and the means of recording itself, were exotic in origin. Originally these descriptions were made using techniques probably borrowed from India or China. Inscriptions were made on stone, or on palm leaves trimmed and bound together with cord, or else written on paper. The scripts employed were similarly of Indic or Chinese origin (Guy 1982; Marr 1987).

Traditional Medical Texts

In addition to short references to disease in chronicles, or other official records, certain works were devoted solely to medicine. These appear to have been a feature of almost every major civilization in the region, including those of the Burmese, Thai, Lao, Khmer, Vietnamese, Malay, Javanese, and Balinese (La Loubère 1691; Sangermano 1833; Macey 1910; Pigeaud 1967; Pham Dinh Ho 1973; Martin 1983; Social Research Institute 1986; Lovric 1987; Reid 1988). Commonly, the contents of these books consisted of passages relating to theories of illness, lists, and descriptions of diseases, and details of the methods used in their treatment.

It is likely, however, that such texts provide incomplete accounts. One reason for this is their perishability. Being sensitive to decay and insect attack, traditional texts had to be continually recopied in order to preserve their contents. Not only did this introduce the possibility of human error through mistakes in transcription, but, more importantly, there was always the threat that disruptions caused by warfare or other adversity would result in the loss of large numbers of texts. For example, in 1767 the Siamese capital of Ayuthaya was sacked by the Burmese, an event which, in itself, resulted in the destruction of much of the court's medical library (Koenig 1894). Moreover, the loss was compounded by the slowness of the subsequent recompilation process, which was not completed until some 40 years later, around 1816.

Another difficulty in the use of traditional texts as source materials is in determining the extent to which their contents reflected diseases actually occurring in Southeast Asia, and their prevalence. It is quite possible that accounts of diseases contained in texts may be largely based on Indic, Chinese, or, later, Arabic medical treatises. This is certainly the case with other types of texts, such as literary or astrological works (Quaritch Wales 1983; Reid 1988). On the other hand, evidence suggests that, although Southeast Asian medical texts may incorporate disease terms and concepts derived from tradi-

tions outside the region, they are not simply translations of texts belonging to those medical systems. It appears that in the area of disease, as with other aspects of Southeast Asian culture, a process of localization took place, resulting in the selective emphasis of certain concepts of parts of theories, and changes in the meanings of words borrowed from languages outside the region. Some examples of these processes will be considered later in this essay.

Travelers' Accounts

A further important source of information on disease in Southeast Asia consists of the accounts written by early travelers to the region. These included the Chinese Buddhist monk Yi Jing, who passed through the region on his way to India toward the end of the seventh century A.D. (I Tsing 1896), Chou Ta-kuan (1951), who accompanied a Chinese ambassador to Cambodia in the thirteenth century, and the later European travelers such as S. de La Loubère (1691), and E. Kaempfer (1906). Kaempfer's account is of particular interest, because he represented a class of scholarly voyagers whose interests often extended to a number of disciplines. As a physician and botanist, he took care to record accurately what he saw and heard, including indigenous terms and descriptions. When compared with accounts obtained from indigenous texts, such information is extremely useful.

Ethnomedical Studies

Modern-day studies of indigenous perceptions of disease in the Southeast Asian region constitute another important kind of available information. As well as information on disease appearing in the context of more general anthropological or linguistic studies, a number of specific examinations of indigenous medical systems in Southeast Asia have been conducted. These include those of insular peoples, as well as those of mainland Southeast Asia (see, e.g., Frake 1961; Martin 1983; Boutin and Boutin 1987; Brun and Schumacher 1987; Gumpodo, Miller, and Moguil 1988; Bamber 1989). Although there have been far-reaching changes in Southeast Asian life, it is probable that, until quite recently, for a large number of people in the region, life was lived in much the same manner as it had been centuries ago (Hall 1981). It is thus likely that, for certain sections of the Southeast Asian population, present-day perceptions and treatment of disease bear a strong resemblance to those of the past. An analysis of such contemporary "folk" medical beliefs and disease classifications, made in conjunction with information

derived from the other sources discussed above, may thus make an important contribution toward our understanding of disease in Southeast Asia in ancient times.

Indigenous Views of Disease

It is clear from the information contained in the various sources described above that in the past, Southeast Asian peoples recognized a large number of diseases, and classified them in ways that were, in many cases, quite complex. One feature, which is immediately striking to an observer familiar with Western concepts, is that conditions that are understood to be diseases in modern medicine were not necessarily viewed as such by Southeast Asians. This is especially evident in the area of diseases affecting the gastrointestinal tract which, along with "fevers," occupy perhaps the most prominent place in accounts of illness in the region (see Dampier 1927; Chou Ta-kuan 1951; Schafer 1967; Cook 1968).

A number of severe gastrointestinal diseases were well differentiated by Southeast Asians and elicited treatment responses. Symptoms and treatments for conditions such as cholera, dysentery, severe diarrhea, and certain types of parasitic infestations were, for example, described in traditional texts (Mulholland 1979; Lovric 1987; Terwiel 1987). However, certain other conditions that biomedicine would recognize as diarrhea were apparently not always considered to be diseases. Recent studies indicate, for example, that in certain areas of Southeast Asia infant diarrhea is not necessarily viewed as pathological. Thus, among some Northeast Thais one type of diarrhea (su) may be regarded as a normal phenomenon, common to all infants (Earmporn, Pramote, and Stoeckel 1987). This would also appear to be the case for people in parts of northern Thailand and Laos. Similar findings have been reported for the Acehnese and other Indonesian peoples (Raharjo and Corner 1989).

It is likely that such poorly defined boundaries between pathological conditions and "normal" bodily states are also to be found for other types of disease. Included in these are a number of Southeast Asian disease categories that are unrepresented in modern medicine. Examples of these that are better known because of their dramatic expression are the conditions of amok and latah, Malay behavioral syndromes that appear to have counterparts in other parts of Southeast Asia (Westermeyer 1973; Simons 1985).

Other conditions, lacking such overt behavioral symptoms, reflect classifications of illness that are

equally different from those of modern medicine. One such disease is the Thai category *saang* (children's disease), which includes a range of symptoms mainly affecting the mouth and skin of young children (Mulholland 1987). The onset of this disease has strong links with Thai beliefs regarding "soul loss" (Hanks and Hanks 1955; Hanks 1963).

Shared Disease Terms

It is apparent from a comparison of disease terms in a number of Southeast Asian languages that certain categories were widely shared throughout the region. One explanation for this situation is the contact that resulted from the movement of large populations within the region, such as occurred with the establishment of the Tai peoples in the Chaophraya River valley and the Malay Peninsula from the mid-eleventh century A.D. (Wyatt 1984). Contact with peoples already established in the region, such as the Malay, Mon, and Khmer, was reflected in the adoption of disease terms from these languages. Thus, for example, the Malay disease *sawan* (convulsions), which affects small children (Wilson 1985), also appears, as *saphan* or *taphan,* in traditional Thai medical texts (Mulholland 1987).

A similar though more complex process seems to have taken place with respect to terms for certain types of skin diseases. This may be seen in the case of the ancient Mon–Khmer term *mren,* which probably referred to skin afflictions in general. This term appears to have undergone a change in meaning at some stage, possibly prior to contact with the Thai, to signify ulcer in Khmer, and superficial skin conditions in Mon (Shorto 1971).

Following contact with the Mon and Khmer, the term *mren* was adopted by the Thai, cognates appearing in traditional medical texts as *mareng* and *baheng.* In this case, however, because in Thai skin diseases appear to have been well differentiated prior to contact with the Mon and Khmer, there is evidence of an accommodation with existing terms (Li 1977). Thus in central Thai, which was in close contact with Khmer, *mareng* came to mean "deep-seated ulcer" (McFarland 1944). However, in northern Thai *baheng* refers to superficial skin diseases, indicating that the term was adopted from the neighboring Mon peoples (Brun and Schumacher 1987).

These examples also point to the existence of more complex processes within the Southeast Asian region which contributed to the sharing and interchange of terms and concepts related to disease. Medicine was an area of culture that was particularly amenable, for a number of reasons, to trade

and exchange (Golomb 1985). These processes would have involved not only concepts and terms indigenous to the region but also those originating from outside Southeast Asia – in Chinese, Indic, or Islamic medicine. Perhaps the most well-known example of the integration and adaptation of foreign concepts of disease into the Southeast Asian framework is that of the so-called wind illness.

"Wind Illness," Humoral Theories, and Therapeutic Practices

A type of illness common to most of the peoples of Southeast Asia has been termed wind illness (Hart 1969). The disease has been reported among Indonesian and Malay peoples, where it is referred to as *masuk angin,* literally "wind enters" (Gimlette 1939), among Filipinos (Hart 1969), Burmese (Sangermano 1833), Khmer (Headley 1977), Vietnamese (Eisenbruch 1983), and a number of Thai groups. The conditions represented by wind illness vary widely through the region, ranging from symptoms of the common cold among Indonesians and Malays, to fainting, dizziness, and, more rarely, leprosy, among mainland Southeast Asian peoples.

Most explanations for the phenomenon have been made in terms of theories derived from the major medical systems with which Southeast Asian peoples have come into contact. In Chinese medicine, for example, wind illness figures as part of a theory that sees disease arising through the entry of wind into the body (Unschuld 1982). Wind illness is similarly important in the humoral theories of Indic and Islamic medicine. Here, however, it refers to diseases of the wind element, one of the four elements (the others being earth, fire, and water) of which the body is said to be composed (Hart 1969; Ullmann 1978). According to the Indic version of this theory, the wind element denotes the quality of bodily movement, or sensation. Any disease that involves an impairment or abnormality in these faculties would thus be designated as a wind illness. Following from this rationale, wind illness includes a number of diseases or conditions, such as paralysis, epilepsy, and leprosy, which are considered in modern medicine to constitute quite separate disease entities (Caraka 1949).

Versions of both these theories are to be found in the Southeast Asian region. The Indic theory of the four elements is expounded, for example, in Thai medical texts (Mulholland 1979); Islamic humoral theory is widely known in peninsular Malaysia and Indonesia (Manderson 1986); and beliefs regarding the ill effects of the entry of wind into the body

accompanied Chinese who settled in the region (Kwa Tjoan Sioe 1936). However, the wind illness of Southeast Asia does not always fit neatly with these theories. Early writers on Thai medicine commented, for example, on the prevalence of wind illness in comparison to diseases affecting the other three elements (Pallegoix 1854; Bradley 1967). Thai wind illnesses also appear to have encompassed a far wider range of diseases than one would expect on the basis of Indic theory (Muecke 1979).

Discounting the unlikely possibility that Thais, or other Southeast Asian peoples, are predisposed to diseases affecting bodily sensation or movement, it would seem that the Indic concept of wind illness has been reinterpreted to accord with indigenous concepts relating to the cause of illness. These concepts probably have more to do with beliefs linking disease to soul loss, or the spirit world, than they do with humoral theories (Laderman 1987). The resulting concept of wind illness represents a complex, incorporating elements derived from both within the Southeast Asian region and outside of it.

Similar interactions may be seen throughout the region in relation to other aspects of disease. For example, the etiological concept of hot and cold physical states is also widespread in Southeast Asia. Accordingly, certain diseases, foods, and treatment practices are regarded as heating or cooling (Hart 1969; Manderson 1981). As with wind illness, this concept appears to be the result of an integration of indigenous beliefs with Indic, Islamic, or Chinese theories (Manderson 1981; Marr 1987).

Therapeutic practices were also shared throughout the region. One well-known example is in the ritual ridding of a person, or community, of disease. Among the central Thai this was termed *sia kabaan*, and consisted of the symbolic transference of the disease to inanimate objects, such as dolls or animal images, which were subsequently floated away on streams, or otherwise removed from the locale of the patient (Anuman 1958). Similar rituals have been described for most other Thai groups (Terwiel 1980–1), and in several other regions of Southeast Asia, with variations according to the local culture (Snouck Hurgronje 1893; Skeat 1900; Reid 1988). Often these local variants included elements derived from Indic or Islamic tradition.

The picture that emerges from this brief look at some of the features of Southeast Asian views of disease prior to increased contact with the West is one of a dynamic state. Close contact among peoples within the region ensured that conceptions of disease and its treatment were frequently shared. The development of links with the major civilizations outside of the region meant that different perceptions of disease and therapeutic techniques continued to be introduced to Southeast Asia, and incorporated into indigenous systems (Owen 1987). The result was a matrix of classifications and strategies that could be brought to bear on the experience of illness.

Disease in the Premodern Period

As noted earlier, from around the beginning of the sixteenth century, a marked economic and social development occurred in most Southeast Asian states. The development of the region had significant effects in relation to disease. These included changes in the types of disease suffered by Southeast Asians, their susceptibility, and the ways in which they viewed and treated disease. One important feature of this period was the large-scale intervention of the state in the control and prevention of disease. This period saw the initiation of public health measures, the establishment of hospitals, and the commencement of vaccination campaigns. It also saw Southeast Asia come to play an important role in the development of Western science. In this section of the chapter, some of these features will be examined against the background of the cultural and socioeconomic changes that came about at this time.

Changes in the Types of Disease

From the medical historian's point of view, one important legacy of the European colonization of Southeast Asia was the propensity of the colonizers to collect statistics, compile reports, and make detailed observations on illness. These range from simple parish records, as in the Philippines (Owen 1987), to colonial office records such as those that exist for Java and Malaya (see Gardiner and Oey 1987; Manderson 1987). Moreover, European interest in Southeast Asia was not limited to administrative concerns; the region was visited by a good number of scholars, encompassing a diversity of disciplines, and their accounts contain detailed descriptions of the region, its peoples, and history.

Nonetheless, considerable care must be taken in the interpretation of the sources because they generally reflect European preconceptions, regarding both Southeast Asia and disease. Thus whereas figures are generally good for foreign communities, the reliability of statistics for the indigenous populations is often questionable (Boomgaard 1987; Gardiner and Oey 1987). As has been noted by a number of commentators, there was a strong tendency in Western sources to emphasize dramatic events such as epi-

demics (Boomgaard 1987; Owen 1987). Epidemics of "plague," smallpox, and a number of other diseases were indeed a frightening and regular feature of Southeast Asian life during this period. However, insofar as they posed no threat to the health or commercial interests of the European community, other less dramatic diseases of the region tended to be neglected in accounts. Yet, in the long run, the toll they took of human life was probably considerably greater.

It is true that references to disease in certain types of indigenous sources, such as chronicles, are also often concerned with epidemics. However, these references, which occur mainly in connection with accounts of crises, and the performance of state ceremonies, reflect the political or religious function of such sources, rather than an attempt to provide balanced descriptions of disease. In other indigenous sources, such as medical treatises, much space is often devoted to the description of diseases that do not figure significantly in either European or official indigenous accounts.

A further difficulty in the interpretation of European and indigenous sources alike is that both the systems of classification and the illnesses they sought to classify were changing. In the indigenous languages of the region it was not uncommon, at different times and in different contexts, for a disease to be known under several names. Similarly, early European accounts often differentiated poorly between illnesses, references frequently being confined to such general terms as fluxes, or fevers (see Dampier 1927; Cook 1968).

The difficulties thus posed for the identification of illness in modern terms are illustrated by the case of the history of cholera in Siam (Terwiel 1987). It is generally agreed that the first major epidemics of cholera in Southeast Asia occurred in the early nineteenth century as the result of the spread of the disease from India. Yet in earlier Thai sources cholera was known under several names, including *ahiwaat, khai puang yai,* and *rook long raak.* Thus, owing to both the difficulties in interpreting indigenous accounts, and the lack of sophistication of early Western classifications of the illness, it remains unclear whether a less virulent strain of cholera had previously existed in the region (Boomgaard 1987; Owen 1987; Terwiel 1987).

Similar difficulties are encountered in the identification of other diseases, as seen in the case of leprosy, another condition with a long history in Southeast Asia. Human figures with features consistent with leprosy are depicted in Khmer bas-reliefs on

the Bayon at Angkor, and at Ta Keo (Coedès 1941). The disease was also noted by a Chinese traveler during his stay in Cambodia in 1296 and 1297 (Chou Ta-kuan 1951). Legend also has it that in ancient times, there was a Khmer "leper king" (Coedès 1941; Chou Ta-kuan 1951). But other written accounts do not always permit a fine distinction to be made between leprosy and other skin afflictions. In traditional Thai medical texts, for example, the term that today is used to denote leprosy, *ru'an,* also includes a range of other skin conditions such as tinea. This is also the case in some early European accounts. Thus the leprosy which William Dampier reported to be widespread in Mindanao and Guam during his 1686 visit was probably the same fungal skin disease, possibly *tinea imbricata,* later reported by John Crawfurd in Java (Crawfurd 1820; Dampier 1927).

Some of the difficulties mentioned above may be attributed to the complexities of indigenous disease naming, as in the Thai examples, or to the lack of diagnostic expertise of the individual observer, as was perhaps the case with Dampier. More importantly, however, the examples above point to the fact that diseases, their incidence, and the ways in which they were classified, were continually changing. Thus as diseases were changing in virulence, the susceptibility of the population to disease was also changing. Moreover, new diseases were being introduced into the region, and, largely due to the development of Western medical science, changes were occurring in the understanding of disease. Here, we look at some of the factors that were central to these changes.

The Development of Cities

The most important factor concerning disease during this period was probably the redistribution of populations, associated in particular with the development of large cities. Whereas in the past the location of cities was primarily determined by strategic considerations, which almost certainly would have included the provision of secure food and water supplies, trade and industry now became a major determinant.

In Southeast Asia major cities, such as Batavia, Singapore, Manila, and Bangkok, developed in coastal or estuarine areas as port cities with their associated commercial activities. In these areas, which were usually low-lying or marshy, drainage, the removal of wastes, and the supply of clean household water quickly became a problem. The poor, on whose labor the operation of ports and commerce depended, were faced with the additional problems of crowded housing and a diet that was often barely

adequate. In addition to the dangers these conditions posed for health, the constant port traffic and the linking of Southeast Asia with the rest of the world meant that the region was increasingly open to the entry of communicable diseases.

Of the Southeast Asian port cities that emerged during this period, Batavia probably had the greatest reputation for unhealthiness. The city was reported to be relatively free from disease for some years following its establishment in 1619. But its growth and the development of an adjacent hinterland placed such demands on the city's drainage systems and water sources that from the early eighteenth century onward disease became a major problem (Blussé 1985). By the time the explorer James Cook called at Batavia in late 1770 to take on supplies and prepare his ship for the journey back to England, conditions were extremely bad. After a long voyage heretofore notable for the good health of its crew, Cook wrote that his ship, the *Endeavour*, left Batavia "in the condition of an Hospital Ship."

European residents of Batavia were able to insulate themselves to a large degree from the disease prevalent in the city by moving away from the old areas within the city walls. But the Chinese and Indonesian inhabitants, unable to move, continued to suffer illness at rates that were higher than most other towns in Java (Abeyasekere 1987). Although Batavia provides just one example, this pattern of disease, related to overcrowded and unsanitary living conditions, existed in most other Southeast Asian coastal cities (Lord 1969; Worth 1985; Manderson 1987).

The growth of cities was, of course, not the only stimulant to disease. Labor, often immigrant, was also required to work plantations and mines, under conditions that also posed considerable risks to health (Cohen and Purcal 1989). Changes in the exploitation of the rural environment also created circumstances that led to the spread of disease, as seen in the association between wet rice cultivation and the spread of malaria in Java (Boomgaard 1987). Similarly, plantation agriculture was instrumental in the spread of malaria and dengue as well, by providing opportunities for mosquitoes to breed, such as in the water trapped in Latex cups and coconut shells or husks (Wisseman and Sweet 1961).

Economic changes in Southeast Asia also contributed to changes in disease by the creation of a landless and impoverished class. In part, this class was brought about by the disruption of traditional forms of agriculture, particularly by the development of plantations, the introduction of money economies,

and wage labor (Robison 1986). Thus under colonial administrations, the imposition of taxes, to be paid in cash rather than by goods or labor, has been pointed to as a significant factor in the impoverishment of many (Worth 1985). On the other hand, as Lysa Hong (1984) has pointed out, taxation systems did not necessarily serve to impoverish populations. But when combined with crises such as droughts, they could produce extreme hardship. Such was the situation in Siam in 1844, when farmers in Suphanburi, already affected by successive rice crop failures, were faced with the added burden of taxes (Terwiel 1989).

The many economic changes that produced widespread poverty meant, of course, that large sections of the population were placed in situations where they were more susceptible to disease, through either direct exposure or poor resistance. Individuals were also less able to afford the medical care that might have promoted recovery from disease. Thus, in addition to famines, and problems directly related to nutritional deficiencies such as beriberi and rickets, the effects of poverty showed up in a range of other diseases. These included chronic respiratory disease, tuberculosis, and eye ailments. Infant children were one group particularly at risk, and this was reflected in high infant mortality rates, as in Malaya in the early part of the twentieth century (Manderson 1987). The conditions of poverty also meant that the effects of epidemic diseases, as in the influenza pandemic of 1918, were considerably more pronounced among the non-European population of Southeast Asia (Brown 1987).

Changes in Susceptibility

Balancing the deleterious effects of the development of the region on health were a number of other factors. It was, after all, in the interests of colonists and Southeast Asian rulers alike to ensure a supply of productive labor. By the same token, these economic interests also meant that they often did not do much more than they had to. As Owen (1987) has put it, the colonial system "forced the poorest to the brink," but it "kept most . . . from toppling over." Yet the things that kept the majority of the population from "toppling over the brink" with regard to health were not all attributable to the direct intervention of the state in the treatment and prevention of disease. A number of the changes affecting the susceptibility of individuals to disease occurred at this time, following from increased contact with the rest of the world. Indeed one consequence of prolonged contact between Southeast Asian populations and the rest of

the world was the development of disease resistance. Thus although initial exposure to diseases previously unknown to the region resulted in a high mortality, long-term exposure produced resistance to them. Indeed the openness of the region to trade, it has been argued, meant that immunity to most serious epidemic diseases was already developed in much of Southeast Asia prior to contact with Europe (Reid 1988). Moreover, the existence of some diseases in the region prior to contact may also have had some effect in minimizing the impact of introduced diseases. Thus it has been suggested that the prior existence of yaws in Southeast Asia was a factor in limiting the spread of syphilis introduced by the Europeans (Boomgaard 1987).

Probably of even greater significance in keeping people away from the brink was the introduction of new foods, habits, and customs which followed the European presence in the region. A number of food plants, such as the papaya, potato, tomato, and chilli pepper, which originated in the New World, came to Southeast Asia with the Spanish and Portuguese and rapidly became an important part of the region's cuisine. Footwear also came to be adopted by sections of the population that would have prevented entry through the skin of parasites such as hookworm. Traditional unhygienic practices relating to the cutting and treatment of the umbilical cord of the newborn child, which often produced tetanus, also lost favor during this period (Hanks 1963; Manderson 1987).

The Adoption of Western Medicine

Contact with the West also meant contact with Western medical practices, although it is doubtful that such medicine had any favorable impact on health prior to the late nineteenth century, when the first major benefits of medical science came to be felt. In fact, even then progress was slow. Colonial doctors and administrators were not, in general, representative of the most advanced thinking of the age (Owen 1987). Furthermore, the medical and health services introduced were based on European models and were mainly directed at the European populations, and at the labor force upon whom they depended.

European efforts directed at improving the health of indigenous populations were often carried out without regard for local beliefs and customs. In its extreme this was seen in measures such as the burning of homes and the desecration of the dead, which took place in Java following the outbreak of plague in the early years of the twentieth century (Hull 1987). Where more sensitive attempts were made to use Western medicine to treat the non-European population, ulterior motives such as religious conversion were often at work (Hutchinson 1933; Worth 1985). Besides the suspect attitudes and methods of colonists and missionaries, there were other important reasons why Western approaches to the diagnosis, treatment, and prevention of disease were not readily adopted by Southeast Asians. For most, language and finances also presented practically insurmountable barriers to the acquisition of Western medical knowledge. Prominent, too, were indigenous beliefs regarding illness and the working of the body, and negative perceptions of the efficacy of Western methods. In the latter case although the value of certain aspects of Western medicine, such as the medicinal use of opium, had long been recognized in Southeast Asia, the efficacy of other features was not apparent. Many of the practices introduced by Europeans in the prevention and treatment of illness were hardly any better than local ones they replaced. These included "cholera drinks," "cholera belts" (a broad band of flannel worn while sleeping at night to protect the abdominal organs from chill), and dutch wives (cylindrical cushions used to support or protect the body from chills while sleeping at night) (*Bangkok Times* 1904; *Bangkok Times Weekly Mail* 1906; Abeyasekere 1987; Owen 1987). Indeed, some European practices, such as bloodletting, ran quite counter to local beliefs (Reid 1988; Bamber 1989).

Nevertheless, there were occasions when features of Western medicine appear to have been well accepted. In some cases, such as in the use of quinine to treat malaria, which became available from the late eighteenth century, acceptance came as a result of the demonstrable pharmacological value of the drug. In other cases it appears that Western medical practices were adopted because of a fortuitous coincidence with existing Southeast Asian beliefs. This seems to have been responsible in part for the acceptance of the treatment of smallpox by vaccination, which fitted well with local beliefs that substances inserted beneath the skin could confer magical power (Reid 1988; Terwiel 1988).

Smallpox Vaccination

Smallpox, at least from the time it was recorded in seventeenth-century accounts, was one of the most feared diseases in Southeast Asia (La Loubère 1691; Lovric 1987; Reid 1988). Traditional methods of treatment, such as herbal medicines and bathing, were largely ineffective against epidemics that occurred regularly throughout the region. Little could

be done by the local inhabitants except to limit the spread of the disease (Reid 1988). But with increased contact with peoples outside the region, different methods of prevention became available. One of these was inoculation (variolation), involving the deliberate introduction of smallpox matter into the body, usually via the nose, first practiced by the Chinese and Indian populations in the region (Terwiel 1988). This technique was also later employed by the Dutch in Java around 1780, and appears to have been practiced by Europeans in Siam from 1833 (Boomgaard 1987; Terwiel 1988). At the request of the Siamese king, inoculation campaigns were begun in Bangkok in 1838 (Terwiel 1988).

Vaccination, a less dangerous and unpleasant form of smallpox prevention, began in Java in 1804, although its spread was limited until the introduction of mass immunization programs (Boomgaard 1987). The Dutch also introduced regulations in 1820 that ensured that outbreaks were reported and contained, which may in fact have contributed more to the control of the disease than did the immunization program (Boomgaard 1987). In Siam, largely because of problems in obtaining viable vaccine, vaccination programs against smallpox did not succeed until late in the nineteenth century (Terwiel 1988). In Vietnam, smallpox vaccination appears to have been initiated in order to protect the French military and settlers: Free smallpox vaccination campaigns were introduced among French troops in 1867, and compulsory vaccination of villagers took place in 1871 when a major epidemic occurred. Further mass vaccination campaigns, mainly in the south and center of the country, were conducted in 1895 and 1896 (Worth 1985; Marr 1987).

It may have been the case that methods adopted by the colonial administrations in the introduction of vaccination were at times heavy-handed. However, the practice does not, in general, seen to have met with resistance from the local inhabitants of the region. This is suggested by the active interest taken by the Siamese, for example, in the pursuit of knowledge about vaccination. Where there was reluctance to employ the technique, it appears to have arisen from doubts regarding the viability of the vaccine, rather than from the method itself. This was not always the case in the introduction of other Western practices used in the management of disease, particularly in regard to the establishment of hospitals.

Hospitals and Public Health

State involvement in public health care was not new to Southeast Asia. Departments of physicians were a feature of the courts of a number of Southeast Asian rulers (Worth 1985; Marr 1987; Bamber 1989). It is likely, however, that the services of such "hospitals" were largely confined to the elite (Marr 1987; Reid 1988). By the same token, it is unclear whether the hospitals that existed in Cambodia during the twelfth century under the reign of Jayavarman VII were in fact "open to all" as their inscriptions suggested, and whether they can be regarded as "hospitals" in the Western sense. On this point the inscriptions are not clear, and could simply mean dispensaries (Coedès 1941). That this may have been the case is supported by later accounts which comment on a reluctance by Southeast Asian peoples to build or enter hospitals (Hutchinson 1933) because of an association of hospitals with death. For many Southeast Asians, hospitals were seen as places where one went to die, and in all likelihood harbored the spirits of those who had already died there (Chai 1967; Thompson 1967; Abeyasekere 1987). The fact that a number of hospitals were originally founded by missionaries as hospices for the care of the victims of epidemics, or those suffering incurable illnesses, would have done little to change this view (Yuwadee 1979; Worth 1985).

Hospitals created by colonial governments were generally not intended for the use of most non-European Southeast Asians but, rather, for the military and civilian personnel serving the colonial administrations. Thus, the health care service provided by the Dutch East India Company was for company servants, as was the hospital system introduced by the British in the Malay states from 1878 (Chai 1967). In Vietnam hospital facilities were introduced in the late nineteenth century, largely for the care of the colonial army and administration (Worth 1985).

Where hospitals were established specifically for the benefit of workers, the funding appears to have come mainly from the groups concerned. For example, the Chinese Hospital established by the Dutch in Java was financed by taxes on Chinese residents (Abeyasekere 1987). The "paupers" hospitals associated with mining centers, which were established by the British in Malaya, were also funded by taxing the Chinese workers (Chai 1967).

The impetus to establish hospitals in Southeast Asia did not come solely from colonialists. In the case of Siam, for example, the monarch played an important role in introducing the hospital system. On a temporary basis, hospitals had been established in Siam, from the early nineteenth century, in order to care for the victims of epidemics (Yuwadee

1979; Muecke and Wichit 1989). In 1855 an offer of land and materials for the building of a hospital was made by the King to an American missionary doctor, but was not taken up (Terwiel 1983). The first state-financed hospital, Siriraj (Wang Lang), was established at the order of the King following the cholera epidemic of 1881, and officially opened in 1888 (Sanguan 1973). Although it is probable that he was counseled by the European and American doctors in Siam at the time, the Siamese monarch was well acquainted with Western medicine, having previously traveled to Singapore and Batavia, and there is no reason to doubt that the initiative came from the Court (Yuwadee 1979).

Medical services were initially staffed, in both colonial and noncolonial Southeast Asia, by European or American doctors. Some attempts were made to train local people in medical procedures, for example, the *dokter-djawa* of Java, who carried out some basic treatments (Boomgaard 1987; Gardiner and Oey 1987). In general, however, access to a full Western medical education was beyond the reach of most Southeast Asians, and even where entry to medical schools was possible, problems remained. For example, for some years after its opening in 1890, the Western medical school established in Bangkok suffered a shortage of Siamese students, probably because of the long, difficult nature of the course, its expense, and the uncertain prospects facing graduates (Yuwadee 1979). In Malaya, positions in the Civil Service were closed to non-Europeans and non-Malays, thus denying Chinese doctors employment, regardless of their qualifications (Chai 1967).

Southeast Asian Disease and the Development of Western Medical Science

Closely linked to the development of colonial medical services was the establishment of research institutes for the study of "tropical diseases." From the standpoint of scientific inquiry, Southeast Asia had long played an important role in Western medicine. The region was an important source of Western materia medica such as cloves, menthol, camphor, benzoin, and, after 1850, quinine. Southeast Asia also figured prominently in the development of botanical and pathological taxonomy, and a number of influential figures in the development of Western natural science traveled to the East Indies as doctors in the employ of the Dutch.

The first research institute concerned with tropical medicine, later to become known as the Pasteur Institute, was set up by the French in Saigon in 1890, and a further three branches were established

in other parts of the colony (Morin 1938; Worth 1985). Their purpose was initially military, being intended to carry out research on the diseases – in particular, dysentery and malaria – which severely affected French troops stationed in Vietnam.

The British also founded research institutes. The London School of Tropical Medicine was opened in 1899 in order to undertake scientific inquiry into tropical diseases, and to prepare medical officers for service in the Crown Colonies (Chai 1967). In 1901, in response to a request from the Resident-General of the Federated Malay States, a Pathological Institute, which later became the Institute for Medical Research, was opened in Malaya (Chai 1967).

In the context of the development of the specialty of tropical medicine, the establishment of these institutes has been viewed by some writers as "imperial arrogance" (Owen 1987). Certainly, by their focus on scientific research into diseases, rather than public health measures, they served imperialist ends in several ways (Worboys 1976; Owen 1987). In the short term, it might therefore be argued that Southeast Asia did far more for Western medicine than Western medicine did for Southeast Asia. Nevertheless, in the long term, Southeast Asians came to benefit substantially from the knowledge of disease that was generated by these research institutes. The French laboratories in Vietnam were, for example, the site for important research on plague, smallpox, rabies vaccine. The Malayan Institute was largely responsible for undertaking the research that established the nutritional basis of beriberi, a discovery that was given wide publicity at the first biennial meeting of the Far Eastern Association of Tropical Medicine. This conference, held in Manila in 1910, was attended by medical officers from most of the countries of the region (*Bangkok Times Weekly Mail* 1904; Chai 1967). The findings were subsequently disseminated into areas of Southeast Asia that were outside direct colonial control, and otherwise unlikely to benefit from the work of the research institutes.

The Impact of Western Medicine on Traditional Perceptions of Disease

Indigenous views of disease were largely disregarded in the introduction of Western medical systems (Owen 1987). Even in Siam, where there was a degree of freedom in the adoption of Western-style medical education, traditional medicine was officially neglected. In fact, it was originally omitted from the curriculum of the medical school when that curriculum was set up under the direction of West-

ern doctors in 1889. Later, however, at the request of the king, traditional medicine was included, but only as an optional subject; because of differences between the Siamese and Western doctors engaged to teach in the school, it was only in 1907 that courses in Siamese medicine became a compulsory part of the curriculum (Yuwadee 1979). Tellingly, one reason for the pressure to introduce traditional medicine into the medical curriculum in Siam came from doctors who had completed the course and gone to work in provincial areas. They complained that they were unable to make use of indigenous medicines to treat patients when the scarce supplies of Western medicines and equipment were exhausted. The doctors argued that if only they had had some basic training in traditional medicine, they could be of greater value to the provincial population (Yuwadee 1979).

Although Western medicine may have been beyond the reach of most Southeast Asians, it nevertheless produced changes in the ways in which those without direct access perceived disease (Owen 1987). The germ theory of disease, for example, was integrated into indigenous beliefs regarding illness causation. For example, among the Agusan Manobo of Mindanao there is a belief that disease may result from germs carried by supernatural agents (Montillo-Burton 1982). However, in applying germ theory, a distinction may be made by Southeast Asians between diseases endemic to the region and those that are "foreign." In this case, it is only the foreign diseases that are caused by germs (Montillo-Burton 1982).

In other cases, there appear to have been semantic changes in traditional terms for illness in order to accommodate Western disease categories. An example is the Thai term *mareng*, which (as discussed earlier) in the past signified a "deep-seated ulcer" and came to refer to cancer. Similarly, *wannarok*, the currently employed Thai term for tuberculosis, formerly referred to "illnesses involving infections or abscesses" (Bamber 1989). In both these cases, the effect has been to emphasize one part of a wide semantic range, so that the resultant meaning conforms more closely to that of disease categories in Western medicine.

Conclusions

Just as Southeast Asia is not unique in terms of its geography, so are its diseases, as seen in biomedical terms, not unique to this part of the world. The distinctive profile of disease in the region is more the result of a complex interaction among the Southeast Asian

environment, its inhabitants, and the world outside. In this essay this interaction was examined over two broad periods of time, the division of which was marked by the arrival of Europeans in the region.

How Southeast Asian peoples perceived and responded to disease prior to contact with the West reflects the processes of localization seen in other aspects of their culture. Perceptions of disease were dynamic, integrating features deriving from other regions of Southeast Asia, as well as from Chinese, Indic, and Islamic civilizations. These processes (which were evident in the naming of diseases), theories of causation, and therapy continued after contact with the West.

With the development of large, more concentrated, populations in the region, different types of disease became prevalent, most notably epidemics. The prominence of these diseases in accounts probably served to enhance the notoriety of the region for unhealthiness, among both Asians and Europeans (Schafer 1967). However, underlying these diseases and the many others that were less dramatic in their effects and that did not figure prominently in accounts were widespread poverty and poor nutrition. These, rather than miasmas and steaming swamps, were the reasons for the prevalence of numerous diseases in the region. Thus, despite the introduction of public health measures, hospitals, vaccination, and eventually some of the other advances made by medical science, what could have the greatest effect on the prevalence of disease in the region was the relief of poverty. This is still the case.

VI.14 Diseases and Disease Ecology of the Modern Period in Southeast Asia

Southeast Asia can be visualized as the part of Asia that spills into the sea, comprised of long coasts, tidal plains, peninsulas, and islands. There are high mountains, inland plains, plateaus, and upland valleys; nonetheless, to a very large degree, human culture has developed with an acute awareness of water, from the sea, the rivers, and the monsoon rains. It is therefore not surprising that many of the endemic health problems in the region are related to water; indeed, since prehistoric times, nearly all major areas of habitation have been exposed to global contact by water transport.

Maritime routes linking the littoral civilizations of the Eurasian landmass have passed through Southeast Asia for more than two millennia. We can accordingly assume that from early times the region experienced all of the epidemic diseases familiar to the ancient world. What inhibits discussion of diseases in the earlier historical periods of Southeast Asia is the lack of data. Because of the prevailing tropical–equatorial climate, the preservation of written records has, until recently, required greater effort than most human societies were prepared to make. Our first information comes from the observations of Chinese annalists, whose works survived in the temperate climate of northern China. As the Chinese moved southward into what is today northern Vietnam, they recorded perceptions of disease associated with what for them were southern lands.

Most prominent among the health problems encountered by ancient Chinese armies in Vietnam were malaria and other "fevers" associated with the monsoon rain season. Chinese generals timed their expeditions into Vietnam to coincide with the dry season, from November to May. When, in 542, ill-informed imperial officials ordered a reluctant army to move into Vietnam during the rainy season, 60 to 70 percent of the army was soon reported dead from fevers (Taylor 1983). Earlier, the general of a Chinese army encamped in Vietnam during the rainy season of A.D. 42 described the scene as a kind of exotic hell: "Rain fell, vapors rose, there were pestilential emanations, and the heat was unbearable; I even saw a sparrowhawk fall into the water and drown!" (Taylor 1983).

It became customary for Chinese generals to explain their failures in Vietnam in terms of "miasmal exhalations" by which they associated the heat and humidity of the area with disease. One of the most famous episodes of disease among soldiers was in 605 after a Chinese army successfully plundered a Cham city in the vicinity of modern Da Nang, on what is today the central coast of Vietnam: The army nearly disappeared when it was struck by an epidemic on its return northward (Taylor 1983). This disease was not malaria, but may have been cholera, smallpox, or possibly even plague. In 627, a prominent Chinese official refused an imperial order to serve as governor of the Vietnamese territories on the grounds that in Vietnam "there is much malaria; if I go there I shall never return." He ultimately chose to be beheaded for insubordination rather than accept the assignment (Taylor 1983). Previously in 136, a Chinese official had argued against sending an army to Vietnam because, among other reasons, the anticipated losses to disease would require the sending of reinforcements who would be disaffected at being ordered into a pestilential region (Taylor 1983). The failures of Chinese invasions against Vietnam in 980–1 and 1176–7 were accompanied by large losses of manpower to malaria.

Generally, malaria has never been a serious problem in preurban lowland areas where waterworks are kept in good repair and the population is at peace (Fisher 1964). Those species of anopheline mosquitoes that breed in the swamps, irrigation canals, and ricefields of the lowlands tend to prefer the blood of animals; and since animals are not susceptible to human malaria and therefore do not provide a reservoir for the disease, these mosquitoes normally do not carry malaria (Stuttard 1943). On the other hand, those species of *Anopheles* that breed in the shady, cool water of streams in the foothills and mountainous areas are strongly attracted to human blood and are dangerous vectors of malaria (Stuttard 1943; Fisher 1964).

Chinese armies entering Vietnam by land must pass through upland areas where malaria is endemic. This fact, along with the desire to achieve the advantage of surprise, explains why Chinese generals, having had the luxury of water transport and enough time to lay plans without haste, preferred to invade Vietnam by sea (Taylor 1983). Malaria became a threat in populated lowlands only when warfare or other disorders led to large-scale slaughtering of animals, a scattered population, and a breakdown of the water control system (Murphy 1957).

Beginning in the late nineteenth century, malaria became a problem on a larger scale than had been previously known because of circumstances associated with the development of colonial and semicolonial economies. These included the improvement of communication systems, large-scale population movements, the opening of new ricelands, and the extension of urban settlement. All of these changes required relatively large-scale construction and engineering projects that opened new areas congenial to certain mosquito species and to epidemics that decimated cattle populations, thereby turning mosquitoes toward human beings (Boomgaard 1987).

In the early 1950s, when the Malayan emergency resulted in the resettling of large numbers of people into crowded lowland camps, an observer noted that the health of the population improved the farther upriver one went; the same observer argued that upland peoples who had been resettled in more densely populated areas near the sea experienced an "accentuation of an already existing pattern of disease" as a consequence of "the loss of interest in life due to the breakdown of the old culture" (Polunin 1952). It may be that any disease ecology must also take into account the political and psychological conditions of a population.

Another observer has claimed that cultural factors can be important in the experience of disease and illness, that there is a relationship between disease and social marginality, and that the incidence of disease can operate as a mechanism of social control enforcing respect for authority. In fact, he has written that "the social system tends to precipitate events which validate the medical beliefs, and this in turn affirms the principles upon which the social structure is based" (Feinberg 1979). It is relatively easy to discuss this approach in relation to the practice of medicine in premodern societies (Lan-Ong 1972), but contemporary attitudes toward modern medicine tend to resist this line of analysis.

Beginning in the tenth century, Southeast Asians began to record observations and write annals that provide local information, first in Vietnam and eventually in Thailand, Burma, Cambodia, and Java. Epidemics are mentioned regularly, particularly in times of warfare, though it is very difficult to determine with certainty what diseases were being observed. Some modern researchers believe that cholera was absent from Southeast Asia until the 1820s, and bubonic plague was likewise absent until 1911. The evidence, however, is ambiguous (Boomgaard 1987; Hull 1987; Terwiel 1987; Reid 1988). The great outbreaks of cholera and bubonic

plague in the nineteenth and twentieth centuries were apparently related to the circumstances of European colonial expansion in the region and represented a more virulent experience of these diseases than can today be imagined for earlier times. Southeast Asia's historic openness to maritime trade and the global contacts that went with it surely resulted in a measure of immunity being built up in the population against the diseases common to international entrepots.

A relatively dispersed village settlement pattern and the Southeast Asian habit of bathing frequently are two other factors that appear to account for what has been called the "relatively mild epidemic cyle" in premodern times (Reid 1988). The most serious epidemic disease, according to Siamese chronicles from the fourteenth century and European observers in the sixteenth and seventeenth centuries, was smallpox (Terwiel 1987; Reid 1988). Leprosy and yaws also figured prominently in early European perceptions of disease in Southeast Asia, probably because of their disfiguring effects (Reid 1988). Plague, according to French observers in Indochina, was found only where there were large numbers of Chinese, namely port cities with a concentration of ships, large stores of grain, and consequently an abundance of rats (Stuttard 1943). In the 1960s, by which time plague had been eradicated in most of Southeast Asia, outbreaks still occurred in Vietnam as a result of wartime conditions (South East Asian Regional Centre for Tropical Medicine 1967).

From the 1960s, there has been a growing literature enumerating and analyzing diseases in Southeast Asian countries, particularly Thailand. The category of "tropical diseases" is sometimes used to emphasize that most of the health problems encountered in the region are now seldom seen in temperate climates. The 1967 syllabus of the "tropical medicine" course at Bangkok's University of Medical Science, Faculty of Tropical Medicine, covered the following illnesses, all identified as "common diseases": (1) viral, such as smallpox, rabies, dengue, hemorrhagic fever; (2) rickettsial, such as typhus fever; (3) bacterial, such as typhoid fever, bacillary dysentery, food poisoning, cholera, leprosy, and plague; (4) spirochetal, such as amebiasis, malaria, kala-azar, and giardiasis; (5) helminthic, such as hookworm infection, ascariasis, trichuriasis, enterobiasis, strongyloidiasis, gnathostomiasis, filariasis, fasciolopsiasis, and paragonimiasis; (6) nutritional, such as protein–calorie deficiencies, mineral and vitamin deficiencies, and food toxicants; and (7) miscellaneous, such as effects of heat, heat exhaus-

tion, blood diseases of the tropics, hemoglobinopathies and other genetic factors, as well as snake and other venomous bites (South East Asian Regional Centre for Tropical Medicine 1967).

In the same year, South Vietnamese disease specialists identified malaria and plague as their greatest problems and categorized "endemic infections" as follows: bacteriological (cholera, salmonellosis, bacillary dysentery, and typhoid), parasitic (amebiasis, ascariasis, hookworm infections, gnathostomiasis, strongyloidiasis, diphyllobothriasis, sparganosis, and taeniasis), viral (hemorrhagic fever and dengue fever, smallpox, infectious hepatitis, Japanese B encephalitis, and rabies), bacterial (leprosy and venereal diseases), and mycotic (cutaneous mycoses) (South East Asian Centre for Tropical Medicine 1967).

What can be emphasized is that a very large percentage of these diseases are waterborne or are transmitted by a parasite that depends upon a water-dwelling host such as the snail. In a region where a large part of the population is involved in paddy agriculture requiring barefoot work in fields covered with water, where sanitation depends upon the common use of rivers and ponds, and where nearly half of each year is a time of heavy rainfall, such diseases account for much of the burden of unhealthiness. Dysentery, amebic infections, intestinal worms, and skin afflictions are endemic. The linkage between health and seasonality is obvious to any observer and has been an object of study in recent years. The wet season, in addition to providing an environment in which many disease vectors thrive, is also a time of food shortages and of a consequent relative increase in poverty and decrease in physical well-being. Women and children are particularly at risk during this time (Charles 1979). This writer was in Hanoi in May 1986 during the onset of the rainy season and saw that within a few days a large part of the population had become ill with fevers and other "flu" symptoms; local people considered this a normal phenomenon.

Medically trained observers in Southeast Asia have difficulty in determining mortality statistics. Such compilation efforts are complicated by the fact that although death may be occasioned by the onset of a particular disease, such as malaria, the person's inability to resist the disease is generally due to prior debilitation from a combination of other afflictions, such as intestinal parasites and nutritional deficiencies (Institute for Population and Social Research 1985).

Beriberi, caused by vitamin B deficiency, was in

premodern times largely confined to the islands of eastern Indonesia where sago rather than rice was the main dietary staple (Reid 1988); recently, however, it has become a more general regional phenomenon as a result of the increasing use of polished rather than whole-grain rice (Fisher 1964). Beriberi was first reported by the Portuguese in Southeast Asia during the sixteenth century, and the term is of Malay derivation (Reid 1988).

The ecology of disease in Southeast Asia is currently in a period of rapid and significant change, the beginning of which is usually dated around 1970. For one thing, except for infants and children under 5 years, infectious diseases are no longer a significant threat to health. Tuberculosis remains a hazard for the aged population (which has grown), and malaria remains endemic in many areas, but, in general, tuberculosis, pneumonia, malaria, diarrheal diseases, and nutritional deficiencies, along with other infectious diseases, have declined. On the other hand, death rates for heart-related diseases, cancer, and accidents along with violent deaths have significantly increased (Institute for Population and Social Research 1985). Increasing attention is being given to the problem of infant mortality, for persons under 5 years have benefited least from the overall improvement in health. Diseases of pregnancy, delivery, and puerperium have also become more prominent of late. In addition, cirrhosis of the liver and hepatitis have appeared as significant health problems (Institute for Population and Social Research 1988).

The rise in noninfectious diseases, namely coronary–cerebrovascular diseases and malignant neoplasm (cancer), is primarily a phenomenon of the large urban centers such as Bangkok. It is believed to come not only from improvements in diagnosis but also, in the words of a Thai government report, from "real increases in the incidence rate due to various environmental hazards of the present living conditions" (Kanchanaraksa 1987).

Larger proportions of the populations of the Southeast Asian countries are increasingly concentrating in major urban centers. Living conditions in these places are increasingly exposed to the chemical environment of modern industry and to the emotional pressures of modern business activity. As Southeast Asia is integrated into a global system of manufacturing and markets, we can expect that its disease ecology will begin to display characteristics already familiar to areas where this system has been in place for several decades.

PART VII

The Geography of Human Disease

VII.1 Disease Ecologies of Sub-Saharan Africa

Disease Patterns Before A.D. 1000

The prevalence and distribution of diseases in sub-Saharan Africa have been determined by the natural environment, indigenous living patterns, and the interrelationships between African peoples and newcomers from other continents. The spread of agriculture since about 3000 B.C.; the extensive commercial contacts with the Moslem world from about A.D. 1000, and with Europe since the fifteenth century; and the establishment of colonial rule in the late nineteenth century – all have had important consequences for health conditions in Africa.

There is little evidence about the disease environment confronting Africans until fairly recent times. Literacy dates back to only about A.D. 1000, and then only in Ethiopia and some areas of the savanna zone just south of the Sahara desert. Written accounts of conditions on parts of the western and eastern coasts begin with the Portuguese voyages of the fifteenth and sixteenth centuries, but literary information on most of the vast interior is not available until well into the nineteenth century. Serious medical data collection really began with the colonial period, but even today knowledge of disease incidence and prevalence is far from adequate.

Africa south of the Sahara is a vast area with many different ecological zones. Besides the Sahara itself, there are extensive desert regions in the Horn of northeastern Africa, and the Kalahari in Namibia and Botswana in the southwestern part of the continent. Tropical rain forest prevails along most of the west coast, in the Zambezi valley of Mozambique, and in large areas of western equatorial Africa, including much of Gabon, Congo–Brazzaville, and northern Zaire. Forest, however, covers only about 10 percent of the land area. Rolling grassland, often called savanna or sudan, predominates between the desert-edge lands and the forest, both north and south of the equator. The desert and the equatorial forest have always been relatively sparsely populated; most Africans have always lived in coastal West Africa or the savanna areas north and south of the equatorial forest.

Paleontological studies indicate that hominids almost certainly evolved in Africa, and our species, *Homo sapiens,* probably was widely distributed over the continent by at least 40,000 years ago. Scattered bands of stone-age hunter-gatherers spread lightly over the entire continent. Signs of permanent settlement by fishermen around lakes and rivers are evident in eastern Africa and places that are now in the Sahara from about 7000 B.C. Knowledge of stock-raising diffused from southwest Asia from about 5500 B.C., and agriculture followed the same course shortly afterward. The Sahara region did not begin to become a desert until about 2500 B.C., so these developments first reached peoples in and just south of the present Sahara. Here the new ways of life allowed the gradual development of settled village life, population growth, the rise of political and economic specialization, and, in general, the more complex societies associated with the Neolithic "Revolution." Iron technology diffused from the North African coast to what is now the West African savanna by about 300 B.C., giving peoples in the belt south of the desert, the ancestors of most modern black Africans, an additional advantage over more isolated populations further south.

As of the first or second century B.C., demographic growth among these iron-age, agricultural groups was encouraging them to expand southward against weaker, less numerous hunting and gathering peoples. Peoples ancestral to the modern pygmies probably dominated much of the forest. Further south were the ancestors of the Khoisans, who once inhabited most of the southern third of Africa, but are now restricted to parts of the Kalahari and bordering regions. In the west the farming peoples soon reached a barrier, the Gulf of Guinea, but members of one linguistic group in the borderlands of modern Nigeria and Cameroun had a continent before them. For roughly 2,000 years these technologically superior peoples have been gradually colonizing half a continent, driving away, killing, or absorbing most of the indigenous groups. The descendants of these people, speakers of languages of the Bantu family, now dominate most of the continent from the equatorial forest almost to the southern tip.

Disease Patterns from A.D. 1000 to 1500

By about A.D. 1000, most of the better agricultural lands had been settled by village farmers. There was still a frontier in the extreme south, and pastoral groups were important in and near the deserts and in parts of the East African interior, but the pygmy and Khoisan peoples were increasingly being pushed into pockets of marginal jungle or desert – a process that has continued until the present. Farming was often of a slash-and-burn type, with villages moving

to seek new lands at intervals of several years to a generation or more, but hundreds of people often lived close together in compact, relatively permanent settlements. Small cities began to develop in response to long-distance trade in parts of the western Sudan and along the east coast.

These long, complex processes must have had important implications for health conditions. Hunting-gathering populations were too sparse to support many acute diseases, especially smallpox, measles, poliomyelitis, chickenpox, and other viral infections that produce long-lasting immunities. They were mobile enough to avoid living for long in close proximity to accumulations of their own wastes.

Village life, on the other hand, whether based on fishing and intensive collecting or on agriculture, put much larger numbers of people in close, continuous contact in fixed places. Diseases of crowds, like many of those caused by respiratory transmission of common bacterial and viral infections, could be readily transmitted. Disposal of wastes and contamination of water became problems, and failure to solve them resulted in much greater opportunities for the spread of gastrointestinal infections, such as dysentery and diarrhea of various etiologies, as well as *Ascaris, Trichuris,* and other parasitic worms. Hookworm, transmitted by fecal contamination of soil, was also common in many places. Villages and land cleared for agriculture helped provide breeding sites for the mosquito vectors of malaria, yellow fever, and filariasis. Animal husbandry also provided enhanced opportunities for transmission of beef and pork tapeworms, anthrax, and other diseases. Animal manure attracted disease-carrying flies. In Africa, as elsewhere, the price for the advantages of village life and a more reliable and abundant food supply was a dramatic increase in the variety and frequency of infectious diseases.

Africans gradually developed immunologic and cultural defenses against many of these diseases, and population grew, although much more slowly than in recent decades. Although direct evidence is lacking, it is likely that the pool of diseases afflicting sedentary populations was especially deadly for indigenous hunting-gathering groups beyond the expanding agricultural frontier. As in the Americas, Australia, New Zealand, and probably also Siberia, diseases from what William McNeill has called "civilized disease pools" helped to pave the way for newcomers by killing large numbers of the aboriginal populations.

By about A.D. 1000 the more densely inhabited portions of Africa, or at least those north of the equatorial forest, probably had had at least limited experience with most of the infectious diseases common to the Eurasian land mass. There was some attenuation, however, due to distance and relative isolation, as well as modifications from the tropical environment and the fairly low average population density. The disease mixture would be enriched and the frequency of outbreaks increased in later centuries as a result of more intensive commercial and other contacts with the Moslem world and with western Europe.

We have little direct knowledge of health conditions before about 1500, but scattered data and inferences from more recent times allow some general, if somewhat speculative, comments. Many Africans suffered from a wide range of intestinal parasites spread by the fecal–oral route, and from dysentery and other bacterial and viral diseases associated with poor sanitation, although cholera did not exist here until it was imported from Asia in the nineteenth century.

Some have argued that there is an old focus of plague in central Africa, but the evidence for this is not compelling, and it is not clear that plague had any real importance in Africa before the late nineteenth century. Smallpox was known in Egypt by the sixteenth century B.C., and may have been epidemic in Ethiopia as early as 570. South of the Sahara, smallpox and perhaps also measles were probably uncommon and tended to occur in epidemic form at long intervals. Respiratory infections like pneumonia were uncommon, and tuberculosis was rare or absent, except perhaps in trading towns. Cerebrospinal meningitis probably did not appear until the late nineteenth century. Guinea worm and schistosomiasis were, then as now, focal waterborne infections with high prevalence rates in some localities.

Except in the deserts, malaria was ubiquitous. It tended to spread in the forest as land clearance for farming created better breeding sites for *Anopheles* mosquito vectors. The antiquity of falciparum malaria is indicated by the widespread prevalence of sickle cell trait, a costly but effective genetic defense. Most African groups lack Duffy antigen, probably another old genetic adaptation, which protects them against vivax malaria. Yellow fever existed in forest areas, but attacked mainly children and may have caused relatively little harm. Yaws and leprosy were especially prevalent in moister climates. Trachoma was more common in arid regions. Gonorrhea probably had been established by the first century A.D., at least in the towns of the western Sudan, but syphilis was a post-Columbian im-

port via Europe and North Africa. Human and animal trypanosomiasis occurred in places where tsetse flies lived. Then, as now, animal trypanosomiasis prevented stock raising in forest areas. Pockets of savanna bush were infested with flies carrying both human and animal pathogens; these places were generally known and avoided.

Disease Patterns of 1500–1900

More intensive trade and political contacts with the outside world, especially Europe, developed from the sixteenth to mid-nineteenth centuries. These contacts, accompanied by more extensive long-distance trade within Africa and by widespread patterns of political centralization, helped to spread many infectious diseases.

Europeans and Africans began a long commercial relationship with the arrival of the Portuguese in the fifteenth century. Trade grew rapidly over the centuries, and came to involve most of the states of western Europe and the Americas and, directly and indirectly, most African groups living within a few hundred miles of the sea. Coastal African merchants sold slaves, ivory, gold, dyewood, and other commodities for cloth, guns, metal goods, tobacco, alcoholic beverages, and other manufactured items. African products were obtained by trade networks extending far into the interior. Negotiations between the coastal middlemen and foreigners were often long and complex, providing ample opportunities for exchanges of pathogens; the trade routes provided paths for diseases to spread into the interior.

Among the most important and best documented diseases in early African history was smallpox. Although it was widespread in North Africa by the seventh century, and had almost certainly reached the western Sudan as a by-product of the trans-Saharan caravan trade by about A.D. 1000, smallpox may not have been indigenous to the western coast or the southern half of the continent until the seventeenth century. Ships brought infection from abroad or carried it from place to place along the coast at irregular intervals, after enough time had passed to allow the appearance of a new generation of susceptibles. An epidemic caused great loss of life along the Gold Coast in the 1680s, and by at least 1700 some West African peoples had adopted or invented variolation techniques. Smallpox epidemics were frequent in the eighteenth and nineteenth centuries, and a major shipborne outbreak swept the whole coast as far south as Gabon and Angola in the early 1860s. In South Africa, where the Dutch East India Company had established a colony at Cape

Town in 1652, smallpox epidemics introduced by sea in 1713, 1755, and 1767 had serious demographic consequences for the colonists and were devastating for the indigenous and already hard-pressed Khoi pastoralists. On the east coast, it is likely that smallpox was an early accompaniment of the Indian Ocean trade, but there is little evidence for it in the pre-European period. The Portuguese recorded a major epidemic in 1589. Smallpox diffusion into the East African interior probably occurred later than in West Africa because of weaker trade networks; it may date back only to about 1800.

Measles and chickenpox were probably also introduced by traders from time to time, but there is little documentation. Tuberculosis probably reached coastal West Africa in the early days of contact, but it did not become widespread until after 1900. Venereal diseases were a different story; syphilis and gonorrhea were common among coastal groups by the eighteenth century, and these diseases must have spread inland as well. Gonorrhea may well have been an indigenous disease whose diffusion was facilitated by new conditions; syphilis almost certainly arrived from the outside world.

Trans-Saharan trade had existed for centuries prior to 1000, and no doubt the caravans, like the sailing ships, sometimes were accompanied by infectious diseases. Smallpox could well have reached the Sudanese market towns, either with infected merchants or in goods. Tuberculosis, measles, and gonorrhea no doubt diffused from North Africa with trade, although they may have already existed in the savanna. Similarly, the extensive pre-European trade along the east coast, between the Swahili towns and merchants from India, Persia, and Arabia, must have resulted in some disease transmission.

It is clear, despite the weakness of the data, that contacts with Europeans and other foreigners had serious disease consequences for many African peoples in the precolonial period, especially those along the west and east coasts and in the market centers for the Sudan. However, although some small groups may have suffered heavily, there was no postcontact pattern of mass death in Africa similar to what occurred in parts of the Americas or the Pacific. Africans shared enough of the Old World disease pool to avoid major demographic disaster. Stronger social systems of African peoples may also have played a role in their enduring and recovering from great epidemics. Even with the drain of the Atlantic, trans-Saharan, and Indian Ocean slave traders, Africa was not depopulated. Disease resistance, strong local social and political systems, and the introduc-

tion of new food crops like maize and manioc helped to sustain populations.

The African disease environment did have very serious consequences for foreigners. We still know relatively little about how Moslem traders fared, but North African visitors to the Sudan did try to finish their business before the rainy season brought malarial fevers, and Omani Arabs suffered severely from falciparum malaria on the Swahili coast.

The fate of Europeans on the west coast is much better documented. "Fevers" and "fluxes" – especially malaria, yellow fever, and the dysenteries – took a frightful toll among sailors, soldiers, traders, missionaries, explorers, and slavers. Studies of British, Dutch, and French experiences have shown that death rates of 50 percent in a year were not uncommon. It is possible that Portuguese death rates were somewhat lower, but they too paid a heavy price for their African commerce. Mortality prevented any serious European military activity in most of West Africa; maintaining weak, sickly garrisons in a few coastal forts was all that they could normally do. Disease not only helped save West Africans from European encroachment, but also gave them a considerable commercial advantage. African merchants could, and frequently did, drag out trade negotiations, knowing that the Europeans were anxious to complete a deal and leave before the fevers began to reduce their numbers. The limited Portuguese expansion in northern Angola, although hampered by disease, took place in a drier area where malaria was not as serious as elsewhere on the western coast. European colonization at the Cape was possible only because the Dutch were operating south of the tropical disease environment.

Africa was more important as a donor than as a recipient in the post-Columbian exchange of diseases. Falciparum malaria and yellow fever reached Europe from time to time, but probably did not have major demographic consequences there. Much more significant was the transfer of African diseases to the New World, mostly as a by-product of the slave trade. Falciparum malaria and yellow fever played a major role in the population history of the warmer parts of the Americas, from the southern United States to southern Brazil. Whites suffered severely, and these diseases were leading causes of deaths among the American Indians, especially in the Caribbean basin. The African hookworm, misnamed *Necator americanus,* came over in the bodies of enslaved Africans, and was a very serious cause of sickness and death in the southern United States and in much of the West Indies and Brazil well into

the twentieth century. Other African diseases, including onchocerciasis, filariasis, *Schistosoma mansoni* infection, and yaws, also became established in American foci.

Cosmopolitan diseases like dysentery and smallpox were frequently introduced into ports along with cargoes of slaves. In Brazil, slave imports often rose when there was drought and famine in Angola. Drought conditions caused people to migrate in search of food; they tended to congregate, often as defenseless, disorganized refugees, in areas where they could find sustenance. Such aggregations encouraged flare-ups of endemic smallpox as well as the depredations of slavers. The virus was often transported by captives, and there is a strong correlation between smallpox epidemics in Brazil and in its Angolan slave supply territory.

In sum, the biological consequences of the African slave trade included millions of deaths in the Americas, among both Europeans and Indians. African labor was crucial in many New World economies, but the demographic costs were enormous for inhabitants of North and South America and for European sailors on slave ships, as well as for sub-Saharan Africa. Indeed, at least in the United States, the demographic balance was almost certainly unfavorable. About 300,000 Africans were imported, probably far fewer than the number of whites who died of falciparum malaria, yellow fever, and hookworm infection from the eighteenth to the early twentieth centuries. The period of the European conquest of Africa and the consolidation of colonial rule, roughly from 1880 to 1920, was the most deadly period in history for much of the continent. West Africa, perhaps because of its earlier experience with introduced epidemics, did not suffer as severely as portions of equatorial, East, and central Africa. Intensified long-distance trade, warfare, labor demands, and famine characterized this era, as many African peoples found their relative isolation shattered. People, pathogens, and vectors all moved, and there were radical changes in living conditions. Smallpox spread widely, especially in East Africa, where coastal Moslem merchant caravans had begun to operate in the interior from the 1830s. Cholera was introduced several times into East Africa and diffused over the trade routes, with an especially destructive epidemic occurring in the 1850s. Cerebrospinal meningitis epidemics appeared, probably for the first time, in the western Sudan in the 1880s; there were several great epidemics there and in parts of the Anglo-Egyptian Sudan and East Africa during the twentieth century. On a less spectacular

but still important level, even short-distance moves might bring people into contact with antigenically novel strains of familiar organisms, such as the protozoa that caused malaria and amebic dysentery.

Tuberculosis, noted in the coastal towns of West Africa around the turn of the century, spread slowly inland. In the Cape Verde Islands migrants returning from the United States facilitated the spread of infection by the 1880s. The rise of the mining industry in South Africa and the Rhodesias was dependent on migrant labor. Poor conditions in the mines in the early twentieth century led to extremely high tuberculosis rates and explosion of the disease among the rural African population as infected miners returned to their homes.

Besides mining, other development efforts of the colonial era often had unexpected and deleterious health consequences. Major infrastructure projects usually depended on migrant labor and sometimes took a heavy toll in lives. For example, thousands of workers conscripted in the savanna country of southern Chad and Ubangui-Chari died from dysentery, respiratory ailments, and other diseases during the construction of the Congo–Océan railroad in French Equatorial Africa in the 1920s. Water projects frequently facilitate disease transmission in tropical climates. The Gezira irrigation scheme in Sudan, for example, as well as the massive Volta Lake in Ghana, has resulted in hyperendemic schistosomiasis. On a smaller scale, dam ponds may also become foci for malaria and guinea worm infection, and, in parts of northern Ghana, dam spillways and bridge pilings provided breeding sites for the vector of onchocerciasis, a worm disease that often causes blindness.

Venereal diseases also diffused rapidly in the late nineteenth and early twentieth centuries, as labor migration and urbanization disrupted social patterns. Equatorial Africa experienced a very destructive gonorrhea epidemic as a direct result of harsh Belgian and French colonial policies; this resulted in widespread sterility, which is believed to be largely responsible for the very low fertility rates in the region even today. Movements associated with the early colonial period were also apparently responsible for great outbreaks of human trypanosomiasis in French Equatorial Africa and the Lake Victoria region of East Africa in the first decade of the 1900s. At least 250,000 died in East Africa alone.

On a more trivial but still significant level was the rapid spread of the burrowing flea *Tunga penetrans* (chigoes). This insect invades tissues under the nails and may result in secondary infections that cause disability, or a loss of digits or limbs. Native to Brazil, the fleas were introduced into the Senegambia region about 1800, and to the Angolan coast about 1850. From Angola they spread over central and East Africa in a few decades, causing great misery in any given place, until people learned how to remove them.

Disease Patterns of 1900–60

The most explosive and most destructive epidemic ever to strike Africa was the influenza pandemic of 1918–19. Introduced at Sierra Leone in late August 1918, and to ports around the continent in the next several weeks, the disease spread rapidly inland over the newly constructed colonial roads, railroads, and river transport systems. Diffusion was especially rapid on the southern African rail system and on the river steamers in the Belgian Congo. Indeed, so quickly did the disease move by these means, that places in the Congo only 100 miles from the coast were first attacked by way of the Union of South Africa. Almost every inhabited spot on the continent was struck in a matter of 6 or 7 months, graphic proof that the old isolation was gone forever and that the continent was an epidemiological unit closely linked to the rest of the world. Approximately 2 million people – about 2 percent of the population – died during the epidemic.

The demographic balance began to shift by the 1920s in much of West and South Africa, and by the 1930s elsewhere. The harsher aspects of colonial rule were being mitigated, famine relief was made more effective with better transportation, and medical measures began to have some effect. Progress was most rapid in the Belgian and British colonies and in French West Africa; medical services were slower to develop in Portuguese territories and in French Equatorial Africa.

Colonial medicine had little to offer Africans for many years, except for surgery, yaws therapy, and smallpox vaccination. But by the 1930s, efforts to control smallpox, cerebrospinal meningitis, tuberculosis, louse- and tick-borne relapsing fever, and other epidemic diseases were beginning to have some impact. Plague broke out in several territories in the early twentieth century, but public health measures prevented serious loss of life. Extensive efforts to contain trypanosomiasis, primarily by vector control in the British colonies and by chemical treatment and prophylaxis in the French territories, had considerable success. The growing cities continued to function as nodes for the diffusion of infectious diseases into the countryside, but measures to

improve water supplies and waste disposal, control malarial mosquitoes, provide vaccinations, and treat patients began to have a positive impact in almost all urban areas by 1940. Ironically, improved water supplies meant that fewer people were exposed to polio virus as small children when they were most likely to have mild or asymptomatic cases. Postponement of infection until adolescence created an increase in the number of paralytic cases in the post–World War II period – an unintended by-product of incomplete sanitary reform.

The advent of sulfa drugs in the late 1930s and especially the antibiotics in the 1940s provided a revolution in the effectiveness and, consequently, the popularity of the colonial medical services. Africa's rapid demographic growth dates from the late 1940s and is partially the result of the success of most colonial medical services in lowering death rates from bacterial diseases. Populations are growing at rates that will double the numbers of people in most countries in around 20 years, a situation that is already placing grave strains on medical services and food supplies.

Disease Patterns Since 1960

Most African states became independent after 1960, but they have not been able to effect radical improvements in health conditions. Colonial medical services and their successors in sovereign African countries have tended to stress therapy over prevention, and to favor cities over the rural areas. There has been some real progress. Smallpox has been eradicated, thanks to a concerted worldwide campaign. Vaccines, many developed only after 1960, have begun to make inroads against measles, diphtheria, polio, cerebrospinal meningitis, and other common infections, but new vaccines are urgently needed for other diseases, including malaria and the bacterial and viral agents of childhood diarrheas. The most urgent need is to improve rural water supplies and sanitation, which would greatly reduce the incidence of a host of infections. Greater attention to nutrition and to infant and child health is also essential.

Malaria and schistosomiasis are still major causes of morbidity and mortality, and almost no progress has been made against the common intestinal parasites. Even yaws, which is readily treated with penicillin, has reemerged in areas such as Ghana where economic distress has curtailed medical services. Similarly, internal strife and misgovernment in Uganda have disrupted trypanosomiasis control, with predictable results. Campaigns sponsored by the World Health Organization and other groups

against such major scourges as malaria, onchocerciasis, schistosomiasis, trypanosomiasis, and leprosy are promising, but high death rates, weak and sometimes declining economic and political systems, and the AIDS epidemic show that grave problems remain. More than ever, Africa's disease environment is determined by its poverty.

VII.2
Disease Ecologies of the Middle East and North Africa

This study of disease ecologies of the Middle East and North Africa aims to demonstrate the interrelationships of environmental and etiologic factors in the diseases endemic to that region. In so doing, the essay surveys the area between Morocco in the west and the Iranian border in the east, including the Anatolian Peninsula in the north and the Arabian Peninsula to the south.

Conditions before the mid-twentieth century are generally emphasized in this study. The population data and some obviously changing current conditions are, however, pertinent to conditions in the late twentieth century. The State of Israel is not included in the discussion because of the general time frame and for other reasons. Israel does not fit into most generalizations about the region because of its diversified economy and the comprehensive health-care system created by preindependence settlers. The chapter also will not deal with the region's emerging pattern of the degenerative, metabolic, and genetic disease concerns of industrialized societies. Many of the data are derived from the accumulation of information assembled by the attempt of European nations to deal with epidemics and exotic diseases encountered during the nineteenth century in Africa and Asia. This material is sufficient to sketch a tentative disease profile, stressing infectious diseases. Moreover, twentieth-century investigations in nutrition have been used to supplement and qualify this information.

Geography, Topography, and Climate

The Middle East and North Africa occupy that part of the Earth's crust where three tectonic plates converge, causing great ranges of high-fold mountains to be thrust up, notably in western North Africa and in the northern tier states of Turkey and Iran. Peaks in the high Atlas Mountains of Morocco and the Taurus range in Turkey exceed 12,000 feet, whereas Mount Damavand, in Iran's Elburz mountains, exceeds 18,000 feet. Running north and south, the Hijaz, Asir, and Yemen ranges are high escarpments in the southwestern Arabian Peninsula, paralleling the anticlinal highlands that form the Lebanon and Anti-Lebanon mountains and the Judean Hills of Palestine.

The Middle East and North Africa lie roughly between latitudes 20° and 40° north in a transitional climatic zone between equatorial and mid-latitude climates. Because of general atmospheric circulation patterns, a characteristic of these latitudes is prevailing aridity – the "Mediterranean Rhythm" of winter rain and summer drought. Only westward-facing coasts and mountain ranges receive the 250 millimeters (about 10 inches) rainfall considered the minimum necessary for cultivation. The lack of cloud cover is a major factor influencing temperature, for clear skies and intense solar heating of the land cause very high temperatures during the day although temperatures fall considerably at night. Another characteristic of the region is scanty water supply. Except for the Nile, Tigris, and Euphrates, the majority of rivers are short streams with a rapid and intermittent course down rugged mountain sides. The lack of wooded land is another serious deficiency. Long occupation has meant prolonged exploitation of the land over millennia, almost total deforestation, and removal of ground cover, resulting in uncontrolled water runoff and soil erosion. Aggravated by overcultivation and unrestrained grazing, especially by goats, soil erosion has led to extensive desiccation and desertification. Hence, at mid-twentieth century, it was estimated that only 5 to 7 percent of the total area is cultivable naturally.

The implications of prevailing aridity and great expanses of mountainous or desert terrain have been significant for human survival: Population has been relatively sparse and discontinuous in distribution; until recently, nomadism was widespread; and settled argiculture most often has required irrigation and complex infrastructures to govern the allocation of scarce water resources.

Population

The total population in 1984 of countries under consideration in the region, estimated at 257 million, was about 5.6 percent of the world population, in an area occupying about 10 percent of the Earth's surface. The largest populations were in Egypt, Turkey, and Iran, which comprised 52 percent of the inhabitants of the region.

Turkey was the only country in which population was distributed relatively evenly. Even at the mid-twentieth century, about 75 percent of the inhabitants lived in small villages scattered over the Anatolian Peninsula, whereas in other states, the population had already been concentrated along the seacoast or river banks, on oases, or around the countries' metropolitan centers. Since midcentury,

population pressure on the land has reduced the percentage of people in agriculture and accelerated the move to urban centers. By 1984, it was estimated that 42 percent of the population of North Africa and 53 percent in the Middle East had gravitated to towns or cities. At the same time, 40 to 45 percent of the populations surveyed were under 15 years. (An overall annual growth rate of 2.8 percent means almost doubling the population in 25 years.)

About 93 percent of the people of the region are Muslim and about 57 percent speak Arabic; other important languages are Turkish, Persian, Hebrew, Kurdish, and Berber (Fisher 1971; Drysdale and Blake 1975).

Economic Life

Until very recently, about 60 percent of the population cultivated the traditional crops of the Mediterranean – cereals and olive and fig trees – whereas date palms and sugar cane predominated in the southern deserts. Antiquated and inequitable land-holding and tenancy systems have discouraged long-term development by individual farmers, and the traditional but excessive subdivision of land has worked against cost-effective production. This region still must remain vigilant for periodic swarms of destructive locusts, both Saharan and Arabian types, in addition to the pests that damage crops in other parts of the world.

Whereas most lands capable of cultivation have been planted with cereals, areas where water and good soil are lacking have been left to herders. Sheep are preponderant in all areas; goats also are kept in large numbers, especially in steppe and mountainous areas; and water buffalo have provided most animal power in the marshes of Iran and Iraq and the irrigated fields of Egypt. As transport has become increasingly mechanized, the use of the camel has declined, but the donkey still carries people and commodities everywhere. Neither cattle nor horses are important economically because of lack of pasturage. Mineral resources are limited, with the exception of petroleum in some states, and large-scale extraction has begun only relatively recently. Good-quality coal exists only in northwestern Turkey, but hydroelectric power and petroleum have been supplying energy for industrialization in recent decades.

The traditional handicrafts and manufactures of the Middle East and North Africa – metal working, glassware, textiles for articles of clothing, and woolen carpet-making – have suffered from the competition of foreign imports, but many countries are now promoting them for export. Four countries –

Egypt, Israel, Syria, and Turkey – no longer conform to the typical Third World economic pattern, in that one-fifth or more of their gross domestic product is derived from the manufacturing industry. Generally, however, the countries of the Middle East and North Africa belong to the Third World, being still heavily dependent upon the export of primary products and the import of food, consumer goods, equipment, and technology (*Oxford Regional Economic Atlas* 1964; Fisher 1971; Drysdale and Blake 1985).

Disease Patterns

The foregoing sketch suggests a distinctive ecological disease pattern for the Middle East and North Africa. Pastoralism and the farmers' reliance on animals for transport, power, fertilizer, and dung fuel have made these occupational groups, living in close proximity to their livestock, vulnerable to zoonoses and to insect-borne diseases, some of which infest domestic or wild animals. Another important disease complex has developed out of the necessity for irrigation: the widespread incidence of parasitism due to favorable conditions for proliferation of the insect carrier and an intermediate host where required. At an agricultural conference in 1944, it was reported that expanding irrigation in one area of Egypt had raised the incidence of both malaria and schistosomiasis from 5 to 45 or even 75 percent of the population in that area (Fisher 1971). This survey, therefore, will begin with those ailments most closely related to the rural environment: arthropod-borne diseases and parasitic infestations. Next it shall consider the "crowd diseases," most characteristic of urban societies, but also found in crowded villages and oases. Last it shall sketch the diseases caused by nutritional deficiencies among rural and city people. Within those categories, diseases are listed in descending order of their prevalence or importance as death- or disability-threatening experiences.

Major Arthropod-Borne Diseases

Because the many species of anopheline mosquitoes have adapted to breeding in the widest variety of hydrological conditions – from swamps and stagnant irrigation pools to fast-moving mountain streams, and from freshwater springs to brackish marshland – they are found throughout the region except in stretches of desert lacking any surface collection of water. From 9 to 19 species of anopheline mosquitoes exist in each Middle Eastern and North African country, of which 3 or 4 have been identified as vectors of *malaria*.

Although mosquitoes cannot survive dry, hot

weather, their proliferation in oases in Libya's Fezzan Desert and in the Arabian Peninsula demonstrates their tenacity. One species of *Anopheles* endemic in southwestern Arabia has caused recurrent epidemics of malaria under favorable rainfall conditions. The last such epidemic was reported in 1950–1, when this species spread inland from Jidda along the road to Mecca, carried by the increased traffic of the Muslims' annual pilgrimage.

Malaria has been reported in all the countries of the Middle East and North Africa. Since World War II the World Health Organization (WHO) has carried out extensive mosquito eradication projects. Nonetheless, malaria continues to break out periodically, and in 1950 a public health survey in Morocco reported that it was still the most prevalent disease in the country (Simmons et al. 1954; *Nosologie marocaine* 1955; Kanter 1967; Benenson 1975).

The *Aedes Aegypti* mosquito that transmits *dengue fever* also is a potential vector of yellow fever, but that infection has not been reported in the Middle East and North Africa. Dengue is endemic in the eastern Mediterranean area but has not been observed at heights exceeding 600 meters (2,000 feet) and has been largely confined to coastal areas. Most countries in the Middle East have sporadic outbreaks of dengue fever, and a few cases are reported in Libya every year; whereas in Morocco, Algeria, and Tunisia, the infection has remained only a potential threat (Simmons et al. 1954; Kanter 1967; Benenson 1975).

Because early symptoms of *Bancroftian filariasis* may be simply fever and lymphadenitis, the disease was not reported historically until prolonged and repeated infection caused elephantiasis of the limbs or outer genitalia. Today, although the most common mosquito vector of filariasis is abundant throughout the region, the threat of the disease has remained potential. In Lebanon, filariasis appears occasionally. There is one focus of infection in the southwestern Arabian Peninsula and another in Egypt, where the mosquito vector proliferates in numerous brackish wells in Rosetta (Simmons et al. 1954; Benenson 1975).

Bubonic plague is transmitted by the bite of an infective flea, usually *Xenopsylla cheopis*, and marked by acute lymphadenitis forming buboes, at the site of the infection; *septicemic plague* occurs in severe and advanced bubonic plague, causing petechial hemorrhages; *pneumonic plague,* the most infectious and fatal form, is airborne, spread by inhalation of exhaled droplets from infected patients.

The Middle East and North Africa suffered se-

verely in the sixth-century plague of Justinian, and repeatedly thereafter. Because Procopius had placed the origin of that pandemic in Egypt, the Nile Valley became identified in Europe's popular and professional imagination as "the cradle of plague." However, the recurring epidemics of bubonic plague in this region were initially imported. Infected fleas on rats infesting the holds of cargo ships transmitted the infection to domestic rats in Mediterranean port cities and established endemic loci for the disease. Only the coast is naturally vulnerable to plague. Inland areas are too hot or too cold, and above all too dry to be susceptible to enzootic plague. However, irrigation systems acted as networks for transmitting infective fleas by providing harborage for rats in the embankments of canals. Epidemics flared periodically whenever optimum weather conditions – high humidity and moderate temperatures – coincided with an adequate rat–flea density. After the adoption of quarantine measures in the southern and eastern Mediterranean in the nineteenth century, followed by the discovery of the rat–flea nexus, most areas of the world including the Middle East and North Africa managed to bring plague under control until the epidemic of 1894, which originated in northern China.

Plague, however, continues to be a potential danger in the Middle East and North Africa. A reservoir of sylvatic (wild rodent) plague in the mountains of southwestern Arabia and the Kurdish highlands, shared by Iran, Iraq, and Turkey, may spread infection by contact with domestic rats. In Libya sporadic cases transmitted by steppe rodent fleas broke out almost annually from the time of World War I until 1940. In Morocco as well, plague recurred sporadically until 1946, and it was also reported in Tunisia, Algeria, and Egypt up to the early 1950s (Hirsch 1883; Hirst 1953; Pollitzer 1954; Simmons et al. 1954; *Nosologie marocaine* 1955; Kanter 1967; Benenson 1975; Gallagher 1983).

Characteristic of colder climates, *typhus* is not common in this region and has occurred chiefly during the winter among nomads who wear the same heavy clothing day and night. The human body's humid microclimate provides a favorable environment for the louse to deposit eggs (*nits*) that hatch into young lice in a few days. Warm dry weather is unfavorable for breeding because humans dress more lightly, exposing the lice to high temperatures and sunlight. Displacement of people and crowding during World War II contributed to a series of epidemic outbreaks of typhus in North Africa, but delousing campaigns appeared to eliminate the dis-

ease. Nonetheless, occasional outbreaks have been reported in Iran, Iraq, Syria, and Jordan, from congested villages and town quarters as well as from refugee camps (Rodenwaldt 1952; Simmons et al. 1954; *Nosologie marocaine* 1955; Kanter 1967; Benenson 1975).

Other Arthropod-Borne Diseases

Although foci for endemic *tick-borne relapsing fever* (alternating febrile and afebrile periods) exist throughout the region, the disease is rare. Epidemic *louse-borne relapsing fever* is more common; between 1942 and 1945 a series of epidemics spread throughout North Africa from Morocco through Egypt and extended into Turkey, but it has occurred only sporadically since then. *Boutonneuse fever* is a mild to moderately severe febrile illness widely distributed in countries adjacent to the Mediterranean, Caspian, and Black seas. The disease, which is transmitted by the bite of an infected dog tick, occurs occasionally in Morocco, Algeria, Tunisia, Libya, and Turkey, and rarely in Israel and Lebanon. Also, another tick-borne disease, *tularemia,* a plaguelike infection of wild and domestic animals, especially rodents and rabbits, is found only in Turkey (Rodenwaldt 1952; Simmons et al. 1954; Benenson 1975).

Of the three types of *leishmaniasis,* only *cutaneous leishmaniasis* (*Leishmania tropica*) is common in the Middle East and North Africa. In 1756 Patrick Russell named the affliction the "Aleppo boil," and today it is also known as "Baghdad boil" in Iraq and "Jericho boil" in Jordan. In Israel it is most common in the Haifa area. It also occurs sporadically in the Arabian Peninsula and in southeastern Turkey, where it is known as "Urfa sore." In North Africa cutaneous leishmaniasis is endemic and prevalent in Algeria and Morocco, widespread in Tunisia and Egypt, but rare in Libya (Russell 1794; Rodenwaldt 1952; Omran 1961; Kanter 1967; Benenson 1975).

Kala-azar, or *visceral leishmaniasis,* is a chronic systemic infection disease characterized by fever, enlargement of the liver and spleen, anemia, and progressive emaciation and weakness. Untreated, it is a highly fatal disease. Although the vectors of kala-azar are not common in this region, three species of sandflies are suspected of transmitting visceral leishmaniasis that appears sporadically in the northern and western coastal provinces of Turkey, and the littoral of Algeria and Morocco (Simmons et al. 1954; Benenson 1975).

Sandfly fever or *pappataci fever* (phlebotomus fever) is a viral 3- or 4-day fever that resembles influenza and is carried by the same phlebotome – *Phlebotomus papatasii* – transmits cutaneous leishmaniasis. Sandfly fever reportedly is endemic in Syria, Lebanon, Israel, Iraq, Iran, and sporadic in Jordan and Saudi Arabia (Simmons et al. 1954; Benenson 1975).

Finally, numerous species of flies are abundant throughout the Middle East and North Africa; among the most common of these are species of the *Muscidae* family, thought to be implicated in the mechanical transmission of intestinal and eye infections. For example, *gastroenteritis* causing infantile diarrhea and dehydration, which has been held responsible for more than half the infant deaths in Egypt, shows a striking peak of incidence during the hot, dry, fly season (Labib 1971). Several species cause myiasis in livestock and occasionally in humans, but cases of these invasions are rare (Simmons et al. 1954).

Helminth-Transmitted Diseases

Of the four species of blood flukes infecting humans – *Schistosoma haematobium, Schistosoma mansoni, Schistosoma intercalatum,* and *Schistosoma japonicum* – only the first two are endemic in the Middle East and North Africa. Persistence of the disease depends upon the presence of freshwater snails as the intermediate hosts.

The evolution of schistosomiasis probably occurred during the period when human populations were shifting from hunter-gathering economies to societies based on settled agriculture. Parasitism requires a stable relationship between host and parasite, such as is available in settlements close to slow-moving water in which snail hosts of the disease dwell. Vesical or urinary schistosomiasis probably existed in both ancient Mesopotamia and Egypt. Babylonian inscriptions and Egyptian papyri (Ebers, Kahun) refer to hematuria and prescribe remedies. In 1910 Marc Ruffer discovered ova in Egyptian mummies dating from 1200 B.C., and J. V. Kinnear-Wilson considers the finding of shells of the most common host snail, *Bulinus truncatus,* in the mud brick walls of Babylon evidence that *S. haematobium* was the cause of hematuria described in Babylonian texts. French soldiers suffered with hematuria during the occupation of Egypt in 1798–1801, but the causative parasite was not identified until 1851 when Theodor Bilharz recovered adult worms from the portal system during an autopsy in Cairo. The life cycles of the intermediate molluscan hosts were demonstrated early in the twentieth century.

Studies and clinical records between 1931 and 1961 reported schistosomiasis in all the countries of the Middle East and North Africa. However, because of prevailing desert conditions, North Africa, except for Egypt, has not harbored parasites that require surface water or moist soil for survival. A notable exception is the Fezzan in Libya, where in some oases with shallow wells, up to 86 percent of the inhabitants have been infected. However, outside a relatively small radius the groundwater available to oases has too high a salt content to support the host snail. The highest incidence, up to 100 percent in some villages, has occurred in Iraq and especially in Egypt where the inhabitants of the Nile Valley have maintained irrigation systems for millennia.

The widespread species has been *S. haematobium;* infection with *S. mansoni* has appeared only in Egypt and among Yemeni and Iraqi immigrants to Israel, although the host snail exists in the Arabian Peninsula and North Africa (Ruffer 1910; Simmons et al. 1954; *Nosologie marocaine* 1955; Malek 1961; Farooq 1964; Kanter 1967; Kinnear-Wilson 1967; Benenson 1975; Sandbach 1976; Sandison 1980).

Ancylostomiasis, or hookworm disease, is probably quite old. A chronic disease of the digestive system described in the Ebers Papyrus of 1550 B.C. has been interpreted as hookworm disease. In 1838 Angelo Dubini discovered a worm that he called *Ancylostoma duodenale,* during autopsies in Egypt, and a colleague found the same parasite during autopsies in 1845, but neither related them to specific diseases. In 1853, Wilhelm Griesinger identified ancylostomiasis as the cause of the endemic anemia, called "Egyptian chlorosis," and observed that 25 percent of the causes of death were traceable to the effects of this infestation.

Ancylostomiasis occurs in all Mediterranean countries, but the Nile Valley has been a particular locus of the infection (Khalil 1932; Simmons et al. 1954; *Nosologie marocaine* 1955; Benenson 1975).

Ascariasis (infection of the small intestine caused by *Ascaris lumbricoides,* the large intestinal roundworm) may cause digestive and nutritional disturbances. Pictorial evidence demonstrates the presence of *Ascaris* in ancient Mesopotamia, and numerous prescriptions for roundworm in the Ebers Papyrus indicate that the ancient Egyptians complained of this parasite as well. In the twentieth century, ascariasis has been most common among school children, who may suffer anemia and eosinophilia from high infestation. Serious complications among children may include bowel obstruction and occasionally death due to the migration of adult worms into liver

or gallbladder (Simmons et al. 1954; Kanter 1967; Kinnear-Wilson 1967; Benenson 1975; Sandison 1980).

Other worm-related diseases include *trichinosis,* which, because of the Muslim and Jewish prohibition against pork, is rare in the Middle East and North Africa, and has been reported only in Lebanon. *Taeniasis,* an infection with the beef tapeworm, *Taenia saginata* – causing anorexia, digestive disturbances, abdominal pain, and insomnia – occurs where the larvae are ingested with raw beef. It is particularly frequent among herding peoples whose sheep, cattle, and dogs have a high rate of infection, which may be passed to humans. In Libya, for example, the government hospital at Benghazi reported the existence of the larval form of tapeworm in 20 to 28 percent of the patients annually between 1960 and 1963 (Kanter 1967; Benenson 1975).

Zoonoses

The zoonoses that occur in the Middle East – brucellosis, anthrax, and Q fever – are all occupational diseases of herders, farm workers, veterinarians, abattoir workers, and industrial workers who process hides, wool, or other animal products. *Brucellosis,* which causes a generalized infection, also known as *undulant fever,* has been reported in Morocco, Algeria, Tunisia, Iran, Turkey, Syria, and Lebanon. *Anthrax,* an infectious disease of ruminants, occurs only in Turkey. *Q fever* rarely infects humans in areas where the disease exists enzootically in animals. Occasional cases, however, have been reported in Morocco that were suspected of having been transmitted by tick vectors.

Also increasingly rare is *rabies* or hydrophobia, an acute, almost invariably fatal viral infection of the central nervous system, transmitted to humans by the bite of a rabid animal. At mid-twentieth century, James Simmons and colleagues (1954) reported rabies in Iran, Syria, and Jordan; however, most countries in this region have controlled rabies by quarantining and licensing pets and by destroying stray animals (Benenson 1975).

Food- and Waterborne Enteric Diseases

Acute diarrheal disease in early childhood, most prevalent after weaning, is important in the Middle East and North Africa as in all developing countries. Although it may include specific infections, *infantile diarrhea* frequently is a clinical syndrome of unidentifiable etiology caused by bacteria, viruses, helminths, or protozoa. Common in areas of poor sanitation and prevailing malnutrition, infant diarrhea

may produce as many as 275 attacks per 100 children per year, more than 50 deaths per 1,000 per year in preschool children. Protein–calorie malnutrition is commonly associated with acute diarrheal episodes, which may precipitate kwashiorkor. The highest incidence tends to occur in hot, dry periods, calling for *oral rehydration therapy,* which has become a high priority program for the WHO in recent years (Simmons et al. 1954; Benenson 1975).

At mid-twentieth century, Simmons reported "dysenteries" for all Middle Eastern countries, but provided no data. All North African countries, including Egypt, reported higher incidence rates for *shigellosis* then *amebiasis,* except in Morocco and Libya, where amebiasis was reported more prevalent. Between 1900 and 1950 comparative mortality rates were 8.7 percent for amebic dysentery and 11.8 percent for bacillary dysentery (Rodenwaldt 1952; Simmons et al. 1954; Kanter 1967).

In the Middle East and North Africa, raw fruits and vegetables handled by infected persons are important vehicles of the transmission of *typhoid fever,* and flies are often vectors for spreading contamination. At mid-twentieth century, the disease was reported in all countries considered in this survey but was reported as rare in Libya (Rodenwaldt 1952; Simmons et al. 1954). *Paratyphoid* infection due to *Salmonella* of all groups except *S. typhosa* is a generalized bacterial enteric infection, clinically similar to but with a lower fatality rate than typhoid fever; it occurs only sporadically in this region.

Cholera did not appear in the Middle East and North Africa until the great pandemics of the nineteenth century that were caused by troop movements in the lands bordering India, Afghanistan, and Iran, and by accelerated sea transport linking Asia with the rest of the world. Six pandemic waves of cholera swept around the world between 1817 and 1923, invading all settled communities in Asia, Africa, Europe, and the Americas. Middle Eastern and North African countries were vulnerable to invasion by the disease because returning Muslim pilgrims carried the infection from the holy cities of Arabia, where it was introduced by Muslims from South Asia. After discovery of the cholera vibrio and the rationalization of quarantine practices, as well as nineteenth-century sanitary reform programs, cholera receded as a major threat. The adoption of efficient control techniques, particularly since the Second World War, has effectively neutralized the danger of dissemination from the Muslim pilgrimage sites. The last major outbreak, which occurred in Egypt in 1947, was due to relaxation of quarantine regulations during the Second World War. However, since 1961 a new strain of cholera, El Tor, has spread extensively from a focus in Sulawesi in Indonesia, through most of Asia and the Middle East into Eastern Europe and Africa, and from North Africa into the Iberian Peninsula and Italy (Hirsch 1883; Simmons et al. 1954; Pollitzer 1959; Kanter 1967; Benenson 1975).

Diseases Transmitted Through the Respiratory Tract

Tuberculosis is widespread in the Middle East in the pulmonary form that was known earlier as phthisis or consumption. Egyptian wall paintings depict humpbacks typical of bone tuberculosis of the spine, known as Pott's disease, and tuberculous bones have been found in tombs dating to 3000 B.C. In modern times, tuberculosis appeared to accompany the rise of industrialization and urbanization in the nineteenth century, succeeding smallpox as the most common affliction in city life. In congested slums tuberculosis assumed epidemic proportions because the infection is transmitted by exposure to the bacilli in airborne droplet nuclei from the sputum of infected persons. In the mid-twentieth century, tuberculosis was reported in all Middle Eastern and North African states. Wartime displacement had caused a steep rise in incidence. In Libya, for example, many uprooted nomads from the Fezzan emigrated to shanty towns on the coast. Because food was scarce and sanitary installations were nonexistent, tuberculosis spread rapidly among these desert people in a severe form that was often fatal. In the 1950s, the WHO and UNICEF supported immunization programs with the result that tuberculosis in the Middle East has become similar to the European type, milder and chronic (Simmons et al. 1954; *Nosologie marocaine* 1955; Kanter 1967; Benenson 1975; Sandison 1980).

By contrast, *pneuomococcal pneumonia* was reported to have a significant mid-twentieth-century incidence only in Egypt and Turkey. This may suggest susceptibility among the ill-housed, undernourished poor inhabiting the overcrowded metropolises, as well as an above-average involvement among the coal miners in Turkey (Simmons et al. 1954; Benenson 1975).

Diphtheria typically has been a disease of colder months in temperate zones. It was reported in Egypt, Israel, Jordan, and Iraq in the mid-twentieth century; in Morocco it was identified as one of several diseases that accompanied an influx of Europeans during the Second World War (Simmons et al. 1954; *Nosologie marocaine* 1955; Benenson 1975).

Meningitis occurs more frequently in children and young adults and more commonly in crowded living conditions. In the mid-twentieth century, meningococcal infection was reported in Turkey, Iraq, Lebanon, and Egypt (Simmons et al. 1954; Benenson 1975).

Smallpox had been a recognized scourge in the Middle East since the sixth-century epidemic struck Ethiopian invaders threatening Mecca. The Islamic scholar-physician Rhazes, in the tenth century, wrote the classic clinical description of the disease, implying that smallpox was very common and endemic to the entire Islamic world from Spain to Persia at that time. It is true that plague overshadowed smallpox in the Mediterranean for several centuries, but the latter remained widespread and continued to claim great numbers of victims until the early nineteenth century when Europeans began introducing Edward Jenner's vaccination into their colonies in Africa and Asia. Nevertheless, although most countries in the Middle East adopted immunization procedures during the nineteenth and early twentieth centuries, smallpox continued to break out in all of them until systematic vaccination campaigns coordinated by WHO eradicated the disease in Libya by 1949 and elsewhere in the region by 1977 (Simmons et al. 1954; Kanter 1967; Hopkins 1983; Fenner et al. 1988).

At about midcentury, measles was recorded only in Egypt, Algeria, and Morocco (Simmons et al. 1944; Benenson 1975).

Diseases Transmitted by Human Contact

Eye diseases are widespread in the Middle East and along the Mediterranean littoral. The most serious, trachoma (earlier called "Egyptian ophthalmia"), is a bacterial infection that progresses clinically from tiny follicles on the eyelid conjunctiva to invasion of the cornea, with scarring and contraction that may lead to deformity of the eyelids and blindness. It is often accompanied by *acute bacterial conjunctivitis*, a highly contagious form of conjunctivitis, most often caused by the Koch–Weeks bacillus, characterized by inflammation, lacrimation, and irritation, followed by photophobia, purulence, and edema of the eyelids.

Both trachoma and conjunctivitis are transmitted through contact with fingers or articles contaminated by discharges of infected persons. Flies or eye gnats often spread the infection, and lack of water and exposure to dry winds, dust, and sandstorms are thought to aggravate the problem.

Between 1928 and 1936, trachoma morbidity was very high in the Middle East. Egypt was considered the principal focus, where about 90 percent of the population was reported to have suffered trachoma, often combined with acute bacterial conjunctivitis or occasionally gonococcal conjunctivitis. In Syria, Lebanon, and Palestine, about 60 percent of the Arab schoolchildren and 10 percent of the Jewish children from rural areas were infected with trachoma. In Turkey, 60 percent of the population in the southeast steppe area with no forestation was reported affected. In Iran, the highest incidence also was reported in steppe and desert areas near the Persian Gulf and in the interior south of Isfahan. In Iraq, the high incidence of trachoma in Baghdad – 80 percent – was attributed to susceptibility to infection from exposure to the loess dust from the Tigris and Euphrates flood areas during the hot dry season.

In Algeria and Morocco about 10 percent, and in Tunisia 40 percent, of the population were infected with trachoma. According to practitioners in Morocco, trachoma was not an independent nosological entity; bacterial conjunctivitis accompanied 80 percent of the cases. In Libya trachoma was most common in the Fezzan oases, where morbidity was estimated at 60 percent of the inhabitants. In the post–World War II migration of desert people to the coastal cities, incidence ranged from 30 percent to 70 percent in the shanty towns outside Tripoli. In spite of preventive programs, the disease was still widespread in 1963, when 4,126 cases were recorded in Tripolitania Province (Rodenwaldt 1952; Simmons et al. 1954; *Nosologie marocaine* 1955; Kanter 1967; Benenson 1975).

Among North Africans, *leprosy* was believed to have been imported from the eastern Mediterranean by many peoples. In the ninth century B.C., Phoenicians were blamed for it. Jews driven from Jerusalem in A.D. 135 were believed to have reintroduced it, as were Arab invaders in the eighth century. In addition, it was probably periodically reintroduced by Saharan caravans as well. By mid-twentieth century, however, leprosy had effectively disappeared in North Africa, except among the Berbers, where there were an estimated 8,000 cases, and in Egypt where 30,000 cases were reported (Rodenwaldt 1952; Simmons et al. 1954; *Nosologie marocaine* 1955; Kanter 1967; Benenson 1975).

Finally, in the mid-twentieth century, *scabies* was reported in Egypt, Morocco, Iran, Syria, and Jordan, perhaps aggravated by wartime displacement and crowding, as in refugee camps, with consequent lack of water for bathing (Simmons et al. 1954; Benenson 1975).

Venereal Diseases

Because leprosy was often confused with venereal diseases in antiquity, it is not clear when *syphilis* first appeared in the Middle East and North Africa. Following the Crusades, however, when all Europeans were referred to generically as "Franks," syphilis was associated definitively with Europeans as "*il-franji*" – that is, the Franks' disease. *Gonorrhea* reportedly is relatively rare, but occurs fairly frequently as blennorrhea or gonococcal conjunctivitis among infants or very young children. In the mid-twentieth century, nevertheless, venereal diseases were acknowledged public health problems in all the countries of the Middle East and North Africa (Rodenwaldt 1952; Simmons et al. 1954; Kanter 1967; Benenson 1975).

Nutritional Deficiencies and Disorders

The traditional diet of North Africa reflects the geographic divisions of the area. Each country from the Senegal River to the Nile has a littoral and a desert region that are separated from each other by fertile plateaus and arid mountains. Commonly, the littoral food pattern has been based on cereals and fruit; the plateau diet, on cereals, olives, sheep's milk, and meat; and the desert diet, on dates and camel's milk.

The dietary patterns of Middle Eastern countries also reflect geographic and economic conditions. Except for Israel and Lebanon, where vegetables and fruits abound, cereals provide the major portion of both the caloric and protein intake in the average diet. Wheat is the most widely consumed cereal in all countries; maize is the chief staple in the delta region of Egypt and the Black Sea coast of Turkey; rice is also popular, but its high cost limits its consumption to producing areas (mainly Egypt) and the well-to-do; burghul (parboiled wheat sundried and crushed) is eaten in Turkey, Syria, and Lebanon as a substitute for rice. Lentils and other legumes are consumed widely.

Vegetables such as onions, tomatoes, eggplant, cucumbers, peppers, squash, and cabbages are universally popular but are consumed in inadequate amounts. Consumption of fruits shows wide seasonal variations, except for dates, raisins, grapes, and apricots, which can be preserved by drying. The difficulty of transporting and preserving fresh milk has led to the widespread use of fermented milk, yogurt, and, to a lesser extent, sheep and goat cheese.

Throughout the Middle East, meat is consumed at a low level, mainly because of its relatively high cost. Although the animal population in this region is among the highest in the world, livestock repre-

sent capital to the herdsmen that is not to be wasted by slaughter. Thus, meat contributes only about 2 percent of the total caloric intake, compared with 21 percent in the United States. Mutton is the principal meat consumed in Muslim countries, and to some extent beef and goat are also eaten. Like the nomads' herds, poultry and eggs provide a livelihood for villagers; they are sold and eaten mainly in towns. Fish as food has been important only among the inhabitants of the Black Sea area in Turkey, the delta lakes region in Egypt, and the marsh dwellers of southern Iraq.

Certain cultural and environmental features restrict diet in both the Middle East and North Africa. Both Muslims and Jews, for example, are enjoined from eating meat not slaughtered according to their religious codes, and this ritual slaughter adds to the cost. More generally, climatic conditions and the lack of efficient means of food preservation, refrigeration, and transport drastically restrict consumption of fruits, vegetables, milk products, fish, and meat. The scanty and irregular distribution of rainfall has been a constant factor retarding the development of agriculture. Although production has increased in all areas since the Second World War, the low purchasing power of the population, especially in rural areas, as well as the lack of transport and distribution facilities, has kept consumption of food low. The result of the foregoing is that a significant segment of the population is afflicted with nutritional diseases.

In Egypt, Iraq, and to a lesser extent in Syria, hypochromic microcytic *anemia* has been attributed to the prevalence of hookworm infestation in irrigated farm areas, but there is evidence that parasitic infestation also contributes to the high morbidity of nutritional anemia (May and Jarcho 1961).

One investigation in Algeria found that macrocytic nutritional anemia was common among various population groups in the capital, mainly inhabitants of the city slums or rural areas whose diets were unusually low in protein, fats, fresh fruits, and vegetables. Another survey (May 1967) revealed that a large percentage of children under 1 year of age in Tunisian cities showed signs of nutritional anemia. And in Morocco it was reported that women, especially those pregnant or lactating, showed gross evidence of iron deficiency anemia.

Kwashiorkor is not as common in the Middle East and North Africa as in sub-Sahara Africa, but it has been reported among the poorest classes in Egypt and Israel. In Morocco, Algeria, and Tunisia, it reportedly has been common following weaning of chil-

dren between 1 and 3 years of age (May and Jarcho 1961; May 1967).

Xerophthalmia or night blindness due to vitamin A deficiency is common in the Middle East and North Africa. Lack of vitamin A also lowers resistance to infection. For example, keratoconjunctivitis occurring in a child deficient in vitamin A increases that child's susceptibility to chronic trachoma. Also, in Libya bacterial infections rise during the autumn date harvest when flies proliferate; combined with vitamin A deficiency, an eye infection may lead to serious complications – rupture of the cornea and prolapse of the iris – and blindness (Kanter 1967). Night blindness has been reported in Iran and among sedentary communities of the northern Sahara in North Africa (May and Jarcho 1961; May 1967; Benenson 1975).

Pellagra, by contrast, has been reported only in the Black Sea area of Turkey and the delta of Egypt where maize is the staple grain, and in North Africa during periods of wheat or barley shortage when consumption of corn has become necessary.

Scurvy is rare in the Middle East and North Africa, where citrus fruits are usually available, except in Erzerum in northeastern Turkey, which is isolated from food supply lines during winter months.

Rickets, on the other hand, has been observed in large towns of Iran, Syria, and Egypt where infants were swaddled and therefore not exposed to the sun. In North Africa rickets was reported in the sunless slums of coastal cities in Morocco, Algeria, and Tunisia and among sedentary communities in the northern Sahara. Southern nomads appeared to escape this disease as well as scurvy and xerophthalmia perhaps because of greater exposure to sunlight and higher milk consumption. Erzerum in northeastern Turkey has reported seasonal incidence of rickets as well as scurvy during long, severe, sunless winters (May and Jarcho 1961; May 1967; Benenson 1975).

General Observations on Nutrition

Although malnutrition (overreliance on starch in the diet, with little fat or protein) has been observed, undernutrition (calorie as well as protein-deficient diet) has been far more common in the Middle East and North Africa. In most countries, the population rise has consistently exceeded the increase in cultivated land. The most dramatic example is Egypt, where population is increasing by about a million people each year.

In extensively irrigated countries like Egypt and Iraq, and to a lesser extent Syria, there is a synergistic interaction between inadequate diet and parasitic infestation, particularly hookworm, causing severe anemia and threatening retardation of the physical and mental development of children. Investigators also have suggested that an interaction between poor diet and schistosomiasis may cause pellagra.

In North African countries and the states of the Arabian Peninsula, protein and vitamin deficiencies are reported predominantly among women and children, and are not common among men. This observation is valid as well for other countries in the region that share the patriarchal custom of serving the father and older sons of the family first, leaving what remains for women and children, which may not include meat, fruits, and vegetables.

In North Africa where the child between 1 and 3 years old is weaned abruptly and then given a diet of carbohydrates familiar in family fare, the young may not be able to tolerate the change, which may then cause dyspepsia, infantile diarrhea, lowered resistance to infectious diseases, and kwashiorkor. Nomadic tribespeople of the Sahara south of the Atlas mountains, however, wean the infant over a 6-month period, introducing it gradually first to camel's milk and then to cereals.

On the positive side, the high consumption of whole wheat and other cereal products may explain the comparative absence of vitamin B complex deficiencies. Also, traditional dishes that combine cereals with legumes such as beans, chickpeas, and lentils have been demonstrated to be a good source of protein.

In addition, there are some naturally occurring foods that compensate the inhabitants of unproductive areas for the lack of more common foods. In Iraq, for example, an herb called *khoubbaz* (*Malus rotundifolia*), which is eaten raw by both rural and nomadic peoples, has been found to have a high ascorbic acid content. And in Libya's Fezzan, two naturally occurring foods have been found to be rich in beta-carotene and riboflavin. One, *danga,* is prepared from an alga growing on salt lakes; the other, *duda,* consists of small crustaceans from the salt lakes. Both are kneaded, formed into small cakes, dried in the sun, and later mixed with barley, millet flour, or dates, and eaten as a main dish in a meal. Lastly, dates, an important food among nomadic and seminomadic peoples, are ideal for desert dwellers in that they have a high sugar content, are relatively resistant to contamination with pathological bacteria, and show long-keeping qualities.

Conclusions

In examining these data on the Middle East and North Africa, I have attempted to connect spatial patterns of disease incidence with characteristic fea-

tures of the local environments. The study has indicated how the geography, topography, and resulting climates have been used and misused by humankind over time. The negative aspects of all these factors led to low populations in this region until very recently. With the introduction of hydroelectric power and petroleum, the ensuing industrialization has enabled even greater proportions of the populations to live on the seacoast or river banks, and to develop urban centers.

The disease ecologies resulting from the peculiar rural environment, mainly with insufficient water; the specific problems of overcrowded, spatially limited living areas near water; and the general nutritional deficiencies of poor economies have now been augmented by increasing population. This phenomenal population rise following the establishment of post–World War II stability has especially aggravated conditions of overcrowding, substandard housing, and sanitation and poor nutrition in the urban communities. Although the economic and political patterns of the region vary among the countries, the interrelationships of many of the other factors remain similar.

VII.3
Disease Ecologies of South Asia

Disease ecology refers to the intricate human and environmental relationships that form the context of one or a group of diseases. Diseases are not simply biomedical entities; rather, they have their physical, environmental, sociocultural, psychological, and even political parameters. Distinctive human and biophysical environmental webs form the context of distinctive groups of human diseases. Major changes in this web, whether brought about by human intervention, environmental catastrophes, or a combination thereof, can result in a new context and possibly a new group of diseases. In developing countries, human control of the environment is limited, basic needs of a healthful life are not met, and, therefore, infectious and communicable diseases are the major cause of death. Improvements in health conditions will no doubt reduce the incidence of mortality resulting from infectious diseases and, in turn, bring about the prominence of chronic diseases more closely related to life-styles and life stages than to environmental parameters. South Asia as a geographic region still remains a region of poverty within which there is a marked contrast between the rural and urban *genre de vie*. Morbidity and mortality patterns in the rural and urban areas are, therefore, likely to be somewhat different, although paucity and quality of data make generalizations hazardous.

Ecologically, South Asia is one of the most distinctive regions of the world. Physiographically well demarcated, and climatically distinguished by the monsoonal rainfall regime, South Asian life has a rhythm marked by seasonality. Although agriculture is still the dominant occupation, rapidly swelling cities create air pollution, overcrowding, social stress, and the immense problem of waste disposal. The dominantly agrarian economic base is being increasingly supplemented by the diversity of urban occupations and modern life-styles. Rapidly increasing populations on a large numerical base create an environment of overcrowding, an acute housing shortage, substandard living conditions, and an ever present danger of recurring epidemics. Inadequacy of potable drinking water has meant an endemicity of various gastroenteric diseases. Undernutrition of pregnant mothers and inadequacy of

neonatal and postneonatal infant care result in very high infant mortality rates and a host of nutritional disorders. Under such living conditions, and the highly inadequate nature of the data, discussion of disease ecology of South Asia must remain broad. In order to understand South Asia's health context, it is necessary to keep in mind an outline of some of the essential facts of its physical and human environments.

The Physical Environment

Topography

The Himalaya and its associated mountain ranges form a physical and cultural divide between South Asia and the lands to the north and east. They rise in a series of roughly parallel ranges northward from the plains of Bangladesh, India, and Nepal, with each range progressively higher. The much lower Sulaiman and Kirthar ranges of western Pakistan, with their many passes, have permitted intercourse with other parts of Asia. Mountains closest to the plains have been heavily denuded of their forest cover, and are subject to intense soil erosion.

South of the world's highest mountain system is the densely populated alluvial plain of Ganga in India and Bangladesh, and the Indus Plain, mostly in Pakistan. Both these plains have extensively developed systems of irrigation. Canal irrigation is particularly well developed in the Indus Plain and the western Ganga Plain. These plains are subject to periodic flooding that is especially heavy and periodically devastating in the eastern part of India and Bangladesh.

The Thar Desert, south of the Indus Plain, is shared by India and Pakistan. Here is a vast arid region hemmed in from the east by the low Aravalli Range. This thinly populated desert region is characterized by shifting sand dunes, large playa lakes, salt pans, and, to the southwest, marshlands.

South of the Ganga Plain is peninsular India. Composed of several plateaus, this region, except for the black soils of the Deccan Plateau and the river deltas, is primarily an area of thin, reddish soils of medium to poor quality. Part of the peninsula that is still forested and of marginal quality for agriculture is home to many tribal people. Skirting the peninsula on the west is the narrow but intensively cultivated and densely populated Malabar coast. On the east the coastal plain is broader. The island nation of Sri Lanka is composed of central highlands surrounded by a coastal plain.

Climate

South Asia is very hot during the summer; the highest temperatures are found in the Thar Desert. Hot desiccating winds in May and June are frequent in the entire Indus–Ganga Plain and cause substantial problems of heat stress (Planalp 1971). Temperatures of over 90°F are commonplace. In the mountainous regions elevation modifies the temperatures. During winter there is a general temperature gradient from north to south. Temperatures are in the 40°F range in the north, reaching well over 75°F in the south.

South Asia is characterized by a high degree of rainfall seasonality, with very uneven geographic distribution, and great variability from year to year. In much of India, Bangladesh, Nepal, Bhutan, and Pakistan, most of the rainfall is received from June through September. Over the southern part of peninsular India, autumn rainfall is significant. On the southeastern coastal area the predominant season of rains is autumn. Most of peninsular India and the Thar region suffer from high variability of rainfall. In general, the seasonality of rainfall in the predominantly agrarian societies of South Asia has meant that farming is very dependent upon rainfall despite major developments in irrigation during the twentieth century. Variability of rainfall, therefore, means that farming communities may suffer from frequent seasonal food shortages, undernutrition, lowered resistance, and higher morbidity.

Convincing arguments have been made about the relationship of climatic seasonality to seasonal morbidity, especially among the poor. Evidence from diverse regions of the world, including India and Bangladesh, shows that seasonal fluctuations bear more heavily on the poor than on other social groups (Chambers, Longhurst, and Pacey 1981). High-rainfall regions, especially where humidity is also high (e.g., the Malabar coast, Eastern India, and Bangladesh) are the major endemic areas of infectious diseases such as cholera, typhoid, filariasis, and malaria.

The Sociocultural Environment

The Demographic Aspect

The South Asian nations are characterized by high birthrates, rapidly declining overall death rates, and consequently high natural increases to their already large population bases. For example, Bangladesh, at current rates, will double its population in 25 years, Pakistan in 24, and India in 32 years. The immediate reality is that in spite of much lowered crude death rates in the 1980s, infant mortality rates are very high: 112 per 1,000 live births in Nepal, about 120 in Pakistan, and 138 in Bangladesh. A large proportion – nearly 40 percent – of the population of South Asia is composed of children under 15 years of age. Maternal and child health must therefore consume a large part of the national health budgets. Large families, especially of the poor, lead to a high incidence of protein–energy malnutrition (PEM). Migration to urban areas, and life in overcrowded houses and hutments mean constant exposure to pathogens.

Social Realities

In South Asia, irrespective of religious beliefs, most of which are expressed in Hinduism, there is a strong concept of social groupings or castes. The most important aspect of this system that concerns us here is that the lowest caste groups ("scheduled castes") constitute about 15 percent of India's population. They have not only been socially disadvantaged but also tend to be the poorest. They have traditional occupations such as sweeping, cleaning of human waste, skinning animals, and leather working, and are spatially segregated in the villages and cities. Although they are not ethnically different from the majority population, the hamlets of these predominantly landless workers are located separately from the main villages, and their densely populated clusters of huts are found on the outskirts of cities along major roads and railway lines. Living conditions in their settlements are extremely unhygienic because they lack waste disposal systems. Proximity to urban dumps, and pools of stagnant water in construction pits create ideal conditions for a very high density of flies and mosquitoes in their settlements.

Tribal cultural groups, collectively termed "scheduled tribes," who make up about 3 percent of India's population, live mostly in forested, agriculturally marginal areas of the eastern states, the northeastern part of peninsular India, and the degraded forests in Madhya Pradesh, Maharashtra, Rajasthan, and Gujarat. Many of these groups practice *jhumming,* or slash-and-burn agriculture, but others have migrated to cities and mining areas in search of employment. Because virtually all of their traditional habitat has been isolated, health programs have rarely been extended effectively to them.

Differential gender valuation is common in South Asia. Male children are valued more than females. This tendency is reflected in the actual share of food and health care that is available to female children,

who may get a less nutritious diet. When sick, the males are more likely than females to receive medical attention. In general, it would appear that female morbidity is underreported.

General Health Conditions in South Asia

South Asia is home to most diseases of humankind; surprisingly, yellow fever and some others are absent. The major causes of death include infectious and parasitic diseases such as tuberculosis, diarrhea, malaria, typhoid, gastrointestinal disorders, and a variety of childhood diseases such as tetanus, pneumonia, whooping cough, diphtheria, measles, and other preventable diseases (Nyrop 1984). A health survey in Pakistan during the mid-1970s revealed that nearly 30 percent of the people had malaria, and almost 100 percent had worm or parasitic afflictions (Nyrop 1984). Although published data on many health indicators are lacking or woefully deficient, some indication of health conditions may be obtained from life expectancy, crude death rates, and infant mortality rates. Death rates in South Asia, as in most developing regions of the world, have declined markedly since the 1970s, although they are still above the world average. Within South Asia, Sri Lanka has the lowest death rate (about 6 per 1,000), which is lower than most of the European countries and the United States (9 per 1,000). Death rates are higher for India (10 per 1,000) and even higher for Pakistan (14), Bangladesh (15), Nepal and Bhutan (17 each). Infant mortality rates, however, reveal a grimmer picture of the prevalent health conditions. Despite official claims to the contrary, infant mortality rates are very high, except in Sri Lanka, thanks largely to a very high female literacy rate compared with other South Asian countries. Considering Sri Lanka as the exception, South Asia as a whole shows clear signs of environmentally related causes of death, especially of infants.

Sanitation conditions in South Asia are appalling, made worse by the monsoon rains. Most rural inhabitants and those living on the outskirts of the cities use fields and any open space as a latrine. Although the new "Sulabh" (semiflushing) latrine is gaining ground in Indian cities, human waste disposal remains a serious problem, leading to a variety of gastrointestinal diseases. Contamination of municipal drinking water during the rainy season, including cities such as Delhi, results in periodic outbreaks of hepatitis epidemics.

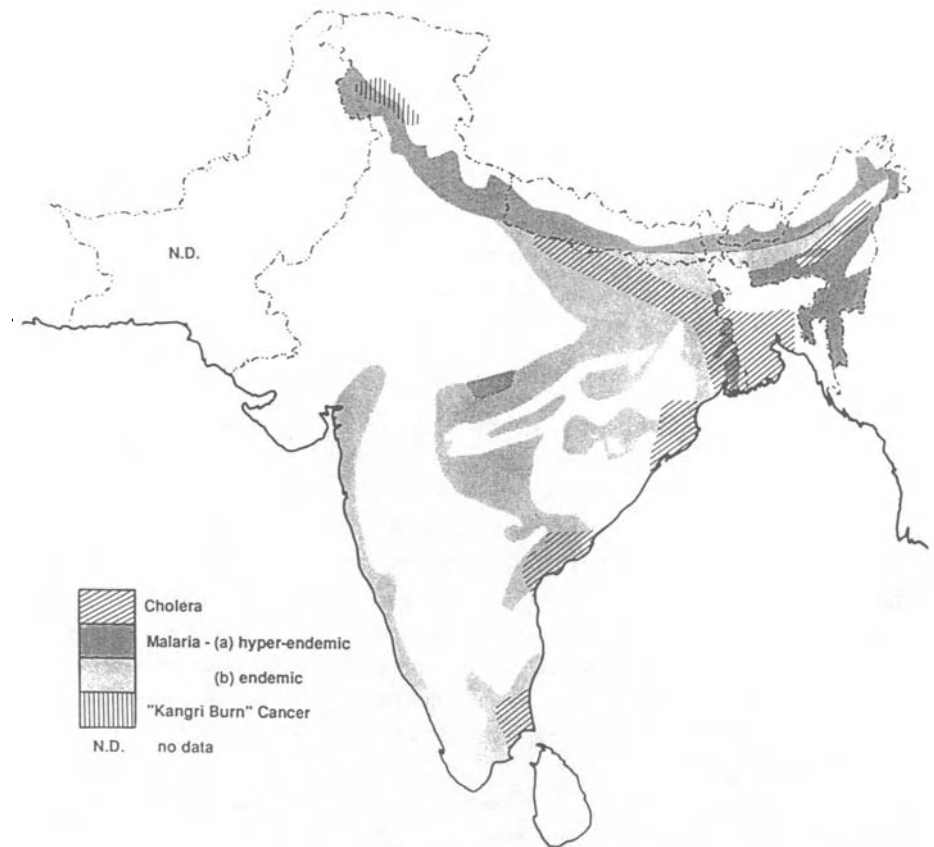
The process of urbanization in South Asia is bringing vast numbers of rural unemployed workers to the cities. Those unable to find relatives, or who are too poor to rent, must live wherever they can. Thus, many semipermanent urban accretions have developed. Health conditions in these periurban slums are very poor. In fact, these settlements form a virtual ring of high morbidity around growing cities. Engulfed by rapidly growing suburban housing, these shanties are frequently found in close proximity to outward developing metropolitan areas. City governments are constantly trying to "clear" these semipermanent worker settlements (in India called *jhuggies* and *jhonparies,* or simply *JJ's*), often with great difficulty. In the meantime, they remain as centers of high morbidity and infant mortality.

Expanding cities are also engulfing preexisting villages, thus juxtaposing two very different ways of life. Demand for milk and meat in the burgeoning urban populations has spurred these farming communities to intensify their farming by growing vegetables, and by keeping dairy cows, buffaloes, and chickens. The lower castes raise goats and pigs in these periurban locations. One effect of this urban agriculture is that the density of flies and mosquitoes in these areas is very high, thus helping to maintain endemicity of gastroenteric diseases.

Ecology of Selected Diseases in South Asia

In the space of this essay, it is possible to focus on only a few selected prevalent diseases in South Asia. Thus, smallpox, in spite of the fact that it was once a major killer disease in India, has been omitted because it has been eradicated. Likewise, although plague has some endemicity, its incidence is now very limited. Instead the focus is on diseases of high endemicity or prevalence.

Cholera

Although cholera, an acute communicable disease, is not peculiar to South Asia, there are endemic areas of cholera in this region from which periodic outbreaks have occurred (see Map VII.3.1). Cholera etiology is relatively simple, since this disease is caused by the ingestion of *Vibrio cholerae.* Two distinct modes of cholera transmission are usually recognized (Craig 1986). In the "primary" transmission, the vibrio is ingested through vegetables and fish raised in water that is contaminated with the vibrio. The "secondary" mode is the fecal–oral transmission. In nonimmunized persons with relatively lowered stomach acidity, symptoms of cholera develop rapidly, marked by frequent watery stools, vomiting, and fever. Since the vibrio is present in great quantities in the characteristic watery stools, flies may carry the germ from them to human food. Consumption of this contami-


Map VII.3.1. General endemicity of cholera, malaria, and "kangri burn" cancer. (Based on Misra 1970; Hutt and Burkitt 1986.)

nated food results in the ingestion of the vibrio, thus creating a fecal–oral link, resulting in manifestation of the disease. Death occurs as a result of excessive dehydration, electrolyte imbalance, and the pyrogenic endotoxins of *V. cholerae.*

Cholera remains endemic in the delta lands of Ganga in West Bengal and Bangladesh. Indeed, the "cholera pandemic that scourged the world in the first half of the nineteenth century began in the Bengali basin and spread as far and as rapidly as man was then able to travel" (Cahill 1976). The reasons for cholera's endemicity have to do with a combination of physical, environmental, and human conditions. The deltaic region is characterized by heavy monsoon rainfall from June through September, resulting in frequent and often disastrous flooding. In the aftermath of rains, slow-moving water in the maze of Ganga's distributaries and stagnant water in numerous shallow pools characterize the landscape. Tanks and wells used as a resource for drinking water are filled with surface flow. Algal infestations of these ponds and tanks greatly increase the alkalinity of stagnant water, and create favorable conditions for the multiplication of *V. cholerae* (Jusatz 1977). Most people defecate outdoors and seek proximity to water for cleaning themselves. Thus, chances for the accu-

mulation of cholera germs in pools of water increase, putting at risk individuals who use this water for drinking. During the dry season, shrinking pools and tanks, owing to intense heat, become even more concentrated with the vibrio. Fish taken from these sources, and vegetables washed with this water, can transmit cholera. Since most drinking water is neither filtered nor boiled, chances for vibrio ingestion remain high. During the monsoon season, when heat and humidity are high, people tend to lose large amounts of moisture with sweating. Drinking large quantities of water greatly dilutes the stomach acidity. If vibrio-infected food or water is taken under this condition, the chances for disease manifestation multiply. This situation happens usually at village fairs, periodic markets, or other big gatherings in the open. Because the disease has a very rapid course, causing vomiting, fever, and passage of watery stools, vibrio from such body wastes can be easily conveyed by the ubiquitous flies to food items being consumed by other participants at the fair. Cholera epidemics are therefore notorious for their speed and virulence during the summer monsoon season.

From the delta region of the Ganges, cholera has often spread in epidemic forms (May 1958; Ackerknecht 1972), although today the death rate is quite

low because of widespread immunization in South Asia. In the past, cholera has also been spread through the agency of pilgrims, both Hindu and Muslim (Misra 1970; Dutta 1985). Hindus visiting their sacred places in different parts of India have been exposed to cholera. The massive Kumbha bathing festivals that attract pilgrims from all over India have been the scene of cholera epidemics. Pilgrims from the endemic areas have inadvertently carried the cholera germ to sacred centers, where sanitation breakdowns have occurred, leading to the exposure of pilgrims from nonendemic areas. Muslim pilgrims on *hajj* to Mecca from Bengal in the past may also have been both carriers of and affected by cholera. Although these religious convergences remain a potential mechanism for the diffusion of cholera, large-scale immunization efforts and improved water supplies at these religious centers have prevented epidemics of cholera. At large pilgrimage congregations in India, pilgrims are routinely checked for certification of cholera immunization at points of entry to the designated area of religious fairs. Those without a valid certificate are inoculated on the spot before proceeding further on their religious journey.

Dysentery and Diarrheal Disease

Intestinal infections of various types are widely prevalent in South Asia. Cholera has been the focus of much attention because of its notorious epidemics and pandemics; however, it is dysentery (both amebic and bacillary) that generally leads in morbidity in most normal years. Unfortunately, dysentery and diarrhea (due to a variety of diseases of the alimentary canal) have not been accorded the attention they deserve because they are predominant among poor rural children. Perhaps as many as 80 percent of rural India's children are infected by parasitic worms (Nyrop 1986). Tropical diarrhea, mostly a traveler's disease, has attracted far more attention in the literature than the killer infantile diarrhea, which is linked to high infant mortality throughout India, Pakistan, Nepal, Bhutan, and Bangladesh.

The causative agent of bacillary dysentery is bacteria of the *Shigella* group, whereas amebic dysentery is produced by protozoa. However, both diseases manifest after ingestion of the pathogen whether by food infected by flies carrying the pathogen, by one's own infected hands, or by infected vessels, such as food containers. Thus, cultural practices, personal cleanliness, and the nature of the food available determine whether the disease will actually develop in an individual or family. The practice of using water on bare hands for cleaning the anal area after defecation increases the chances that the pathogen could be carried under the fingernails, and conveyed to food. Many middle-class South Asian families employ servants as cooks who come from poor families. Dysentery pathogens may be inadvertently conveyed to the food of these families, even though the latter may have a high standard of personal hygiene. Many edible items in stores and shops are exposed to flies and dust in spite of public health regulations. It is virtually inevitable that such items when consumed (without cooking) will carry pathogens with them. In cities, where it is easier to enforce environmental hygiene regulations, and where the modernizing consumers themselves exert sufficient pressure, store owners do respond by adopting strict hygienic practices. But most of the population of South Asia is rural, and therefore the enforcement of public health measures is highly problematic. In addition, the population – especially the adult rural population – of South Asian countries (Sri Lanka is again the exception) is mostly illiterate, and does not effectively demand hygienic practices from food vendors. Thus, dysentery, a highly preventable disease, persists.

As expected, dysentery shows marked seasonality in South Asia, because conditions for the multiplication of flies, a major carrier of dysentery pathogens, become ideal during and soon after the rainy season, through summer and early autumn. This is also the season when many types of melons, other fruits, and vegetables are sold in the open. Thus, even the more literate urban populations are placed at risk. Poor sections of the cities – the slums and the shanties – are particularly vulnerable because of the virtual lack of sanitation facilities that lead to a very high density of fly population. Many sanitary systems break down, and wells get polluted. The diffusion of tube wells as sources for irrigation and drinking water in the rural areas may have had some impact on the incidence of dysentery. The prevalence of dysentery in South Asia illustrates the fallacy of considering disease as only a biomedical entity. It forces us to recognize the significance of looking at the web of ecological relationships between people and their total environment.

Malaria

Fevers of many types have been described in the ancient Vedic literature of India. Vedic hymns speak of fevers that cause chills and high body temperature, and torment the sufferer during summer and autumn (Filliozat 1964). An intermittent fever, *takman,* seems to have been particularly feared by

the Aryans living in the Indus Basin. Their descriptions indicate characteristics of the fever much resembling malaria in its seasonality and symptoms.

Unlike cholera, malaria ecology is complex, since this infection depends upon the life cycles of the parasite *Plasmodium* and the vector *Anopheles* mosquito on the one hand, and human contact with the infected vector on the other. This contact has to be close enough for the infected vector to take a human blood meal and, in the process, to inject the pathogen parasite into the human bloodstream. Repeated infections are not uncommon, and once the plasmodium parasite is in human blood, fever relapse can occur. Characterized by chills, high fever, splenomegaly, and debilitation, malaria fever has had a serious impact on economic development by affecting millions of people. Between 1947, India's year of Independence, and 1953, the year the Malaria Control Program was first launched, malaria incidence was about 75 million, of which nearly 800,000 lives were lost to this disease annually (India 1987).

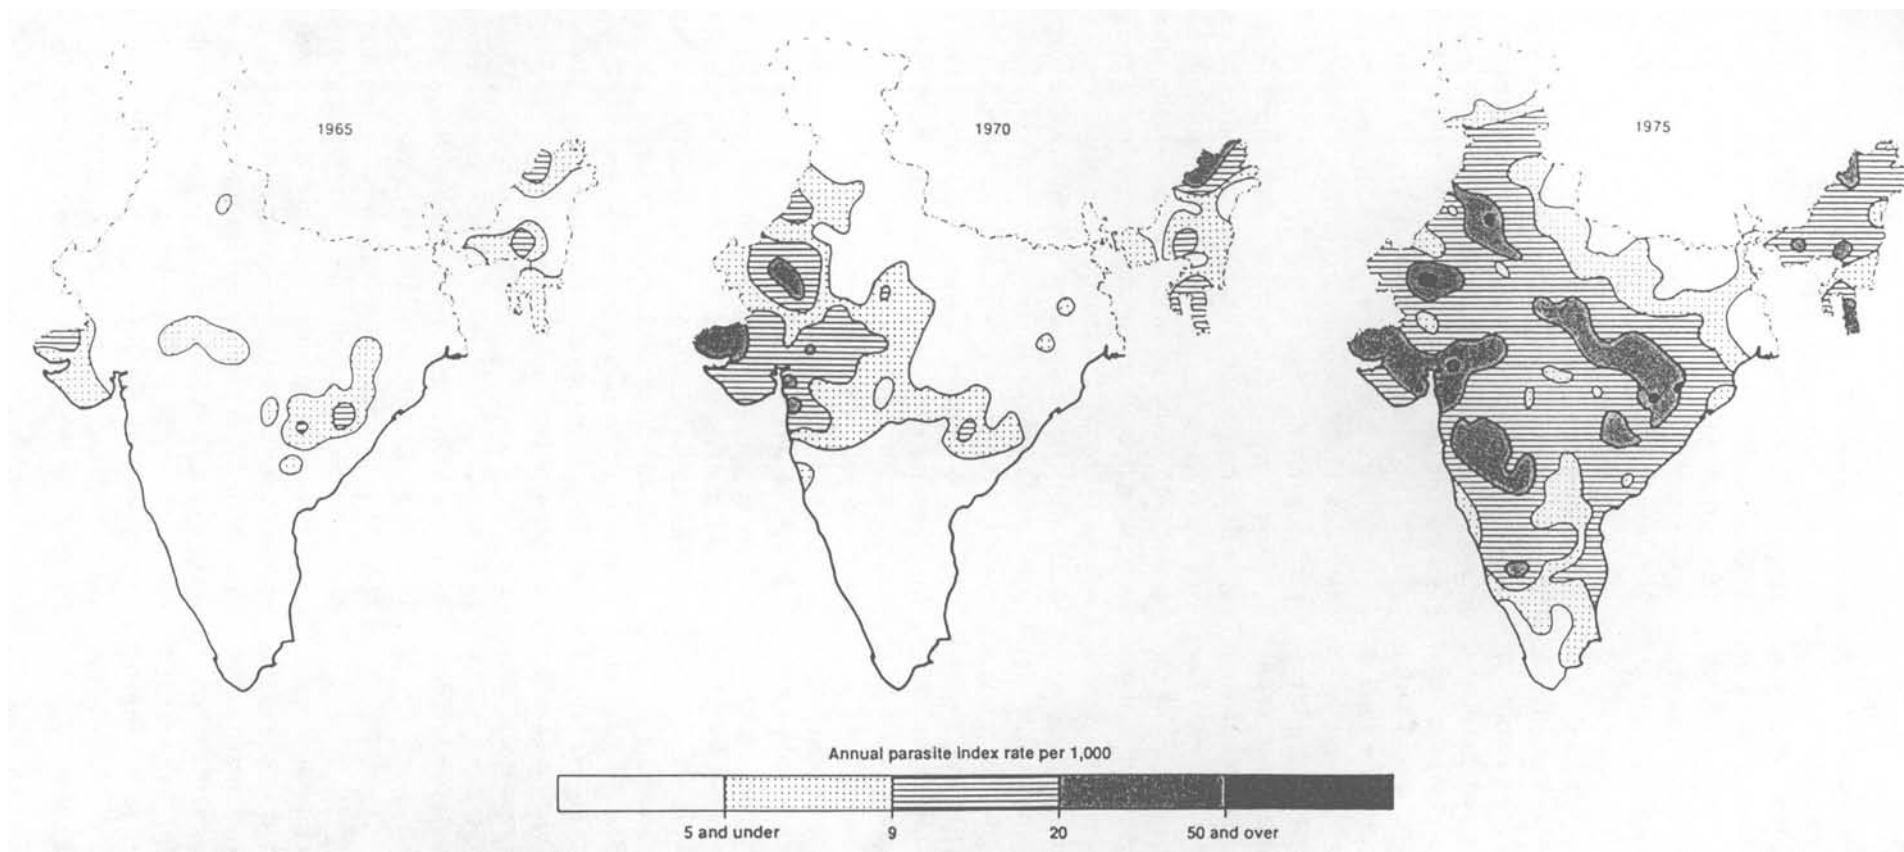
Distribution. Geographic distribution of malaria, as indeed of several other diseases, has been affected by socioeconomic changes in South Asian countries since the 1950s. Before Independence, the major hyperendemic areas (spleen rates over 75 percent) included the following:

1. The narrow *tarai* belt along southern Nepal and northern Uttar Pradesh. Lying at the foot of the Himalaya Mountain system, this strip was characterized by tall thick grass and *sal* forest on a relatively thin stony soil. Rainfall in this region decreases toward the west but is generally over 60 inches per annum.
2. The hills of eastern India up to a height of about 5,000 feet. These forested and poorly accessible areas have been thinly populated by tribal people who practiced considerable slash-and-burn agriculture. Rainfall in these areas is very heavy and is highly concentrated during the months of June through September.
3. The Chota Nagpur Plateau and the Eastern Hills region of the Indian Peninsula. Covered by forests, these regions have poor reddish soils and marginal agriculture carried on by tribal people. Rainfall is well over 40 inches and occurs mostly in the months of June through September.
4. A narrow forested strip along the crest of the western Ghats. This region receives heavy rainfall during the monsoon season, but the rest of the year is quite dry.

5. The western part of the Ganges Delta, and parts of the Coromandel coastal region of peninsular India. The Ganges Delta, of course, has the typical monsoon rainfall regime, but the Coromandel coastal region is an area of mostly autumn rainfall. These are densely populated, dominantly agricultural areas.

In addition to these areas of hyperendemicity, most of India, with over 40 inches of rainfall, was considered endemic for malaria. Moderate malaria endemicity also was found in the plains of Punjab, especially along the rivers and the irrigation canals. The rest of India, with rainfall of less than 40 inches, suffered from periodic, but severe, epidemics of malaria. Especially intense "fulminant" epidemics occurred in the western Ganga Plains and the adjoining Punjab Plains.

Malaria Resurgence. A. T. Learmonth (1957, 1958), A. K. Dutt, R. Akhtar, and H. Dutta (1980), and later Learmonth and Akhtar (1984) have added significantly to our knowledge of malaria ecology in India. In a series of maps, they bring out the story of malaria resurgence from 1965 to 1976. Through the efforts of the government of India, aided by the World Health Organization (WHO), and the active support of the state governments, malaria seemed to have been brought under control. The success of the Malaria Control Program, consisting mostly of the spraying of DDT, encouraged the government of India to convert this program to malaria eradication, which showed spectacular success until about 1965. In that year, malaria incidence had declined to 100,000 as compared to 70 million in 1947. But two India–Pakistan wars (1965 and 1970–1), the war of Bangladesh's liberation, and later the oil crisis resulted in massive disruption of the campaign against malaria. In addition, both the *Anopheles* vector species and the pathogen *Plasmodium* have developed resistance to antivector and anti-*Plasmodium* chemicals and drugs, respectively. Thus, hopes of malaria eradication were replaced by the stark reality of its recrudescence. From a low of about 100,000 cases in 1965, a resurgence of malaria developed, with over 5 million cases in 1975. In spite of further malaria control efforts, there were still 2 million cases in 1979, only marginally declining to about 1.6 million by 1985. A similar resurgence has occurred in several other countries (*Development Forum* 1988).

Geographically, as Learmonth and Akhtar (1984) have showed, by 1965 most of India had a low annual parasite index (API) (see Map VII.3.2). An API of


Map VII.3.2. Malaria: annual parasite index (API), per 1,000 population, for selected years.
(Based on Learmonth and Akhtar 1984.)

Annual parasite index rate per 1,000

5 and under   9   20   50 and over

over 5 per 1,000 existed in the hyperendemic region of Eastern Hills, parts of Chota Nagpur Plateau and northeastern peninsular India, western Vindhyan Range, the marshlands of Kachch and western Gujarat, and the foothill zone of western Uttar Pradesh. Relative inaccessibility is a major common attribute of all these areas. Their rainfall and soil characteristics vary widely, but all these areas have a high proportion of "scheduled tribes." It needs to be stressed that these people have a somewhat different *genre de vie* than do the nontribal populations of India. Formerly much more widespread, the tribal peoples now occupy "refuge areas" of marginal agricultural productivity. Malaria control – eradication programs of the government of India – seemed to have been ineffective in these poorly accessible areas. Thus, these areas remained highly endemic malarial time bombs. Slackening of the eradication programs, due to diversion of the national resources to two major wars in the subcontinent, in 1965 and again in 1971, meant a partial reassertion of the pre–Malaria Control Program pattern of malaria epidemics. From these focal points, malaria spread again to virtually all parts of India, although as a result of antimalarial drugs and greater availability of medical facilities, mortality is now minimal. A virtually similar process of malaria resurgence occurred in Bangladesh (Paul 1984). Malaria had been beaten back to the remote tribal areas of Chittagong Hills, from which it has reasserted itself.

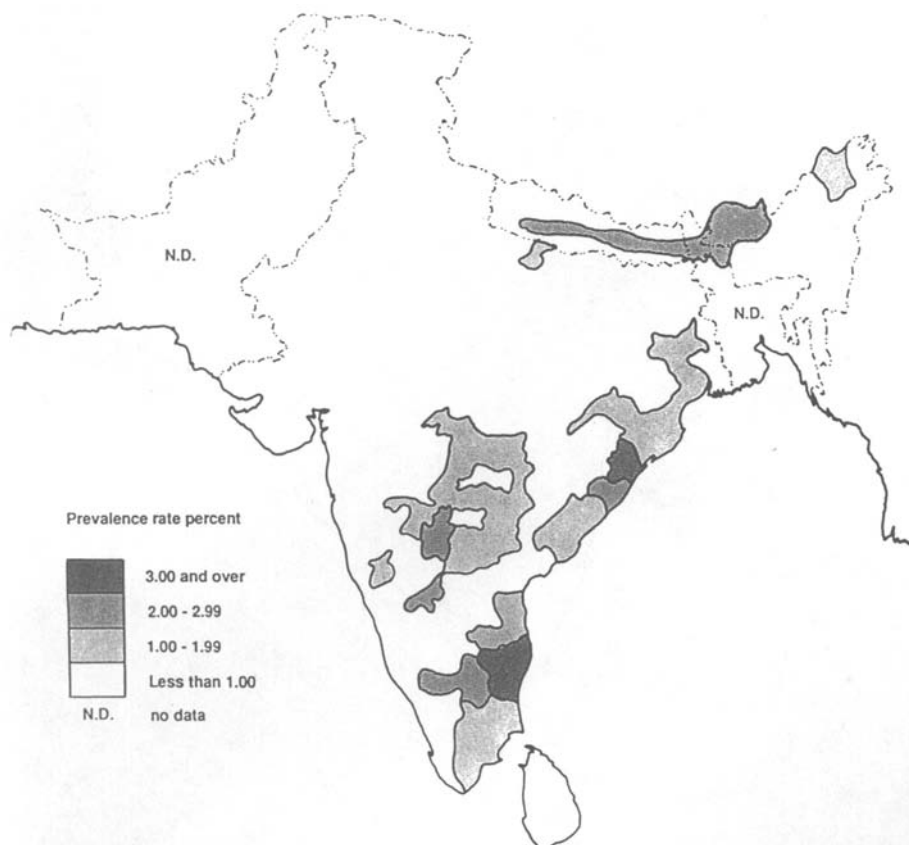
The history of malaria control holds a major lesson for all concerned. That lesson is that a disease with a complex ecology deserves a multipronged approach. It is necessary to have a well-orchestrated plan of action by specialists in various pertinent fields of science and bureaucracy, but it is imperative that the political leadership exercise wisdom. Malaria control, let alone eradication, is possible only under conditions of political stability, permitting an uninterrupted commitment of national resources. Current interethnic conflicts in Punjab, eastern Indian states, Bangladesh, and Sri Lanka will surely affect malaria control programs adversely.

Leprosy

Leprosy (Hansen's disease) has been known in South Asian countries since antiquity. Called *kustha* in the Hindu medical literature, it was considered to be transmittable to the child from parents "when a woman and a man have (respectively) the blood and sperm vitiated by leprosy" (Filliozat 1964). During the British rule in India, the Census of India (1913) collected data on four types of disabilities for each

decade since 1881: insanity, deaf-muteness, blindness, and leprosy. The last disease is usually of two types – tuberculoid and lepromatous. Tuberculoid leprosy is usually self-limiting, whereas the lepromatous form is progressive. The causative pathogen of leprosy is the bacillus *Mycobacterium leprae*. Lepromatous leprosy is the classic dreaded disease in which, in advanced cases, loss of digits and other deformities occur. The pathogen is usually thought to enter the body through the mucous membrane of the upper respiratory tract, or through repeated and close skin contact, but there is controversy among leprologists as to the exact mode of transmission (Cahill 1976; Sutherland 1977). The incubation period is long – 1 to 5 years – making research, early detection, and understanding of the diffusion process very difficult.

Persons with advanced stages of leprosy are frequently found begging at the railway stations, at the bus stations, and especially at the holy places all over South Asia. Even though legislation against begging has been frequent, the problem is far from solved. Likewise, the stigma attached to leprosy has made early treatment very difficult by discouraging patients to seek appropriate treatment. Since the disease is considered the greatest misfortune, sufferers from it arouse pity rather than understanding. In general, leprosy sufferers are isolated from the society either because of their own voluntary response or as a result of government policy. India has in place a national leprosy control program under which 434 leprosy control units along with 6,784 survey, education, and treatment centers, 721 urban leprosy centers, and 46 leprosy training centers have been developed (India 1987). In neighboring Nepal, the National Leprosy Control Program was established in 1975; now the Leprosy Service Development Board, it provides treatment and rehabilitative services for leprosy patients.

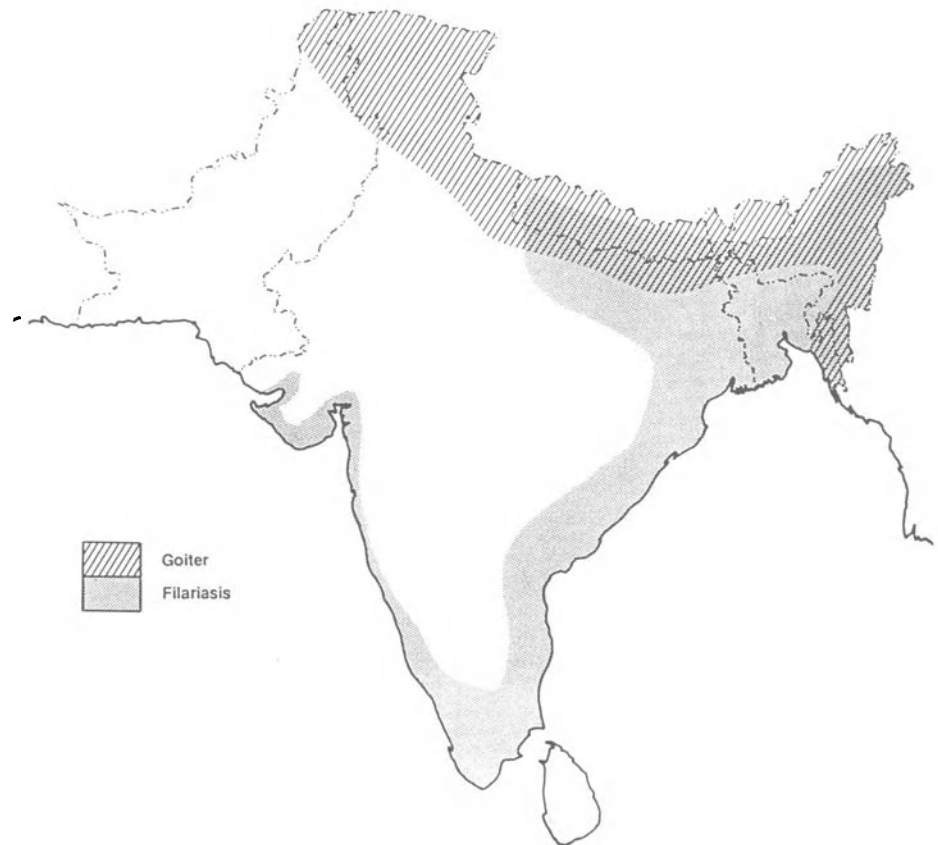
Geographic Distribution. South Asian countries have a medium rate of leprosy, but the very large total population base results in a correspondingly large absolute number of sufferers. In India alone, the prevalence rate of 5.7 per 1,000 population in 1986 suggests that the number of leprosy patients exceeds 4 million, according to government data (India 1987). Areas of high leprosy prevalence in India (over 10 per 1,000) include the following: (1) a belt of coastal districts of Tamil Nadu, Andhra Pradesh, and Orissa, which continues into most of West Bengal and adjoining southern Bihar; (2) western Maharashtra and the adjoining eastern Andhra Pradesh,


Map VII.3.3. Leprosy: prevalence rate percentage, 1974–5. (Based on Pearson 1984, 1988.)

a substantial part of which was once the princely state of Hyderabad (all of this area lies in the interior section of the Deccan Plateau); (3) isolated areas in other parts of India, including the *tarai* region of Uttar Pradesh and the far eastern parts of India. Surprisingly, Bangladesh reported only 110 cases of leprosy in 1979; Pakistan, 3,269; and Sri Lanka, 751 (WHO 1981). The longitudinal river valleys of Nepal apparently show a high prevalence of endemic leprosy – over 10 per 1,000 population.

Problems of Leprosy Control. Because leprosy is prevalent in both flat coastal areas and hills and valleys, and in areas of low and high rainfall, any relationship with broad physical environmental factors seems only tenuous at best (see Map VII.3.3). Secrecy surrounding earlier phases of the disease and the victims' fear of social ostracism in the latter stages make control and curative efforts difficult to implement. Slow progression of the disease and the necessity for prolonged treatment compound both the preventive and curative problems. It has been found in Nepal that people do not necessarily use the treatment facilities located nearest to them, for fear of being stigmatized in their local community. Patients seem deliberately to seek treatment at distant facilities (Pearson 1988). This trend has major implica-

tions for the diffusion of leprosy. With increasing mobility, the disease could spread without notice. As Kevin Cahill (1976) observed, in the "meagerness of our knowledge of the clinical, the bacteriological and the pathological course in the incubational phase of leprosy lies the primary reason for the failure of international control and eradication programmes." Peoples along traditional routes of commerce – for example, the river valleys in Nepal – could be especially at risk (Pearson 1984). In spite of the argument that leprosy is not easily communicable, intrusive tourism does place the visitors at risk of carrying the disease from the traditional endemic areas to other parts of the world.

At one time it was hoped that the disease could be eradicated because human beings are known to be the only significant reservoirs of the leprosy pathogen (Lechat 1988). That this has not occurred seems reason for less optimism, at least in the foreseeable future. However, "multidrug therapy" (MDP), early identification of cases and at-risk populations, social and cultural sensitivity toward the patient, long-term commitment of the governments, and immunologic and epidemiological research, can together make a major impact. Immunologic advances, based upon the cultivation of large quantities of *M. leprae* bacilli in armadillos, and advances in molecular


Map VII.3.4. General distribution
of filariasis and goiter. (Based on
May 1961; Misra 1970; Schwein-
furth 1983; and *India, a reference
annual* 1987.)

genetics seem to promise positive results, but large-scale confirmatory results are awaited from field trials (WHO 1985).

Filariasis

Filarial infections, caused by worms such as *Wuchereria bancrofti* and *Brugi malayi,* are widespread in the tropical climates of Africa, Southeast and South Asia, and the Caribbean. In India alone, over 15 million people suffer from filariasis, and over 300 million are at risk (India 1987) (see Map VII.3.4).

Filariasis is endemic in the entire Konkan and Malabar coastal areas of western India, the coastal areas of Tamil Nadu, Andhra Pradesh, and Orissa. Its incidence declines rapidly toward the interior and the northwestern parts of India. The lowest incidence is found in the Himalaya region. Sri Lanka's major endemic area of filariasis is in the hot, humid, and high rainfall areas of the coastal southwest (Schweinfurth 1983). Filariasis is found in both the rural and urban areas of this coastal region, although there are significant differences in the implicated pathogen of the two settings.

Microfilariae of the worm pathogens entering the human bloodstream through mosquito bites, circulate in blood, develop into larvae and, under suitable conditions, into adult worms. Filariasis leads to fe-

ver, lymphadenitis of the groin, and epididymitis. As the worms multiply, reach adulthood, and die, conditions such as hanging groins and elephantiasis of the legs develop. The high prevalence rate of elephantiasis of legs on the Malabar coast of India has led to the nomenclature "Malabar legs."

The essential components of the filaria ecology in South Asia are the pathogens *W. bancrofti* and *B. malayi,* several species of the mosquito vectors (*Culex, Anopheles, Aedes*), a hot and wet climate with high humidity, moist and warm soil, availability of stagnant pools of water, and a population of predominantly poor people. *Culex* and *Anopheles* mosquitoes, both abundant in all parts of South Asia, but especially in the high rainfall regions, pick up microfilaria through a blood meal from infected human beings, which reach the larva stage in the mosquito. These larvae are then introduced to other human beings through repeated mosquito bites. Filarial larvae reach adulthood in from 1 to 3 years, and may produce swarms of microfilariae. Most of the pathological symptoms are due to larvae and adult worms (Cahill 1976).

More than women, men are susceptible victims because of their outdoor agricultural activities and relatively less protective clothing. There is increasing concern that filariasis is becoming an urban

disease as well. This is happening primarily as a result of the migration of rural males to large cities in search of jobs. Many of these poor migrants must live on the outskirts of the cities, where there is an abundance of stagnant water pools as a result of construction activity. These pools serve as breeding grounds for the urban mosquitoes, which, in turn, become intermediate hosts of the pathogen between new immigrants and the established city populations. Thus, a disease that at one time was thought to be primarily rural is on its way to becoming an urban phenomenon as well. U. Schweinfurth (1983) provides a very interesting case study of filariasis infections at the University of Peradenya in Sri Lanka. The beautification of the campus also provided a very good habitat for the breeding of *Culex* vector. Students attending this university from infected areas were the carriers of *W. bancrofti* in their blood. In the beautified university campus, they became the source of the pathogen for the mosquito that also found the university campus environment conducive for breeding. The vector mosquitoes in turn introduced the disease to students from nonendemic areas as well.

Difficulty of detection of the disease (microfilariae show no pathogenic symptoms) at the early stage makes preventive measures difficult as well. Sadly, filaricidal and larvicidal treatment is available to only about 10 percent of the population in the endemic areas of India (WHO 1984). Efforts to introduce larvivorous fish in pools of water where mosquitoes breed may be helpful as part of a comprehensive filaria control program. This strategy, however, may be ineffective in the periurban areas where pools of water quickly become polluted and filled with urban waste. These pools are useless for fish culture, but do invite mosquitoes to breed.

Ecology of Nutritional Deficiency Diseases

Attention to communicable diseases may tend to mask the prevalence of a great variety of diseases that are the result of undernutrition as well as malnutrition. With a very large number of people living in extreme poverty in South Asia, dietary deficiencies are to be expected. Although "diseases of poverty" do not constitute a special category in the official *International List of Disease Classification,* the international medical community is increasingly cognizant of such a class (Prost 1988). M. S. R. Hutt and D. P. Burkitt (1986) go so far as to say that "most so-called tropical diseases are, in fact, diseases of poverty, rather than of geography." On the basis of his field studies on the nutrition of children in

Haryana, S. K. Aggarwal (1986) found that "no other factor seems to affect the nutritional status of the children as much as family income." The scientific concept of balanced diet in South Asia is only of academic importance; the real concern is dietary sufficiency.

The Indian Council of Medical Research found in its surveys that about 35 percent of children have protein–calorie malnutrition (Mitra 1985). Earlier emphasis on protein deficiency has given way to the more widely acceptable concept of protein–calorie malnutrition (PCM) or protein–energy malnutrition (PEM) (Learmonth 1988). India, Bangladesh, and Nepal together have a serious problem of malnutrition and hunger, even though in recent years agricultural production has been rising, especially in India. The situation in Pakistan and Sri Lanka is, on the average, "adequate," but in India, Bangladesh, and Nepal, less than 90 percent of the average daily energy requirements are met.

The relationship between food in the market and its availability to an individual for actual consumption depends on a host of intervening factors (Aggarwal 1986). Among these factors are family income, gender, age, season of the year, government regulations, and cultural factors such as dietary restrictions, taboos, and preferences. Addressing the role of cultural dietary preferences in disease ecology, A. K. Chakravarti (1982) provides evidence to show that existing regional differences do translate into a significantly higher incidence of diet-related diseases. These facts were earlier noted by J. M. May (1961). In predominantly rice-eating areas, where highly polished rice is preferred, beriberi is preeminent, because of thiamine deficiency, which results from the polishing process. Where parboiled rice is widely employed, however, the incidence of beriberi is claimed to be significantly lower. Consumption of *khesari* as the basic pulse in eastern Madhya Pradesh has been associated (Chakravarti 1982) with the incidence of lathyrism, which is characterized by muscular atrophy, causing the typical "scissors gait," incontinence of urine, and sexual impotence (Manson-Bahr 1966).

The impact of malnutrition is not easily measured, but some of the effects are well known and include anemia, goiter, night blindness, rickets, beriberi, and probably permanent damage to the nervous system, resulting in mental disorders. The long-term economic, social, and personal impact of these dietary deficiencies can only be imagined. In addition, undernutrition of pregnant mothers has adverse consequences both for them and for their

babies, who are often of low-birthweight. It is a well-established fact that low-birthweight is a major correlate of infant mortality. Thus low-income, undernourished mothers are likely to have a higher frequency of low-birthweight babies, and thus contribute disproportionately to higher infant mortality. Even in the same village infant mortality among the poor is twice that of the privileged people (Mitra 1985).

Some of the nutritional deficiency diseases have a clear regional prevalence. Goiter, for example, has a high rate of endemicity in a sub-Himalayan belt extending from Arunachal Pradesh and other states in northeast India through Bhutan, West Bengal, Sikkim, Bihar, Nepal, Uttar Pradesh, Himachal Pradesh, Jammu, and Kashmir. Goiter is also found in parts of Gujarat, Madhya Pradesh, and Maharashtra (India 1987). Endemic goiter is primarily due to a dietary iodine deficiency, resulting in enlargement of the thyroid gland. At one time considered only an unsightly inconvenience, goiter is now known to be a possible precursor of cancer of the thyroid, and is associated with below normal mental and physical development. It is also possible that very high infant mortality in these regions is related to regional iodine deficiency (Hutt and Burkitt 1986). The government of India in 1983 launched a major program, through both private and public channels, of iodizing salt, in an effort to combat iodine deficiency and decrease goiter incidence.

Every culture has some distinctive practices that may be associated with culture-specific diseases. For example, only in Kashmir do people use an earthen pot (*kangri*) containing live coal, nestled in a wicker basket, that hangs by a thread around their neck during the winter season, as a portable personal body warmer. Heat and irritation from this *kangri* practice is significantly associated with the kangri-burn cancer, especially among the elderly (Manson-Bahr 1966). Similarly, cancer of the buccal cavity is found to be associated with the long-term habit of chewing betel. This habit is common in eastern Ganga Plain and southwestern India.

Economic Development and Disease Ecology

In his influential book, *Man, Medicine, and Environment* (1968), Rene Dubos makes a poignant observation about disease and development:

Disease presents itself simultaneously with so many different faces in any given area that it is usually impossible to attribute one particular expression of it to one particular set of environmental circumstances. Nevertheless, some generalizations appear justified. Without question, nutritional and infectious diseases account for the largest percentage of mortality and morbidity in most underprivileged countries, especially in those just becoming industrialized. . . . In contrast, the toll taken by malnutrition and infection decreases rapidly wherever and whenever the living standards improve, but other diseases then become more prevalent.

South Asian societies are in the process of major change, since economic development has become the goal of all the nations (except perhaps Bhutan). In pursuit of this goal, national governments have become deeply involved in directing the nature and pace of change. Against heavy odds, the processes of social and economic change are beginning to show their impact. Even in some rural areas of India, a major reduction in seasonal morbidity of communicable diseases has been observed concomitant with agricultural prosperity (Bhardwaj and Rao 1988), suggesting that Western-style development is not a *sine qua non* for better health conditions. Sri Lanka, which placed great emphasis on education, has achieved a high female literacy rate (over 80 percent). This has had a major impact on the reduction of the birthrate and has helped greatly to reduce the infant mortality rate, even though Sri Lanka has not become an economically well-developed country. Nepal, India, Pakistan, and Bangladesh have not been able to accomplish the same for their female population, and consequently their infant mortality rates are still very high. Female literacy in India varies widely between social groups and regions. Where female literacy is high – for example, in the urban areas and in the southwest (Kerala) – birthrates and infant mortality have come down.

One of the results of the Green Revolution has been an increased labor demand in the highly irrigated areas of western U.P., Punjab, Haryana, and Rajasthan. Long-distance agricultural labor migrations from Bihar and eastern U.P. to the above areas have now become commonplace. This means that *Plasmodium* from the eastern part of India has a greater chance of establishing itself in the farming communities of northwestern India. Increased availability of water in the irrigated areas provides an expanded habitat for the *Anopheles* mosquito vector as well.

International migration and tourism, which are intensifying in South Asia, have been implicated in the importation of newer diseases; AIDS is only one example (*India Abroad,* October 26, 1990). When the first few cases of AIDS were reported in India, the

Indian government was alarmed enough to enforce serotesting of foreign students, especially coming from AIDS endemic areas of sub-Saharan African countries. This action immediately aroused the anger of exchange students and strong reactions from several African governments. According to a WHO warning, there may be already over 250,000 HIV-positive cases in India with an expectancy of over 60,000 AIDS patients by 1995 (*India Abroad,* October 26, 1990). The incidence of AIDS is, as yet, reported primarily from the major metropolitan areas such as Bombay, Madras, Calcutta, and Delhi, and is currently associated mostly with prostitution. Precisely because of this association, however, AIDS will very likely spread into the general population. Since migration to cities is large, and rural–urban interaction is intensifying, the vast rural areas will not be immune from AIDS for long. Existing models of AIDS diffusion strongly suggest this possibility (Shanon and Pyle 1989). Thus, the context of health is becoming much wider than imagined under the older health paradigm in which the physician was considered the final health authority. L. Eisenberg and N. Sartorius (1988) have rightly asserted that "health will have to be seen as a state of balance between human beings and their environment. Human ecology can help to develop this approach to health and its promotion." South Asian countries have already started to prove the efficacy of such an approach.

VII.4
Disease Ecologies of East Asia

East Asian scholars have begun only recently to examine Chinese, Korean, and Japanese sources for evidence of the history of disease in East Asia. Research is at a very early stage: There is much that we do not know, and some of what we think we know may turn out to be wrong. At present, scholars disagree about basic facts as well as about how to interpret them. It is possible, however, to discuss how disease ecologies changed as East Asian civilization developed, and this essay will consider how long-term historical change in East Asia altered the disease ecologies of this major world region.

East Asia is a large ecological niche bounded on all sides by less hospitable terrain. To the north and northwest lie the vast steppe lands of Central Asia and the virtually impossible Takla Makan Desert. To the west lie the high Tibetan Plateau and the Himalayan Range with the world's highest mountains. To the south is the mountainous terrain of southwest China and the jungles of Southeast Asia. And to the east lies the Pacific Ocean. These formidable barriers and the great distances between eastern and western Eurasia long separated East Asia from the ancient civilizations of the West, and permitted a distinctive culture to develop and to spread throughout the region with relatively little influence from the outside.

East Asia can be divided into two major ecological zones. The northern zone encompasses the steppe and forest lands that lie north of China's Great Wall and today includes the modern regions of Inner Mongolia and Manchuria. This vast territory is unsuitable for agriculture, and it has long been the homeland of nomadic tribes who migrate with the seasons seeking grazing lands for their livestock. The steppe supports relatively few people, and thus has been sparsely settled throughout human history. Low population density and a pastoral, nomadic way of life have prevented the buildup of endemic foci of disease organisms in any one place.

Ecological conditions south of the Great Wall are altogether different. North China, which includes the areas drained by the Yellow River and its tributaries, as well as the northern tributaries of the Yangtze River, has a temperate, semiarid climate with hot summers and cold winters. Rainfall is lim-

ited and uncertain – about 400 to 800 millimeters per year. North China is most suitable for growing millet, wheat, and beans, and one or two crops a year can be grown in a growing season that lasts from 4 to 6 months.

South China, generally the region from the Yangtze Valley to the coast of southern China, has a subtropical climate, abundant rainfall (approximately 800 to 1,600 mm per year), and temperatures that are less extreme than those of North China. Rice is the dominant crop in the south, and two or three crops can be grown during 9 to 12 months of the year. Despite these differences in climate, North and South China have been bound together historically by a dominant, distinctive culture common to them both. And in historic times both regions have supported far greater population densities than the frontier regions north of China's Great Wall.

In prehistoric times Paleolithic humans roamed over all of East Asia. Early hunters and gatherers inhabited the forests and steppes of northeastern Asia, the highlands and plains of North China, the semitropical and tropical regions of South China, the Korean peninsula, and the Japanese islands. As long as primitive humans moved from place to place in search of food, the disease ecologies of East Asia must have been essentially unchanging. Although early humans may have been afflicted with maladies caused by microparasites indigenous to the different regions of East Asia, they did not suffer from many of the diseases with which we are familiar today, because the microparasites that cause them require large and concentrated host populations that did not yet exist.

The history of changing disease ecologies in East Asia begins with the emergence of Chinese civilization in late Neolithic times. In East Asia, as in other parts of the world, human society underwent a fundamental change in the late Neolithic period when the ancestors of the Chinese people began to engage in agriculture and to live in permanent communities. This transition from shifting to permanent places of residence occurred in at least two and possibly several regions of China about 6,000 years ago. The best known Neolithic sites are found in the loess region of North China near the juncture of the Wei and Yellow rivers; however, recent excavations in the Yangtze River delta have turned up evidence of Neolithic communities that may be even earlier than those of North China. The historic relationship between these cultures is not clear, but it was from these core regions that the culture we regard as distinctively East Asian evolved.

The Neolithic Revolution in China was clearly successful. Archeological evidence and early forms of Chinese ideographic script reveal an advanced society based on labor-intensive agriculture from the time of the Shang dynasty (1765–1122 B.C.). The need for labor led to dense concentrations of people and the need for protection to walled cities where grain could be stored and defended. These fundamental changes altered the size, density, and distribution of populations on the East Asian mainland. The growth of cities brought new problems: Human and animal wastes accumulated, drinking water became contaminated, parasites that thrive in stagnant water flourished, and people who now lived close together in permanent settlements became a reservoir for microparasites that cause human disease.

The range of Chinese expansion to the south and east was virtually unlimited. As indigenous peoples took up an agrarian way of life, more land was brought under cultivation and China's population grew. From the time of the Shang dynasty to the unification of China in 221 B.C., the Chinese people were ruled by great regional lords who controlled large territories in North and South China. There are no census statistics to serve as benchmarks, but other kinds of evidence indicate that even before unification China had produced a large population. The size of armies increased 10-fold during the Warring States period (421 to 403 B.C.), and by the fourth century B.C. each of the leading states of China was able to support a standing army of about 1 million men.

In 221 B.C., Shih Huang-t'i, ruler of the state of Ch'in, conquered all of China, unifying the states and regions of North and South China. He ordered the construction of large-scale public works designed to consolidate political control and to unify China economically. These projects, which included the construction of a national network of roads and the completion of the Great Wall on China's northern frontier, offer further evidence of an abundant labor force. The latter project alone required an estimated 700,000 laborers to build.

Long periods of warfare and large public works projects helped to homogenize the disease environment. The amassing of soldiers for battle and the concentration of many thousands of workers provided an ideal environment for disease organisms to propagate. And when the participants returned home, they carried diseases to the towns and villages through which they passed. Hence, the construction of roads and canals, whose function was to strengthen centralized control, promoted the spread of disease throughout the empire.

The Ch'in dynasty was short-lived, but the consolidation of political power under centralized imperial rule continued under the dynasties that followed. The four centuries of Han rule (202 B.C. to A.D. 220) were a period of expansion in which the Chinese way of life based upon labor-intensive, irrigated agriculture became the dominant culture on the mainland. And during the Sui (581–618) and T'ang (618–907) dynasties, the completion of the Grand Canal that connected the Yangtze and Yellow rivers reinforced the links between north and south China.

Urbanization was another prominent feature of social development in the early empire. By T'ang times, China had 21 cities with more than a half-million inhabitants. The largest urban concentration was at the T'ang capital of Ch'ang-an, which had 2 million registered inhabitants. Even smaller cities like the southern port of Canton and the bustling economic center at Yangchow, where the Grand Canal joined the Yangtze River, were centers of human density large enough to serve as reservoirs for many human disease pathogens.

In short, from very early times China had one of the world's largest populations and conditions of life that could support many of the density-dependent diseases of civilization with which we are familiar today. Indeed social, demographic, and environmental conditions in the early empire were such that China must have had a full range of indigenous diseases that varied by region according to the climate, the available host and vector populations, the density and distribution of human host populations, and the sanitary conditions in those regions. But for the most part, we do not know what diseases were present in the early empire.

We do know, however, that many different kinds of human disease existed in China from very early times, because they were written about on the Shang oracle bones that were used for divination (as indicated in Lu and Needham, in this volume, VI.1). According to these ancient writings, the diseases prevalent at the time exhibited many different symptoms and were called by many different names. But whether they were caused by pathogenic agents that exist today, by related pathogens, or by unrelated pathogens is uncertain.

Introduction of New Diseases

The introduction of new diseases to a virgin population can be calamitous. The most celebrated case is known as the "great dying" that followed the introduction of Old World diseases to the New World in the sixteenth century. But contact between virulent disease-causing organisms and nonimmune populations must have been repeated over and over again in the course of human history as civilizations with different disease ecologies came into contact with one another. Thus it is appropriate to ask whether East Asian populations also suffered major demographic catastrophes as a result of the introduction of unfamiliar disease organisms.

Undoubtedly there was such a time, but Chinese historians have not defined it as such. A likely time for such an occurrence was around the beginning of the Christian era, when growth and expansion of the early empire brought China into more frequent contact with neighboring peoples to the south. By the first century B.C., a string of populous communities stretched from South China to Bengal, and by the first century A.D., traders and Buddhist missionaries were traveling overland from northern India to China through Central Asia and by way of Vietnam. Chinese scholars also traveled to India to study at Buddhist monasteries, and they returned with foreign diseases as well as foreign philosophies.

One of these foreign diseases, possibly the first to be reported in Chinese sources, was smallpox. Smallpox, a prominent, density-dependent disease of the past, is used here as a paradigm for disease in general, because it was highly visible and because changes in its incidence and distribution reflect changing disease ecologies.

It is not clear exactly when smallpox first reached China, but at least two early references to it are known. Donald Hopkins (1983) suggests that a disease called "Hun pox" that came to China from the north around 250 B.C. may have been smallpox. He also suggests a second introduction of smallpox from the south about A.D. 48, when a Chinese general and half his troops lost their lives to a "barbarian" disease as they were putting down a rebellion in southwest China. The first unmistakable description of smallpox comes from an account written in the fourth century A.D. (Leung, in this volume, VI.2). However, given the extent of earlier Chinese contact with India – where it is believed this disease was known before 400 B.C. – smallpox must have reached China earlier than the fourth century.

We do not need to know precisely when smallpox first reached China to understand that early smallpox epidemics would have been very costly in terms of human life. Smallpox normally produced a 25 percent case-fatality rate, and in virgin-soil epidemics the rate would have been much higher. Thus given China's population size and the links between many centers of density, we can be certain that the

introduction of smallpox to China caused a demographic crisis of considerable magnitude.

Population trends for the early empire suggest that there were several demographic crises that might have been caused by unfamiliar diseases. Periods of population growth alternated with periods of population decline: From the Warring States period through the T'ang dynasty, China's population fluctuated, reaching and then retreating from a maximum of about 60 million people. The periods of decline during these centuries have been associated with natural disasters and China's periodic wars, but high mortality from disease, undoubtedly exacerbated by war and famine, certainly contributed to population decline.

After the initial shock waves subsided, however, the demographic characteristics of China's population would have ensured that smallpox became an endemic disease rather quickly. Hopkins estimates that a population of less than 300,000 people was sufficient to maintain smallpox as an endemic disease, because enough new susceptibles would have been borne each year to sustain the chain of smallpox infection indefinitely. As an endemic disease, smallpox would have circulated throughout the empire, appearing most frequently in the larger cities and least often in the sparse populations of the hinterlands. We know that smallpox continued to claim numerous lives in China for many centuries; however, once smallpox and other infectious diseases became endemic, the risk of a catastrophic demographic crisis would have been sharply reduced.

The history of smallpox in East Asia reveals a curious chronology in the transmission of this disease. Of particular interest is the fact that smallpox is documented much earlier in the ancient civilizations of the West. Egyptian mummies 3,000 years old have been found with scars that resemble the typical pockmarks left by smallpox; and the people of ancient Greece, as well as the people of India, are believed to have been afflicted with this disease before 400 B.C. The much later documentation of smallpox in China suggests that smallpox spread to eastern Asia from the West – a journey, if estimates of when smallpox reached China are even close to being correct, that took more than a thousand years.

The Dissemination of Disease Within East Asia

By late Han times Chinese culture began to spread to the other regions of East Asia. As the indigenous peoples of Korea and Japan began to adopt irrigated, wet-rice agriculture, their numbers increased, cities were built, and these countries began to be afflicted with the civilized diseases of China. Contact between China, Korea, and Japan increased after the sixth century, and smallpox and other epidemic diseases were spread along with Buddhism and other cultural exports.

Japanese accounts of smallpox epidemics in A.D. 585 and 735–7 provide excellent early descriptions of this disease. The smallpox epidemic of 735 came from the kingdom of Silla in southern Korea. It began in the part of Kyushu nearest to Korea, and it spread toward the major population centers in the region around the capital at Nara. Although this was not Japan's first smallpox epidemic, it caused high mortality among all age groups in the population, indicating that smallpox epidemics did not reach Japan very frequently. Wayne Farris believes that high mortality from virulent, imported diseases between 645 and 900 caused Japan to suffer a demographic setback that had a major impact on Japan's political, economic, and social development in this early period.

Once imported epidemics reached Japan, the direction of spread was invariably from the southwest – where ports of entry for foreign ships were located – to the northeast along routes where Japan's population was concentrated. Japan had a high population density very early in its history, and as in China, most diseases became endemic with little difficulty. Smallpox was clearly endemic in Japan by the twelfth century and probably well before (Jannetta 1987).

The more sparsely settled and remote areas of East Asia could still be seriously threatened by severe epidemics as late as the seventeenth century. In Japan, offshore islands, villages in the northeast, and mountainous regions remained vulnerable. In China it was the dispersed, low-density populations that lived in semiautonomous areas along the enormous northern and western frontier that were at greatest risk of suffering highly disruptive mortality from epidemics.

During the seventeenth and eighteenth centuries, the dissemination of disease intensified as these peripheral regions were gradually incorporated into the main networks that operated in East Asia. Several factors contributed to this intensification process: East Asian populations increased in size and density, urbanization accelerated in both China and Japan, contact between core and periphery increased, and activity on China's frontier intensified.

Changes in tribute relations accompanied the consolidation of Tokugawa and Ch'ing power in the sev-

enteenth century, and promoted the dissemination of disease within East Asia. Between 1637 and 1765, contacts between China and Korea increased: An average of 3.8 tribute missions a year traveled from Korea to Peking, and in fact Korea and the Ryukyu Islands sent tribute missions to Japan as well. The King of the Ryukyus was regularly required to pay his respects to the daimyo of Satsuma and on occasion to the Tokugawa shogun in Edo (Sakai 1968). In Japan, the shogunate institutionalized contact between core and periphery with the creation of the *sankin–kotai* system. This system required that large numbers of retainers travel to Edo from each of the provinces in alternate years to pay attendance upon the shogun. All of these activities would have increased the rate of disease dissemination in Japan.

The development of interregional trade in Japan also served to disseminate density-dependent diseases throughout the islands. As outlying regions were drawn into a more widespread market network, they were also incorporated into a wider network of disease dissemination. Local records show that epidemics became more frequent in the hinterlands of Japan during the Tokugawa period. By the end of the seventeenth century, smallpox epidemics were occurring every few years in outlying villages; by the end of the eighteenth century, smallpox epidemics had become increasingly frequent on the island of Tanegashima, and in the Ryukyu Islands. Even the most isolated islands of the Izu chain south of Chiba Prefecture were stricken by smallpox – reportedly for the first time – in the late eighteenth century. By the late 1700s density-dependent diseases common to the urban centers were afflicting even the most remote regions of Japan (Jannetta 1987).

On the East Asian mainland, the disease ecology of China began to expand across the northern frontier. To the north and northwest the range of Chinese expansion had been sharply limited. The steppes of Mongolia and Manchuria and the high Tibetan wastes had no great river systems from which water could be drawn to support intensive, irrigated agriculture, and a pastoral society that stood in stark contrast to that of China had developed on China's northern frontier. The steppe had become the home of nomadic tribes whose wealth was moveable herds of livestock, not land or grain. The Great Wall of China, built to keep out the "barbarian" peoples who raided Chinese settlements, marked the frontier between two fundamentally different cultures.

The Great Wall also marks the frontier between the two major disease ecologies of East Asia. The dispersed and mobile populations north of the Great Wall had much less exposure to human pathogens than did the densely settled populations to the south. And because of infrequent exposure they were extremely vulnerable to the civilized diseases of China.

During the late Ming (1368–1644) and early Ch'ing (1644–1911) dynasties, Chinese civilization began to encroach on territories to the north, and there was increasing contact between northern Chinese and the nomadic peoples of the steppe. China's traditional policy had been to forbid trade with these barbarian enemies. But as this policy simply encouraged invasion raids and seizure of whatever goods were available, at times the Chinese government reluctantly set up official markets to facilitate the exchange of goods.

The numerous military campaigns of the late Ming period required large supplies of horses. In the second half of the sixteenth century, the Chinese set up official horse markets on China's northern frontier, where cloth and grain were exchanged for Mongol cattle, sheep, mules, and horses. Initially there were four market locations – at Tatung, Hsuan-fu, Yen-sui, and Ningsia – where horse fairs were held during the spring and summer months. In time, smaller markets were added at other places along the Great Wall where forts were situated. These small markets permitted Mongols who lived near the frontier to come to trade once or twice a month, and the regularization of these markets provided a more dependable supply of goods for Chinese and Mongol alike (Hou 1956). At the same time, more frequent contact between Mongols and Chinese permitted the dissemination of the density-dependent diseases of China to the tribal peoples of the steppe.

The disease problems that followed the growth of fairs and the border trade in the second half of the sixteenth century are documented in both Chinese and Mongol sources. The Mongols were most fearful of smallpox, which was rare in Mongolia. The biography of Tu T'ung, a military commander in Shensi, tells of an incident in which men returning from the border caught smallpox and died. The incident resulted in several border clashes, because the Mongols, who were unfamiliar with smallpox, thought that the men had been poisoned by the Chinese.

Chinese contacts constituted the gravest danger from smallpox for the Mongols, who recognized that danger and did what they could to contain the disease and prevent further contamination. It was customary strictly to avoid the stricken person, whether a parent, brother, wife, or child:

They provide [the sick] with a Chinese to take care of him; and if there is no Chinese available, they prepare his food and other necessities in a place other than their own and let the person stricken with smallpox take care of himself.... [T]hey regard China as a house on fire, and they refuse to stay there long for fear of contracting smallpox. (Serruys 1980)

For the Mongols the danger of exposure to smallpox and other diseases increased during the sixteenth century because of increasing contact with the Chinese. Not only did they encounter them during invasion raids and at the border markets and fairs, but also after midcentury many Chinese immigrants settled north of the Great Wall and lived intermingled with the Mongols. These communities were particularly vulnerable to high mortality from epidemic diseases. One Chinese observer claimed that the border communities had grown to 100,000 by the 1590s, but "luckily" a great epidemic had cut their numbers down by half (Serruys 1980).

The Manchus, too, had increasing problems with the civilized diseases of China. In Manchuria, as in Mongolia, smallpox was a relatively rare disease. The widely scattered populations, often on the move, had prevented the virus from gaining a foothold. However, in the late Ming as Chinese began to settle in Manchuria and as contacts between Manchus and Chinese increased, the diseases of China – smallpox in particular – became a serious threat.

An observation relating to the year 1633, when the Manchu armies were ready to invade China, indicates their awareness of this threat: "Order *beiles* who have already once contracted smallpox to lead an army from I-p'ien-shih to take Shan-hai-kuan" (Serruys 1980). The order to pick only immunized troops for an extended stay in China shows that they understood the great risk of contracting smallpox there, and they knew that those who had once had the disease would not get it again.

Even after China was conquered by the Manchus, Ch'ing legislation for the Mongol bannermen indicates that the Manchu rulers continued to take the problem of smallpox seriously. Proscriptions against going to the capital when one had not been already infected with the disease were incorporated into the Ch'ing codes. Two expressions – "those who have already had smallpox" and "those who have not yet had smallpox" – became almost technical terms in the Li-fan-yuan code, which was translated into Mongolian. Mongols who inherited a rank within the administration, and who would normally go to Peking to receive their succession, were excused if they had not yet contracted smallpox. They would go instead to Jehol for the ceremony. Although some scholars have thought that the code was designed to protect the Chinese from Mongol infections, it is clear that its intent was to protect the Mongols who would needlessly be exposed to a grave danger.

These examples illustrate the changes that took place in East Asia in the early modern period. There were real differences between the disease ecologies of the East and West, and these differences continued to be important. Unlike Africa, the Americas, and many of the more sparsely settled countries of Europe, many density-dependent diseases were already endemic in East Asia before the sixteenth century. Disease ecologies in the West were completely transformed by the discovery of the New World. The high level of epidemic mortality in the early modern West may well be related to the unusual disease exchange that took place between the urban centers of Europe and the peripheral primitive societies with relatively low-density populations with which they came in contact.

No such transformation took place in East Asia. There was much greater stability in the high-density populations of China and Japan where many diseases were endemic and circulated regularly within a relatively closed system. Thus the arrival of the Europeans in the sixteenth century changed the disease ecology of East Asia very little.

The disease environment of early modern East Asia did change, but the reason for change was totally unrelated to new foreign contacts. In East Asia the dissemination of disease intensified because of population growth, increasing urbanization, an increase in the volume of trade within the region, and the integration of more sparsely populated frontier regions into the network of civilized diseases. This process was affected very little by outside developments. In the modern period, however, when rapid transport began to connect all of the world regions, East Asia's large, high-density population emerged as a disease center that could disseminate diseases to the rest of the world.

VII.5
Disease Ecologies of Australia and Oceania

Geography and Demography

The islands of Oceania are divided into three large geographic areas. Polynesia occupies an enormous triangle in the eastern and central Pacific, stretching from Hawaii in the north, to French Polynesia and Easter Island in the east, to New Zealand in the west. Melanesia encompasses the western island chains that lie south of the equator and extend from New Guinea to New Caledonia and Fiji. Micronesia includes the groups of islands that lie west of Polynesia and north of Melanesia. Although Polynesia is spread widely across the Pacific, the physical environments – whether volcanic high islands or coral atolls – are all quite similar in being lushly vegetated and almost all rich in food resources from land and sea. Melanesia has the greatest variety of physical environments: mountain rain forests, grassy plateaus, gorges and valleys, low jungles and alluvial plains, mosquito-ridden riverine and coastal swamps, sandy beaches, volcanic fields, and earthquake-prone rifts. In western Micronesia, weathered volcanic islands are interspersed among small, lush coral atolls. Farther to the east (Marshall Islands and Kiribati), the Micronesian atolls are generally much drier and larger. Except for temperate New Zealand and arid or temperate Australia, the climate of Oceania remains generally hot and humid year-round. It is generally accepted that Oceania and Australia were populated by waves of immigrants initially from Southeast Asia (Oliver 1962; Howe 1984; Marshall 1984). In fact, it was over

30,000 years ago that Southeast Asian hunter-gatherers crossed land bridges and narrow channels into New Guinea, Australia, and Tasmania. Inter-migration among these landmasses was curtailed around 8,000 years ago, when New Guinea and Tasmania became separate islands.

A later wave of Malay-type horticulturalists from islands of Southeast Asia invaded the coasts and rivers of New Guinea about 6,000 years ago, bringing root crops, pigs, chickens, dogs, and polished tools. These agriculturalists then spread out through the islands of Melanesia around 3,000 to 4,000 years ago in their sailing canoes. At this same time, other Southeast Asian agriculturalists migrated from the Philippine Islands to Yap and the Mariana Islands and from Sulawesi to Palau, thus settling the high islands of western Micronesia. After the voyagers had settled the major islands of Melanesia, they pushed north from Vanuatu into Kiribati, thence into the Marshall Islands, and finally into the Caroline Islands about 2,000 years ago. As Micronesia was thus being settled, other voyagers advanced from Fiji east to Samoa and Tonga around 3,000 years ago. From this cradle, they moved out through the rest of eastern Polynesia – to the Marquesas 2,000 years ago and from there to the Society, Cook, and Hawaiian Islands around A.D. 600, New Zealand around A.D. 750, and Tokelau and Tuvalu and assorted scattered outliers after A.D. 1000.

With rare exception, these Pacific Basin island people were gardeners and fisherfolk, supplementing their diet with various parts of wild plants, small animals of the beach or bush, or pigs and chickens that they raised. Most lived in small hamlets of close relatives, although sizable villages were to be found especially on the coasts of the larger islands. The Australian aborigines were nomadic within circumscribed territories. Like the aboriginal Australians, the New Zealand Maori were hunters and gatherers without pigs or chickens, yams or taro. Unlike the Australians, the Maori lived in large settlements and had sweet potato and fern root as well as a rich variety of birds, reptiles, and fish to eat (Oliver 1962).

Water supplies were often limited throughout most of the region (Henderson et al. 1971). Atoll dwellers were without rivers or lakes, and had to rely on rain catchment or brackish pools. The volcanic islands generally had freshwater sources, but settlements near them caused pollution, and people living on ridgetops above them had to transport the water over long distances. Water kept near shelters

was easily contaminated. Lack of abundant freshwater for washing resulted in poor hygiene.

Indigenous Diseases

Those European explorers who commented upon the health of the indigenous people they contacted described them as strong, well-shaped, clean, noble, and generally healthy (Moodie 1973; Howe 1984). Because the weak, ill, or deformed were unlikely to be among the greeting party, such an appearance might be made even if endemic diseases were present. Although geographic isolation had protected Pacific peoples from the epidemic diseases that had swept Europe, Africa, and the New World, their continued if infrequent contacts with Southeast Asia, ever since the initial migrations to Australia and New Guinea, exposed them to some of the diseases extant there (Ramenofsky 1989). Diseases known (from explorers' journals or dated skeletal remains) to be present in the region before first contact with Europeans include malaria (restricted to Melanesia as far south as Vanuatu), respiratory infections, enteritis, rheumatism and degenerative arthritis, dental wear and decay, eye infections, filariasis, ringworm, boils, tropical ulcers, yaws, and a disfiguring ulceration of the skin. Infant mortality rates were high, and those who survived could expect to live into their thirties (Howe 1984; Denoon, with Dugan and Marshall 1989).

Contact with the Outside World

Early in the sixteenth century, the first Europeans ventured into the Pacific, beginning the waves of foreigners who reached this region carrying assorted new infectious diseases (Oliver 1962). Magellan's ships crossed the Pacific from the Americas to Southeast Asia, making the initial contact with the Marianas Islanders. Within a few decades, Guam was a regular port of call on the Spanish trade route between Mexico and the Philippines, and Spanish missionaries were proselytizing the Marianas. In the latter part of the century, Spanish explorers sailed from Peru to the Marquesas and to the islands of Melanesia before reaching the Philippines.

In the seventeenth century, Dutch traders explored the northern, western, and southern coasts of Australia, coastal New Guinea and New Ireland, and island groups in eastern and western Polynesia. British parties during this time period harried the Spanish galleons in the Pacific Basin and along the New Guinea coast, calling in at islands as fresh food and water were needed. In the latter half of the eighteenth century, British explorers first contacted most of the islands of Polynesia, including New Zealand, as well as the Marianas and the east coast of Australia. At this time, the French were charting some of the same islands in Polynesia plus groups of islands off the east coast of New Guinea.

British, French, and American missionaries; British, French, German, and American merchants; and British and American whalers began to move into the Pacific in the late eighteenth century. The British established their first permanent settlement in eastern Australia in 1788, and claimed sovereignty over Australia and New Zealand by 1840. Whaling peaked in the 1850s, but the missionaries and merchants had become a continuing feature of Pacific island life in the nineteenth century. In the latter half of that century, coconut and sugar plantations were developed on many of the islands, and "blackbirding" sailing ships raided islands in Micronesia and Melanesia for indentured laborers to work on plantations in the islands, in Peru, and in northeastern Australia. By the late nineteenth century, only residents of the interior highlands of a few large Melanesian islands had escaped extensive experience with Westerners.

In addition, Chinese, Japanese, and Filipino laborers were brought to the plantations of Hawaii, South Asian laborers to Fiji, Southeast Asian laborers to Vanuatu and New Caledonia, and Chinese traders were prevalent on many of the large islands. Gold mining operations in the late 1800s led to the importation of Southeast Asian workers who lived in overcrowded camps and towns in Melanesia under worse living conditions than laborers residing on plantations.

Commerce and communication were somewhat disrupted in the region by World War I, but the main effects of that war were the shuffling of colonial powers and the major influx into Micronesia and Melanesia of Japanese, Korean, and Okinawan businessmen, fishermen, miners, and military. Hong Kong laborers flocked to the phosphate mines of Nauru and Banaba after the war. The discovery of large deposits of gold in northeastern New Guinea, Fiji, and the Solomons in the 1920s triggered new interest in these areas and encouraged the exploration of New Guinea's central highlands by airplane. This opening up of previously impenetrable landscape by air allowed the first contact between the large populations of highlanders and Europeans. Contact among all the islands of the Pacific and between the islands and the continents bordering the Pacific was greatly facili-

tated by the establishment of transpacific and Australia–New Guinea air routes in the decades before World War II.

Pacific islanders suffered greatly during the Second World War. When peace finally returned, the United States replaced Japan as the colonial presence (U.N.-mandated trustee) in much of Micronesia, and joined Britain, France, Australia, and New Zealand in major disease-eradication projects in the region, made possible by the advent of new drug therapies. In the subsequent years, towns and cities have grown up, opportunities for formal education and for travel abroad have increased markedly, tourism has replaced plantation produce, and even the small islands of the Pacific Basin have become integrated into the world economy and communication network. Yet the diversity in environments and cultures remains. As in any Third World situation, many indigenous people in the urban centers face overcrowding, unemployment, poverty, poor sanitation, and easy availability of all sorts of imported foods and drugs, while their relatives in the hinterlands have poor access to any services (including health care) or often even to clean water. Mortality rates and malnutrition are often higher in remote areas than near the centers, and in most cases the indigenous people in this entire region have inadequate housing, poor screening, less pure water, inadequate food storage facilities, poor diet, inadequate waste removal, inadequate health services, and high birthrates. The greatest value this region now has to major political powers is a strategic one. In addition to hosting a few military bases, some of the islands have been sites for controversial weapons storage and nuclear testing by the United States, England, and France.

Imported Diseases

The European explorers and missionaries who first contacted the indigenes brought with them diseases common in their own homelands or in the ports they had been visiting. However, in the small isolated communities common throughout this region, most diseases could not be maintained indefinitely and needed to be reintroduced through outside contact after a new pool of susceptibles had developed. Such reintroductions were accomplished by interisland voyaging, trade among different tribal groups, explorers, merchants, whalers, missionaries, soldiers, "blackbirders," Asian laborers on plantations and in mines, and soldiers from afar. Lacking the immunity that develops after centuries of coexisting with pathogens, Pacific populations provided a "virgin

soil" for these epidemics from the rest of the world or even – in the case of malaria in the Papua New Guinea highlands – from circumscribed areas of endemicity within the region.

Because it involved translocating large numbers of people around the Pacific and concentrating them in crowded unhygienic quarters, the labor trade had a particularly devastating effect on health (Saunders 1876; Schlomowitz 1987). Laborers not properly screened or in a preclinical phase of a disease when recruited could infect the entire ship during the journey. If the pathogen survived in new susceptibles until the ship landed, the disease rapidly spread throughout the labor camp. Moreover, in addition to introducing infections, the new recruits were particularly susceptible to any diseases present in the camps. Excessively heavy work, poor shelter, lack of sanitation, poor diet, impure water, and lack of health care meant that many did not survive the first year.

Along with internecine warfare and the usual natural disasters that led to famine and water shortages, diseases in this region caused extensive loss of life before preventive or curative methods were successful. Endemic diseases regulated fertility and mortality over time; epidemics of new diseases often caused severe depopulation in all age groups when first introduced. The latter were devastating not just because of their initial toll but also because the loss of mature adults reduced the group's ability to provide food, shelter, and nursing care for itself or to reproduce itself. Pneumonia, diarrheal diseases, and – if present – malaria are still major causes of severe morbidity and mortality for infants and toddlers in the region (Prior 1968; Moodie 1973; Marshall and Marshall 1980; Townsend 1985).

However, as in other regions of the world, infectious diseases have not constituted all of the health problems in Oceania and Australia. Nutritional deficits or excesses, either alone or in concert with infectious agents or predisposing genotypes, have caused a number of important diseases, as have environmental toxins. Hemorrhage, obstructed labor, and sepsis in childbirth have had fatal consequences in the many areas where specialized care is relatively inaccessible (Marshall and Lakin 1984). The same has been true for any trauma leading to hemorrhage or sepsis. In addition, since the post–World War II years, the chronic life-style diseases (obesity, diabetes, cardiovascular disorders, cancers, substance abuse) have become common throughout most of the Pacific.

Diseases of the Region in Time and Space

Arthropod-Borne Diseases

Malaria. Malaria has been a major cause of morbidity and mortality at least in the historical period throughout Melanesia, except Fiji, New Caledonia, and certain coral atolls. Although the anopheline mosquito vector is present in Micronesia, the *Plasmodium* parasite has not been introduced. Malaria is also absent from Polynesia (Norman-Taylor et al. 1964; Gurd 1967; Willis 1970; Henderson et al. 1971). The disease was endemic in the aboriginal lands of northern Australia before its eradication in 1962. Because of the continued presence of *Anopheles* in Australia, reintroduction from New Guinea or southeast Asia remains a threat (Moodie 1973).

In New Guinea, malaria is hyperendemic in the hot, wet lowlands. As the indigenous people were "pacified" by colonial administrations and forced to live in larger village units, the resultant proximity of large groups of people and numerous small pools of mosquito-breeding water facilitated the spread of malaria (Vines 1970). It did not reach the highlands, however, until the 1930s, as a result of European road building, airstrip construction, pond and ditch digging, along with increased migration of contract workers between coastal plantations and highland homes (Riley 1983). In some remote mountain valleys, the unstable parasite pool has become nearly self-sustaining in the 1970s. *Plasmodium* cannot, however, complete its life cycle in *Anopheles* at altitudes above 2,000 meters, where temperatures are below 16°C, even though its vector can survive higher up (Nelson 1971; Sharp 1982).

Although the Polynesian outlier atolls in Papua New Guinea and the Solomon Islands were initially free from malaria, it was introduced within a decade of first European contact in the nineteenth century to Ontong Java and Sikiana (Bayliss-Smith 1975). Malaria control efforts in the 1950s–70s have had varying degrees of success (Moodie 1973; Bayliss-Smith 1975; Taufa 1978). The Institute for Medical Research in Papua New Guinea has initiated clinical trials of a malaria vaccine.

In areas of endemic malaria, the disease has its greatest effect on children from 6 months to 5 years of age. Before 6 months they are protected by maternal antibodies, and after 5 years they have generally acquired some immunity of their own from repeated infections (Burnet and White 1972). However, increased incidence of malaria in Melanesia is not necessarily associated with increased infant mortality (Van de Kaa 1967). Low-protein diets for children under 3 years of age in some New Guinea communities may increase resistance to or decrease severity of the symptoms of malaria (Lepowsky 1985).

Malaria may have indirect effects on child health as well. Decreased maternal immunity to malaria during pregnancy poses problems for fetal oxygenation and growth – and consequent infant health – in that the unchecked plasmodia clog the placenta, disrupt red blood cells, and induce high fever. Thus, birth weights in the Solomon Islands increased a few months after initiation of a malaria control program (Taufa 1978).

Malaria has been a scourge of settlers, colonists, missionaries, laborers, soldiers, and tourists in Melanesia, just as it has been of the indigenous people. Symptoms are worse for those adults who have not acquired some immunity in childhood or are malnourished. Nineteenth-century Samoan missionaries for the London Mission Society died of malaria at various stations in Vanuatu (Howe 1984). In World War II, it caused considerable mortality among the Australian, American, and presumably Japanese forces, as well as among Melanesians from regions other than the coastal lowlands (Burnet and White 1972). Tourists, anthropologists, and Peace Corps volunteers in Melanesia today regularly take their weekly antimalarial doses, which are generally available over the counter in local pharmacies.

Filariasis. Filariasis was indigenous throughout the tropical Pacific. Different strains of *Wuchereria bancrofti* are transmitted by different mosquito vectors in different regions. *Culex* in Micronesia and *Anopheles* in some of the Papua New Guinea islands as well as the Solomon Islands and Vanuatu carry nocturnally periodic strains, whereas daybiting *Aedes* transmit nonperiodic strains in Polynesia, Tuvalu, Kiribati, Fiji, and New Caledonia (Norman-Taylor et al. 1964; Iyengar 1965; Gurd 1967; Vines 1970; Henderson et al. 1971; Chowning 1989). In the first half of the twentieth century, filariasis was highly prevalent in Polynesia except New Zealand (Iyengar 1965; Henderson et al. 1971; Montgomerie 1988). In the Cook Islands in 1946, 75 percent of the school children were infected (Beaglehole 1957), as was nearly half the Tahitian population in 1949 (McArthur 1967). However, in the same time period, the disease was much less common in Papua New Guinea, the Carolines, Marshalls, Marianas, and Kiribati (Kraemer 1908; Hetzel 1959; Maddocks 1973), and the progression to elephantiasis was rare. In Fiji, adult male plantation workers generally have the highest rates of infection, although equally

high rates are found in women who work near mosquito-breeding areas in pandanus and coconut groves. Filariasis is more common on the less developed islands, where screens on windows are often absent and mosquito-breeding puddles are plentiful near houses; yet it does not exist on the very small islands in this archipelago. Major mosquito eradication campaigns in the middle of this century were fairly successful in Micronesia (Henderson et al. 1971), Marquesas, Tahiti, Samoa, Tonga (Iyengar 1965), and Torres Straits islands.

Dengue. Dengue epidemics have occurred for at least a century in Oceania in places where the *Aedes* mosquito has been present, generally on lush wet islands where unscreened rain catchment is close to houses. The 1885–6 epidemics in Fiji and New Caledonia spread eastward into Tahiti, causing miscarriages and excessive mortality in children in southern French Polynesia (McArthur 1967). Wallis and Futuna experienced an epidemic in 1907, as did Torres Straits islands in the early twentieth century, the northern Cook Islands in 1930–1 (McArthur 1967), Kiribati in the 1950s, and Fiji in 1943–4 and 1953 (Wilkinson et al. 1973). Epidemics occurred infrequently in aboriginal lands in tropical northern Australia, probably arriving from nearby southeast Asia (Moodie 1973).

Dengue hemorrhagic fever, which is frequently fatal in children, appears to be a post–World War II phenomenon along major transport routes in southeast Asia and the Pacific islands. It has appeared in Tahiti and elsewhere when at least one other strain of the virus co-occurred with the type 2 strain (Chastel and Fourquet 1972; Hammon 1973). In 1971–2, major outbreaks of dengue of varying severity occurred in coastal Papua New Guinea, Vanuatu, New Caledonia, Fiji, Nauru, Kiribati, Tuvalu, Western Samoa, Tonga, Niue, and Tahiti (Pichon 1973; Wilkinson et al. 1973; Zigas and Doherty 1973). The symptoms were relatively mild in most areas, with a type 2 strain as the sole causative agent. In Rabaul, the clinical features of the type 2 infection were more severe, but hemorrhage and shock were not seen (Zigas and Doherty 1973). Over half the population of Tahiti was affected, some of whom developed hemorrhagic fever. Severe hemorrhagic symptoms and high mortality characterized the Niue outbreak that struck one-third of the population (Pichon 1973).

Although dengue had ceased to exist in Micronesia by 1948 (Hetzel 1959), it was reintroduced into Palau in the late 1980s by Indonesian drift voyagers who landed on the southwestern outer islands. Since then, cases have appeared in neighboring Yap and in Guam. *Aedes* was thought to have been eradicated in Palau, but seems to have been reintroduced from southeast Asia. Signs in an eastern Micronesian airport in 1988 warned visitors of the danger of dengue spreading from Palau.

Respiratory Diseases

Respiratory infections, which are extremely common in hot humid climates, still constitute a major cause of mortality everywhere in the Pacific region. Upper respiratory infections routinely spread throughout villages or whole island populations soon after the arrival of a ship. Transfer is rapid in the generally crowded conditions where handwashing is far less frequent than personal touching, coughs and sneezes are rarely covered, and flies are plentiful.

Influenza. Influenza epidemics followed quickly upon first contact with Europeans and continued almost annually thereafter. The disease was first reported in Tahiti in 1772, Fiji in 1791–2, Samoa in 1830, the Cook Islands in 1837 (McArthur 1967), Pohnpei before 1841, Yap in 1843, the Marshall Islands in 1859, Pingelap in 1871 (Hezel 1983), Papua New Guinea in 1889 (Allen 1989), and remote Australia before 1890 (Moorehead 1966). The first epidemic in Fiji indirectly brought on a famine because of the depletion of food resources by the excessive number of funerary feasts prompted by the heavy mortality (McArthur 1967).

Adult mortality was high in the early influenza epidemics in each location. Later, given the wide-based population pyramid, the very young began to account for the greater share of mortality, although lessened immune responsiveness at both ends of the age spectrum has made influenza a special threat to the elderly as well. Certain of the subsequent epidemics were particularly severe in the mortality they generated. Among them were those that struck New Zealand in 1838 (Owens 1972), Fiji in 1839, Tahiti in 1843, Samoa in 1837 (McArthur 1967), Pohnpei in the 1840s, Kosrae in 1856–7, Palau in 1872 (Hezel 1983), Vanuatu in 1863 (Howe 1984), Wallis and Futuna in 1870 from Fiji, Polynesian outliers in Melanesia around 1900 (Bayliss-Smith 1975), Caroline Islands in 1877, 1927, and 1937 (Marshall 1975; Nason 1975), Kiribati in 1915, 1935, and 1956, Papua New Guinea in 1957 and 1965 from eastern Australia (Warburton 1973), and Kiribati and Tuvalu in the 1960s (Henderson et al. 1971).

The influenza pandemic of 1918–19 swept across

most of the Pacific, but spared Papua New Guinea, the Marquesas, and Australia, and some remote islands in every group. Although the highest mortality rate in the world for that epidemic was in Western Samoa (25 percent), neighboring American Samoa escaped altogether by quarantining all ships in its harbor. A single ship from Auckland carried the disease to Fiji, Tonga, and Western Samoa. However, the New Zealand-dependent Cook Islands major port was infected from Tahiti, where mortality was similar to that in Western Samoa. The highest mortality throughout the region was among 15- to 40-year olds and was generally caused by secondary bacterial pneumonia (McArthur 1967; Burnet and White 1972).

Diphtheria and Pertussis. Epidemics of diphtheria and pertussis (whooping cough) have been reported in various parts of the region since colonial times. The first diphtheria outbreaks in Australia occurred at a time when the disease had intensified in England and Europe. The disease appeared in southeast Australia and Tasmania in 1858–9 and in small scattered settlements in the far west in 1864 (Burnet and White 1972). Vanuatu experienced an epidemic in the 1860s (Howe 1984). It has since been rare in isolated aboriginal Australian communities (Moodie 1973) and in Papua New Guinea, although epidemics did occur in the 1950s and 1960s in the highlands of the latter. After the construction of their jet airport in 1965, Easter Islanders experienced a diphtheria epidemic.

Pertussis has caused high mortality in the nineteenth and twentieth centuries among infants and children in the highlands and islands of Papua New Guinea (Vines 1970; Paine 1973; Lindenbaum 1979), Vanuatu (Howe 1984), Australian aborigines (Moorehead, 1966; Moodie 1973), Kiribati, Fiji, Tonga, Western Samoa, Tahiti, Leeward and Cook Islands (McArthur 1967), and New Zealand Maori (Prior 1968).

Pneumonia. Secondary pneumonia usually causes the respiratory infection fatalities in this region. Pneumonia epidemics have occurred following influenza epidemics since first European contact (Maddocks 1973). Mortality has been highest among the very young, the very old, and those in remote areas (Allen 1989). Pneumonia was rife in the goldfield labor camps in the mountains, perhaps because of the chilly nights with close contact among the workers around smokey fires and the scanty food rations which had to be carried in on workers' backs (Vines

1970; Riley 1973; Schlomowitz 1988). Because pneumonia is a particular problem for everyone in the highlands, a vaccine for the common pneumococci has been tested there recently (Riley 1973). In Papua New Guinea, pneumonia is endemic in rural areas and prevalent among young men who have recently migrated to towns (Hocking 1974). In highland Papua New Guinea domiciliary smoke has also been implicated in the *chronic obstructive pulmonary disease* (COPD), which is so common there (Vines 1970), although its high prevalence on the coast as well suggests repeated acute infections as a more likely cause (Woolcock, Colman, and Blackburn 1973).

Streptococcal Infections. Sequelae of repeated untreated *streptococcal throat infections* have also been a problem in many areas of Oceania. *Rheumatic carditis* is prevalent in Fiji (Gurd 1967), in French Polynesia, where it occurs frequently in children under 5 years of age (Houssiaux, Porter, and Fournie 1972), and among Australian aborigines (Moodie 1973) and New Zealand Maori (Prior 1968). *Post-streptococcal glomerulonephritis* is one of the most common causes of death among adult Australian part-aborigines in south Australia (Moodie 1973).

Tuberculosis. Tuberculosis, or "wasting sickness" as it was called, was introduced into Fiji in 1791 by a British ship (McArthur 1967). Reports of "consumption" among the Maori living near missionaries and sawyers from England began to increase in the 1820s (Owens 1972). Tuberculosis became common in much of Polynesia and some of Melanesia and aboriginal Australian lands by the mid-1800s, and was a major health problem for Australian aborigines by the turn of the century (Kuykendall 1966; Moorehead 1966; McArthur 1967; Moodie 1973; Bayliss-Smith 1975; Howe 1984). Interisland migration as well as ships from outside spread it widely throughout the Pacific during the nineteenth century. Although present in even remote areas of the New Guinea islands by the early 1900s (Chowning 1989), it reached the highlands only decades later. Travelers from the eastern highlands avoided overnight stays in the nearby lowland valleys because they feared tuberculosis; this custom also protected them from night-biting anophelines (Riley 1983). Tuberculosis was first introduced into certain populous areas of the highlands in 1970, and has occurred only sporadically since (Pust 1983).

The disease remains an important health problem in the modern Pacific, where crowded households

and extensive sharing of personal articles facilitate spread, and intercurrent infections decrease resistance. The 1960s campaigns with screening, immunization, and chemotherapy have been at least somewhat successful in most island groups (Henderson et al. 1971).

Scrofula, characterized by tumors, wasting, neck swellings, and spinal curvature, was widespread in Polynesia in the early nineteenth century. A number of authors have equated it with tubercular adrenitis. Said to have been brought to Tahiti by British and Spanish explorers in the eighteenth century, scrofula was carried by Tahitian teachers to the Cook Islands in the 1830s, where it spread throughout the group in a time of famine, causing many deaths over the next 15 to 20 years (McArthur 1967).

Other Infectious Diseases

Leprosy. Leprosy was introduced into the region by Asian workers and immigrants in the nineteenth century, then spread with interisland migration. Although called the "Chinese disease" in Hawaii, the actual circumstances of introduction to those islands are unknown. It was present in the 1830s, and numerous cases were reported in 1863, a few years before the Molokai leper colony was established to isolate the afflicted. Hundreds were sent to Molokai over the years, yet many remained in their own communities. Hawaiian islanders did not fear the disease and therefore resisted this internment (Kuykendall 1966). Leprosy appears to have entered New Zealand in the 1850s, perhaps with Asian travelers, but was rare until the 1900s (Montgomerie 1988). Australian aborigines in the northeast acquired the disease from infected Chinese and Melanesian laborers in the nineteenth century (Moodie 1973). It was present in New Guinea in 1875 (Maddocks 1973) and was brought into the northern Cook Islands in 1885 by a native son who had spent several years in Samoa with a leprosy sufferer from Hawaii (McArthur 1967). The disease spread to Easter Island (where it is still greatly feared) from Tahiti, and although widespread in Polynesia in 1900, it still had not reached the Caroline Islands (Kraemer 1908).

After World War II, leprosy also become widespread in Micronesia west of the Marshall Islands (Hetzel 1959), but was brought under control – even in a spot of high incidence – by 1970 (Sloan et al. 1972). In the 1970s, it was still sufficiently prevalent in Polynesia (including outliers), Fiji, and Kiribati, that immigrants to New Zealand from these islands reintroduced the disease every year (Gurd 1967; *Leprosy Review* 1973). Shared sleeping mats have been suspect in areas of increasing incidence. Leprosy is present throughout Melanesia as well (Gurd 1967; Willis 1970; *Leprosy Review* 1973; *WHO Weekly* 1973). In Papua New Guinea, the highest incidence is in the highlands, although it is also prevalent along the New Guinea coast (Vines 1970; Russell 1973). There are endemic foci among the northern Australian aborigines, but it is rare in other aboriginal communities (Moodie 1973). Many cases in rural areas remain undetected, so rates all over the region may actually be much higher. Outpatient treatment has largely replaced the leprosy hospitals built earlier this century (Henderson et al. 1971).

Measles. Measles, although present in much of the Pacific Rim in 1800, did not reach eastern Australia until 1828 and Hawaii until 1848. In the 1850s, it spread throughout Australia, to New Zealand, and into the islands (McArthur 1967; Cliff and Hagget 1985). In 1875, a London Mission Society ship carried measles along the Papuan coast of New Guinea. In the same year, a ship carrying Fijian royalty home from a visit with the governor of Sydney transported the virus to Norfolk Island, the Solomon Islands, and Vanuatu as well. The effect on Fiji was particularly devastating, as over a thousand representatives from most of the individual islands had gathered to greet the ill prince and to celebrate for 2 weeks Fiji as a new Crown Colony before dispersing home. The sudden loss of so many adults in Fiji, Tahiti, and Vanuatu contributed to the heavy mortality, as few remained able to provide food or care (Cliff and Haggett 1985).

Similar epidemics struck Kiribati in 1890 (Lambert 1975), and Tonga and Western Samoa in 1893 (McArthur 1967). Quarantine kept Fiji from all but local port outbreaks until 1903, when measles again swept through the group. The 1911 outbreak was mild on most islands, but severe in those few remote islands that had escaped earlier. Every epidemic thereafter came at shorter intervals, caused fewer deaths, and affected ever younger children only (Cliff and Haggett 1985). The same pattern – sporadic epidemics that become more frequent and less severe – has occurred everywhere in the region with regular outside contact or large populations. Small remote islands still have rare epidemics with variable mortality (McArthur 1967; Van de Kaa 1967; Brown and Gajdusek 1970; Vines 1970; Willis 1970; Henderson et al. 1971; Moodie 1973; Lindenbaum 1979; Cliff and Haggett 1985).

Rubella. Rubella epidemics have been recently documented for Guam, remote Micronesian atolls, Western New Guinea, and Papua New Guinea and have been associated with excessive hearing impairment from in utero exposure (Brown and Gajdusek 1970; Stewart 1971; Allen 1989).

Mumps. Mumps was already present in the Cook Islands when it reached Samoa on a ship from California in 1851 (McArthur 1967). The disease subsequently spread over much of the region, although it did not appear in the New Guinea highlands until the 1940s (Lindenbaum 1979).

Scarlet Fever. Scarlet fever caused deaths among foreigners in French Polynesia and the Cook Islands in 1846–7, but remained mild among the islanders (McArthur 1967). Symptoms are similarly mild among Australian aborigines in recent times (Moodie 1973).

Chickenpox. In the twentieth century, chickenpox became more common and is now widespread in the region. High prevalence was reported from numerous island groups, New Guinea, and Australia in the 1930s (Moodie 1973; Allen 1989). In fact, it has been suggested that some of the smallpox reported for Australia and Papua was actually chickenpox (Maddocks 1973; Moodie 1973).

Smallpox. Smallpox epidemics in the Pacific region resulted primarily from contact with outsiders. The first reported epidemic was in the Spanish colony of Guam in 1688 (Carano and Sanchez 1964). A century later, within a year of the founding of Port Jackson (now Sydney) in 1788, smallpox erupted among the aborigines camped nearby. The immune settlers were relatively unaffected, but large numbers of aborigines died (Moorehead 1966).

Trade ships and whalers brought the disease to many islands: Gambier in 1834, Tahiti in 1841, Pohnpei in the 1840s and in 1854, Hawaii in 1853–4, the Maori, Palau, and Polynesian outliers in Melanesia in midcentury, Papua in 1865, and the New Guinea coast in 1870–90. In many of these cases, sick passengers or crew were put ashore and died on the island, passing the disease to any who helped them. Islanders visiting the port spread the virus to their home communities nearby (McArthur 1967; Kuykendall 1968; Owens 1972; Maddocks 1973; Bayliss-Smith 1975; Nason 1975; Allen 1983, 1989; Hezel 1983).

The labor trade also introduced smallpox from Asia and South America. In the 1860s, Polynesians returning to their homes after years of involuntary servitude in the mines of Peru contracted smallpox on board the ships (McArthur 1967). The first shipload of plantation workers from India introduced smallpox and cholera to Fiji in 1879. The need to train vaccinators locally led to the construction of the Suva Medical School in 1885 (Lander 1989). Cantonese laborers reintroduced the disease as they slipped undetected into Hawaii in 1881 (Kuykendall 1967). Before 1900, Javanese laborers for the plantations along the New Guinea coast introduced smallpox as they arrived. It spread into the nearby coastal mountains, up the Sepik River and across the channel to New Britain to remote areas not yet contacted by Europeans (Allen 1989; Chowning 1989).

Yaws. Yaws was present in the Pacific region prior to outside contact. Before the eradication campaigns of the mid-twentieth century, yaws was found among Australian aborigines, and in all of Melanesia, western Polynesia, Micronesia, French Polynesia, and Hawaii. Conversely, it was not present in New Zealand, Gambier, Easter, or Pitcairn Islands (Hetzel 1959; Pirie 1971–2; Moodie 1973). It occurred less commonly in particularly dry, cool, or high-altitude areas or in islands settled late.

Yaws was usually acquired by children from regular playmates. After recovery from the debilitating skin lesions, solid immunity to treponeme-caused yaws and to syphilis as well is attained. Incidence of yaws decreased as people washed with soap and covered their bodies with clothes (Pirie 1971–2). After World War II, the disease was virtually eradicated by penicillin injections, although antibodies remained in those who had been infected (Norman-Taylor et al. 1964; Fischman and Mundt 1971; Henderson et al. 1971; Davenport 1975). Some pockets of infection remained after the campaigns in the Marshall Islands (Hetzel 1959) and tropical northern Australia (Moodie 1973).

Hepatitis. Hepatitis B has been highly prevalent in the 1980s in Micronesia and in American Samoa, where public health posters announce "Hep is not hip." The Australia antigen for identifying the virus was isolated in 1967 from the blood of an anemic Australian aborigine who had received numerous transfusions. In the Solomon Islands, the antigen was commonly present in those with no clinical symptoms or predisposing history (Burnet and White 1972).

Hepatitis A is endemic in much of island Oceania

and tropical Australia, subclinically infecting most of the indigenous population under age five (Moodie 1973), as might be expected in view of the warm climate and casual hygiene among children.

Poliomyelitis. Poliomyelitis, being epidemiologically similar to infectious hepatitis in unvaccinated populations, was endemic in tropical Australia and the Solomon Islands before World War II, but provided only rare instances of paralysis (Cross 1971; Moodie 1973). Before the massive vaccination campaigns of the 1960s, most Guamanian under 3 years of age were already immune (Burnet and White 1972). Western and American Samoa experienced an epidemic in 1935 with highest mortality and morbidity among young adults rather than children. New Guinea and Guam had also been "virgin soil" for earlier polio epidemics (Burnet and White 1972). After World War II and before vaccination, epidemics occurred across the South Pacific (Peterson et al. 1966; Cross 1971). Vaccination and quarantine finally limited the spread (Peterson et al. 1966).

Acquired Immunodeficiency Syndrome (AIDS). AIDS has surfaced in various indigenous Pacific population in 1988–9. It is now present among urban-dwelling Australian aborigines, as well as among the people of Papua New Guinea, French Polynesia, Tonga, Marshall Islands, Guam (Karel and Robey 1988), Fiji (*Pacific Island Monthly* 1988), Northern Marianas, American Samoa (but not Western Samoa), and Hawaii (information received at the Hawaii exhibit, Fifth International Conference on AIDS, Montreal). On the other hand, extensive screening in the Solomon Islands and Papua New Guinea found no individuals with the virus (HIV) in 1985–6.

Venereal Diseases

Syphilis and *gonorrhea* were brought into the Pacific by early explorers and whalers. Because syphilis might have been mistaken for yaws, tropical ulcer, scrofula, leprosy, or gonorrhea, confusion exists about the circumstances of introduction even though early ships' logs did comment on the presence of venereal diseases. In tropical Australia and the wet islands of the southwestern Pacific, where yaws was highly prevalent and promiscuity was not customary, syphilis has been a relative newcomer; in cooler New Zealand and drier or more recently settled islands of Micronesia and eastern Polynesia where yaws was less common and Europeans and island women often mixed more freely, syphilis was re-

corded soon after regular contact. British and French explorers in 1767–9 gave each other credit for the syphilis in Tahiti reported by Captain James Cook in 1769 and spread elsewhere in French Polynesia by explorers over the next few decades. Cook's surgeon wrote that the ship's crew introduced syphilis accidentally to Tonga in 1777 and knowingly to Hawaii in 1779, although other observers stated that the disease was present earlier in Hawaii (Moorehead 1966; McArthur 1967; Pirie 1971–2; Smith 1975; Stannard 1989). Venereal syphilis was found among the Maori before 1840 and became more prevalent but with milder symptoms by 1855 (Pirie 1971–2; Owens 1972). Pohnpei, Kosrae, the Marshall Islands, and Kiribati were also infected by whalers and traders in the 1840s and 1850s, but a century later the disease there had become almost nonexistent (Hezel 1983). Syphilis was unknown in northern Australia before 1939, but since then has spread among the aborigines around the country (Moodie 1973). Papua New Guinea highlands, where yaws had never existed, experienced an epidemic of syphilis in 1969, after the new highway opened up access. It was first reported in 1960 and has remained largely confined to the highlands (Lindenbaum 1979; Lombange 1984).

Gonorrhea, often referred to in the region as "venereal disease," was first noted in 1769 in Polynesia and 1791 in Palau. Whalers, traders, and beachcombers passed gonorrhea back and forth with islanders in the 1830s through 1850s in the Caroline and Marshall islands, French Polynesia, and Hawaii, which were popular ports of call with more relaxed sexual attitudes than in most of western Polynesia or Melanesia (Pirie 1971–2; Hezel 1983). Venereal disease did reach one frequently visited Polynesian outlier by the 1850s, but has never been present on its more remote neighbors (Willis 1970; Bayliss-Smith 1975). The first reports of venereal disease on Papua New Guinea coasts were in 1902–8, but it has since become prevalent throughout the country (Pirie 1971–2; Lombange 1984). Thus with rare exceptions, the disease has become ubiquitous in Oceania, as it has in Australia in the same time period (Moorehead 1966; Moodie 1973).

Food- and Waterborne Diseases

Enteric infections flourish in conditions commonly found throughout this region (Marshall and Marshall 1980; Allen 1983; Burton 1983; Reid 1983). They are often fatal in the very young or in those who for any reason quickly become dehydrated in the hot climate. Gastroenteritis is ubiquitous, al-

though less common in nomadic or low-density populations (Willis 1970; Reid 1983).

Cholera. Discrete epidemics of cholera have occasionally occurred. It was reported in Kiribati in 1841, among the Maori in 1838 and after 1840 (Owens 1972), and carried into Fiji by new South Asian plantation laborers (Lander 1989). Cholera has not been documented for either Papua New Guinea or Australia, even though the easily spread El Tor strain was present in neighboring western New Guinea and Sulawesi in 1962 (Moodie 1973; Riley 1983). Still a threat in modern times, cholera broke out in Kiribati in the late 1970s. An infected crewmember on a Japanese fishing vessel debarked in Truk, causing a major epidemic in 1982–3 which, until recently, devastated the tourist trade.

Diarrhea, Dysentery, and Clostridial Diseases. Epidemics of the "bloody flux," or *bacillary dysentery,* have plagued Pacific islanders at least since 1792, when a British explorer brought it to Tahiti. Unlike measles, these epidemics did not become more frequent and less severe with repetition in a given population. Severe epidemics of bacillary dysentery were often associated with concurrent civil wars, famines, typhoons, droughts, measles, incarceration on labor vessels, employment on the goldfields in Papua New Guinea, or ship visitations (McArthur 1967; Prior 1968; Bayliss-Smith 1975; Allen 1983; Burton 1983; Howe 1984; Schlomowitz 1988). Two notable epidemics of bacillary dysentery occurred in Papua New Guinea during World War II: one introduced by Japanese in the course of building an airstrip on the north coast using indigenous labor, and one introduced by members of an American military team in the central highlands. Australian soldiers also brought dysentery that they had earlier picked up in North Africa (Allen 1983; Burton 1983). The Marshall Islands have had epidemics of dysentery in recent years soon after imported chicken has been off-loaded and sold in local stores. It is endemic in most groups of aborigines (Moodie 1973). *Typhoid fever* and *amebic dysentery* have appeared throughout the islands and Australia as well (Hetzel 1959; Gurd 1967; McArthur 1967; Burnet and White 1972; Moodie 1973).

The third leading cause of death in the Papua New Guinea highlands is *enteritis necroticans,* known locally as *pigbel.* Peak incidence of this syndrome of bloody diarrhea, stomach pain, nausea, and vomiting occurs at 4 years of age. Those over 40 years old generally have developed immunity to the causative agent, *Clostridium perfringens* beta toxin. Feasts with literally heaps of pork occasionally punctuate the usual highland low-protein, largely sweet potato diet. *Clostridia* enter the slaughtered pork as it sits in the dirt and is handled regularly for about 4 days before the feast. It is ingested with the meat, colonizes the gut, and produces a toxin that should be inactivated by intestinal trypsin. However, protein deprivation or the presence of trypsin inhibitor from sweet potato (or from the ubiquitous *Ascaris*) prevents the enzyme from doing so. A vaccine for the toxin became available in the 1980s (Lindenbaum 1979; Murrell 1983).

Another clostridial disease, *tetanus,* occurs widely in the Pacific islands and Australia, even in areas without domestic animals (Gurd 1967; Moodie 1973; Lindenbaum 1979). The disease is not found on Easter Island, however, even though horses, cattle, goats, sheep, *Clostridium tetani,* and bare feet are common. Immunization as part of prenatal care in Papua New Guinea has reduced mortality from neonatal tetanus, which was once very high in rural areas where umbilical cords were cut with contaminated objects (Townsend 1985).

Helminth-Transmitted Diseases

Intestinal-dwelling *nematodes* have been very common in the Pacific region wherever the soil is moist enough to keep their eggs alive. Generally prevalence of *Ascaris* and *Trichuris* is lower on dry atolls (e.g., Marshall and northern Cook islands) or in lowland rainforests (as on the New Guinea coast). However, the southern Cook and Caroline islands rainforests have had very high rates, whereas *Ascaris* is rare in Vanuatu (Hetzel 1959; Norman-Taylor et al. 1964; Vines 1967, 1970). *Ascaris* is widely distributed in aboriginal lands in Australia, but is more common in the cooler drier south (Moodie 1973). *Enterobius* is ubiquitous (Vines 1967).`Hookworms have had a low prevalence in Kiribati and isolated Pitcairn and Easter islands but are plentiful on wet lowlands. *Necator* has been far the more common parasite, although *Ankylostoma* has replaced it in Vanuatu. They have been highly prevalent in aboriginal lands in Australia, except in the Central Desert. They spread out from the tropical north with cattleherders. Eradication campaigns in many islands and among the Australian aborigines have had no enduring effect (Hetzel 1959; Norman-Taylor et al. 1964; Vines 1967, 1970; Willis 1970; Moodie 1973).

Zoonoses

Other health problems have arisen as well from the close association between humans and various ani-

mals in this region. The disabling or even fatal dog tapeworm is common among Australian aborigines who keep dogs closeby in their camps (Moodie 1973). *Cysticercosis,* from pig tapeworm, was first introduced into the densely populated pig-raising highlands of Western New Guinea via a gift of infected pigs from nearby Bali in 1971. Within 4 years it had spread to the border with Papua New Guinea, and within 10 years had become a major cause of morbidity and mortality in that region, which has been a hotbed of rebellion against the alienation of Papuan lands by Indonesian settlers (Hyndman 1988).

Since 1948, epidemics of *eosinophilic meningitis* generally attributed to ingestion of rat lungworm, *Angiostrongylus,* have been reported in small areas dotted across the Pacific: New Caledonia, Pohnpei, Cook Islands, Tahiti, and Hawaii. In some of these cases, shellfish eaten raw were the intermediaries (Rosen et al. 1967).

Toxoplasmosis is endemic in much of Oceania and Australia, where cats appear to play a critical role in transmission (Wallace, Marshall, and Marshall 1972; Moodie 1973). Contact through breaks in the skin with water or mud contaminated with the urine of rats, pigs, or cattle has been responsible for *leptospirosis* among Australian aborigines working in sugarcane fields, as swineherds, or as stockmen in tropical northeastern Australia. This infection causes intermittent fever and meningitis (Burnet and White 1972). *Bubonic plague* persisted for 10 years in seaport rats in southeastern Australia before eradication efforts succeeded (Burnet and White 1972). *Scrub typhus* mites flourished in grassy clearings away from human villages in Papua New Guinea and northeastern Australia, causing minimal problems for indigenes but becoming the second leading cause of death – after malaria – among the foreign soldiers cutting through the Bush there in World War II (Burnet and White 1972).

Diet-Related Diseases

Anemia.   Anemia is widespread among women in Oceania, especially at sea level. The proportion of women having hemoglobin levels below 12 grams-percent is higher than in any other region of the world (Wood and Gans 1981; Royston 1982). Anemia is especially common among children in Vanuatu and among New Zealand Maori (Norman-Taylor et al. 1964; Prior 1968). It has been documented occasionally for Micronesia, less in the western Carolines than in the Marianas or Marshalls (Hetzel 1959). Diet and malabsorption problems are respon-

sible for the high prevalence of iron-deficiency anemia among Australian aborigines (Moodie 1973).

Protein–calorie deficiency does occur, mostly in poor remote areas of the New Guinea mainland. Diet on the smaller islands, while simple, is usually sufficient (Vines 1970).

Goiter and *cretinism* have been problems in patches in inland Melanesia, where highland people have had to trade with coastal people for their sea salt. In 1955, colonial patrols worsened the situation in the Papua New Guinea highlands by trading in noniodized salt, which the highlanders preferred to their traditional supply. A campaign in the 1960s to reverse the deficiency with injections of iodized poppyseed oil was successful (Henderson et al. 1971; Lindenbaum 1979).

Diabetes and Obesity.   Chronic diseases have increasingly become primary causes of morbidity and mortality in industrialized societies since the 1950s as immunization and chemoprophylaxis have reduced infectious diseases, as sedentary wage employment has become available, and as imported foods constitute an ever-growing share of people's diets. These diseases are distributed unevenly, occurring far less regularly in remote rural areas.

Non-insulin-dependent *diabetes mellitus* (NIDDM) is unusually prevalent among certain Pacific societies: Australian aborigines (Moodie 1973), New Zealand Maori (Prior 1968), Cook Islanders (Prior 1968), American Samoans (Baker and Crews 1986; Hanna and Baker 1986), Marshall Islanders and I-Kiribati (King et al. 1984), Nauruans (Patel 1984; Taylor and Thoma 1985), Torres Straits islanders (Patel 1984), Fijian women (King et al. 1984), and residents of Papua New Guinea's most acculturated urban but not rural or highland areas (Savige 1982; Patel 1984). The disease is more common among the wealthy (34 percent prevalence in affluent Nauru), the more acculturated, the urban, and perhaps the female. Its meteoric rise in the mortality statistics has paralleled increases in dietary refined carbohydrates and calories and decreases in exercise and dietary fiber.

Obesity even beyond the cultural ideal has also accompanied these changes in all of these areas as well as in the Marquesas and Solomons (Friedlaender and Rhoads 1982; Darlu, Couilliot, and Drupt 1984). Yet similar dietary changes and decreased activity level have not led to obesity or NIDDM on Easter Island. The familial tendency apparent within these populations and the extremely high rates among certain related island groups suggest a partial genetic basis. According to J. M.

Hanna and P. T. Baker (1986), the metabolic ability to gain weight rapidly and hold it may have given a selective advantage for long interisland voyaging with limited space to transport food. Crowding and psychosocial stress in acculturated urban areas may also play a role in the etiology. Compliance with treatment regimes (diet, exercise, daily insulin) in the absence of frank clinical symptoms has been low, especially among men who avoid seeking help unless their problem is evident and severe.

Surveys of blood pressure after World War II indicated that for most Pacific people, adult blood pressures averaged lower than for equivalent age groups in industrialized societies and did not rise with age (Norman-Taylor et al. 1964; Vines 1970; Shaper 1972; Moodie 1973; Gee 1983; Patrick et al. 1983; Ward 1983). However, in recent years *hypertension* and age-related increases have become much more common in areas where modern wage-earners are concentrated, obesity is obvious, and imported salt intake is high (Prior 1968; Henderson et al. 1971; Moodie 1973; Gee 1983; Patrick et al. 1983; Ward 1983; Taylor and Thoma 1985; Hanna and Baker 1986; Prior 1986). Coronary artery disease is also becoming more common in these same situations (Hanna and Baker 1986).

Chronic Degenerative Neurological Diseases

Certain chronic degenerative neurological diseases that have close parallels in the industrialized world have been highly prevalent in very restricted locations in Oceania. *Kuru,* a subacute spongiform cerebellar encephalopathy caused by an unconventional slow virus, has been present in the Fore area of the eastern highlands of Papua New Guinea since 1920. In the 1950s, it was the most common cause of death in adult women and in children 5 to 16 years old in that area. The unusual age distribution was due to the local practice – extant from 1910 to 1955 – of cannibalism. The dead were consumed by female kin and young children of either sex. The virus entered via cuts in the skin as the flesh and brain were prepared. Two to 20 years later, symptoms appeared: ataxia, tremoring, pain, slurred speech, loss of smooth and voluntary muscle control, and pathological laughter. Death followed within nine months. The number of cases declined progressively after cannibalism was discontinued (Burnet and White 1972; Gajdusek 1977; Lindenbaum 1979).

Since before World War II, the indigenous Chamorro of the Marianas Islands have had an extremely high incidence of a syndrome with varying combinations of *Alzheimer-like dementia, amyotro-*

phic lateral sclerosis, and *Parkinsonism.* Occasional cases with similar symptoms have also been found among Caroline Islanders, Filipinos, and Caucasians resident in the Marianas. The syndrome has also appeared in Chamorros 30 years after leaving Guam. Until recently, the Chamorro ate great quantities of the false sago plant seeds, which contain a toxin that causes degeneration of the same motor neurons that disappear in amyotrophic lateral sclerosis and Parkinsonism. On the other hand, a genetic susceptibility to the effects of such a toxin in this population has not been ruled out (Mathai 1970; Lewin 1987).

High incidence of an autosomal recessive *congenital blindness* (tapetoretinal degeneration with cataracts) on a single Carolinian atoll has been attributed to the fact that the island was almost isolated in the 2 centuries following the 1780 typhoon that killed all but nine of the men on the island (Brody et al. 1970).

Ciguatera, a frequently fatal fish poisoning caused by a curare-like toxin present in certain fish throughout the region, has been of grave concern in the Pacific islands where fish is the major protein food. The source of the toxin appears to be algae that grow on submerged World War II equipment or nuclear testing apparatus and are consumed by the fish. It has been reported in French Polynesia, Guam, Marshall Islands, and Hawaii, all of which provide appropriate surfaces for the algal growth (Banner et al. 1963; Henderson et al. 1971; Bagnis 1972).

Afterword

Oceania and Australia have been spared many of the major scourges of the tropical Third World: schistosomiasis, trypanosomiasis, onchocerciasis, and leishmaniasis. Yet they have coexisted for millennia with malaria, filariasis, and other troublesome diseases. Through contact with Asia and the New World in the past several centuries, they were exposed to all of the major epidemic diseases, which have largely become preventable childhood illnesses. The continued lack of comprehensive public health programs for basic sanitation, hygiene, and home screening in the region means that the threat of fatal epidemics as in the past still remains. Lack of refrigeration and transportation problems make it difficult to deliver antibiotics and vaccines to those in need.

In the more affluent areas, decreasing infant mortality rates, a sedentary life-style, and a change in diet have permitted an increasing number of people who reach adulthood, and who may be particularly genetically susceptible, to experience chronic dis-

eases generally more common in industrialized areas. Although the recreational drugs of the West became available only after first contact and were often prohibited to indigenes until recently, substance abuse has become a major problem. In recent years the islanders and Australian aborigines exposed to experimental radioactive fallout have shown the world some of the minor health complications of nuclear warfare, which would be – for all – the final epidemic.

The Pre-Columbian Period

The belief that the American Indians were indigenous persisted until relatively recently. But today it is generally accepted that the first Americans were actually wandering Asians who took advantage of the prevailing ice age to cross the Bering Straits from Siberia to Alaska and enter a continent devoid of human life. Then, perhaps 10,000 years ago most of the large ice caps melted and seas rose, inundating the land bridge and sealing off the Asian pioneers in what would later be called the New World.

They were hunter-gatherers, these pioneers, with a nomadic way of life, which meant that when a band became too numerous to function efficiently, a part would break off and move on to new lands. Gradually this hiving out took them southward, and archeological remains tentatively suggest that some 9,000 years ago the southerly thrust finally came to an end as they reached the southern tip of South America.

It seems to have been much later, however, that the first humans settled the islands of the Caribbean, although there is neither a firm date nor agreement on the mainland from which those first to arrive came. For example, the northern Antilles, Cuba, is a short sailing distance from both southern Florida and the Yucatan Peninsula, whereas on the other end of the island chain, to the southeast, lies Trinidad, just off the South American continent.

When the first Spaniards reached the Caribbean, they found at least four Indian cultures whose bearers had apparently arrived at different times, with the levels of those cultures reflecting the stage of human development on the mainlands when the migrations occurred. There is some evidence to indicate that one of these peoples may have come from Florida, although this is in dispute. Most, however, came from the northeast of South America. Because of these various migrations it is probably safe to assume that the Caribbean Indians carried most of the same kinds of pathogens as their mainland counterparts, meaning that they too were blessed with a freedom from illnesses that had been denied to most of the rest of the world's peoples for millennia. The pioneers who had crossed into the Americas made that crossing before the Old World was caught up in

its Neolithic revolution. This was before Old World hunter-gatherers with stone tools (which the pioneers were) became sedentary farmers with metal tools, and settled down to domesticate plants and animals and, not incidentally, to propagate disease.

The animals that gave these Old World farmers milk, eggs, meat, and hides also passed on bacteria and viruses and helminthic parasites that flourished in the new environment, which humans were creating for them. Unlike hunter-gatherers who were always on the move, sedentary farmers stayed put to pass those pathogens back and forth among themselves through fouled water supplies, mounting human garbage, and filthy housing that harbored insects, rodents, and other assorted pests adept at spreading illness. Moreover, no sooner did one group develop immunities to local ailments than human migration and trade brought them into contact with another group and new diseases, or new and deadly strains of old diseases.

The later construction of cities also saw the construction of a near perfect pathogenic paradise to provide a last crucial step in the immunologic tempering of Old World peoples. Crowded together as they were, spitting, coughing, and breathing on one another, surrounded by the excrement of humans and animals alike to contaminate all they consumed with the aid of swarms of flies buzzing about, the city peoples were natural targets for epidemic disease. But their growing numbers meant that diseases once epidemic soon became endemic and thus became childhood diseases to be endured as a kind of a rite of passage that would ensure immunity against them as adults.

By extreme contrast, New World populations experienced very little of this sort of immunologic preparation. Rather, their pioneering ancestors had left home before the Old World Neolithic Revolution had begun. Thus, they came without animals with whom to share diseases, while those humans who were sick or weak would have been summarily weeded out by the hardship and cold inflicted on them in their passage to Alaska. The result was that the salubrious environment of the Americas remained relatively disease-free despite human invasion.

One says "relatively," because by 1492 a New World Neolithic Revolution had been under way for some time. Many had settled into sedentary agriculture, some animals had been domesticated, and some complex civilizations such as the Mayas, Incas, and Aztecs had long before constructed large cities. Thus, some kinds of tuberculosis had developed, at least among the city dwellers, and they were tor-

mented by ailments that derived from their water and food such as intestinal parasites and hepatitis. In addition, pinta seems to have been endemic among those in warmer climates whose dress was sufficiently scanty to permit ready skin-to-skin transmission. Whether they had venereal syphilis has long been a matter of dispute, with one of the reasons for that dispute being that pinta would have provided some cross-immunity against syphilis.

There is little question, however, that the New World Indians were "virgin soil" peoples for the host of diseases about to descend on them from Eurasian and African Old Worlds. In the words of Alfred Crosby (1986), "They seem to have been without any experience with such Old World maladies as smallpox, measles, diphtheria, tracoma, whooping cough, chicken pox, bubonic plague, malaria, typhoid fever, cholera, yellow fever, dengue fever, scarlet fever, amebic dysentery, influenza and a number of helminthic infestations."

The diet of the Indians of the hemisphere, in contrast, was apparently considerably more varied than their diseases. In the Caribbean, the principal nutriment of those engaged in sedentary agriculture came from manioc (yucca), which they grew in cultivated fields and processed into a bread, which the Spaniards called "cassava." Corn was not the important staple that it was elsewhere in the Americas, but it did supplement some West Indian diets as did white and sweet potatoes, beans, pumpkins, and peanuts. With no domesticated animals save for a kind of dog (sometimes eaten), animal protein was served up mostly in the form of fish along with certain reptiles and insects.

Fishing, however, appears to have been more a leisurely activity than an industry, and it would seem that animal protein played a fairly minor role in the diet. This essentially vegetable diet based largely on manioc, which is notorious for its lack of important nutrients, coupled with the Spanish observation that the Indians ate very sparingly, suggests that they probably suffered from some nutritional deficiencies, and these, in combination with the Indians' lack of disease immunities, would have rendered them even less able to ward off the Old World illnesses about to arrive.

European Diseases

Perhaps no other region on the globe has ever experienced such a sudden and devastating ecological assault as the islands of the Caribbean with the arrival of the Europeans. Ship after ship arrived to disgorge humans bearing Old World pathogens in their blood, bowels, and hair, and on their breaths and skin. Disease-bearing insects and rodents winged their way and scampered ashore, while cattle, horses, and especially hogs wobbled down gangplanks on stiff legs to begin munching and trampling their way across the fragile flora of the islands, reproducing wildly as they went with no natural predators to thin their numbers.

The long-run consequence of this Old World invasion is that today the islands are truly artificial; only their limestone, volcanic rock, coral, and the underlying mountain ranges upon which they rest are of this hemisphere. The plants that grow on them, along with the animals and humans that inhabit them, are practically all Old World immigrants.

Of the pre-Columbian island inhabitants, the humans were the first to depart, and their disappearance unfortunately was accomplished very quickly. They left behind them little more than a few artifacts and the unanswered question of how numerous they were prior to the arrival of Columbus so that the magnitude of the demographic disaster that befell them can be measured. There has been a tendency to disregard early Spanish estimates as excessive and to portray the West Indies as sparsely populated. More recently, however, considerably more respect has been accorded the earlier estimates, and the size of pre-Columbian populations is being revised sharply upward. For example, S. F. Cook and W. W. Borah (1971, 1974, 1979) have calculated that the island of Hispaniola (today the Dominican Republic and Haiti) contained close to 4 million Indians; they suggest that by 1508 that population had dwindled to less than 100,000, thereby providing us with at least a glimpse of the holocaust of disease the islands had become.

Another glimpse comes from Cuba, which was conquered in 1511. Just a few short years later, Francisco López de Gomara could write that this island "was once heavily populated with Indians: today there are only Spaniards." This of course was an impression only, and the Cook and Borah estimate, although based on an array of evidence and informed demographic reasoning, remains an estimate only. Yet knowledge of what specific diseases have done to immunologically defenseless peoples lends a good deal of plausibility to theories that urge the existence of much larger pre-Columbian populations than previously believed.

Francisco Guerra (1988) argues convincingly that the first epidemic disease unleashed on the Indians was swine influenza; it reached the West Indies in 1493 with swine brought by Columbus from the Ca-

nary islands on his second voyage. Certainly some disease began sweeping the islands shortly after the discovery and long before smallpox apparently made its Caribbean debut. There were reports of massive die-offs not just in Hispaniola but in Cuba and the Bahamas as well.

Typhus had surfaced in Spain during the war with Granada and doubtless also reached the islands (and the Indians) even before smallpox began its relentless assault on Hispaniola in 1518, and on Cuba the following year. There ensued a decade during which dozens of other diseases were probably introduced, before the next reported epidemic, measles, which struck in 1529.

Swine influenza has been known on occasion to precipitate mortality levels as high as 20 to 25 percent of a population, and smallpox has killed upward of 40 percent of a people experiencing it for the first time; measles, a relatively benign disease for Europeans, has thinned the ranks of "virgin soil" peoples by 25 percent; whereas typhus has historically produced mortality for between 10 and 40 percent of those ill with the disease.

Clearly then, with maladies capable of producing these high levels of mortality, conceivably the pre-Columbian populations of the Caribbean could have been much larger than heretofore believed. This also ignores mortality generated by other illness such as chickenpox, diphtheria, scarlet fever, typhoid, whooping cough, and bubonic plague, all of which were also introduced from Spain. No wonder then, that by 1570 most of the Indians of the region had vanished. Only the Caribs still survived in the eastern Caribbean – an area not yet much frequented by the Europeans.

It is important to note, however, that all of these maladies struck equally hard at mainland populations. But although they also experienced massive die-offs, the survivors slowly built immunities, and after a century or two those populations began to grow once again. But this was not the case in the West Indies. Part of the reason was that the Caribbean was a corridor through which all Europeans had to pass to reach various parts of the mainland; therefore, those in the corridor had more exposure to disease than those outside it. But the main reason was that the West Indian Islands became the target of still another wave of disease – this time from Africa. The most deadly of these diseases were mosquito-borne and seldom reached up into the cooler elevated regions of the mainlands, which were home for so many Indians, but they turned the low-lying areas of the West Indies into one huge death

trap for the remaining original Americans as well as for the white newcomers who up to this point had found the islands reasonably healthful.

African Diseases

Vivax malaria probably arrived in the blood of the first Europeans and, although a relatively benign form of the disease, nonetheless joined in the slaughter by claiming its share of Indian lives. As the Indian die-off progressed, the Spaniards found themselves forced to look elsewhere for hands to put to work colonizing the Americas, and they chose the black African. By 1518 the transatlantic slave trade was under way, which almost immediately opened a conduit for the transatlantic flow of a much more deadly form of the disease: falciparum malaria.

The circumstances surrounding the introduction of yellow fever from Africa are less clear: Although it is now generally accepted that the anopheline mosquitoes that spread malaria were on hand in the New World to do just that, the *Aedes aegypti* vector of yellow fever most probably was not. Thus both vector and virus had to be imported and to reach human populations dense enough to support them. A case has been made that all of these conditions were met by 1598 at San Juan, Puerto Rico, and there is absolutely no question that they were met by 1647 when yellow fever launched assaults on Barbados and Guadeloupe, before continuing on to Cuba and the Gulf coasts of Mexico and Central America.

The slaves had lived with both of these tropical killers for eons and in the process had developed a relative resistance to them. But in addition, they were also accustomed to most of the other Old World illnesses that had proven so devastating to the Indians. The ironic result of this ability to resist disease was that it made blacks even more valuable as slaves. The Indians died of European and African diseases, the whites died of African diseases, but the blacks were able to survive both, and it did not take the Europeans long to conclude that Africans were especially designed for hard work in hot places.

This view was not limited to the Spaniards, although they had been the first to discover the blacks' durability. Other Europeans had begun trickling into the Caribbean, impelled from their mother countries because of wars, religion, politics, crimes committed, or just outright lust for adventure and riches. They settled first on the islands of the eastern Caribbean, which had been left relatively untouched by the Spaniards, and brought disease to, and ultimately an end to, the surviving Caribs.

If at first these new arrivals grew any "cash

crops," they grew tobacco in small plots, which the Dutch, by then ubiquitous in West Indian waters, marketed for them. All this changed abruptly, however, when the Dutch, who had moved into Brazil, were driven out, taking with them the secrets of sugar production. These they gave to the small planters of the eastern Caribbean along with financial assistance, and the sugar revolution was under way. Tobacco growers became sugar planters, small tobacco plots were consolidated into large sugar plantations, and the demand for black labor soared. The Dutch met that demand with their slave ships, which brought African pathogens as well as Africans, both of which had heretofore only trickled into the Caribbean and now began to pour in.

In addition to yellow fever and falciparum malaria came the filarial worm, also carried by mosquitoes, to create the infamous disease "Barbados leg." It seems to have broken out on that island first, but soon was widespread throughout much of the Caribbean, although always strangely absent in Jamaica. The Africans also carried with them the misnamed hookworm *Necator americanus,* which found the West Indian sugarcane fields an especially favorable habitat. That dracunculiasis was rife among them could be noted as Guinea worms poked their heads out of slave legs to be patiently wound on a stick by the victim until all of the worm was removed. In addition, yaws blossomed on the bodies of slave youngsters, leprosy assaulted the adults, and onchocerciasis invaded the eyes of both. Indeed, even smallpox began arriving from African rather than European reservoirs, and the Caribbean was transformed practically overnight into an extension of an African, as opposed to a European, disease environment.

Paradoxically, the increasing dangers of such an environment paralleled the increasing value of the West Indian Islands in the eyes of the capitals of Europe. As colonies that sustained a slave trade, purchased products from mother countries, and supplied sugar for processing to those countries, the islands fit marvelously into – indeed helped to shape – the prevailing mercantilist philosophy, a part of which prescribed grabbing as many more islands as possible from European competitors.

The political consequence was that Europe's wars of the seventeenth and eighteenth centuries were fought out in the islands as well as on the continent. The epidemiological consequence was the slaughter of tens of thousands of nonimmune soldiers and sailors sent to do that fighting who died, not from battle, but from yellow fever and malaria. During the years 1793–6, for example, the British lost 80,000 troops

in the West Indies, the bulk of them to this pair of tropical killers. Much of that mortality had been sustained during the British invasion of San Domingue, where the slaves were revolting against French masters. Because of their ability to resist the disease, the ex-slaves had a strong ally in yellow fever, as the disease counterattacked the British with deadly effect.

Next came the French attempt to retake San Domingue. Briefly they met with success. Then they met with yellow fever and within 10 months of landing had lost some 40,000 men including 1,500 officers and their commander, Napoleon's brother-in-law.

Yellow fever flourished in the Caribbean wherever the virus discovered a sufficient number of nonimmune persons to host it, for the *A. aegypti* is a domesticated mosquito that lives close to and feeds on humans and breeds in rain-filled gouges humans have made in the earth or in any of the discarded accoutrements of civilization that hold water. Anopheline mosquitoes that carry malaria, however, are not so tied to humankind and consequently are not spread evenly across the Caribbean. Thus August Hirsch (1883–6) identified Cuba, Jamaica, Santo Domingo, Guadeloupe, Dominica, Martinique, St. Lucia, Grenada, Trinidad, and Tobago as the places where the disease was most prevalent. He termed malaria "rare" in the Bahamas, Antigua, St. Vincent, and Barbados, where today we know that for a variety of reasons anopheline mosquitoes had difficulty in breeding successfully.

It should be stressed that, although yellow fever and malaria were the chief killers of whites in the West Indies, the victims were generally newcomers. Old residents, by contrast, usually suffered from yellow fever while quite young, at an age when the malady is relatively gentle with its victims, and in the process earned a lifetime of immunity against another visitation. Similarly, resistance to malaria was gained by repeated bouts with the disease although this was not so perfect an immunity as that acquired against yellow fever.

Blacks, on the other hand, although remarkably resistant to these diseases, suffered greatly from other illnesses that generally bypassed whites, and their resulting experience with disease was so different from that of whites that physicians were moved to write whole books on the subject. They identified one of the most fearful diseases of slave infants as the "9-day fits," which today would be diagnosed as neonatal tetanus triggered by an infected umbilical stump. Another example of a presumed black disease came from the same source. Plantations were

littered with the droppings of horses and oxen containing tetanus spores, so the almost always fatal illness struck hard at slaves with open wounds resulting from frequent accidents with machinery, and because almost all went barefoot.

Poor nutrition, however, was probably the biggest destroyer of slave life, either directly because of nutritional diseases or indirectly because it left slaves less able to combat other ailments. Their basic diets of very little salted fish (jerked beef in Cuba) and lots of manioc and other root crops, plantains, rice, and corn produced symptoms of frank beriberi (related to thiamine deficiency) and pellagra (related to niacin deficiency) among slaves all across the Caribbean. Of the two, beriberi had the greatest demographic impact because thiamine deficiency is passed along from mother to infant in her milk, and infantile beriberi has proved historically to be almost invariably fatal.

Another major disease of the slave young was protein–energy malnutrition (PEM) brought on by a lack of whole protein in the diet. Slave infants were nursed by their mothers for about 3 years and were thus safe from the disease, which struck after they were weaned to a diet of pap almost totally devoid of good-quality protein. Some developed marasmus, a symptomatic pole of PEM in which the child simply wastes away. More often, however, they developed the swollen bellies of kwashiorkor, which are evident in physicians' descriptions of slave children. The prevalence of PEM in Barbados can be assumed from the conclusions of an investigation of the teeth of excavated slave skeletons, which revealed considerable nutritional stress at the time of weaning (Handler and Corruccini 1986).

The term *dropsy* was very frequently recorded as the cause of slave deaths, and doubtless when a child died of kwashiorkor, this was called dropsy. Similarly, the fluid accumulations of wet beriberi would have been called dropsy. Other dropsy cases were probably the work of hypertensive heart disease. Apparently in the largely salt-free environment of sub-Saharan Africa, black bodies had developed an ability to retain the mineral that is crucial to life itself (Wilson 1986). In the West Indies, however, slaves received an abundance of the mineral in their salted fish or beef, and in addition, were issued a great deal more as a condiment. For a people with the knack for retaining salt, this must have provoked much fluid accumulation and frequently proved deadly.

Dry beriberi's symptoms are remarkably similar to those of a mysterious illness of the slaves called the *mal d'estomac* in some islands and *hatiweri* or *cachexia Africana* in others. Physicians first thought that the lack of energy, breathlessness, and nerve problems including an unsteady, high-stepping gait – the symptom constellation of *mal d'estomac* – were caused by dirt eating; later investigators have suspected that the cause was hookworm disease. But because, as will be discussed shortly, blacks of West African origin are very resistant to the ravages of hookworm infection, dry beriberi remains the best explanation for this particular ailment.

Another disease that remained a mystery at least until recently, and which struck white troops as well as slaves, was the "dry belly ache." But research by Jerome Handler, Arthur Aufderheide, and others (1986) has made it clear that this ailment was actually lead poisoning; the lead being ingested in non-aged rum made with distilling equipment containing the metal and from molasses and sugar whose production also involved the leaching of lead from some of the equipment.

The successful slave revolution in San Domingo brought ruin to one major sugar-producing area of the Caribbean, whereas the abolition of the British slave trade in 1807, and then of British slavery in 1833, severely damaged most other sugar islands. This left the field to Cuba, which developed a flourishing contraband slave trade, and became the new focus of such African diseases as filariasis, leprosy, and yaws while at the same time achieving the unhappy distinction of becoming the nineteenth-century yellow fever capital of the hemisphere.

Other diseases also became prevalent during this period. Typhoid, for example, was an increasingly serious health problem in the West Indies throughout the century, although in part this trend doubtless reflects nothing more than better diagnosis as physicians learned to untangle typhus and typhoid from each other and both from the whole bundle of fevers that bedeviled the region. Because the fouled water supplies that brought typhoid were serious problems everywhere, it was predictable that the islands would pay a steep price for this condition when the pandemics of Asiatic cholera reached them. This first occurred in Cuba where, during the years 1833–6, the disease wiped out at least 8 percent of the slave population.

The 1850s, however, were the real cholera years for the Caribbean during which as many as 34,000 slaves in Cuba perished, between 40,000 and 50,000 individuals died in Jamaica, another 20,000 to 25,000 lives were lost in Barbados, and at least 26,000 succumbed in Puerto Rico. Cholera returned

a final time to Cuba in 1867, where it claimed a few thousand more lives before leaving the region forever. In its wake, however, it left a far greater percentage of black than white victims. Because there is no racial predisposition to cholera, the best explanation for this lies in the impoverished circumstances of blacks on the one hand and lesions of nutrition that deprived them of gastric acid to fight cholera vibrios on the other (Kiple 1985).

The fact that tuberculosis waited until the nineteenth century to fall on blacks with the fury that it did is less easy to explain. Tuberculosis was not one of the Euroasian diseases that blacks had experienced in Africa, and they proved to be extraordinarily susceptible to it when exposed. That such exposure was so long delayed suggests that the plantation probably served as a kind of quarantining device. After slavery, however, the disease exploded among them as many impoverished blacks crowded into the cities. In Havana, for example, the disease generated mortality rates approaching 1,000 per 100,000 population.

Nonetheless, although tuberculosis continued to rage, it was during the last half of the nineteenth century that much of the region began to experience a significant decline in mortality. Certainly some of the decline was due to nothing more than the end of slavery. But empirical observation also played a considerable role. Cholera had drawn attention to the dangers of bad water, and the last decades of the century witnessed important efforts to improve water supplies, with a resulting decrease in the prevalence of typhoid and dysentery. Empirical observation had also established once and for all the efficacy of quinine against malaria, and its regular use also brought important mortality reductions.

Cuba, however, was largely exempted from the mortality decline enjoyed elsewhere during this period. No sooner had the contraband slave trade come to an end, capping the pipeline of disease from Africa, and no sooner had cholera receded than the Ten Years' War (1868–78) erupted. Soldiers arrived from Spain to extinguish the rebellion only to introduce smallpox and be extinguished themselves by that disease in tandem with yellow fever and malaria. A few years later, this pattern was repeated as Spain once more sent soldiers to Cuba to quell the rebellion that began in 1895. In both instances, yellow fever and malaria claimed far more lives than did bullets, with war and disease slashing Cuba's population from about 1.8 million in 1895 to 1.5 million in 1899 – fully a 15 percent reduction in less than 5 years.

The Twentieth Century

The twentieth century has been a time of a tremendous mortality decline in the Caribbean as it has in much of the rest of the underdeveloped world. Improved nutrition, great strides in public health and sanitation, and the increasing sophistication of modern medicine have all played significant roles.

Yellow fever's Caribbean career came to a close during the occupation of Cuba by the United States when the theory of Cuban physician Carlos Finlay that the disease was mosquito-borne was proved correct by a Yellow Fever Commission headed by Walter Reed. Ensuing mosquito control measures were successful in throttling the long-dreaded malady in Cuba, and, armed with this new epidemiological understanding of the disease, William Gorgas was able to eliminate yellow fever in Panama where the canal was under construction. The disease flared up one last time in Cuba in 1905 but, after that, retreated from the whole of the Caribbean.

The public health activities of the U.S. Army also brought sweeping sanitary reforms to Cuba, which in Havana resulted in a decrease of "close to 30 percent in the crude death rate in that city by 1902" (Diaz-Briquets 1983). Similarly the annexation of Puerto Rico, and the occupation of the Dominican Republic and Haiti by the United States, although deplorable, nonetheless brought important health benefits to these countries in the form of cleaner water supplies, adequate sewage disposal systems, mosquito control, and medical treatment.

Just at the time when one African disease, yellow fever, was conquered, however, another African malady was revealed. In Puerto Rico, the Puerto Rico Anemia Commission discovered a hookworm problem estimated to be causing one third of all deaths on the island. War was declared on this disease, as well as on malaria and yaws, in much of the Caribbean by the Rockefeller Sanitary Commission and later by the Rockefeller International Health Board. The Rockefeller physicians in the West Indies and in the southern United States discovered that black people were resistant to hookworm disease although not to hookworm infection, whereas pockets of poor whites and Asians in the West Indies living side by side with blacks suffered severely from the disease.

Tuberculosis receded among Caribbean blacks as mysteriously as it had appeared, and it had ceased to be much of a health problem long before the end of World War II when medicine finally got its "magic bullet" against the malady. Yet the greatest gains in reduced mortality have taken place among the very young. Infant mortality rates, which were as high as

303 per 1,000 live births in Barbados earlier in the century, have plummeted in most places to rates of 20 per 1,000 or below. Exceptions are the Dominican Republic and especially Haiti, where age-old problems of neonatal tetanus, malaria, yaws, and other African diseases still linger.

Less satisfactory have been improvements in the nutrition of the young, and it is quite possible that fully half the deaths that have taken place among the age group 1 to 4 years in Hispaniola and Jamaica in recent years are the result of PEM – the same disease that proved so devastating to the slave young of yesterday. Other problems or potential problems left over from the disease ecology of that period also remain. Yellow fever is still very much alive in its jungle form in the treetops of South America and, with the present lax mosquito control measures, could easily return to the Caribbean as it in fact attempted to do in Trinidad during 1954. Indeed the ever increasing number of dengue epidemics that have taken place of late in the region show just how vulnerable the West Indies are to yellow fever, because the same mosquito spreads both diseases.

Similarly the pockets of falciparum malaria that still exist may also suddenly expand, as happened in Cuba during the 1920s when tens of thousands of Haitian and Jamaican laborers entered the country bringing the illnesses with them. Haiti, in particular, remains a focus of the infection, as an epidemic there in 1963 so vividly demonstrated by assaulting some 75,000 individuals.

Filariasis has not been completely eradicated. In fact, the people of Puerto Rico were found to have a surprisingly high rate of infection during a survey in the 1960s. In Barbados, however, where the disease was once notorious, the malady (or at least its most notable symptoms) has become rare. Schistosomiasis may still be found in some of the Lesser Antilles, and small endemic foci have been located in the Dominican Republic as well, and intestinal parasites remain widespread across the Caribbean region. In addition, another new, seemingly African disease – AIDS – has surfaced in Haiti, although the extent to which this threatens the rest of the Caribbean remains to be seen.

One of the greatest assaults of late mounted on remaining health problems in the region has taken place in Cuba, where the government of Fidel Castro has made improved health a top priority. The extension of health services to the countryside, mass vaccination campaigns, and important advances in sanitation have allowed the Cuban people to attain a life expectancy considerably more favor-able than that enjoyed by those in most other developing nations.

Yet it is ironic that today the greatest threat to the health of West Indian people is their own relatively good health. With the tremendous strides made in reducing infant and child mortality, populations have mushroomed in alarming fashion. In the past, much of the excess population of the region migrated to Great Britain or to the United States; that safety valve has been shut down by the recent restrictions both of these countries have placed on immigration from the islands. And they are islands, which by definition means a limited area of land. If, as is the case in so many of them, land is put into sugar instead of foodstuffs, then the latter must be imported. Thus, swelling populations can only threaten the level of their nutrition while placing perhaps impossible pressures on the ability of governments to continue to deliver essential medical and sanitary services.

VII.7
Disease Ecologies of Europe

We can consider the ecology of disease to be the sum total of all the influences on pathogens and their hosts and, because of the interdependence of the two for disease expression, the internal structures and systems of both that bear upon a disease question. Thus we are clearly considering a structure of relations whose complexity surpasses all comprehension. Such may also be said of a single disease. No one has yet fully defined all that constitutes the expression of even one disease, and such an explanation would be its ecology. To describe the disease ecology of Europe is a task at first so daunting as to admit no possibility. Still, there are a few aspects of the ecology of disease in Europe that can be described, if without claim to completeness or ultimate value, at least with an eye to creating a target for more detailed studies and criticism.

With such cautions in mind, I should like to offer a few general comments on human disease and its expression, and then set forth a very limited number of aspects of the totality of my subject, which I feel can be discussed. For most of the sojourn of humankind on Earth, we have only skeletal remains upon which to build any concept of disease in the past. Even after the advent of agriculture and the earliest civilizations, we have little upon which to develop a coherent view. General trends are perceptible in classical times, and very sketchy numbers can be offered for population in the late medieval period. Modern times have, of course, brought masses of statistics, but these as often confuse as enlighten. Still, it is possible, at least, to discern some of the impact of disease upon demography and to infer some aspects of the influences that played upon certain diseases. Because it is so difficult to identify diseases in the past, I confine myself largely to the specific diseases of plague, leprosy, tuberculosis, and smallpox. Otherwise, the influence of epidemic disease of unknown type will be the other main consideration, along with some presumed diseases of childhood. There is at least some reason to feel that the four specific diseases may be identified as factors in human demography in the past, as can epidemic and endemic diseases whose exact nature is unidentifiable.

All human populations share some common features, and European populations carry some particular features, which can help us at least conjecture about factors influencing the expression of disease. For example, about 105 males are born per 100 females (Russell 1977). Although malnutrition can cause disease, major population losses do not necessarily reflect malnourishment (Wilson 1957; Wrigley 1962; Rotberg and Rabb 1983). Certainly the diseases of postindustrial society are those of an abundance of food. Despite the fascination since ancient times with food as a cause, predisposing factor, and therapeutic agent in disease, very little is actually known about the relationship between food and health beyond the effects of some vitamin-deficient states, and full-blown protein–energy malnutrition.

The ability of human populations to replenish themselves is limited. A birthrate above 50 per 1,000 population per year is truly exceptional, and above 30 is quite uncommon (Wrigley 1962). There are well-known age and sex predilections for a variety of diseases, but they are as etiologically obscure as they are epidemiologically well documented (Wilson 1957). For example, although infants are extremely susceptible to tuberculosis, children between the ages of 5 and 15 exhibit a relative immunity to the disease. Then a sex predilection occurs, with women much more commonly the victims from about 25 years up to around age 45, at which time men are the predominant victims of the disease until late in life (Wilson 1957). These observations are based on data gathered mainly in the British Isles during the nineteenth century, but no one knows the extent to which they represent the result of metabolic versus environmental factors in pathogen and host. It is also generally

felt that societies tended to have more males than females among adults because more women than men die between the ages of 25 and 45 (Russell 1977). This generalization, however, is based to a very great extent on the perceived epidemiology of tuberculosis, a disease neither universal nor of equal importance in all societies.

In Europe, several generalizations are usually accepted regarding human populations. Since classical times until the Industrial Revolution, cities have harbored more women than men. Cities have also been unable to replenish their own populations, at least from medieval times until the nineteenth century, because of the unfavorable disease climate of urban life (McNeill 1976; Russell 1977). Before the nineteenth century, the vast majority of humans in Europe lived in villages or on farms, with only a very small fraction residing in cities (Guillaume and Poussou 1970; Russell 1977). The total population of preindustrial societies contained at least one-third children, of whom less than half lived to adulthood from medieval until modern times (Flinn 1985).

Humans also affect their environment and in turn affect their own disease ecology. Practices we take for granted, such as the domestication of animals, change another species' disease environment, and the interaction of domesticated animals with humans has often led to human disease (Lovell 1957). An example of a disease that became of at least minor importance among humans primarily in this way is *brucellosis,* usually introduced to humans through goats. During the Crimean War, for example, Malta became an endemic area for brucellosis; in 1906 the means of human infection was described (Alausa 1983).

Disease in turn may alter the character of human populations. After major epidemics of infectious disease associated with high mortality, a period of markedly reduced mortality generally begins. It is felt that such epidemics "weed out," at least in some cases, the weaker elements in a population, leaving a healthier one behind (Wrigley 1962). On the other hand, diseases such as plague and some rickettsial infections often kill the healthy.

If we limit our generalizations about humans in Europe, our knowledge of their pathogens is even sketchier. The whole question of virulence among various bacteria is extremely complicated, and, since it is not well understood in modern infections and since organisms can mutate, virulence can be assessed only by effect. The effect of an organism in turn is related to host, pathogen, and environment, so that any comments about organisms in the past is

unrealistic. Host–parasite relations vary from nonspecific, in which multiple species support the organism, to those in which the organism is dependent upon a single host. In the second case, it is felt that the organism has lost the ability to synthesize its own essential nutrients to an extreme degree (Lovell 1957). Leprosy is an example of an organism that cannot be cultured in an ordinary fashion and is highly host dependent (and even specific to certain cells in the host). This characteristic suggests that the susceptible tissues contain some chemical or provide some enzymatic function (or possibly something entirely different) that cannot be provided in culture media (Wilson 1957). If we consider virulence to be the property that permits an organism to cause death or damage to the body parts invaded, we are left with a multitude of factors to consider. An increase in virulence toward one species may decrease that strain's virulence to others (Wilson 1957), indicating the intimacy of the relationship to a given host. The same strain of *Mycobacterium tuberculosis* is generally much more virulent when entering the host via the respiratory route as opposed to the gastrointestinal tract, but with bovine tuberculosis the situation is the opposite. Such information, however, offers little practical guidance in the history of diseases, for the specificity of an organism toward humans (e.g., organisms causing leprosy, meningococcal meningitis, typhoid fever, and smallpox) only tells us that if the disease is present, so are humans, which is rarely in question.

In general, organisms are tissue specific. *Clostridium tetani,* for example, is harmless to intact skin, but can be deadly when in contact with abraided or necrotic tissue (Wilson 1957). The longer an organism is in contact with the environment and outside a host, the likelier it will be damaged. Organisms that affect the gastrointestinal tract, such as *Salmonella typhi,* are able to withstand environmental pressures longer than those not waterborne or foodborne (as a generalization) (Wilson 1957). Insect vectors may result in significant effects on the expression of disease. Arthropod vectors are more important, generally, in parasitic infections than in bacterial ones (Wilson 1957), but plague and typhus are notable exceptions.

Despite the staggering complexity of host–pathogen relationships, the presence of certain diseases can reveal important aspects of human populations. Measles is a human disease only and requires at least a population of some hundred thousands in some contact to remain endemic (Bailey 1954, 1957; Bartlett 1957, 1960; Becker 1979; Smith 1983). Diseases such

as measles and smallpox (another human disease whose pathogen needs a fairly large population to remain active) tend to become childhood diseases (McNeill 1976; Smith 1983). Thus the first observation of measles would tell us when a communicating population of humans reached a certain level. Unfortunately, we do not know when this occurred in Europe because we do not know when measles first appeared. The clinical expression of a given disease can also tell us about genetic factors in a population. Susceptibility to leprosy, in both its polar forms (although more in tuberculoid leprosy), is in part genetically mediated (Smith 1979; Eden et al. 1980; Keyu et al. 1985). When measles and TB have fulminant courses with high and dramatic mortality, they are present in a previously unexposed population (Wilson 1957; McNeill 1976). The same may have been the case when syphilis appeared in Europe at the end of the fifteenth century, but this is hardly an undisputed subject. It is also becoming apparent that some resistance to particular diseases reflects prior exposure to others that confer cross-immunity (Ell 1984a).

Characteristics of childhood diseases, especially measles, have become the subject of mathematical modeling. Birthrate has been shown to be an important factor in determining whether or not a disease like measles can remain endemic and in predicting interepidemic periods (Bailey 1957; Bartlett 1957; Becker 1979). Unfortunately, such models, although of great theoretical and some practical interest, cannot explain much of what occurs in a given epidemic. They are based on populations of constant size and without immigrants – factors from which deviation has been crucial in many other epidemics (Siegried 1960; Biraben 1975). This mathematical modeling is of very limited value in considering the disease ecology of Europe in the past. Too many of the factors are unknown (population size, birthrate), and the effect of social customs has not proved very susceptible to quantification. Further, in this chapter we perceive childhood mortality as a nearly constant background factor for much of the time period discussed, with major epidemics, which have proved resistant to neat equations, the more influential factors.

In the following pages, I try to discern, within what is known about the demographic history of Europe, the effects of disease on that history. Partly because war has been an invariable aspect of human behavior, and partly because it reflects so much else about a society, I focus often on military strategy, on the composition and size of armies, as well as on the direct effects of disease upon armies. The time frame considered extends from the hunter-gatherers of prehistoric

Europe to late twentieth-century society. I have very little to say about medicine, because I do not believe it has had a significant effect on the ecology of disease except in very limited circumstances.

Geographically, I define "Europe" as extending as far east as western Poland down through Greece, as far north as Scandinavia (but excluding Iceland), as far west as the British Isles, France, and Spain, and as far south as Greece, Italy, and Malta.

Prehistoric Europe

Hunting-Gathering Societies and the Neolithic Revolution

It is often observed that hunter-gatherers are healthier than their supposedly more "civilized" contemporaries. This anthropological observation of the still-extant human groupings that practice hunting-gathering has been extrapolated into the past to suggest that, because of a meat-rich diet, very low population density, natural birth control through lactation, and a variety of other factors, hunter-gatherers innately enjoyed more healthful circumstances than did other preindustrial societies. There is, however, little evidence of any kind to support such claims. Skeletal remains have been used to claim a life expectancy similar to that of the rural poor of the nineteenth century (Birdsell 1957; McNeill 1976). (What is less obvious is that skeletal remains from the very distant past will tend to support this hypothesis because the skeletons of children and infants neither weather as well nor were often buried as carefully as those of adults.) Although it is true that hunter-gatherer groups do not have enough population to support measles, they do have diseases exquisitely adapted to their circumstances. An example of this phenomenon is *kuru,* a slow virus that afflicts cannibal aborigines. There is no reason to imagine that hunting-gathering peoples of the past did not experience diseases equally consonant with their particular patterns of life. There is no real foundation for the claim that the hunter-gatherers of prehistoric Europe were healthier than people from the Neolithic and pre-Industrial periods. We simply lack any evidence to support a conclusion of any type.

Likewise, we do not know much about the changes in disease ecology occasioned by the development of agriculture and the first numerically more substantial groupings of persons. Observations about remaining societies that mirror Neolithic times, or even about remaining hunting-gathering peoples, are suspect simply because the groups' mere sur-

vival indicates something not generalizable about them. Of the population of Europe before historical times, it would be difficult to frame a convincing argument for a number with an order of magnitude error included.

It is felt that parasitic, especially helminthic infestations are among the oldest of diseases (Smith 1983), but beyond noting the claim, we can do nothing to confirm it. The prehistory of Europe is just that; to impose a demographic and disease structure upon it is folly.

Bronze Age Civilizations

The civilizations of Mycenaean Greece and of Minoan Crete are discoveries of the last century. Before excavations at the site of Troy and among the Greek cities of Homeric renown, along with Crete, the period covered by the Homeric epics was an unknown. Scholarship has translated much, inferred much, and given us striking impressions of these lost societies. From the point of view of disease, we have little to offer. Mycenaean civilization seems to have fallen to outside invaders. There is no evidence to support disease as a major factor in the decline of either mainland Greek or Minoan civilization. The latter may plausibly be linked to a natural disaster. The disease history of these fascinating cultures remains beyond our grasp.

Classical Antiquity

The Golden Age

The time limits of classical antiquity are as protean as all artificial periodization. For the purposes of this discussion, I shall concentrate on Greece from the sixth century B.C. through the Western Roman world into the second century A.D. Overall, the disease picture here suggests societies with significant overpopulation expanding into new territories and experiencing few major epidemics, until a point was reached when exposure to infectious epidemic disease began a process of demographic decline and cultural retraction.

If one considers classical Greece, the former part of this process can be seen in full swing. The settlement of Magna Graecia by colonists from the Greek mainland speaks clearly of population pressure. The Greeks also colonized the coast of what is now Turkey. The Italian and Sicilian settlements became major sources of grain for mainland Greece, and the need for reliable grain sources has been linked plausibly to the Athenian military debacle in Sicily during the Peloponnesian War (Guillaume and Poussou 1970).

The Peloponnesian War also saw the famous Plague of Athens. In Thucydides' description of this plague, there is no sense of epidemic disease on this scale being any part of ordinary Greek life. To that author, the epidemic was one of the main factors in Athens' ultimate loss because it bore away Pericles whom Thucydides clearly felt could have led his people to victory (Thucydides 1958).

The exploits of Alexander the Great resulted in the Hellenization of parts of Asia and Africa. The army of Alexander was able to campaign for 12 years in Asia without suffering a significant loss to disease. Fresh recruits from Macedonia and Greece arrived mainly to replace those retiring or lost in battle. The whole concept of a campaign like that of Alexander, which lacked temporal and spatial goals, would be either unthinkable or pure folly in an environment similar to that found in Renaissance Europe wherein plague could easily defeat both opposing armies. The size of the armies of the Persian king, Darius III, although beyond the scope of the ecology of Europe, also bespeaks a very heavily populated realm (Bosworth 1988).

Although no social custom so complex and deeply rooted in Greek society as the exposure of infants (Veyne 1987) can admit an easy explanation, the practice still argues for significant population pressure. In response to most severe epidemics, the birthrate rises, probably partly consciously to repopulate, but also because many epidemics remove weaker elements from the population (Wrigley 1962; Neraudau 1984). The deliberate abandonment of infants in places where their survival would depend on some other adult's desire for a child being strong enough to rescue them presents a picture of children as an apparently significant economic liability. This is rarely the perception when epidemic disease makes day-to-day life totally unpredictable and when an outbreak can destroy entire family lines. The Greek myths are filled with tales that bear on the abandonment of infants, of which the story of Oedipus is but the most famous. Many others involve the abandonment of children by the poor.

There is reason to believe that children were an economic liability in fact as well as in perception. A worker in Periclean Athens could earn enough to live comfortably, if he did not marry. Once married, he could still afford food and shelter. But each child added significant strain to that ability (Austin and Vidal-Naquet 1977; Finley 1981). The mindset of past societies cannot reliably be reconstructed, but it seems reasonable to imagine that persons exposing children had little reason to suppose that the family

was at significant risk of being decimated by disease. Classical Greece seems to offer the picture of a society at the limits of its population potential, but which perceived and experienced minimal risk of epidemic disease altering the tenor of life.

The Hellenistic Age shows little difference in this regard. Greek became the *lingua franca* of much of the Mediterranean world, and Alexandria, an Egyptian city founded by Alexander, became one of the intellectual (and population) centers of the world. Greek influence is clearly to be found in sculpture native to India during this period, a measure of how extensive Greek expansion and culture became.

It is said that as he spent his last months of life in Babylon, Alexander the Great considered the conquest of Rome, a state just then beginning to become prominent in Mediterranean affairs (Bosworth 1988). Alexander died short of his thirty-third birthday without having affected Rome other than through the latter culture's admiration of him. Rome then began perhaps the most impressive expansion in all of world history. In order to gain some insight into the disease ecology of the Roman world, it is instructive to consider the Second Punic War, which established Rome as the most important power in the western Mediterranean. This war, fought at the end of the third century B.C. (ending in 202 B.C.), gives glimpses of both a very highly populated Italy and a military strategy that excluded any significant impact secondary to epidemic disease.

Hannibal invaded Italy (with his elephants, as every Western schoolchild used to know), commanding an army of around 40,000 mercenaries. These men had marched through Spain, across southern France (for convenience, I refer to places by their modern names, insofar as is possible), over the Alps and into northern Italy. According to contemporary sources, Rome could have put an army in the field 20 times the size of that of Hannibal. Rome could call upon a reserve of 700,000 foot and 70,000 cavalry (figures sometimes adjusted to 580,000 and around 60,000) (Caven 1980). Rome replied more cautiously but, using smaller armies, lost 15,000 and 5,000 men in the first two major encounters with Hannibal. At Cannae, a larger Roman force left around 25,000 men on the field and a similar number prisoner (Caven 1980). Yet Rome refused to ransom the prisoners, even though Hannibal offered. (It may have also been good strategy to keep Hannibal's soldiers busy guarding prisoners.)

The Roman reserve of soldiers, the losses sustained, and the disdain for ransoming prisoners in one of the darkest hours of Republican Roman his-

tory are impressive. No army of medieval or Renaissance Europe could have approached the size of the army Rome could have mustered from its Italian population alone. Losses such as those sustained at Trasimeno and Cannae would likewise have left even many early modern states without the manpower even to consider continuing a war. The Roman Senate judged that a similar number of men were not worth ransoming to help fend off an incredibly skilled opponent; rather, the image of what a Roman soldier should be was more important.

If the early course of the war argues for abundant population and little risk or heed of epidemic disease, the remainder of the conflict shows the same features. Hannibal was able to campaign in Italy for nearly 2 decades, with only minimal reinforcements. He was never defeated on Italian soil. When Rome finally produced a general capable of opposing the Carthaginian commander, the strategy employed again indicates the same picture with regard to epidemic disease.

Scipio Africanus the Younger took his army to Africa to threaten Carthage, reasoning that Hannibal would be obliged to return and defend his homeland. This he did, and Scipio defeated the Carthaginian master at the battle of Zama in 202 B.C. Once again, in moving the most important Roman army to Africa as a strategic ploy, we see no fear of an epidemic destroying Rome's greatest chance to end the war. Indeed, the relative ease with which armies traversed great distances during this war argues for a relatively uniform environment in terms of disease and one that had little to frighten an adult. Hannibal's army operated on two continents, yet never experienced significant loss to disease. In 1630, the Venetian army met that of the Hapsburgs at Mantua. At a fraction of the distance from home traversed by the armies of the Second Punic War, plague caused so much mortality that neither the victorious Hapsburgs nor the beaten Venetians could even reorganize their forces (Lane 1973).

The Mediterranean world in the centuries before the first emperor of Rome appears to have been an environment abundantly populated, but relatively free of at least major epidemic disease. Of the fate of children, we know much less. The Romans continued the practice of exposure or abandonment of infants. The head of a Roman household decided on the fate of any infant born into that household. Once again, there are complex cultural phenomena at work, but children were definitely an expendable commodity (Veyne 1987).

All of this speaks of the great classical civilization

being largely spared devastating epidemics of infectious disease. Of the disease background we know little. The writings of the Hippocratic corpus, in particular, describe many illnesses (it is felt by some that brucellosis is described therein), but putting modern names to them is another matter. No one has successfully identified the disease that caused the Plague of Athens. Background causes of morbidity and mortality are simply beyond reach. At a time when fever was considered a disease and not a symptom or sign, there is no realistic way to translate most diseases from Ancient Greek or Latin into a modern equivalent.

Some generalizations seem reasonable, nonetheless. There was probably a surplus of men among the adult population because more women died in the 25- to 45-year age group. Much of this is probably attributable to death associated with childbirth. If this period had the attributes common to most preindustrial societies, about 30 to 40 percent of the total population was composed of children. What is singularly lacking is a sense of what the probability of a child at birth growing to adulthood was. This is both the most important factor in determining life expectancy at birth (much of the spectacular change in this parameter in modern times is the result of decreasing childhood mortality).

The Tide Begins to Turn

As we have seen, military strategy in the early Roman Empire again depended upon abundant manpower and low risk of epidemics. A controversial but compelling reassessment of Roman strategy over time has divided the military strategy of the empire into three phases (Luttwak 1976): First was the use of client or buffer states to separate Rome from potential enemies. These states, such as those along the Asian border of the empire, could be paid or otherwise induced to mediate or simply physically separate Rome from potential enemies. If attacked, such states also buffered the conflict to give Rome the time necessary to concentrate forces and plan a campaign against the opponent. Such a strategy could operate only when the empire could confront any enemy on the battlefield with an army that might be gathered from many regions and transported a long distance, while the buffer state was itself strong and populous enough to hold off the enemy at least for enough time for the Romans to make their military reply.

The second strategy was that of fixed frontiers. Perhaps here is the first inkling that the population situation was not so favorable. Even though this

strategy had in position soldiers in the hundreds of thousands, the soldiers over time also became colonists and were defending their own land. Hadrian's Wall across England is an example of this phase of strategy. Its sophistication and effectiveness speak for themselves. It was perhaps no longer so safe to move armies to strange countries. Recall that Marcus Aurelius died near Vienna while on a frontier campaign. In fact, the "plague" epidemic of the end of the second century has been seen by Robert Lopez (1967) as perhaps the most important of the myriad of factors in the subsequent decline of the empire. In any case, after the second century, the empire was obliged to develop new and increasingly risky military strategies to maintain itself.

A.D. 200–1000: The West Reaches Its Nadir

The Barbarians, c. A.D. 200–600

When it was no longer feasible for Rome to defend the frontiers from the barbarians who lurked upon the eastern side of the Rhine–Danube frontier, the empire enlisted them to defend what they coveted. Given land in the empire, the barbarians were partially Romanized and, in return for their land, were asked to defend the frontier. At this point, the third phase of the tripartite strategy comes into play. Because armies were not available in sufficient size to guarantee the immense frontier of the empire, and because the colonized barbarians themselves might decide to sack a nearby town or two, a "defense in depth" approach was developed. Strongly fortified positions were built, which could be supplied and manned to hold out for a long time in the rear of an enemy encroachment. These fortifications gave the Romans a foothold in areas that could only too easily be overrun. These strongholds could shelter and defend the frontier population until adequate military strength could be massed to counter the incursion. A strategy of this type clearly depends upon a much smaller population. For a stronghold to house more than a token population, the frontier population had to be small in the first place. This is further attested by the fact that the forts were victualed for long campaigns. Generally such fortifications were set upon natural defensive positions, minimizing the manpower necessary to defend them.

Even if this picture of the strategy of the empire is incorrect, there are too many other signs of population decline and of the increasing importance of local environments to deny convincingly that the demographic and disease picture had not changed immensely. The empire itself, which had dominated the

Mediterranean world, divided itself up into two main units, with a "second Rome" emerging in the form of Constantinople. By the fourth century it had become two major territories, each usually with its own emperor. No longer could armies feasibly be moved around so effortlessly as in the Punic Wars. The Greek and Latin empires drifted apart. The Latin Empire was increasingly the prey of barbarians. Peoples on the borders of the empire in the West, whether under population pressure of their own or because of pressure from more remote peoples, invaded and often settled in the lands that had comprised the empire. Often, they tried to revive Roman government and customs, as with the Ostrogoths, only to fall prey to more aggressive and less civilized peoples such as the Lombards. Matters were further complicated by the advent of Christianity, as if the empire was not experiencing enough travails.

The Christian religion arose (and was seen so to arise by divine plan by Augustine) in the empire. Its appeal was undeniably greatest to people who found the world they lived in unsatisfactory. Again so complex a subject as the change in the overall concept of the cosmos cannot be related to something as simple as disease, but there is little question that Christianity denigrated the world, as human beings lived in it, in favor of a life that would come after death. St. Augustine died while the Vandals besieged the city of which he was bishop. It would be an incredible oversimplification to attribute the fact that the City of God could not exist in this world, to the world Augustine lived in, but the religions of classical antiquity with few exceptions (and those exceptions became the rule as the situation of the empire worsened) saw this life as real life and what came after as a shadow thereof.

What diseases weakened the empire? Did the Romans come in contact with a distant disease pool, as has been suggested by William McNeill (1976)? We have essentially no hope of knowing the details. Nonetheless, epidemic diseases played an increasing role in the fate of the empire. In the sixth century, Justinian made a supreme effort to reunite the two halves of the empire. He might have succeeded had not a monstrous epidemic (in this case identifiable as plague) wreaked such mortality that the prospect was not entertained again for centuries.

The barbarians who occupied Roman lands first were almost invariably displaced by others who obviously had the manpower and freedom from epidemics to oust their rivals, who in their turn seem to have suffered much the fate of the Romans them-

selves. The first wave of barbarian invasions ended with western Europe in the hands of barbarian kingdoms and the East still a state with considerable territory and the ability to defend itself.

Cities, the cornerstones of classical antiquity, declined. In a famous example, the inhabitants of one city declined to the point where they lived in the city stadium. Effective government collapsed and local strongmen became the only powers that affected most of the population. In this decline of cities in particular, plague may have had a major role. In general, plague favors city over rural populations. Barbarians came from nonurban civilizations, but typically settled in the Roman cities they conquered. As epidemic followed epidemic (or, in the case of the Plague of Justinian, continued well into the seventh century), succeeding waves of barbarians probably profited from their predecessors' disease experience. Certainly there is reason to believe that the Huns were displaced by another tribe that was experiencing overpopulation.

Aside from the Plague of Justinian, we can identify few of the epidemics that afflicted Europe. The practical knowledge that permitted the Romans to drain swamps to lessen malaria was replaced by superstition and senseless violence. When an epidemic threatened the lives of the children of one of the Frankish kings, he decided that he was being punished by God for taxing the people. He burned the tax rolls, Gregory of Tours (1905) tells us, and his children survived. Again a single incident has much to tell us. First, unlike the societies that exposed children, we see a king terrified that his children will die. Partly this is a difference in religion and culture – barbarian Christian versus classical Greek – but partly there is a background of epidemic diseases that pose terrifying threats. There is also a population on the edge of disaster, low in number, and barely managing to subsist. There are enemies everywhere in the form of humans, diseases, and the supernatural (the term dates from the fourteenth century).

Among the myriad factors that have been argued to have contributed to Rome's fall, the unfavorable epidemic disease picture, as opposed to the threat of the barbarians, is a factor that cannot be discounted.

The Early Middle Ages, c. A.D. 500–1000

However influential the Plague of Justinian was, once its century-long devastation of Europe ended, plague did not recur in western Europe again until 1347. Why this is so is totally obscure. Even if cities and overall population density declined, plague is

primarily a zoonosis and, once established, counts humans as incidental victims. It seems likely that the plague never established an enzootic focus in Europe, or if it did, that focus died out quickly. This pattern has been documented in recent years for Hawaii (Ell 1984a; Tomich et al. 1984). In such places, a few susceptible animal strains allowed the disease an enzootic foothold, but could not sustain it indefinitely.

Despite the temporary absence of plague, the Early Middle Ages saw its share of disease. Chronicles rarely covered more than a few years before noting some outbreak of epidemic disease.

Although charges of abandoning children, suffocating them in their sleep, and so forth, remained part and parcel of medieval lore, children were certainly not subjected to a formal decision on survival at birth. We can read little or nothing into this as regards population dynamics, however, because we are in the world of Christianity and Germanic custom rather than classical practice.

If the barbarians started their careers in a favorable demographic position relative to the Romans, this situation seems to have lasted a very short time, as suggested above. Despite the influx of barbarians into western Europe, cities contracted further, and secondary waves of barbarians overwhelmed earlier arrivals. The best example of this phenomenon is the primacy of the previously obscure Franks, who were the only barbarian tribe that by chance had not converted to what was rapidly perceived as a heretical form of Christianity.

There was certainly little enough to favor population growth. The Roman governmental apparatus was among the most elaborate the world has ever seen and certainly surpassed anything to be seen in Europe at least until the Renaissance (and then on a much smaller scale). When the barbarians tried to take over this system, the results were indeed barbaric. Roads were not repaired. Tax rolls were not updated, so that someone living in a given place might legally be someone long dead and owe the latter's taxes. The newly risen landowners might live a life unencumbered with taxes, while identifiable units from the past were asked for money they could not pay. War, which was the king's truest business and accounted for much of his revenue, contributed little to this already bleak picture. Every spring, the Frankish kings reviewed their armies and went off to war. Since war generally increases epidemic disease, the annual royal endeavor again would be likely to worsen the disease situation.

As if political ineptitude, gratuitous violence, and an unfavorable disease climate were not enough, the experience of the Romans was about to be mimicked by their inheritors. The comparatively settled barbarian kingdoms had by 800 coalesced (largely by force of arms, to be sure) into the Empire of Charlemagne. What the future of this empire left to itself might have been, we will never know. A storm of new invaders fell mercilessly on western Europe, and a near parody of what had gone before occurred.

Evidence from Scandinavia suggests that that region was overpopulated (Musset 1971). Again, for unclear reasons, peoples outside what was left of the Roman Empire seem to have enjoyed a much more favorable disease ecology and significant population growth. In 796, the first Viking raid sacked the monastery at Lindisfarne. A little over two centuries later, a Dane ruled England. Until very recently, the English Book of Common Prayer contained the phrase "God protect us from the fury of the Northmen." William the Conqueror was the descendant of the Viking conquerors of Normandy.

The north was not the only battleground. For more obscure reasons, the Magyars, fierce horsemen from central Europe, began to press the eastern borders of the old Carolingian domains. Their depredations destabilized the precarious hold of the young German monarchy, which finally crushed them at the Battle of Lechfeld in 955.

In the south, Islam entered one of its periodic expansionist phases and threatened Europe. Pirates and small armies made every locale anywhere near the Mediterranean coast unsafe. No single engagement or event ended this incursion, but it ebbed away almost completely by the year 1000.

The wave of barbarian invasions ended differently from the first. Despite high cost, the existing institutions proved capable of driving off or absorbing the invaders. More importantly, the second wave of barbarian invasions was the last. By 1066, Europe was free to develop politically without outside threat. The weak had begun to grow strong again.

The High Middle Ages, 1000–1348

Renewal

A marginal agricultural surplus began to be produced by at least the tenth century, and by the year 1000 the demographic profile of western Europe began to improve dramatically. Whenever the actual improvements in agricultural techniques began is unclear, but so long as Europe was under the siege of the second wave of barbarians, such improvements were unlikely to have a significant effect. Once a

period of relative peace ensued, the small agricultural surplus then available provided the basis for one of the great periods of population growth in European history (Duby 1981). Other factors were also at work, including better government and probably the abatement of a now unidentifiable series of epidemics. In any case, for the next 300 years, western Europe enjoyed very favorable demographic circumstances. Indeed by the year 1300, parts of rural Italy enjoyed population densities that would not be reached again until the nineteenth century (Herlihy 1968). The results of this growth in population were spectacular.

Huge amounts of land were brought under cultivation for the first time. Improvements in plows and crop rotations boosted agricultural yields (White 1962; Duby 1968). Gothic architecture arose at the hands of Suger of St. Denis and cast its magic light over Europe (Duby 1981). Partly because less effort was required for daily life, persons of means turned hungrily toward knowledge and found it on the interface of Christianity and Islam, mainly in Spain and Sicily. The vast storehouse of classical literature, along with the brilliant commentaries and original works of the great minds of Islam, was translated for the Latin world (Southern 1966; Lindberg 1978; Stock 1978). This fueled one of the most exciting intellectual flowerings in Western history. The university, which arose from the cathedral school, dates from the High Middle Ages and remains a foundation of intellectual life.

For the first time, western Europe began to expand against its neighbors. In Urban II's call for the First Crusade, there is an overt reference to an overpopulation of knights, who were creating internal violence. Thus aside from its religious content, the First Crusade was seen as a partial solution to overpopulation. This adventure involved not only knights but also thousands of peasants, who attempted to make their way to the Holy Land, only to perish en route. The Germanic kingdom began to expand to the East, and in Spain the *reconquista* to drive out the Moors was accelerated.

The recovery of classical and Islamic medical writings permits, along with contemporary Western works, the identification of at least a few diseases. Smallpox and chickenpox were separated, and smallpox can occasionally be identified. Like most endemic diseases of humans that require direct contact, smallpox was a major killer of children (Hopkins 1983). Plague made its reappearance only to mark the end of the High Middle Ages, but leprosy was a near obsession in western Europe.

Leprosy in medieval Europe has produced an immense literature. (Probably the most complete and the most extensive bibliography to date is Brody 1974.) In recent years, it has become possible to speak of medieval leprosy as the same disease we know today, at least from around the year 1200 on (arguments summarized in Ell 1986). This statement is based mainly on the results of excavations of skeletal remains from the cemeteries of leprosaria (after the Fourth Lateran Council of 1215, a leprosy patient could not be buried in the same cemetery as a person not suffering from the disease), coupled with the writings of contemporary physicians (Ell 1986, 1989b). In particular, the works of Theodoric of Cervia in the thirteenth century and Guy de Chauliac in the fourteenth show a clear acquaintance with a disease that is readily recognizable as leprosy (usually the lepromatous, or low-immunity type). Many claims made by these authors and dismissed by several generations of more modern commentators can be shown to have a basis in fact, often fact that has only recently been rediscovered (Ell 1984b, 1986, 1989b).

It has been claimed that leprosy was the most common disease in Europe before plague. Unfortunately, there is absolutely no ground for supporting such a claim. Very tentative and speculative work using skeletal remains, and a regression analysis of bone loss in the anterior maxilla as related to duration of lepromatous leprosy, have suggested that part of southern Denmark experienced an incidence of 20 cases per 1,000 population between the years 1250 and 1550 (Ell 1988). It is unrealistic at the current time to extrapolate any aspect of this study to the rest of Europe, and it is well to remember that Scandinavia was probably the highest-incidence area in Europe, and clearly the area in which the disease persisted longest.

If the study cited above is correct, however, the incidence in that region of Denmark was in the highest range classified today (Sansaarico 1981). Not only is it risky to extrapolate the proposed incidence in this part of Denmark to the rest of Europe, but it is well known that the incidence of the disease may vary significantly within a small geographic region. This pale glimpse of the possible prevalence of one disease in a small region is both speculative and isolated, for we have no information at all on other diseases. Tuberculosis, frequently mentioned in discussions of medieval disease history, cannot readily be identified beyond the point of stating that the disease was present in medieval Europe, but at what level and significance we have no idea.

Premonitions of Disaster

Thomas Aquinas, the greatest philosopher of the High Middle Ages and one of the greatest synthesizing authors of all time, when asked who would carry on to completion his reconciliation of classical and Christian sources, is reputed to have replied, on his deathbed, that the work could not be done. Aquinas died on the eve of one of the greatest demographic disasters in the history of Europe, the Plague of 1348, but his remark, apocryphal or not, shows a changing mood in western Europe.

High medieval thought and activity abound with optimism. Intoxicated with new knowledge and increasing material abundance, the prevailing expectations of the future were very high. Around 1300, this mood began to change, and it changed in many areas. Major defaults by important Italian banks, famines reappearing in a population freed from them for two centuries, overcrowded and overworked farmland – all these reverses changed the mood of the fourteenth century to one of anxiety and foreboding. Although Dante would die in 1330, 18 years before plague struck the city in exile from which he composed the greatest work of the Middle Ages, he wrote, "Io non averei creduto che morte tanta n'avesse disfatta" ("I would not have believed death had undone so many" – author's translation of a 1981 edition of Dante). This line might stand as the motto for what was to come. Whatever stance historians may take regarding an economic depression in the fourteenth century, it is clear that Europe was in demographic decline before the plague struck.

The Later Middle Ages

In 1347, the plague began its journey through Europe. When the pandemic ended in 1350, a third of the population of Europe was dead. The population of Europe on the eve of the epidemic has been estimated at 75 million. Although life expectancy at birth was only around 30 years, the very high infant mortality rate artificially lowered this relative to the life expectancy of a person who reached adulthood. Women tended to fare worse, probably as a result of childbirth, although some authors also cite tuberculosis and malaria (Russell 1977). Before the year 1000, no city in medieval Europe had a population exceeding 20,000. In 1340, the largest European cities were Venice, Paris, Florence, and Genoa, each with populations around 100,000. Closely behind were cities such as London, Barcelona, Bologna, Brescia, Ghent, and Cordoba, each of which had populations over 50,000 (Beloch 1937, 1940, 1961; Keyser 1938; Mols 1954–6; Baratier 1961; Herlihy 1967; Acsadi and Nemeskevi 1970; Russell 1971, 1977). It has been suggested that infant mortality was lower in medieval Europe than in early industrial Europe, because there was less crowding and somewhat superior living conditions (Russell 1977). This is a reasonable argument, but no more than that; there is not a shred of evidence to support this.

Plague left Europe, indeed most of the world, in a catastrophic state. In Venice 75 percent of the nobility was dead (Archivio 1348; Ell 1980). Cities routinely lost over 50 percent of their populations (Carpentier 1962a, 1962b). Strange heresies arose, such as the Flagellants, who traveled about, beating themselves unconscious with whips to repent the sins that had brought the epidemic. Medicine, as usual, was powerless to do anything to stop the disease. More damning, the Church failed to offer much real comfort or practical relief. Infant mortality and the loss of elderly adults are most easily absorbed by any society; however, plague tends to affect young adults and children over 5 years old (Ell 1984a, 1985). Yet careful local studies have not always borne out such a pattern in European plague epidemics of this period. The exact epidemiology remains unclear, or perhaps varied from place to place. When plague left infants and the elderly relatively untouched, but decimated the rest, it could destroy the productive and reproductive present and future of whole societies. This phenomenon has been well documented for Orvieto (Carpentier 1962b). Plague did not visit Europe once and then disappear, as did the Plague of Justinian. Rather, Europe became a site of recurrent epidemics, none as ghastly as the first, but even in 1630–1 Venice still lost a third of its population to the disease (Ell 1989a). It is difficult to give a sense of what this level of loss is like. The worst-hit countries in World War II lost 10 percent of their population. Venice lost 7.5 times that percentage in about one-twentieth the time.

No argument can be made for a hypothesis that the epidemic was triggered by population density. As noted, population was already in decline, and plague returned many times after the population density had plummeted. It is also clear that the pattern these epidemics took does not fit the classical rat–flea model of transmission. In fact, the European experience of plague does not fit the general model derived from India and China by the British Plague Commission around the turn of the century. According to that model, animal foci or reservoirs of plague are established among wild rodents, which can harbor the infection indefinitely, either only among themselves

or, as is now more often recognized, among multiple species. The natural history of such foci is that they enlarge. For example, the focus in the United States, which was established in the first decade of the twentieth century, now extends over almost the entire western half of the country (Ell 1980). It is considerably more reasonable to postulate that there was never an enzootic focus of plague in Europe but, rather, that the disease was repeatedly reintroduced, most likely through trade or travelers. The observed epidemiology is much more compatible with interhuman transmission via the human flea than with either rat–flea or pneumonic spread (Ell 1984).

Whatever historiographic stance one takes with regard to the points discussed above, the recurrent plague epidemics undeniably mark a major change in the ecology of disease in Europe. For the first time, in an institutionalized way, European governments began to try to alter disease ecology. In 1486 Venice made permanent the *Provveditori alla Sanità,* a public health board that had first been established in 1348 and was re-formed in response to each epidemic. The invention of the quarantine is credited to Venice, which first tested it in the Venetian colony of Ragusa in 1379. Measures such as quarantine are not always useful against plague, with its complicated transmission pattern, but were valuable against other infectious diseases. More importantly, such measures introduced the concept that human and particularly governmental actions could modify the expression of disease. When plague appeared, city-states, which traditionally were at odds with one another, exhibited a high degree of cooperation, as elegantly documented by Carlo Cipolla (1981). Much of the future of European disease ecology would follow from this none too successful attempt to control plague, and humans would begin increasingly to modify disease. Yet much of what plague brought was considerably less positive.

Artistic and literary styles in the immediate wake of the epidemic of 1348 were profoundly world-weary and pessimistic. The concept of the macabre arose in this period. The so-called transit tomb style, in which the deceased is sculpted both in his well-dressed idealized appearance and as a rotting corpse, being devoured by vermin, is one of the most striking elements of this deep cultural pessimism. This was a society in which the young and healthy adult could die in a few hours without warning or reason. It is likely that such an atmosphere could produce behavior of so careless or dangerous a nature that mortality from other diseases increased, but we have no real evidence to back up such an argument.

The conventional pillars of Christian faith and doctrine began to change to new, more startling views. People turned away from the belief that reason could lead them to God. Radical nominalism developed, and left an indelible mark upon subsequent philosophy. The Doctrine of Double Truth also emerged. According to this view, individuals could by reason arrive at certain conclusions, but only revelation was the source of ultimate truth. Aquinas had tried to keep the comprehension of truth in this world and available to reason. Postplague Europe made truth something separate from and unattainable from this world.

For totally unclear reasons, leprosy had begun to decline in much of western Europe by 1300 and definitely before plague struck. There is no known explanation. It is claimed that the climate of Europe became colder. It is indeed true that climate can affect the epidemiology of disease as well as much else in human society. A change of 1°C average temperature over a year can change the growing season by 2 weeks in England, for example. It is known that figs were grown in England in the time of Charlemagne. The climatic cooling of the fourteenth and fifteenth centuries has been called the "Little Ice Age" (Russell 1977). Such a shift in climate would certainly affect crops and food supplies, as well as some diseases (e.g., influenza is largely a disease of cold weather, whereas enteric fevers tend to occur in summer). Although climatic cooling has been credited for the decline of leprosy, the fact that the disease thrived in Scandinavia renders this argument at best incomplete and probably irrelevant. Whatever the cause, half the previously occupied beds in leprosaria in England were empty in 1300 (Richards 1977). The argument that plague killed an inordinate number of leprosy victims is not supportable in a direct way because leprosy is considered to confer immunity to plague. Indirectly, through the deaths of those who looked after leprosaria patients, plague may have hastened the decline of leprosy in much of Europe, but it neither initiated nor finished the change (Ell 1987).

Although it itself is highly speculative, let us consider another possible cause of leprosy's decline in much of Europe. The elaborate rituals and merciless rules by which leprosy patients were excluded from contact with normal society have been described extensively (Brody 1974; Richards 1977). If we consider the fact that Japan completely rid itself of leprosy early in this century by strictly separating contagious cases from the population (Saikawa 1981), it seems possible that the less scientific, but

still powerful apparatus of medieval Europe may have produced the same end. This hypothesis, however, like so many others, cannot explain the persistence of the disease in Scandinavia. One difference, however, lies in the possibility that the organism is found in parts of Scandinavia outside a human host (in fact, in a type of moss), which would provide a reservoir of the organism able to survive irrespective of what happened to patients with the disease (Huang 1980; Job 1981).

It is often argued (e.g., by Russell 1977) that tuberculosis became the most important infectious disease during this period. Tuberculosis is simply too protean to be identifiable in the Middle Ages and Renaissance, except in rare instances. Its perceived effects on human demography are reasonable, but again real evidence is lacking.

The Renaissance

No two dates for the Renaissance ever seem to coincide. If we judge from art and literature, Giotto and Dante would place the starting date in the fourteenth century. If we follow the reasoning of Hans Baron that the Renaissance is a reflection of a civic image, the date shifts to 1405. Probably everyone would agree that Michelangelo and Leonardo da Vinci belong in the Renaissance, but if we turn to science the greatest change comes with Galileo, who lived after the Reformation! Very artificially, let us put this period at 1400 to 1550.

Two changes in European disease ecology stand out strongly. Both result from the new trade and exploration involving the Far East and the Americas. On the one hand, Europe became a major exporter of its endemic diseases to the Americas and appears to have acquired two diseases in return.

It has become increasingly apparent in recent years that the role of the introduction of European diseases such as smallpox into the Americas was a factor in the ability of the tiny European armies to conquer empires inhabited by millions of persons. Since it appears that the native American population had no previous exposure to such pathogens, the results were disastrous, and estimates have gone so far as to suggest that in the century after the establishment of contact with the Americas, up to 95 percent of the population of the major centers of American civilizations had perished. In part, the shift from ruler to ruled (or, in effect, enslaved) probably worsened the situation, as did the forced adoption of European religion, language, and customs. Europe's extensive prior experience with infectious diseases was to prove catastrophic later when,

for example, the Polynesian peoples were exposed to measles. Smallpox was probably the most disastrous disease for the post-Columbian Indians.

Within a few years of Columbus's discoveries, Europe perceived itself to be plagued by two new diseases, namely syphilis and typhus. The debate over syphilis has raged for many years, with some claiming that it was an import from the Americas, and others claiming that it was either first recognized as a disease entity at the end of the fifteenth century or was a new disease – the result of a mutation. When one considers the fact that skeletal evidence may show the existence of syphilis in pre-Columbian America, whereas no skeleton from Europe before 1495 has ever shown osseous changes, the first hypothesis seems more reasonable.

Typhus was also seen as new. Here the question is more difficult. First, it is not clear at this time whether recognition of typhus preceded the discovery of the New World. In any case, Europe's ties with new trading partners very likely caused typhus to appear in western Europe. Furthermore, typhus was not conclusively differentiated from typhoid fever until the nineteenth century, and thus the question of recognizing a new disease is extremely difficult. Nonetheless, it was perceived as new, and that in itself is of some importance.

In the case of syphilis and typhus, the perception of new diseases helped to end the rather static medical models of the time. They stimulated considerable written discussion and, of course, the poem from which the name syphilis comes. The perception of these diseases as "new" aspects of the human disease experience is perhaps most significant, but it is not clear at what point this perception began. Plague was known, at least in writing, from centuries past when it struck again in 1347, but syphilis and typhus were perceived as new. Probably the most important aspect of the diseases in Europe is the fact that the quality of Renaissance thought permitted observation to allow what mindset would have prohibited in the past.

Syphilis seems to have had a much more fulminant course than would be expected now. This again suggests a new disease in a previously unexposed society. As time passed, the pressure of the disease probably altered European population genetics toward genetic makeups capable, in most cases, of staving off the organism or coexisting with it.

From the point of view of disease ecology, the Renaissance marks the era of new diseases in two senses. The following years would see more and more precise and, to modern physicians, identifiable

descriptions of diseases that had no doubt been extant for many years. Medicine did not, except in exceedingly rare instances, prove capable of combatting them, but at least it differentiated them.

The second sense of new diseases lies in the European export of diseases to previously unexposed peoples. F. Braudel (1979) has argued convincingly that, of the great civilizations of around the year 1500, Europe excelled only in its shipping. That shipping made it richer and more powerful, and permitted it to devastate the Americas and, later, other lands with its own combination of infectious diseases. Although the appearance of cycles of epidemic diseases, often from elsewhere, mark the history of ancient Greece, Rome, and the medieval world, the Europe of the Renaissance and later tended to be a potent exporter of disease.

Early Modern Europe, 1550–1800

What began in the Renaissance continued and accelerated in Early Modern Europe, except that new diseases were not a significant factor within Europe. The population recovered surprisingly quickly from plague epidemics. Some of the Italian city-states made grants of citizenship easier to obtain, so as to repopulate. Plague gradually became less common. Venice enjoyed more than half a century without an epidemic before the outbreak of 1630. By the eighteenth century, plague was rare indeed.

Cities remained unhealthy places, however. It is unclear if major cities could maintain their own population or continued to demand an influx from the countryside. Smallpox was probably the single worst childhood killer, although a variety of unidentifiable diseases took their toll. Among adults, it is assumed that tuberculosis was on the rise, although again evidence to support this contention is precarious. Many diseases can imitate tuberculosis, and tuberculosis can imitate many other diseases. Because the diagnosis became very reliable in the nineteenth century and because tuberculosis was then a severe problem, it is assumed that the same was the case in Early Modern Europe. It may well have been.

The countryside remained healthier than the city. Country homes for the wealthy city noble or merchant probably owe much to this fact. It is interesting to speculate how many of the magnificent villas along the Brenta near Venice would be there if plague had not so often threatened their owners' lives in the city. The population remained predominantly rural, and there are clear signs of population pressure for the first time since before 1300.

Although the first voyages to the Americas were primarily searches for trade routes and later for indigenous wealth to be returned to Europe, more and more colonists left Europe for the New World. At first, the settlers were primarily Spanish and Portuguese, but the British and French soon followed. Behind this one assumes a favorable turn in the disease ecology of Europe, allowing populations to increase. The gradual cessation of plague epidemics cannot have been the only factor. Leprosy maintained a foothold primarily in Scandinavia. What had been a European disease became a largely regional one. Plague pandemics gave way to much more local epidemics, with those more widely spaced in time.

Even medicine, in a practical way, began to offer some help. The discovery of quinine for use against malaria made life less risky in the tropics and even in those parts of Europe where malaria remained. The discovery of the use of citrus fruit to prevent scurvy allowed sea voyages to be longer without the risk of that peculiar ailment, only understood in near completeness in the twentieth century. Variolation and later vaccination began to bring the long reign of smallpox to an end. Smallpox was a perfect disease to attack by vaccination. The causative virus is not known to mutate, and is antigenically similar to the much less virulent virus that produces cowpox. This explanation was beyond the state of medical knowledge of the time, but many other positive contributions in medicine also have arisen pragmatically, whereas theory has often led to adverse treatments. In actual fact, medicine had only a very small impact on disease overall. The hospital, a medieval invention, remained for the most part a charitable rather than medical institution. In eighteenth-century France, 63 percent of all hospital beds were used to look after the needy, not to treat disease (Joerger 1980). In this period, those engaged in childbirthing care in Provence, France, underwent a change from older women serving simply as midwives, to younger, stronger women who could exert the strength sometimes necessary in dealing with difficult labor. An eighteenth-century tract on obstetrics comments on 600 difficult cases, in which 78 mothers and 230 infants died (Laget 1980), hardly a testimony to medical progress in this vital area.

Even the combination of all these effects seems inadequate to explain the growth of Europe's populations. Still, demographic balance is often precarious. Slight shifts in even a small number of diseases can mean the difference between population growth and decline. Clearly the population of Europe was increasing and had been since some point, not clearly

identified, when plague no longer killed off as many as had been born and survived childhood.

It was during this period that Europe as an exporter of diseases proved spectacularly lethal. Measles, introduced into some of the South Pacific islands, resulted in essentially 100 percent mortality. In one sense, there is nothing more fittingly symbolic of the growing power and influence of Europe than the ability accidentally to kill off an entire population.

Just as the greatest generals of the ancient world gave insights into disease demography, so also does the career of Napoleon Bonaparte, with which we may end this brief discussion of the eve of the Industrial Revolution. At the time of Napoleon, we again see armies in the field numbering in the hundreds of thousands of men. Rome also produced armies of such magnitude (even if they were not concentrated in one place), but a very long interval elapsed before this phenomenon repeated itself.

Industrial and Post-Industrial Civilization

The most characteristic change in disease ecology relating to the Industrial Revolution and post-Industrial society is an almost complete exchange of the diseases of importance. Although medicine has claimed credit for the eradication of infectious diseases, it has been convincingly demonstrated that every major infectious disease of earlier times was already sharply in decline when medical cure became available, with only very few exceptions. Tuberculosis is an excellent example. The tuberculosis epidemic in England and Wales can be seen to have become very significant in the eighteenth century. It peaked around 1810 and then began to decline (Lovell 1957). Effective antibiotic therapy was well over a century away. T. McKeown (1976) has shown that the introduction of antibiotic therapy lies in the asymptotic portion of the curve of incidence.

The impact of the Industrial Revolution is difficult to overestimate. It produced profound changes in a nation's gross national product, patterns of raw material usage and consumption, and real incomes that in turn led to improved living standards. All of these helped to permit explosive population growth (Wrigley 1962). For example, the population of England and Wales was under 10 million in 1800, but in 1990 is approaching 50 million; world population took until 1830 to reach one billion and had quadrupled by 1975 (McKeown 1988). Yet another unique feature of the Industrial Revolution is that explosive population growth, which the exponential increase in wealth probably could have supported for a long time,

was replaced in Europe by a demography of indolent growth. This change seems to have been a directly voluntary effect. Contraception – however primitive the means – became the rule rather than the exception. Although the explosive growth begun in Europe during the Industrial Revolution continues, it does so primarily in the Third World, where agricultural progress and decreases in infant mortality allow impoverished populations to expand continuously.

Europe avoided this fate, and proceeded with a relatively stable population. Decreases in infant mortality caused average life expectancy to double, and more sanitary living conditions coupled with abundant food added still more years to the average life-span. Medicine played a major role in decreasing infant mortality, once the germ theory of disease had been accepted and infants were delivered under conditions conducive to their survival. But at the other end of the life spectrum, medicine has not contributed much. The diseases of modern societies are not primarily infectious. Atherosclerosis, interestingly enough the commonest radiographic finding when the royal mummies of ancient Egypt were X-rayed, has come to the fore as the most significant cause of adult mortality. Myocardial infarctions, fatal arrhythmias, and cerebrovascular accidents, respectively, are some of the major causes of death in modern society. This is a strikingly post-Industrial phenomenon. As late as the end of the nineteenth century, upper-class Englishmen ate a diet as rich in fats and cholesterol as the world has known. Obesity was the rule, not the exception. Yet myocardial infarction was almost unknown. For all the pretensions of modern medicine, the ecology of disease is still wrapped in mystery, particularly when it comes to the appearance and disappearance of individual diseases.

Cancer, certainly known for as long as there have been medical writings, but a rare cause of death in antiquity, has also become one of the commonest causes of death in modern society. Genetics plays some role. Some carcinogens have been convincingly identified, such as tobacco and asbestos. Yet the incidence of some cancers continues to rise, whereas the incidence of a commoner cancer of early industrial times (and still common today in parts of the Orient), namely adenocarcinoma of the stomach, is in decline. Diet is assumed to play a major role, but it is sobering to recall that diet has historically been implicated whenever it was unclear why a disease behaved as it did.

If we examine the length of the disease history of Europe, it is striking that patterns of disease experi-

ence, once identifiable, did not change significantly until the Industrial Revolution. In these terms, it is probably appropriate to divide history into post-Neolithic and post-Industrial only. In any case it is clear that the Industrial Revolution changed the disease ecology of Europe almost totally. Medicine has perfected the cure of the diseases that were in the process of disappearing anyway, but has grappled with only very limited success with the diseases of the new age (McKeown 1988). It remains for future historians to determine whether or not humans will be able to alter the disease ecology they have produced by industrialization.

VII.8
Disease Ecologies of North America

America north of the Rio Grande, that life zone sometimes referred to as the Nearctic region, presents the scholar of history and geography of disease with numerous challenges. These include such questions as the following: What potential disease-causing agents existed in the hemisphere before the comparatively recent arrival of human beings? How effective was the "cold screen" (Stewart 1960) in ensuring the health of the migrants crossing the link from Eurasia to the New World? Given the isolation of this population, how varied was it in a genetic sense, and how well adapted did it become to North American ecologies? Were native North Americans indeed "far more healthy than any others of whom we know" (Ashburn 1980)? Just what was the impact of the "Columbian exchange" (Crosby 1972)? Did these invaders receive the country "from the hands of nature pure and healthy" (Rush 1786)? What relative contribution to ill health and disease did the European group provide compared to that of the enslaved African populations? What were the dimensions and timing of the

"epidemiologic transition" in North America (Omran 1977)? How real have urban and rural differences in health experience been through time? How serious is the threat today of "life-style" diseases?

Clearly all of these and other equally intriguing questions arise. This brief discussion can only hope to touch on some of them and to review a portion of the work by persons from biochemists to medical historians, from archaeologists to medical geographers, who have applied their learning to the fascinating question of human well-being through the ages in North America.

The Ecological Region

North America, which is separated from the Old World by major oceans (apart from the Bering Strait, now a mere 85 kilometers wide), encompasses an area of just over 19 million square kilometers. It stretches across 136° of longitude, from 52° west at Cape Spear in Newfoundland to 172° east longitude at Attu Island in the western extremity of the Aleutians, but its latitudinal extent of 64°, from 83° north at Ellesmere Island to the Florida Keys, is all north of the Tropic of Cancer. Nevertheless, tropical influence is not unknown in the region, as the continent is open to climatic incursions along the Gulf coast penetrating across the interior Mississippian lowlands northward to the Great Lakes. In essence, this means that extratropical cyclones develop along the jet stream and migrate from west to east and, in so doing, draw up hot humid air in summer, and lead to incursions of freezing air masses as far south as Florida in winter.

Throughout the eastern and central sections then, seasonal contrasts are marked, especially when compared to those of northwestern Europe. The mountains of the West modify these conditions, giving rise to wet Pacific coastlands in the north and semiarid rainshadow valleys on the eastern lee with subhumid areas extending over more and more extensive areas toward the southwest. The natural vegetation mirrors the climatic conditions. It ranges from luxuriant forests of the Northwest through scrub and grasses of the semiarid plains and the evergreen boreal forests of the northlands, to the deciduous forests of the East fringed on the southeast coast by marshlands, with each presenting its own niches for life forms from buffalo to mosquito.

Indigenous Disease Agents of North America

Within this varied habitat a myriad of organisms lived and died with the usual range of interrelation-

ships ecologists have led us to expect. Birds and mammals must have had their parasites, and, it is assumed, sylvan cycles of infection and death took place. To identify these in the lack of any, as yet, human presence is difficult, but insofar as today's known zoonoses cycles in North America have been elucidated, some endemic conditions can be postulated.

These would include the bacteria known to cause tularemia, botulism, relapsing fever, anthrax, and pasteurellosis (Cockburn 1971; Meade, Florin, and Gesler 1988) as well as the highly localized *Babesia microtia* of ticks infesting rodents on Nantucket Island. Additionally, *Rickettsia rickettsii* of the tick *Ixodes* infested small mammals, and possibly *Rickettsia typhii* was carried by the fleas on native rodent species already present (Newman 1976). More certainly, the viral encephalitis group is nidal in the region (MacLean 1975), as are a number of helminthic conditions such as the tapeworm *Diphyllobothrium pacificum*, whose definitive host is the Pacific seal (Patrucco, Tello, and Bonavia 1983), the pinworm *Enterobius vermicularis*, and the thornyheaded worm *Acanthocephala*; all are parasites of wild animals (Fry, Moore, and Englert 1969; Fry and Moore 1970). The parasitic flatworm of migratory waterfowl, whose intermediate host is the snail, is endemic among the bird populations of the North American flyways, and has probably been so for eons before unfortunate humans encountered the cercariae and experienced "swimmers' itch" (DuFour 1986).

Other organisms associated with water and the faunal population include *Leptospira* (although the agent of Weil's disease was not present until the introduction of its natural host, the brown rat – *Rattus norvegicus*) and a number of *Salmonella* organisms carried by seagulls and other sea-living animals including oysters and fish (Ffrench 1976). Furthermore, the free-living ameba *Naegleria flowleri*, inhabiting soil, water, and decaying vegetation (but only entering medical literature as a disease agent in 1965), along with other similar organisms, has long been in the environmental complex of Nearctica (Craun 1986).

Still another group of organisms associated (in at least 27 cases) with a free-living existence in soil and water is the mycobacteria (Runyon 1971). As is well known, some species of the genus *Mycobacterium* are associated with human tuberculosis and leprosy. Others, however, called "environmental," vary in frequency, depending upon locale, soil conditions, and climate; and modern American studies have shown that human exposure to these is quite

common (Steinbock 1987). Furthermore, *Myco-bacterium bovis* and occasionally *Mycobacterium avium* produce disease in humans that is clinically identical to that caused by *Mycobacterium tuberculosis*. Native Nearctic guinea pigs, mice, bison, and birds may well have harbored these varieties. Thus organisms capable of causing human tubercular lesions were almost certainly in the New World before the advent of humans (Anderson et al. 1975).

Prehistoric Incidence of Disease

According to L. E. St. Hoyme (1969): "[I]t is easy enough to explain why few diseases entered the New World with man; it is far harder to explain the origin of those diseases that man acquired in the New World before the coming of Columbus." The entry of humans into the Nearctic realm through the land bridge of the Bering Straits area up to 35,000 years ago (Yi and Clark 1985) has been assumed to have been sporadic, small scale, and across a harsh environment. More recently, the founding groups have been seen as limited to between 300 and 500 and possibly associated with but three waves of migration — the so-called Amerind, Na-Dene, and the Aleut-Eskimo — none older than 15,000 B.C.; the order of chronology, however, remains uncertain (Greenberg, Turner, and Zegura 1986). Given this general scenario, it is claimed that the numbers would be far too small to sustain a human-to-human mode of infection (Cockburn 1963; St. Hoyme 1969). However:

As man wandered around the world, he would take many of his parasites with him. Those such as the louse, the pinworm, herpes virus, typhoid bacillus, and others that were closely attached to him would not have great trouble in travelling in this fashion. Others that required transmission by a specific intermediate host would die out once the territory of the necessary intermediate hosts was left behind. (Cockburn 1963)

Moreover, it now seems possible that human tuberculosis made the voyage as well, in that one or more of the Bering Strait migrants may have had a childhood primary infection that, like 5 percent of cases today, developed into chronic destructive tuberculosis (Myers 1965; Steinbock 1987). The predisposing factors for this transformation (any condition that impairs acquired cell-mediated immunity) include poor nutrition, diabetes, or an acute infection possibly from a traumatic incident. All of these could have occurred in a band of hunter-gatherer adventurers in spite of the "cold screen." At least one scholar (Klepinger 1987), however, denies that there is any evidence of the disease being carried

over by the Beringia transmigrants, and claims that it would be more likely to arise de novo in the Western Hemisphere.

But what of the "cold screen" or, perhaps more correctly, the cold filter? T. D. Stewart (1960), arguing that New World populations were relatively free of Old World pathogens, stated that "the cold of the Far North has been characterized as a screen serving in past times to prevent the flow of many pathological germs along with the movements of their human hosts," a position that has become widely accepted in the literature (Jarcho 1964; Hare 1967; Dunn 1968; St. Hoyme 1969; Crosby 1972, 1986; Newman 1976; Martin 1978; Dobyns 1983). Thus it has been claimed that

[n]ot only did very few people of any origin cross the great oceans, but those who did must have been healthy or they would have died on the way, taking their pathogens with them. The indigenes were not without their own infections, of course. The Amerindians had at least pinta, yaws, venereal syphilis, hepatitis, encephalitis, polio, some varieties of tuberculosis (not those usually associated with pulmonary disease), and intestinal parasites, but they seem to have been without any experience with such Old World maladies as smallpox, measles, diphtheria, trachoma, whooping cough, chicken pox, bubonic plague, malaria, typhoid fever, cholera, yellow fever, dengue fever, scarlet fever, amebic dysentery, influenza, and a number of helminthic infestations. (Crosby 1986)

The aborigines, then, seem to have been relatively disease-free, as a result of their isolated and limited populations initially, and the harsh climate. Moreover, given the nature of the immigrant economy, and the paucity of animal domesticates, only the guinea pig, turkey, and South American cameloids served along with the dog in the New World as reservoirs for horizontal transfer of disease (Newman 1976). Thus we have an image of human beings in a nearly ideal state of physical health, removed from the main channels of human disease (Dubos 1968). However, B. Trigger (1985) has rightly warned:

Scholars should not succumb to the temptation of believing that in prehistoric times illnesses had not been prevalent or of concern to native people [for] [t]he extraordinary levels of mortality and other misfortunes that followed European contact must have caused them to idealize earlier times as a halcyon age of physical health, economic prosperity, and social harmony.

Alfred Crosby (1986) maintains that the spirochetal diseases of pinta, yaws, and venereal syphilis were present in pre-Columbian America. A great

deal has been written regarding *Treponema pallidum* (the organism causing venereal syphilis) and its virulent expression in Europe following the discovery of Nearctica (Cockburn 1971; Crosby 1972). However, it appears now that like many other organisms this one spirochete has adapted over time to present different clinical patterns under different climatic and sociological regimes (Hudson 1963, 1965, 1968). Moreover, C. J. Hackett (1963, 1967) has argued that pinta was brought into the Americas by the founding groups and has "a long duration of infectiousness which would maintain it in small population groups, even in families, which suggests that it is the early human treponematosis."

Additionally, there is some suggestion that the treponematosis that causes yaws produced depressions in some prehistoric Indian crania, which may indicate a northern extension of yaws in earlier times up the Mississippi into the Midwest (St. Hoyme 1969). On the other hand, as recently as 1967, it was argued that there was no osteological proof of pre-Columbian yaws and that the traditional view that it had been introduced by African slaves was still acceptable (Stewart and Spoehr 1967). In addition, recent reports (Rothschild and Turnbull 1987) of syphilis in a Pleistocene bear skeleton in Nebraska have been discounted, as no authenticated treponemal infections have been found in a nonprimate (Neiburger 1988).

In summary, sparse populations of indigenes would be fairly free of diseases transmitted from other humans, although their contact with game, and especially their ingestion of raw meat and of water, would bring them into contact with some invasive pathogens (Fenner 1970). Their necessarily mobile hunting-and-gathering life-style would protect them from a degree of self-contamination, but failure of the hunt would periodically stress them and accidents would traumatize some.

As the sedentary maize-based cultures spread north from Mexico, villages appearing after 7000 B.C. and, later, larger settlements (possibly as large as 40,000 as at Cohokia, Illinois) created other health problems, among them those of sanitation (Heidenreich 1971; Crosby 1986). Furthermore, the invasion of settlements by rodents and fleas would have led to human contact with the illnesses of native animals (Dobyns 1983). One can only speculate as to the impact of these concomitant aspects of agriculture; but while the carrying capacity of local areas, and hence their population densities, grew, there is no firm evidence that morbidity declined. Rather, there may well have been a shift in the causes of death, reflecting the new relationship between human and land (Martin 1978; Dobyns 1983).

The Native American and Disease Ecology

The long-term result of the development of North American peoples in the absence of contact with others was a healthy population adjusted to its environmental niches. Humankind had multiplied from the founding stock and by the late fifteenth century numbered somewhere between 4.4 million (Ubelaker 1976) and 9.8 million (Dobyns 1966). Within this total, a degree of variety had arisen in the human populations of Nearctica in the course of some 600 generations, reflecting the historical and environmental conditions (Brues 1954; Szathmary 1984).

The genetic characteristics of American Indian populations are sufficiently similar to one another and different from those of other continental groups to permit (as a first approximation) of their description as a "distinct" subgroup of the human species. . . . Closer analysis of genetic affinities reveals that over larger areas the genetic continuity takes the modified form of gradients or clines. Thus the frequency of the gene for blood group A decreases from north to south, that for the allele for the Diego factor and the M gene increases from north to south. (Weiner 1971; see also Suarez, Crouse, and O'Rourke 1985)

Throughout the region the B gene is singularly lacking, with almost all Amerindian groups belonging to the O blood group. This situation may explain a particular susceptibility to smallpox on its introduction (Mourant, Kopec, and Domaniewska-Sobczak 1958). Not all scholars agree even on this point, however:

The role of the blood groups in the resistance of certain infections or parasites has been controversial. If it was demonstrated, its importance would be significant in accounting for the repetition of certain factors . . . [I]n the region of pestilential or variolic endemic diseases, the plague would be worse and more frequent among people with type O, and smallpox, among those with type A. (Bernard and Ruffie 1966, trans. Graham)

This interpretation is based on the discovery that *Pasteurella pestis* possesses an antigen similar to the H antigen, whereas the variola virus has an antigen similar to the A antigen. As people with blood group O are not able to produce any anti-H antibody (which corresponds to the H antigen of *P. pestis*), they have a very poor prognosis when infected (Vogel, Pettenkofer, and Helmbold 1960; Matsunage 1962, 1982). Although anthropologists and others have used these studies to support theories of genetic distance and purity of Amerindian stock (Post,

Neel, and Schull 1968; Roberts 1976; Szathmary 1984), the consensus on the theory of genetic susceptibility to disease is that the case is unproven in the context of the exposure of these peoples to the imported Old World infections (Newman 1976; Ward 1980; Joralemon 1982).

There is, however, increasing evidence in genetic epidemiology that certain conditions are related to genotype–environment interactions. In the case of contemporary North American native peoples, these conditions include inflammation of the inner ear (Gregg, Steele, and Holzheuter 1965), gallbladder disease (Burch, Comess, and Bennett 1968), diabetes (Miller, Bennett, and Burch 1968), and alcoholism (Broudy and May 1983; *Social Biology* 1985). Indeed, it has been claimed that at the present time

Many Amerindian peoples are experiencing a major epidemic of a series of diseases which include a tendency to become obese at an early adult age, adult onset of *diabetes mellitus,* the formation of cholesterol gallstones. [T]his epidemic . . . seems to be due to an interaction between susceptible Amerindian genotype(s) and some recently changed aspect of the environment, probably involving dietary components. (Weiss, Ferrell, and Hania 1984)

It would seem, then, that there is evidence of an ecology of disease specifically associated with the continent's native peoples, one of the three major human stocks presently inhabiting the region.

The Columbian Impact

Although evidence of varying quality exists for human penetration of Nearctica prior to the arrival of Columbus in 1492 (Boland 1961), that event and the almost simultaneous arrival of Africans were to be catastrophic in terms of the disease ecology of the continent (Ashburn 1947; Crosby 1972, 1976; McNeill 1976). Europeans and Africans represented a totally different set of disease foci and introduced pathogens that initially devastated the native Americans. The age of contagious or infectious disease had dawned in America. There were two basic reasons for this, beyond the obvious one of disease importation. The first involved the zoonoses introduced as a result of the transfer of animals previously unknown to the continent; the second related to the colonization that led to communities having threshold populations that could sustain infection.

In the initial period, European diseases spread rapidly into the interior, outdistancing the newcomers who had brought them, while decimating native populations (Dobyns 1983). This fact, in turn, gave

rise to the realization that Europeans – and in the south, Africans – entered what Francis Jennings (1975) has called a "widowed" land. This interpretation, in contradistinction to that of the "Black Legend" (Newman 1976), which blamed the decline of native populations on the cruelty and warfare of the invading peoples, views the role of accidentally introduced disease as critical. "Virgin soil" disease ecologists argue that persons having no previous contact with the larger pathogen pool of humanity are immunologically defenseless. And so the Amerindians who had not before encountered Old World bacteria and viruses succumbed in large numbers to ailments that scarcely touched the immune Europeans (Hauptman 1979; Joralemon 1982; Dobyns 1983; Curtin 1985; Hader 1986). M. T. Newman (1976), however, warns:

There is mounting evidence that American Indians were no more susceptible to most of these infectious disease imports than other populations where these diseases had not struck within the lifetime of the people – none of whom therefore had acquired specific immunities.

For this reason Newman quotes W. R. Centerwall (1968), who called for "a reevaluation . . . with respect to the primary susceptibility of the Indian to . . . diseases of civilization, such as pertussis (whooping cough), smallpox, and tuberculosis"; and Centerwall concluded that "during the conquest, cultural disruption should be added to the impacts of the new pathogens, compounded by the force of European arms and the later ill-treatment of slavery."

Numerous other scholars have also implicated psychological, economic, and social factors stemming from introduced disease in the high mortality and even decimation of Amerindian populations (Crosby 1976; Dobyns 1976, 1983; Meister 1976; Miller 1976; Trigger 1985). In any event, the indigenes went into decline as their battle with disease resulted generally in high death rates – up to 90 percent has been mentioned in some smallpox outbreaks, with case fatalities of 74 percent in others (see Fenner 1970; Joralemon 1982; Hader 1986).

This kind of die-off, of course, did not occur simultaneously or uniformly across the continent (Meister 1976). Pertussis, smallpox, pulmonary tuberculosis, measles, diphtheria, trachoma, chickenpox, bubonic plague, malaria, typhus, typhoid fever, cholera, scarlet fever, influenza, and a number of intestinal infections arrived with the Europeans at various times over 5 centuries. Of these, smallpox has generally been seen as the most dramatic (Ashburn 1947) and was one of the earliest to arrive. In Española it made

16th and 17th Centuries

18th Century

19th Century

Map VII.8.1. Diffusion of smallpox among native Americans. (After Heagerty 1928.)

SCALE

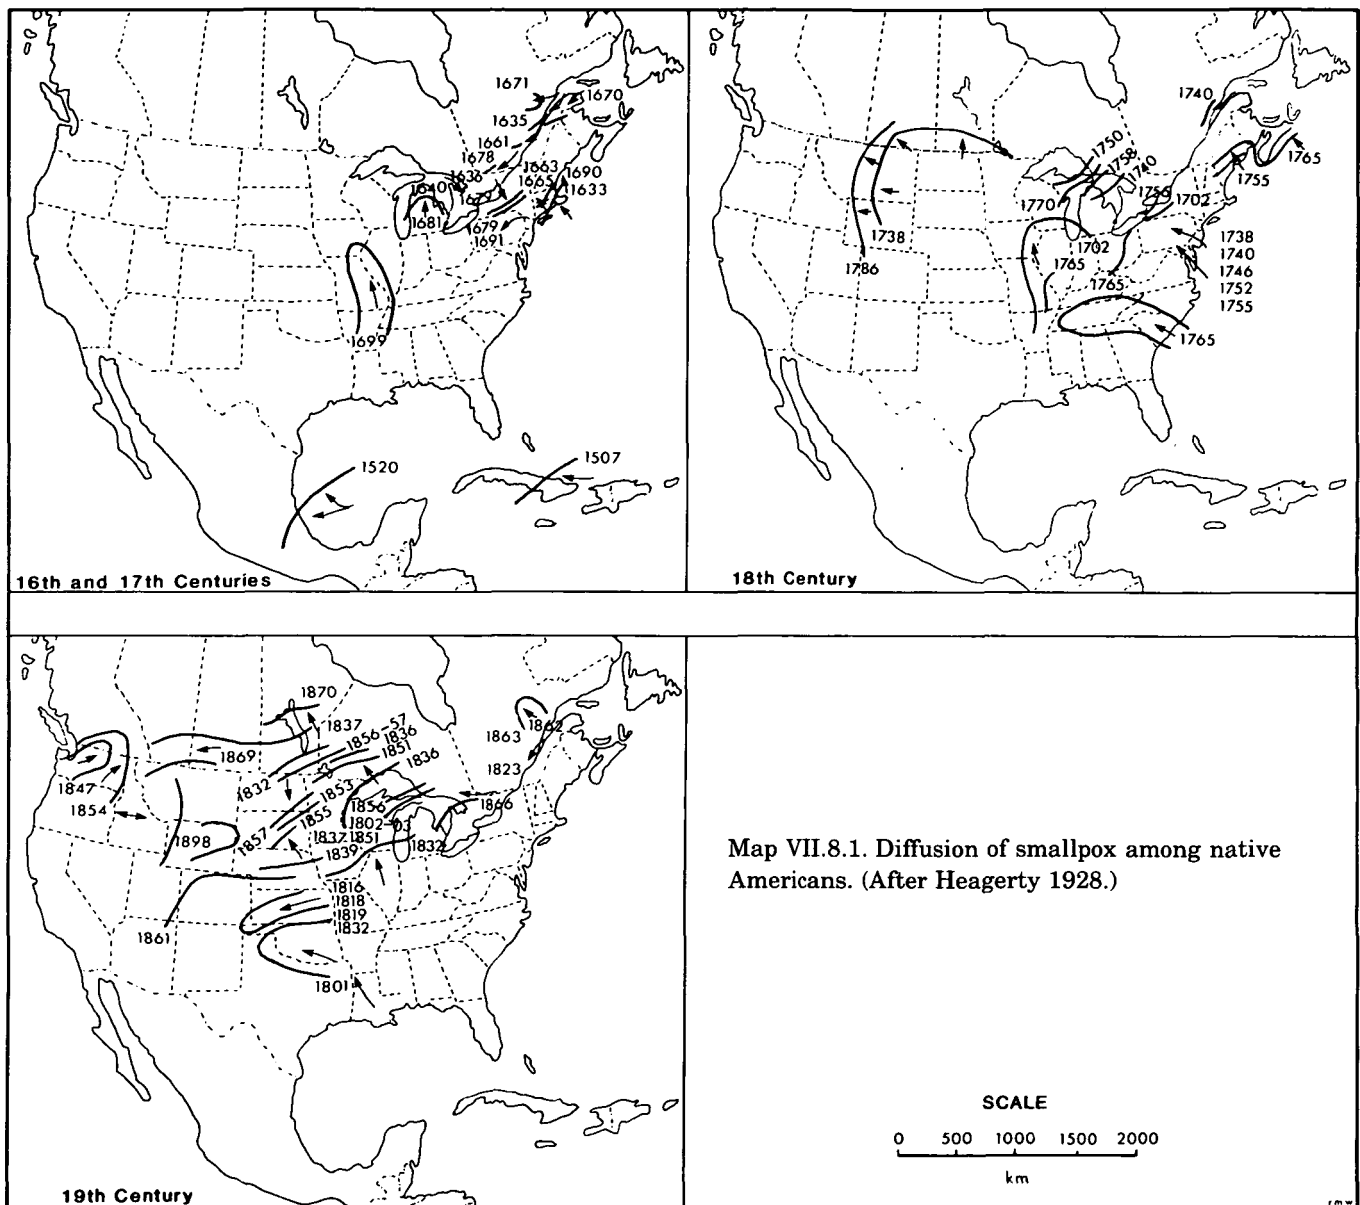
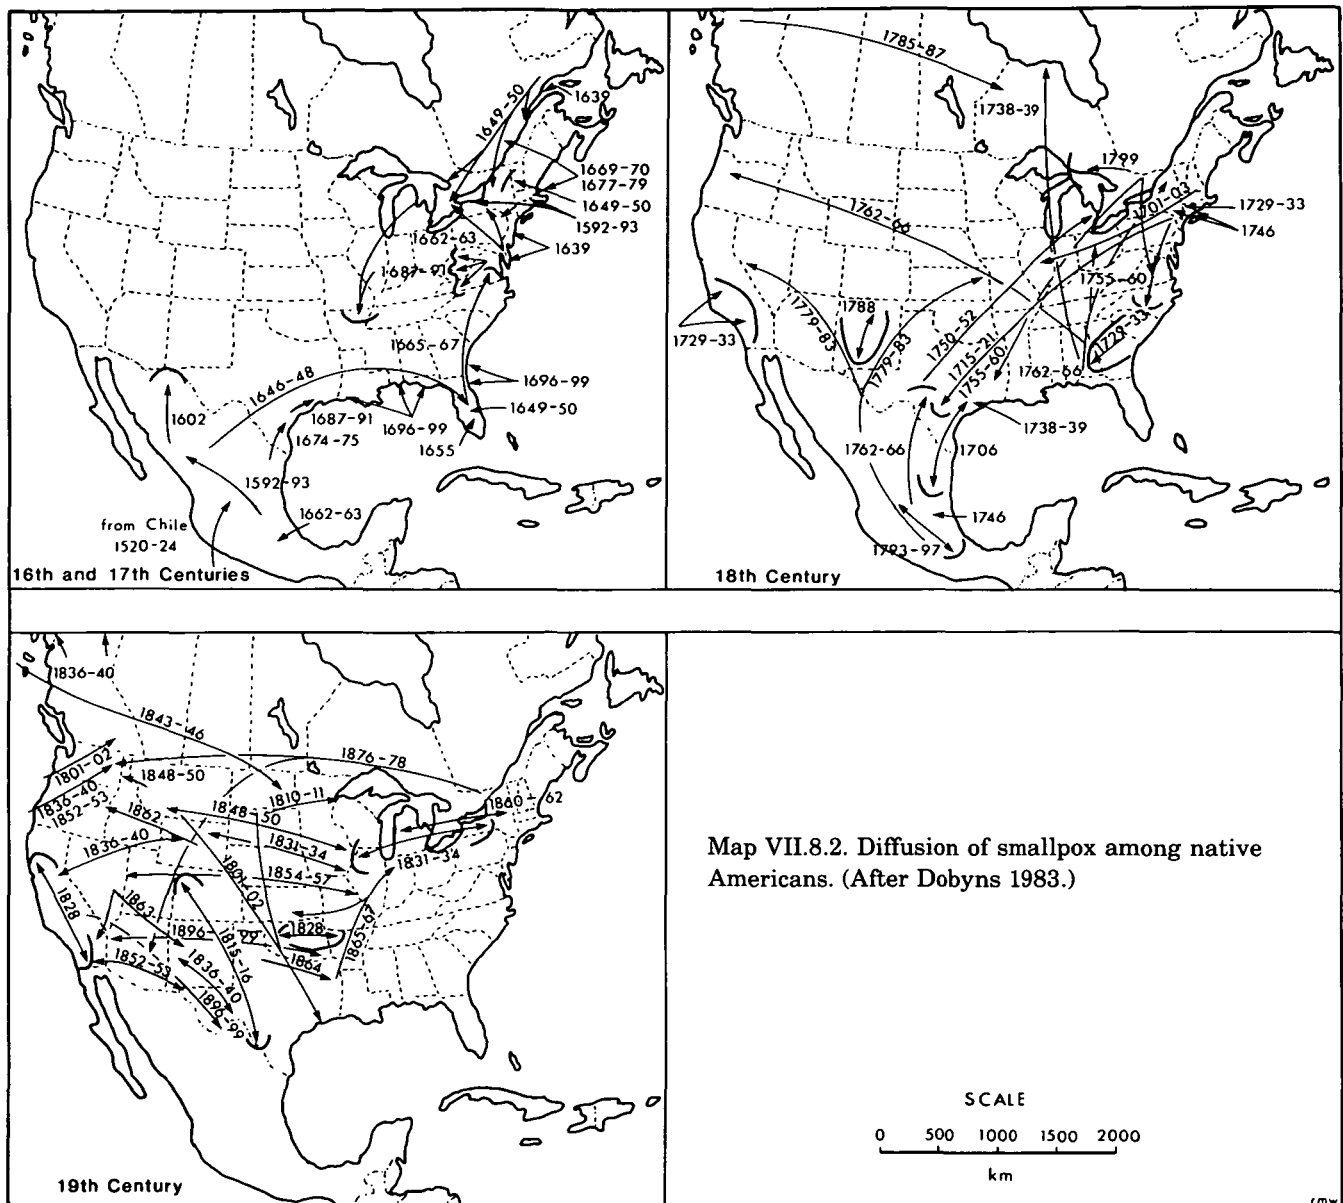
km


its appearance by 1519 (Crosby 1986), and was present in North America prior to the middle of the century, spreading northward from Mexico (Dobyns 1983; Trigger 1985). As a new disease moving without an intermediary vector, from person to person, it hit those of all ages, although the mortality of young males in many populations was especially devastating (Ray 1974).

Most Europeans had experienced smallpox in childhood, and hence were protected, but this was not true for the Amerindians or, for that matter, many of the blacks in America. Repeated introductions along the East Coast and up the St. Lawrence led to further outbreaks from the seventeenth to the nineteenth century, including an outbreak that dramatically influenced the population decline in Huronia in 1639–40 (Trigger 1985), and the 1837 epi-

demic on the Great Plains, which decimated about half the remaining natives there (Hearne 1782, quoted in Innis 1962; Crosby 1976).

Maps VII.8.1 and VII.8.2, based on J. J. Heagerty (1928) and H. F. Dobyns (1983), respectively, summarize in a stylistic manner the history and geography of these outbreaks and illustrate that full elucidation of these events awaits an in-depth study based on original accounts, documents, and interpretations. Thus the hypothesized lower susceptibility, of those with a dominance of blood group O, noted above, is not borne out by the historical evidence. On the other hand, the anomalous group of the Blackfoot Indians, with their A blood group, certainly suffered very severely; over two-thirds or some 6,000 Blackfoot were decimated in the smallpox outbreak of 1837 (Bradley 1900; Ewers 1958).


Map VII.8.2. Diffusion of smallpox among native Americans. (After Dobyns 1983.)

The Europeans, however, were not all immune to smallpox, as population growth in the colonies increased the number of susceptibles. Thus, in Boston a 10 percent death rate from this scourge was recorded for 1721, and in each of the years 1702, 1730, and 1752 over 6 percent of the population of that city died from this one disease (Dobson 1987).

Measles was also introduced in the seventeenth century from Europe, and as early as 1635 the Jesuits reported an outbreak among the French and Indians (Duffy 1972). The disease was very contagious, and a series of epidemics such as those of 1713–15 spread inland from the seaports. Indeed, in 1772 measles was a leading cause of death in Boston (Duffy 1972) and was claimed to be more often fatal in America than in England as in the former it took the form of a series of introduced

epidemics and affected a larger number of adults in the New World. Only late in the colonial period, with population clusters in excess of 500,000, could measles or, for that matter, smallpox become established as endemic in America (Black 1966; Fenner 1970; Cliff et al. 1981). When and where this first occurred is not known, but it was probably not until the nineteenth century (Cartwright 1972). The fact that the pair of diseases was confused in the records does not help in establishing this important turning point.

Unlike the two diseases just discussed (and other purely human diseases such as scarlet fever and diphtheria), vectored diseases and zoonoses required infective agents to become established in the New World. Just two of these – plague and malaria – will be discussed. Plague was one of the earliest diseases

to be introduced from Europe (Williams 1909; Posey 1976). Rats infested every ship that crossed the Atlantic, though only occasionally was the rat–human relationship as close as that described by Colonel H. Norwood (n.d.) in the mid-seventeenth century. "The infinite number of rats that all the voyage had been our plague, we now were glad to make our prey to feed on." No doubt, however, those that survived landed and by 1612–19 in Florida and New England, these newcomers and their fleas had given rise to human plague (Dobyns 1983). As D. A. Posey (1976) explains, "Once the rodent carriers were transported to this virgin territory, the plague would have spread as wild native rodent populations became reservoirs of the dreaded disease . . . and few, if any, animals, except the louse were more common in Indian and colonial camps."

Thus, the conditions were present for plague long before the first fully documented case was recorded in 1899 as having come from Japan into San Francisco (Link 1953; Schiel and Jameson 1973). Three views of plague in the hemisphere can be sustained on the basis of present knowledge. One view is that it has long existed, even from prehistoric times as a sylvatic cycle disease in rodents. The remaining two, more probable, views entail its introduction from Europe, followed by possible extinction in eastern locations, and the documented transpacific reintroduction in the late nineteenth century. Certainly this third route has given rise to endemic plague from the Mexican border to Alberta primarily among ground squirrels and their fleas (Hubbard 1947). Unfortunately, domestic animals from time to time pick up these fleas and transport them into Western homes where occasional human infections are contracted, the annual incidence rate being 3.4 cases per year, 1927–69 (Canby 1977).

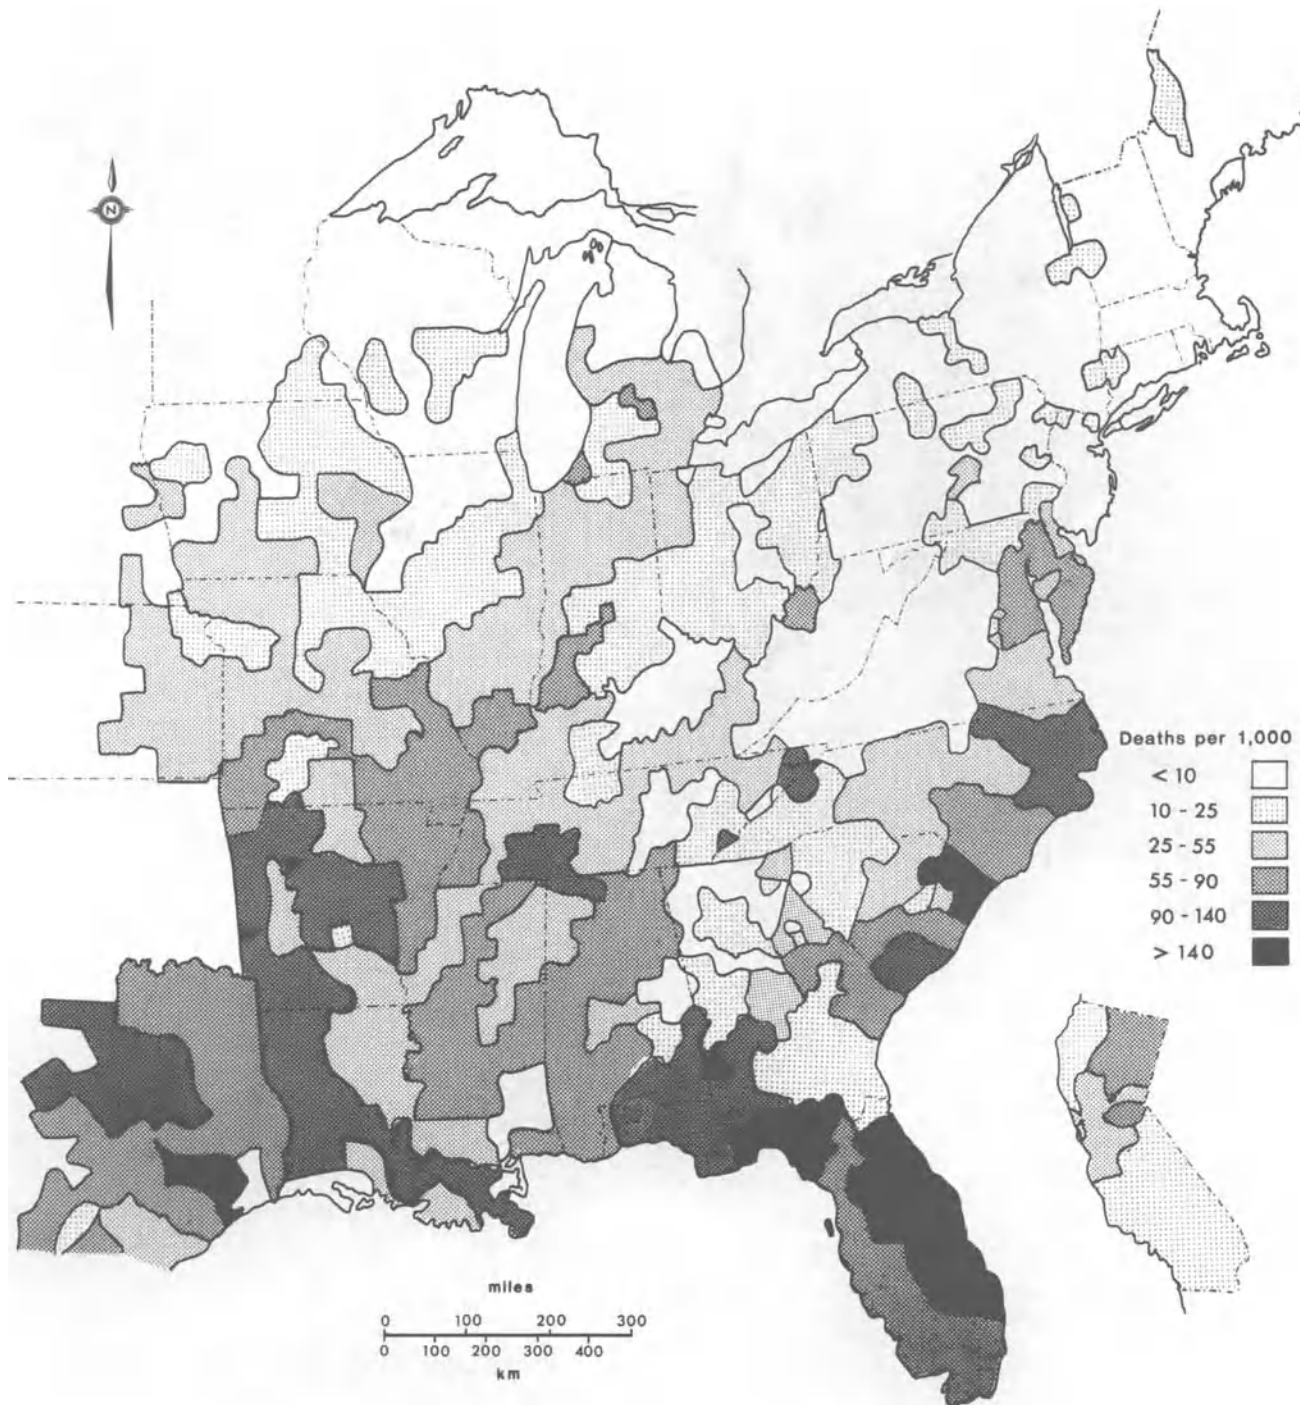
Falciparum malaria, dysentery, smallpox, intestinal worms, yaws, guinea worm, schistosomiasis, and yellow fever were contributed by the African slave (Ashburn 1980; Dunn 1965). Of these African diseases, malaria and yellow fever were the most significant (McNeill 1976), but their impact differed among the major population groups involved (Postell 1951; Duffy 1972; Kiple and Kiple 1977). In the case of malaria, the African slaves usually had been previously exposed, or had blood anomalies to protect them. Malaria among this group was generally a childhood disease in terms of mortality, though recurrence in later years was debilitating. On the other hand, among native Amerindians mortality from malaria could be as high as 75 percent (Dobyns 1983),

but malaria was more often a predisposing condition rather than a fatal disease once the milder vivax malaria (introduced from Europe) became established in the Mississippian west. For Europeans (who may have been exposed to the vivax variety in England), falciparum malaria was deadly wherever it had been introduced to the local mosquitoes by slaves along the marshlands of the Atlantic and Gulf coasts (Childs 1940; Savitt 1978).

Although a variety of strains and perhaps even both major species may have been introduced by diverse carriers at a fairly early date, a more probable model, given the flow of immigration and the prevalence of vivax in Europe and falciparum in Africa, would have strains of the former entering during the first half of the [seventeenth] century, followed by the gradual establishment of areas of stable, low-level endemicity. The shattering of this picture would occur as blacks in numbers began arriving from a variety of African areas, bringing with them new strains of . . . falciparum. . . . [A] qualitative change occurred sometime in the second half of the century as falciparum entered the colony. . . . [T]he benign vivax was prevalent in the 1670's but was supplanted by the more virulent falciparum in the 1680's. (Rutman and Rutman 1976)

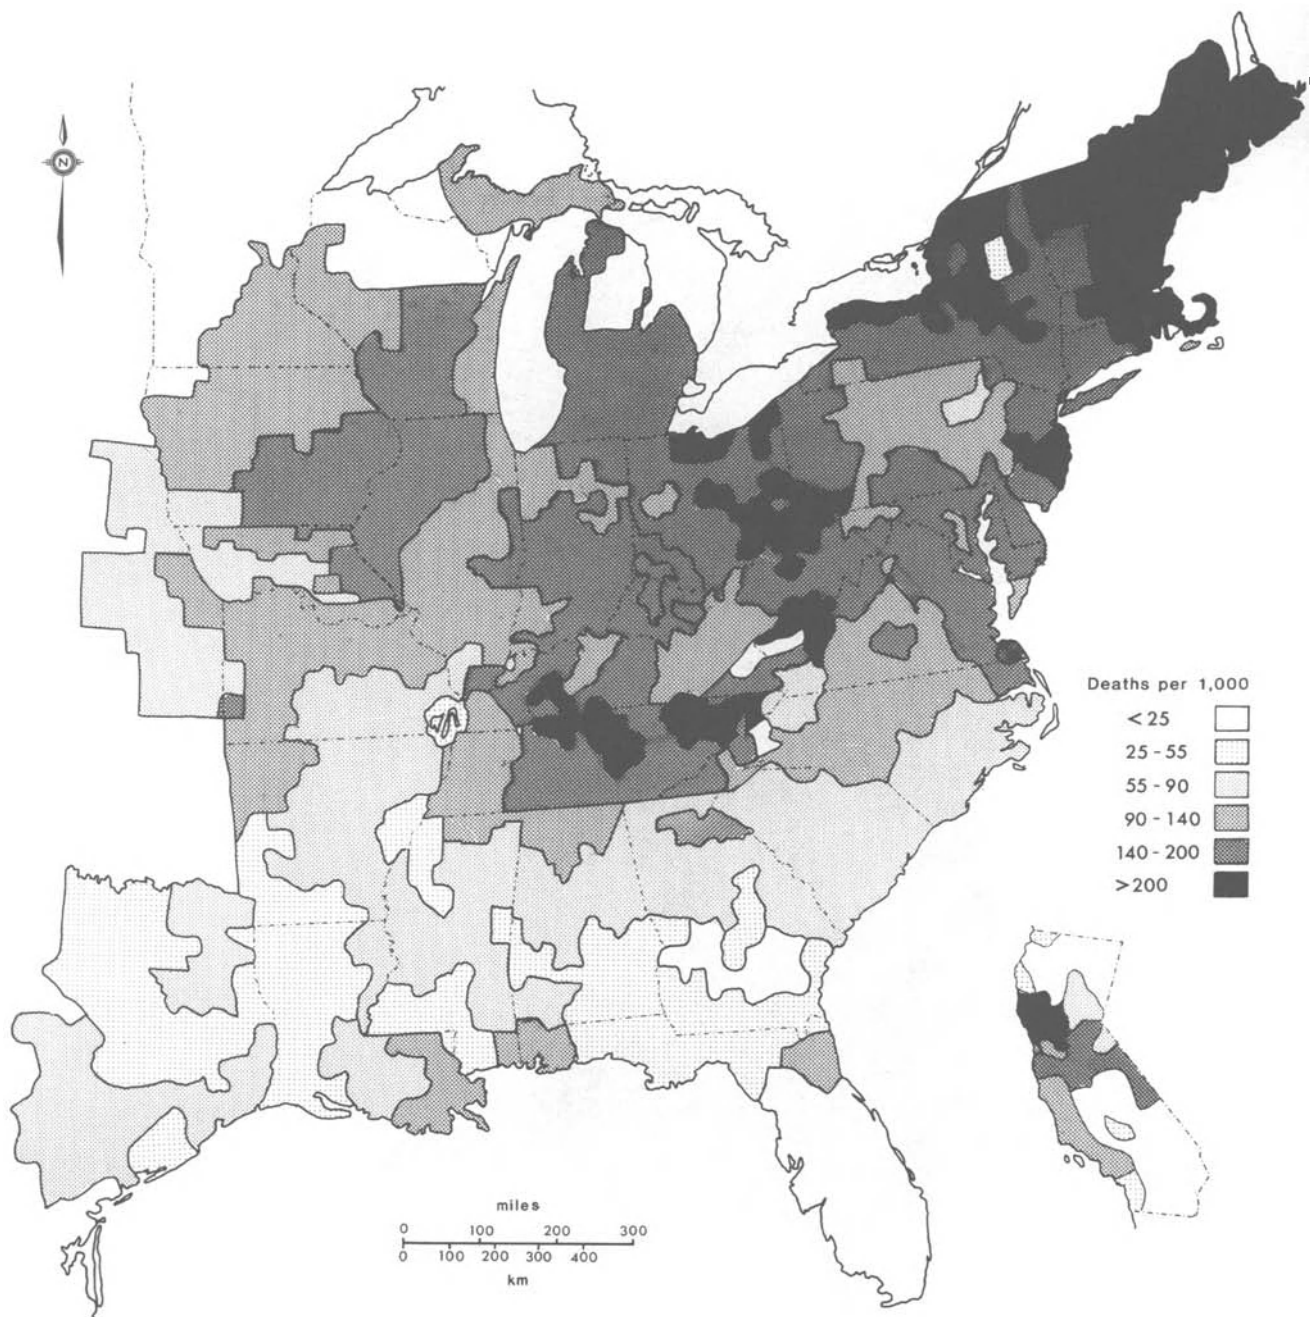
Further vivax introductions from African sources would be strictly limited because of the absence of the Duffy blood group determinants Fy^a and Fy^b in most individuals of African descent, which prevents them from hosting the disease (Mourant, Kopec, and Domaniewska-Sobczak 1976).

The transmission, of course, depended on the transmission of infection to Anopheles mosquitoes from those suffering with malaria parasites. Unfortunately, Nearctica was already amply provided with potential vectors (Freeborn 1949), and these mosquitoes became instrumental in spreading the infection from the south and east right up the Mississippi Valley as far as Canada, where seasonal transmission took place among the native peoples and settlers locally into the 1940s (Drake 1850/1954; Moulton 1941; Ackerknecht 1945). Furthermore, malaria was widespread in the nineteenth century in the Pacific Northwest of the continent (Boyd 1985; see also Map VII.8.3). Indeed, infection and even death from this imported disease still take place in North America, although changed environmental and social conditions led to its retreat to the South. By the 1950s, malaria – "the United States disease of the late 19th century" (Meade, Florin, and Gesler 1988) – had been eradicated. Much of the resurgence of the South and its development as the "Sun Belt" are related to this aspect of disease ecology.

The nineteenth-century social and economic condi-


Map VII.8.3. Malarial disease deaths per 1,000 population, 1870. (Based on Ninth U.S. Census; assembled by author.)

tions, together with improved communication and ever increasing flows of immigrants, opened the continent to further invasions of disease. Indeed, immigrants, poverty, and disease were almost synonymous in many circles in this period. Most dramatic of these imported epidemics were those of cholera, with its ability to kill an estimated 40 to 60 percent of its victims within hours (Morris 1976) and an etiology that was unknown until Robert Koch discov-

ered the microorganism *Vibrio cholerae* in 1883. In the pandemics of 1831–2, 1848–50, 1853–4, and 1866, North America was not spared. Entering at port cities such as New York, Quebec, and New Orleans, the disease spread with the migrants and created terror but eventually catalyzed the development of meaningful public health reporting and treatment networks (Bilson 1980). This result would perhaps have taken much longer to achieve than it


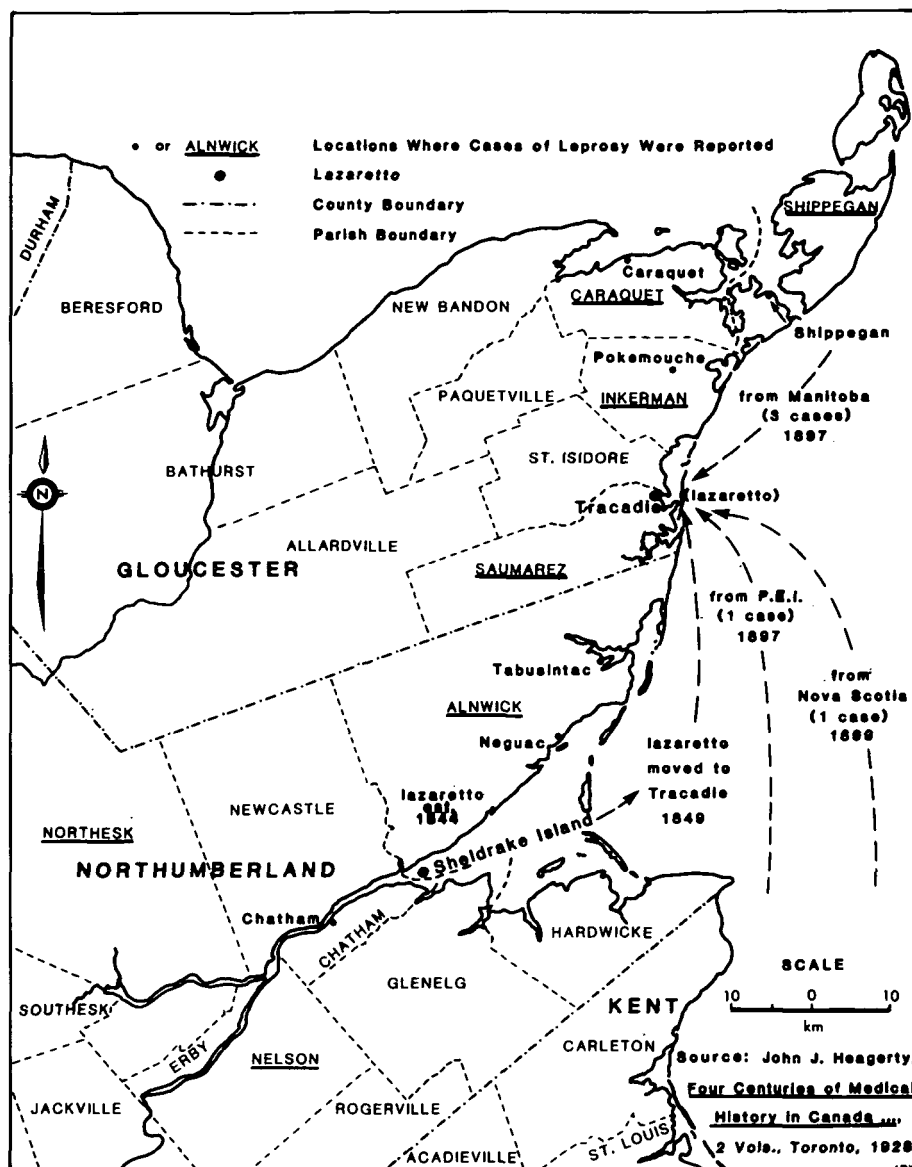
Map VII.8.4. "Consumption" deaths per 1,000 population, 1870. (Based on Ninth U.S. Census; assembled by author.)

actually did had not this one condition had such a powerful effect on the population as a whole.

The other great scourge of the nineteenth century was pulmonary tuberculosis, also known as the "white plague." As previously noted, mycobacteria had long been present in the Western Hemisphere, but it was only in the nineteenth century, with urbanization (crowding of masses of people, often in poor-quality housing and lacking good nutrition), that this person-to-person infection assumed epidemic proportions (Ashburn 1947; Cockburn 1963).

It came to "transcend all maladies in the total number of its victims and the cost to society" (Ashburn 1947; see also Map VII.8.4).

That Amerindians had little experience with epidemic tuberculosis prior to contact with Europeans (Clark et al. 1987) is borne out by the dramatic susceptibility of Indians after exposure. For example, R. G. Ferguson (1934) wrote:

A most disastrous epidemic appeared among the tribes settled on the reservations and within a few years [after


Map VII.8.5. Leprosy area of New Brunswick, predominantly in the nineteenth century. (From Heagerty 1928.)

1879] the general death rate among them was varying from 90 to 140 deaths per 1,000, two-thirds of these due to tuberculosis.

In 1928 the U.S. Bureau of the Census reported that 11.6 percent of Amerindian deaths were due to tuberculosis, as compared to 5.5 percent of Negro deaths and 5.6 percent of all white deaths (Ashburn 1947).

As far as blacks are concerned, some suggest that tuberculosis was rare among slaves (Postell 1951), though all agree that during Reconstruction it became a major cause of ill health and mortality, as social and economic conditions for most blacks declined markedly (Savitt 1978). As for other myco-bacteria, leprosy is said to have been introduced with the slave population (Ashburn 1947) and remained an endemic disease in small numbers into modern times. (Among Europeans, it had been introduced [Heagerty 1928] but never became established, except for a brief period in the Florida Keys. Only a handful of persons – for instance, in New Brunswick – are recorded as having had the disease; see Map VII.8.5; Losier and Pinet 1984).

The Present and the Past

Writing in 1963, A. Cockburn claimed that "tuberculosis had not displaced malaria as the world's number one problem in infectious disease," but like malaria, it has become rare and under control in Nearctica.

Like other so-called developed areas, North America has undergone both demographic and epidemiological transitions (Omran 1977): from high birth and death rates to low birth and death rates, and

from the predominance of infectious diseases in causing death, to a preeminence of degenerative diseases (heart disease and cancers) in causing death (Dubos 1968). Genes replace "germs" as the significant variables in these societies (Ward 1980). Having said that, one can question just how and when these transitions took place. Almost certainly they did not occur simultaneously for each of the three groups discussed here. The Amerindians survived an initial period of adjustment on entering the continent, when adaptation would bring great stress but infections as such would be rare. They then grew in numbers and, with the development of agriculture and sedentary villages, attained densities that gave rise to self-contamination, in addition to the hazards of the field and hunt. However, as St. Hoyme (1969) observed, "At the time of the conquest, Indians suffered less from contagious diseases than from arthritis, nutritional and metabolic disturbances, and non-specific infections associated with traumata."

At this point, the era of exotic contagions dawned, with death rates threatening extinction. This did not happen uniformly or necessarily (Meister 1976). Thus, some areas experienced rapid population decline, and others growth. Gradually white newcomers and, to a lesser extent, blacks, as well as Amerindians, all adjusted to the new disease environment, and populations recovered, only to encounter new hazards as a result of environmental moves from traditional homelands.

Today, however, most Amerindian groups continue to have high infant mortality rates and high rates of infectious disease. The blacks, too, like the Amerindians prior to contact, were in a state of health homeostasis when rudely plucked from Africa and transported to the New World, with a terrible toll being paid en route (Pope-Hennessy 1967; Kiple 1984). Once in America they suffered a large number of infections that, according to William Postell (1951),

may have been caused by dietary deficiency. The great number of dental caries, sore eyes, sore mouths, sore feet and legs, and skin lesions is suggestive of pellagra . . . for it is suspected that the slave received an improperly balanced diet, particularly during the winter months [and] suffered greatly from cholera, pneumonia, dysentery . . . and probably to a lesser extent than his white master, from yellow fever and malaria.

Respiratory complaints or "pleuretical disorders" were particularly fatal to them (Duffy 1972). Since the days of slavery, conditions have improved for black Americans, but much more slowly than for the white segment of the population. Thus there are now fewer deaths from fevers and tuberculosis and infant mortality is declining, but both are still much higher among blacks than among white Americans (Bouvier and Van der Tak 1976). The result is that the national mortality rates for the United States for many ages and causes are inflated by inclusion of the relatively disadvantaged black minority, and the full impact of lower birth and death rates has not yet been seen for this group.

White Americans, like the blacks, experienced an initial seasoning period upon arriving in Nearctica. Thereafter they grew rapidly in numbers, experiencing more healthful conditions than those currently prevailing in Europe (Duffy 1972; Dobson 1987). They did, however, have higher mortality rates in the southern colonies and continually in the coastal towns into which disease was constantly brought from overseas. Thus, urban areas acted as reservoirs of infection that periodically broke out to cause sudden devastation in the new generation of susceptibles in the smaller settlements and countryside (Dobson 1987). Prophylactic measures, notably improved sanitation and standard of living, enabled this group to enjoy the full benefits of the transition model. Thus,

as a result of the ensuing rise in economic standards, diseases associated with toiling for food and coping with natural disasters have been supplanted by those which spring from the complexities of our technological age, in which man's connection with the soil has become less direct. (Furness 1970)

The Present and the Future

Although all three population groups have seen dramatic improvements in their health, disease ecologies continue to evolve. Today virus infections remain as serious public health problems, acting differentially on the genetic variation present on the continent. Often forgotten in this context is that perplexing virus, influenza. It is perplexing because of its mutational history, with each strain – "Asian," "Hong Kong," "swine," and so forth – being distinct immunologically, and ever dangerous in light of the still readily recalled devastation caused by the 1918–20 pandemic. Recent work by Gerald Pyle, a medical geographer, epitomizes the promise of the application of geographic modeling to public health problems of tracing the diffusion of diseases such as this (Pyle 1986). The acquired immune deficiency syndrome (AIDS) has established itself as of prime concern and appears to be following much the same pattern of spread as the earlier urban-centered epi-

Table VII.8.1. *Incidents of serious contamination in U.S. work sites and residential areas*

Location	Chemicals	Health effects	Cause of incident
Southern United States[a]	mirex	Causes cancer in mice. Toxic to crabs and shrimp. Detected mirex in fatty tissue of 25% of people living in area sprayed.	Mirex was sprayed over several of the southern states in order to control fire ants. Its use was phased out in 1978 owing to health effects. Mirex stays in the environment longer than DDT.
St. Louis Park, Minn.[b]	creosote	Severe skin reaction from handling creosote-bearing soil.	Reilly Tar and Creosote Manufacturer had an 80-acre site where waste was dumped. Nearby wells were contaminated by the site.
Hopewell, Va.[c]	kepone	June 1975: A worker became ill with dizziness and trembling due to high concentration of kepone in his blood. State official investigations found 7 workers ill enough to require immediate hospitalization. Over 100 people, including wives and children, had kepone in their blood, and 30 more people were hospitalized with tremors and visual problems. Some people may be permanently sterile, and all are threatened with possible development of liver cancer.	The Life Science Products Corporation produced the pesticide kepone and employed the people affected.
Tyler, Tex.[c]	asbestos	25–40 of 900 workers have died from breathing asbestos. The death toll is expected to reach 200 workers.	The asbestos plant closed in 1972.
Chattanooga, Tenn.[c]	nitrogen dioxide	Exposed persons are more susceptible to respiratory disease, colds, bronchitis, croup, and pneumonia.	TNT plant located nearby. Levels of exposure up to 500 grains/ billion have been shown.
Times Beach, Mo.[c]	dioxin [TCDD] (300 ppb) and others	Effects of dioxin exposure appeared almost immediately. In 10 days hundreds of birds and small animals died; kittens were stillborn, and many horses died.	Man was hired to spread oil on dirt roads; oil residues plus other wastes that remained in the containers were mixed into the oil. Dioxin in the form TCDD as high as 300 ppb (1 part per billion is the maximum dose deemed safe).
Times Beach, Mo.[c]	dioxin [TCDD]	Miscarriages, seizure disorders, liver impairment, and kidney cancer.	EPA purchased every piece of property in the town and ordered its evacuation.

demics of alien origin. Immigrants continue to introduce new potential pathogens and are the source of reintroduction of others to which the resident population may have lost herd immunity (Kliewau 1979). Urban wastes as well as technologies constantly tend to poison the environment (Greenberg 1978), and through disposal efforts and acid rain, virtually the whole population is exposed. The health effects of contamination are not always dramatic, but as Table VII.8.1 shows, the results can be very real.

Perhaps because of the shorter time lapse involved, the monitoring of birth defects and infant mortality provides an important measure of these new hazards (Puffers and Serrano 1973). Although improvements in infant survival rates encourage the belief that a

new homeostasis is being reached, any marked change for the worse and any increase in congenital anomalies need to be treated very seriously.

Much remains to be learned about the natural history of health and disease in the Americas. . . . We do not know why diseases occur or do not occur at a given time and place. Even less do we know what conditions and circumstances cause them to spread within a country and between countries in the Hemisphere. Indeed, accurate knowledge of the etiology of a specific disease does not tell us about the sequence of events that produce it. Today we accept the fact that multiple causes are involved in the development of disease. (Horwitz 1973)

These causes include those of nature, inherited in infancy from the genetic stream, predisposing in all probability to a number of conditions from hypertension in black North Americans to schizophrenia and beyond. The triggers creating recognizable diseased individuals, however, often appear to remain environmental and related to poverty. The comprehensive evaluation of these links of nature and nurture remains the challenge of a historically based medical geography of the Americas.

VII.9

Disease Ecologies of South America

Pre-Columbian Peoples

The natural environment of the continent of South America is overwhelmingly diverse and thus has posed special problems of physiological adaptation to its indigenous populations, as well as later to European, African, and Asian intruders. Indeed, because of the harsh environments of much of the continent, there are but few places in which people can flourish without great effort and skillful labor. In much of the continent's vast interior, even communication and transportation would be impossible without the river systems of the Amazon and the Paraná–Paraguay along with the smaller rivers of Colombia and Venezuela, the Magdalena and the Orinoco, and the São Francisco of northeastern Brazil.

One of the most formidable environments is that of the Andes Mountains, which range from western Venezuela to the tip of the continent, with snow-capped peaks at more than 20,000 feet in altitude and with populations perched at 10,000 and 13,000 feet. At such altitudes, scarcity of oxygen has led to physiological adaptations in the bodies of the indigenous peoples of Peru and Bolivia that permit them to perform hard physical labor in the thin air.

The Andes break the westerly movement of rainfall from the Amazon basin, and rain falls in profusion on the eastern slopes, where lush tropical forests shelter the people of the Upper Amazon from outside invaders. On the opposite side of the Andes, a lack of rainfall creates the semiarid coastal lowlands intersected by small rivers flowing through the desert to the ocean.

As early as 13,000 B.C., people settled in camps along the coast of Peru and Chile. They fished and hunted the marine life of the Humboldt current that sweeps up from Antarctica, and planted crops along the rivers. Some 3,000 to 5,000 years ago, they built temples and monumental structures in "U" shapes along the northern coast (Stevens 1989). They would later construct massive irrigation complexes, cities, and states, the greatest of which was the Kingdom of Chimu, conquered first by the Incas and then by the Spaniards.

From these earliest beginnings in the coastal deserts, civilizations evolved and spread to the highlands

at Chavín de Huantar in the Andes and the great grasslands around Lake Titicaca in the high plain (*altiplano*) of Peru and Bolivia, where stone monoliths recall the civilization of Tiwanaku, whose wealth was based on enormous herds of llamas, alpacas, and vicuñas. In Colombia the golden chiefs of "El Dorado" ruled confederations of chiefdoms from their towns and villages, while the powerful empire of the Incas governed large cities from Ecuador to northern Argentina and Chile, and embraced both coastal deserts and mountain valleys. Great armies swept along the Inca roads, sometimes spreading a mysterious disease, which may have been typhus (Guerra 1979).

While large cities and empires evolved in the Andean world, large towns also arose along the Amazon River and its tributaries, where many people lived before 1500. In fact, Donald Lathrup views the central Amazon and its chiefdoms as the "cradle" of civilization in South America (Stevens 1989). They were in touch with the Andean world. They traded with it, and their armies (along with "fevers") repelled Incan armies that tried to conquer them. When the Spanish under Francisco de Orellana penetrated the Amazon in the 1540s, they encountered "very large cities" whose armies attacked them as they explored the river to its mouth. Civilization thus extended all the way to Santarém at the Tapajós river (where mound builders sculpted fanciful ceramics) and to Marajó Island at the mouth of the Amazon (where another group of mound builders, the Marajoara, buried their ancestors in large funeral urns) until about A.D. 1300, when the people there mysteriously disappeared (Roosevelt 1989). Those who lived along the Amazon River raised maize on the floodplain of the river, or root crops such as manioc on marginal soils. They traded with one another, held large fiestas in which maize beer was drunk, and worshiped their ancestors. In other words, the Amazon region was populated and even "civilized" on the eve of the conquest.

Between the rivers, nomadic hunters and gatherers roamed as far south as the semiarid savanna region (the *cerrado*) of central Brazil or occupied the great swampland (the *pantanal*) of western Mato Grosso and Bolivia. Either too little water for 6 months in the *cerrado* or too much in the *pantanal* during the rainy season forced people to migrate with the changing seasons.

Further south more propitious conditions for settlement existed along the floodplains of the Paraná–Paraguay rivers, where the Guaraní lived a settled agricultural life-style in small towns and villages. Linguistically related to them were the Tupí, who

had migrated to the Brazilian coast and farmed in the tropical forests along coastal rivers. The vast grassland of the *pampas* housed nomads who hunted a "humpless camel" and large flightless birds. Other hunters and gatherers followed their prey to the barren, windswept lands on the edge of Antarctica, where they occupied the rocky outcrops of the Straits of Magellan.

The Spanish, who, following Columbus, landed at Trinidad off the coast of Venezuela in 1498, would confront sophisticated civilizations that had mastered difficult environments from lowland tropical rain forests and deserts without rainfall to high mountain valleys. As settled agriculturalists living in villages, towns, and cities, they raised a variety of foodstuffs, giving many of them an excellent diet, and traded surpluses to neighbors in different localities. Only nomadic hunters and gatherers had uncertain food supplies by 1500. On the eve of the conquest, the pre-Columbian populations of South America were among the best-fed peoples of the fifteenth century, which in turn had an impact on the quality of their health and nutritional status, and hence resistance to disease.

In the Andean highlands, the staples were maize, white potatoes (often stored as freeze-dried chuñu), and the "Andean rice" *quinoa,* which were supplemented by guinea pigs and llama meat. Warehouses built as early as 3,800 years ago stored food against times of famine. In the coastal deserts, farmers raised corn, beans, squashes, peanuts, and sweet potatoes, and caught fish, hunted birds, or raised *guanacos* in Chile. The peoples of the Amazon specialized in the root crops, such as manioc, peanuts, and sweet potatoes, as well as maize, and hunted deer and tapirs, fished in the great rivers, and gathered nutritious wild fruits and nuts. Only away from the rivers were food resources precarious for nomadic hunters and gatherers. Some of these populations, as well as the coastal Tupí of Brazil, supplemented their diet with human victims acquired in wars and eaten in religious rituals.

On the whole, diets were largely vegetarian – low in animal fats but rich in vitamins and vegetable protein from beans, peanuts, and amaranth – with some animal protein from fish, birds, and animals. The lack of dairy cattle and goats, however, often meant calcium deprivation in weaned babies and children and osteomalacia in adult women who had multiple pregnancies. In fact, ceramic figurines from western Mexico and the west coast of South America that depict bed-ridden females with "deformities and bowing of the lower extremities" may document cal-

cium deprivation in pre-Columbian women (Weisman 1966). Otherwise, limited skeletal analysis from Peru suggests that the pre-Columbian people as a group were healthy and died from accidents and war injuries, old age, and ritual sacrifices rather than from frequent epidemic diseases. There is, however, some evidence from bone scars for a severe childhood febrile illness among the coastal cultures of Paracas, Nazca, and Ica (Allison, Mendoza, and Pezzia 1974). All this would change with the arrival of the Europeans and their African slaves, who would alter both the diet and disease environment of South America.

Pre-Columbian Diseases

On the eve of the European arrival, there are only a limited number of diseases that can be documented for South America. The best evidence survives for Peru in the ceramics of the Moche and Chimu, who accurately depicted diseases, ulcers, tumors, and congenital or acquired deformities in their portrait pots, and in the remains of mummies and skeletons preserved in the coastal deserts and at high altitudes in the Andes (Perera Prast 1970; Horne and Kawasaki 1984).

Because so many ancient Peruvians lived in crowded towns and cities, it is hardly surprising that paleopathologists have found evidence for tuberculosis, a disease so often associated with urban populations (Cabieses 1979). In a study of 11 mummies from Chile and Peru, two dating from A.D. 290 had "cavitary pulmonary lesions from the walls of which acid-fast bacilli were recovered." According to William Sharpe, two of these mummies have "diagnoses of tuberculosis about as solidly established as paleopathologic techniques will permit" (Sharpe 1983).

A second disease for which convincing evidence survives is arthritis. According to Fernando Cabieses (1979), Peruvian museums have many vertebrae and bones that reveal "typically rheumatic injuries." While examining these remains, A. Hrdlicka discovered a type of arthritis of the hip in adolescents, which modern experts identify as Calvé–Perthes disease (Cabieses 1979). Another specific study on bone lesions in skeletons from Chancay, in coastal Peru, documents osteoarthritis in the skeletal remains (Berg 1972), and Jane Buikstra (in this volume, V.8) reports a "convincing case of juvenile rheumatoid arthritis in an adolescent from the Tiwanaku period." A mummy of a young girl of the Huari culture exhibits "one of the earliest known cases of collagen disease" with "many aspects compatible with SLE" (systemic lupus erythematosus) (Allison et al. 1977).

Evidence for the presence of treponematoses (venereal syphilis, yaws, endemic syphilis, and pinta) also exists for Peru and northern South America. Although the debate on the origin of venereal syphilis continues unabated, skeletal remains suggest that some type of treponemal disease existed in South America before 1500 (see Buikstra in this volume, V.8). Some deformations in bone surfaces in skeletons and a skull from Paracas in coastal Peru suggest venereal syphilis (Cabieses 1979). Sixteenth-century chroniclers in Peru also described *bubas* (a word used for syphilis and yaws) in Spanish conquistadores, such as Diego de Almagro, who had had sexual intercourse with Indian women. Furthermore, in sixteenth-century Chile more Spaniards than Indians suffered from *bubas* (Costa-Casaretto 1980), which may suggest that the Indians had a longer experience with a treponemal disease than did the Spaniards. At that time it was a "seemingly venereal ailment that produced genital secretions" (Cabieses 1979). According to Francisco López de Gomara, "all Peruvians" suffered from *bubas* (Cabieses 1979). The problem, however, is that *bubas* is such a vague term used for skin sores or ulcers that it could refer to verruga (Carrión's disease) and yaws, whereas Cabieses (1979) believes that *bubas* descriptions resemble Nicolas–Favre disease (lymphogranuloma).

Another treponemal disease, pinta (also *carate*), was called *ccara* by the Incas (Guerra 1979) and is now endemic in Colombia. Descriptions of pinta in Colombia date from the arrival of the Spanish, who adopted the Indian name for the disease: *carate*. The Jesuit Juan de Velasco often observed the disease, and it seems to have been a common skin disease in slaves (Chandler 1972). Colombia is also one of the few countries in which yaws, pinta, and venereal syphilis occur together (Hopkins and Flórez 1977).

Possibly confused with treponemal diseases that cause skin changes was bartonellosis (Carrión's disease, Oroya fever, Peruvian verruga). Characterized by high fever, anemia, and a warty eruption on the skin, it severely afflicted Francisco Pizarro's soldiers when they invaded Peru (Hirsch 1885). In one area of Ecuador, Spanish soldiers died of it within 24 hours or suffered from warts "as large as hazelnuts," whereas the Indians experienced less severe forms of the disease (Cabieses 1979). Pre-Columbian ceramics depict the warty eruptions of the disease, whereas a case of Carrión's disease in the warty phase has been documented in a mummy of the Tiwanaku culture (Allison et al. 1974b). On the basis of this evidence, as well as the high Spanish

mortality in verruga areas in the Andes, there is little doubt that this endemic disease was of great antiquity in the Peruvian Andes (Herrer and Christensen 1975).

Another old Peruvian disease is *uta,* a type of leishmaniasis (Herrer and Christensen 1975). The Spanish called it the "cancer of the Andes," since it left ulcers on the nose and lips and often destroyed the septum. Pedro Pizarro may have described it when he reported that "those who entered the jungle contracted a 'disease of the nose' very similar to leprosy for which there was no cure" (Cabieses 1979). Ceramic evidence of mutilated noses and lips also documents the existence of uta in the pre-Columbian period for Colombia and Peru. A pre-Columbian ceramic from Cundinamarca, Colombia, where leishmaniasis is now endemic, depicted "mutilated nasal tissue" on an Indian's face (Werner and Barreto 1981).

In contrast to uta and Carrión's disease, American trypanosomiasis (Chagas' disease) is difficult to document before the sixteenth century. It is, however, unquestionably of New World origin, because the vectors and the disease do not exist outside of the Americas. Now one of the most important vector-borne diseases in South America, Chagas' disease extends throughout much of the interior of South America, but especially from northeastern Brazil to north central Argentina in a wide savanna corridor sandwiched between the coastal forests and the tropical rain forests of the Amazon (Bucher and Schofield 1981; Schofield, Apt, and Miles 1982). Because this region was remote from the Incas or coastal European settlements, historians know little about the disease before 1500. The earliest descriptions of Chagas' disease symptoms were made in sixteenth-century Brazil, whereas those for the vectors (triatomine bugs) date from the sixteenth century for Chile, Argentina, and Peru and the seventeenth century for Bolivia, where the illness is still endemic (Buck, Sasaki, and Anderson 1968; Guerra 1970; Schofield et al. 1982). Charles Darwin was attacked by triatomine bugs – what he termed "Benchuca" – when he traveled through endemic areas in 1835 (Schofield et al. 1982). Because of the way in which Chagas' disease causes facial edema, it was sometimes confused with endemic goiter, which often occurred in the same regions because of the lack of salt in the diet (Guerra 1970). The Incas identified goiter as *coto* (Guerra 1979).

Another disease of the Brazilian interior that may have existed among "the aborigines of Brazil" (Silva 1971) is *fogo selvagem* (endemic pemphigus folia-

ceus), which means wild fire in English and is endemic in central Brazil along the Tocantins and Paraná rivers and their tributaries. In 1902–3, Caramuru Paes Leme reported it among the Indians living along the Araguaia River of central Brazil, whereas another good description of the disease from 1900 dates from Bahia, a state near the Tocantins River. Apparently, *fogo selvagem* was limited in incidence as long as the Brazilian interior was sparsely settled or people avoided living along the rivers. Since the construction of Brasília and the opening of the interior to the landless poor, the disease has spread to Acre, Amazonas, and Rondonia, where it was once unknown, as well as to neighboring countries (Diaz et al. 1989).

Since many of the pre-Columbian peoples in the Andes raised animals for food and wool or kept them as pets, intestinal parasites may have been common. Some parasite remains have been recovered in autopsies on mummies from Chile and Peru. An examination of the body of a young boy revealed *Trichuris trichiura* ova as well as those for head lice (Horne and Kawasaki 1984). According to chroniclers, the poor in the Inca Empire had to "pay tribute in the form of small containers of lice." Not surprisingly, typhus was "a very common disease in ancient Peru" (Cabieses 1979). Evidence of pinworms from Chile and hookworm from Brazil has been collected in fossilized feces (Parasitologista 1986), whereas a mummy of the Tiwanaku culture yielded hookworms from around A.D. 900 (Allison et al. 1974a). *Tunga penetrans,* the chigger that burrows into the feet where it lays its eggs and causes painful foot ulcers, was native to Brazil. In the nineteenth century it spread to Africa (Crosby 1986) and thus was one of the few New World vectors to migrate to the Old World.

On the eve of the conquest, the people of South America had a limited number of diseases: tuberculosis, arthritis, and one or more treponemal diseases – Carrión's disease, uta, Chagas' disease, endemic goiter, and hookworm infestation. In addition, many doubtless suffered from nonlethal diarrheas caused by other worms and parasites as well as from foot ulcers caused by the chigger. Unspecified fevers, such as typhus, also caused ill health; and viruses have even been found in a well-preserved mummy from near Santiago, Chile (Horne and Kawasaki 1984). Not all diseases existed everywhere, however, because of known environmental limitations, particularly of the vectors. Carrión's disease, for example, occurs only where the sandfly lives, whereas Chagas' disease follows the range of the triatomine

insects. Thus, prior to 1500, diseases were limited to specific environments (tuberculosis in the cities and towns) or vectors, and few deadly epidemics decimated populations.

Old World Diseases

Which of the new diseases brought to the New World by the Europeans first touched South America is unknown, but the best documented disease in terms of its progression is smallpox. In 1514 smallpox may have arrived in Panamá with a group of Spanish colonists (Hopkins 1983). Because of frequent trade and communication between the isthmus and Peru, smallpox preceded the Spanish into the Inca Empire. A devastating illness of the mid-1520s, characterized by "fever, rash, and high mortality," struck the Inca and his imperial court in Quito and killed the Inca, Huayna Capac; it also killed many in the capital of Cuzco. Henceforth, smallpox would sweep ahead of the Spanish *conquistadores* and claim thousands of victims before they arrived. By 1554 it had reached as far south as Chile, where it attacked the Araucanians. A year later it appeared at Rio de Janeiro among a group of French Huguenots, who spread it to the coastal Indians. They in turn fled into the interior, where they passed it on to others living far from the coast. By the 1590s it was decimating the Indians of Paraguay (Luque 1941). Jesuit missionaries unwittingly took the contagion as far inland as the Upper Amazon, and from the seventeenth century on, smallpox epidemics reappeared in even the most remote parts of the interior. The continuous arrival of ships from Portugal, Spain, and Africa would renew the epidemics, and, because control measures were often ineffective, smallpox would continue to ravage South America until it was finally eradicated in Brazil in 1971 (Hopkins 1983; Ruffié and Sournia 1984; Lanning 1985; Alden and Miller 1987).

Less easily traced but often as virulent in its impact on the Indians was measles, which often accompanied smallpox epidemics or was confused with the disease. It arrived in Peru in 1530–1 (Ruffié and Sournia 1984), settled in among all population groups, exacted a high cost in lives among mission Indians and Africans in the slave trade, and reappeared in frequent epidemics throughout the centuries (Luque 1941). It continued to attack isolated Indians as late as the 1980s, as road builders and settlers opened up the Amazon region to migrants and their children from endemic-measles areas.

Next to smallpox and measles, possibly the major killers of the Indians, past and present, were the respiratory diseases, which early missionaries and miners inadvertently encouraged by gathering Indians into mission villages and mines, where influenza and the common cold could sweep from person to person with lethal impact. Pneumonia, tuberculosis, and bronchitis also preyed on the survivors. Peruvian Indians forced to work in the mines died of pneumoconiosis and silicosis (Munizaga et al. 1975); only by fleeing the missions, mines, and European settlements could Indians survive. In the 1990s, their descendants still confront, and die of, the same diseases.

Because so many Indians could and did flee into the interior, the impact of European diseases in sixteenth-century South America was uneven and possibly less catastrophic in some regions than in Mexico. Population decline in the southern highlands of Peru, for example, was not as precipitous as in coastal Peru (Cook 1981) or central Mexico. Nonetheless, all peoples would eventually suffer depopulation as a result of flight, disease, forced labor, warfare, and the massive disruptions in indigenous food supply and consumption that accompanied the European conquests. In other words, although environmental diversity blunted the catastrophe that so quickly overtook the Caribbean and Mexican populations in the sixteenth century, it also prolonged the trauma of the impact of disease through the centuries until the present.

On the other hand, much of South America's environment facilitated the establishment of new mosquito-borne diseases in the tropical lowlands of northern South America, the Amazon basin, and coastal Brazil. These diseases came from Europe and from Africa aboard slave ships and in the bodies of the African slaves forcibly imported into South America.

The first of these great killers was malaria; when and where and in what form its parasites and vectors entered the continent has long been debated (Dunn 1965). Malaria may have been indigenous and hence may have been the reason ancient Peruvians built their houses far from the rivers (Cabieses 1979); it also might have been one of the "fevers" that attacked the Inca armies as they invaded the Upper Amazon (Cabieses 1979). On the other hand, this seems unlikely, given population densities achieved in the Upper Amazon before the conquest.

Prevailing opinion is that malaria was an imported disease, and one or more strains of malarial parasites were undoubtedly introduced into the Americas in the sixteenth century from endemic areas in Europe and Africa (and, as a matter of fact, as

late as 1930 when an epidemic spread by *A. gambiae* erupted with particular virulence in Brazil) (Marks and Beatty 1976). Sixteenth-century Jesuits recorded attacks of fever throughout the tropics; and a century later Europeans discovered the treatment for these fevers, cinchona bark (the source of *quina* or quinine), but did not use it very effectively (Luque 1941; Dunn 1965; McCosh 1977). In the eighteenth century, malaria was known as *sezões* in the Brazilian interior, and by the nineteenth century as intermittent or pernicious fever (Documentos 1942; Karasch 1987). More recently, scientists identified and classified the parasites and vectors as causal agents, and widespread spraying with insecticides followed, retarding malarial incidence until the 1980s, when it once again became a serious problem of health. A chloroquinine-resistant strain of parasite, and massive deforestations in Rondonia and other parts of the Amazon have led to significant outbreaks of malaria among miners, Indians, and settlers in the region.

Urban yellow fever is more easily traced than malaria in historical sources, owing to the distinctive bloody (black) vomit and high mortality with which it is associated (Goodyear 1978). One of the first unmistakable descriptions of the disease dates from 1623, when Aleixo de Abreu, who had served in Brazil and Africa, wrote his *Treatise of the Seven Diseases* in which he described a "disease of the worm" marked by blood vomit. The disease, henceforth to be called *bicha* or *os males* (the evils), took epidemic form in Pernambuco in the northeast of Brazil between 1685 and 1694 (Rosa and Franco 1971) and then apparently disappeared until it attacked Salvador and Rio de Janeiro in 1849 (Ward 1972; Cooper 1975).

The first good descriptions of sylvan or jungle yellow fever date from 1898–9 from the interior of São Paulo when the authorities encountered cases of yellow fever "in full virgin forest" (Franco 1969). Since the mid-nineteenth century, yellow fever (in both its urban and sylvan forms) has swept through tropical and subtropical South America (Henschen 1966). Because of successful twentieth-century eradication programs that began with the efforts of Osvaldo Cruz in Brazil in 1903, yellow fever was eliminated from many parts of the continent. It has, however, resumed the offensive in the 1980s as settlers have moved into areas of sylvan yellow fever or built towns in the Amazon region that created optimal breeding conditions for *A. aegypti,* the most prominent vector of the disease, and thus for the transmission of urban yellow fever. Indeed, the breakdown in public health programs in coastal cities of South America has led to the reappearance of the vector *A. aegypti* in cities such as Rio de Janeiro and sporadic outbreaks of yellow fever. Most cases continue to be reported in the Amazon region or other parts of rural, tropical South America. As James Ward concluded in 1972, "Yellow fever is not a disease of the past" but rather "a disease of the present" in South America.

A third tropical fever is dengue, which attacked Lima, Peru, in 1818 and northern South America in the 1820s. By the 1840s it had reached Rio de Janeiro (Hirsch 1883). Since that time, dengue is often difficult to trace because of its confusion with other fevers. With the eradication of its vector, *A. aegypti* (which also carries yellow fever), in twentieth-century coastal cities, dengue retreated until the 1980s, when it again swept urban, southeastern Brazil – wherever the vector had reestablished itself owing to faltering public health campaigns. By 1990 it was in the Amazon region as far inland as Iquitos, Peru.

Next to the tropical fevers in virulence were other diseases that reached South America from Africa. As long as the slave trade with Africa existed, so too did epidemics associated with Africans and the trade (Karasch 1987). Thus, until the effective abolition of the slave trade to Brazil in 1850, smallpox and measles attacked slave ships and port cities or wherever infected Africans were unloaded for sale. Dysentery (Hirsch 1886; Karasch 1987) preyed on those confined to slave ships and the great slave markets of Cartagena, Salvador, Buenos Aires, and Rio de Janeiro. From the markets it often spread to kill untold victims in the coastal cities and neighboring Indian missions. Intestinal parasites infested most slaves, and sometimes led to wormy ulcers in the rectum, the malady known as *bicho* or *maculo* in Brazil and Africa (Guerra 1970). Schistosomiasis (*S. mansoni*) settled into coastal Brazil (Silva 1983), Suriname, and Venezuela (WHO 1985), whereas leprosy reached into the interior of the continent to as far as Goiás in the eighteenth century and the tropical lowlands of Colombia. Filarial worms (filariasis) found congenial breeding grounds in the swampy lowlands of Brazil and northern South America, and soon the bodies of their human hosts swelled to "elephantine size." The African disease *ainhum,* which led to the loss of toes, was observed in slaves in Brazil (Peixoto 1909). Blinding eye diseases of conjunctivitis and trachoma (ophthalmia) accompanied slave ships and attacked coastal cities and plantation areas. Onchocerciasis found new vectors in

northern South America and settled into the river valleys of Colombia's Pacific lowlands (Trapido, D'Alessandro, and Little 1971), Venezuela, and northern Brazil (Pan American 1974). The Guinea worm arrived in the bodies of Africans, along with a variety of other worms and parasites. The *sarna,* or "itch," caused epidemics of itching on ships and in ports, whereas scurvy, pellagra, and beriberi, as well as other nutritional diseases, affected slaves fed manioc or corn with beans and a little dried beef. Yaws swept through slave quarters and settled down among blacks in coastal Colombia, where it is still endemic (Chandler 1972). In blacks it was often confused with syphilis. Once the slave trade ended, the most lasting legacy of these waves of epidemics was the establishment of the African diseases as endemic diseases in tropical South America.

The diseases of the slave trade were followed by a new wave of diseases in the nineteenth century, as European and Asian immigrants replaced the Africans. German colonists brought epidemics of typhus to southern Brazil, whereas severe outbreaks of diphtheria and scarlet fever, probably accompanying the Europeans, attacked southern South America (Hirsch 1883; Karasch 1987). This was, however, not the first time diphtheria had appeared in South America. In 1614 it struck Cuzco, Peru, and reportedly touched every household (Marks and Beatty 1976; Cook 1981). As once small towns grew into densely crowded cities with slums lacking clean water or sewer systems, the incidence of typhoid fever increased and hepatitis worsened.

Tuberculosis attacked the black slaves and the poor of the growing cities with exceptional virulence. Indeed after the late nineteenth century, possibly more died of tuberculosis in cities like Rio de Janeiro than of the "great tropical killers" as a result of swamp removals and public health campaigns against mosquito habitats. As so many rural migrants crowded into urban slums with precarious food, water, and health care, the frequency and virulence of these "urban" diseases increased dramatically.

These urban slum populations would be among those to fall prey to a new disease that appeared in South America for the first time in the nineteenth century: Asiatic cholera. This Asian import was first reported among sailors coming from Europe to Brazil in 1855. The first Brazilian case occurred in Belém in 1855 with the next in Salvador about a month later, followed by cases in Rio de Janeiro. This first great epidemic of 1855–6 may have claimed up to 200,000 lives in Brazil alone (Cooper 1986). It also attacked Argentina and appeared in a major epidemic during the Paraguayan War (1864–70), where it claimed both civilian and military lives (Reber 1988). Cholera continued to reappear in epidemics throughout the continent until twentieth-century public health campaigns brought it under control.

Another Asiatic disease that has settled into South America is the bubonic plague. How it came to survive in countries as far distant as Brazil and Ecuador is still uncertain. In 1899 the plague broke out in Rio de Janeiro and Santos (Vianna 1975). About 9 years later, in 1908, merchant ships introduced the plague into the port of Guayaquil and coastal Ecuador, from which it spread to the highland populations, among whom it was still endemic in the 1930s (Jervis 1967). Most cases of plague, however, occurred in Brazil, especially in the region of the Northeast. In 1903 an epidemic of plague broke out in Maranhão and Pará, and the disease was well established in the interior of Pernambuco by the 1920s (Oliveira 1975; Vianna 1975). In 1973 Brazil registered 35 percent of the cases of plague reported to the World Health Organization (Marks and Beatty 1976). Over 10 years later, from 1984 to 1986, epidemics of bubonic plague erupted in Paraíba and Minas Gerais, but isolated cases occur every year in the states of Ceará and Bahia. Only rapid medical intervention prevents a high mortality (Peste 1986).

In most of the twentieth century, public health programs and massive immunization projects, combined with the removal of mosquitoes and their habitats, led to the control of many epidemic diseases. Exceptions are the great influenza epidemic of 1918–19, which exacted the same high cost in lives in South America as elsewhere in the world, and the AIDS epidemic of the 1980s, which rages unchecked in the heterosexual population of Brazil. In the 1960s modern medicine and scientific technology had seemed to be victorious over epidemic disease, but in the 1980s the deteriorating economies of South America have stifled public health and immunization programs. Children's diseases such as measles, chickenpox, and pertussis once more prey on the nonvaccinated, whereas polio cripples children and meningitis sweeps through the slums of Brazil. Diarrhea and dehydration kill infants, and intestinal parasites plague the poor. Schistosomiasis saps their strength, and Chagas' disease extends its range as deforestation changes habitats and people continue to live in thatched-roof houses, where the vector hides. Malaria, yellow fever, and dengue have once more re-

sumed the offensive as a result of the environmental changes in the Amazon region and the reestablishment of vectors in the towns and cities. While the ancient Peruvian fevers still attack and disfigure the rural poor, unknown but deadly fevers have erupted in settlers along the Trans-Amazon Highway. Viral hemorrhagic fevers, for example, whose victims died of massive bloody hemorrhages, erupted in the 1970s and 1980s. Even cholera reappeared in South America in the early 1990s.

The combination of population growth, environmental devastation, and deteriorating public health services due to a debt crisis and capital outflows have led to severe setbacks in the modern campaigns to contain epidemic disease in South America. As the number of rural and urban poor increase, so too does the frequency of disease, since so many diseases, such as Chagas', hepatitis, and typhoid, are often linked to low socioeconomic standards of living. Thus, although once isolated from the onslaught of Old World diseases, the South American continent now suffers from all those illnesses that international travelers carry with them from the urban coastal cities to the most remote parts of the Amazon region. Unless economic and political strategies are developed to improve public health in the 1990s, the diseases of both the Old and the New World will continue to flourish and grow in virulence in South America.

PART VIII

Major Human Diseases
Past and Present

VIII.1
Acquired Immune Deficiency Syndrome (AIDS)

Acquired immune deficiency syndrome (AIDS), first identified in 1981, is an infectious disease characterized by a failure of the body's immunologic system. As a result, affected individuals become increasingly vulnerable to many normally harmless microorganisms, eventually leading to severe morbidity and high mortality. The infection, spread sexually and through blood, has a high fatality rate, approaching 100 percent. Caused by a human retrovirus known as HIV-1, AIDS can now be found throughout the world – in both Western industrialized countries and also the developing nations of Africa and Latin America.

Although precise epidemiological data remain unknown, public health officials throughout the world have focused attention on this pandemic and its potentially catastrophic impact on health, resources, and social structure. Treatments for the disease have been developed, but there is currently no cure or vaccine.

Etiology and Epidemiology

Beginning in the late 1970s, physicians in New York and California reported the increasing occurrence of a rare type of cancer, Kaposi's sarcoma, and a variety of infections including pneumocystis pneumonia among previously healthy young homosexual men. Because of the unusual character of these diseases, which are typically associated with a failure of the immune system, epidemiologists began to search for characteristics that might link these cases. AIDS was first formally described in 1981, although it now appears that the virus that causes the disease must have been silently spreading in a number of populations during the previous decade. Early epidemiological studies suggested that homosexual men, recipients of blood transfusions and blood products (especially hemophiliacs), and intravenous drug users were at greatest risk for the disease. For this reason, research focused on a search for a common infectious agent that could be transmitted sexually or through blood. This research led to the identification in 1983, in French and American laboratories, of a previously undescribed human retrovirus. Officially named HIV-1 for *human immunodeficiency virus,* this organism is an RNA retrovirus. Although the biological and geographic origins of the organism remain obscure, the AIDS epidemic appears to mark the first time this organism has spread widely in human populations. There is no evidence for casual transmission of HIV.

Following the identification of HIV-1, tests to detect antiviral antibodies to the virus were devised in 1984. Although these tests do not detect the virus itself, they are generally effective in identifying infection because high levels of antibody are produced in most infected individuals. The enzyme-linked immunosorbant assay (ELISA), followed by Western blot testing, has made possible the screening of donated blood to protect the blood supply from HIV, as well as testing for epidemiological and diagnostic purposes.

Distribution and Incidence

Although identified only in 1981, AIDS can now be found throughout the world. Spread by sexual contact, by infected blood and blood products, and perinatally from mother to infant, AIDS had been reported in 138 countries by July 1988, according to the World Health Organization. Since HIV infection precedes the development of AIDS, often by as many as 7 to 11 years, the precise parameters of the epidemic have been difficult to define. Estimates suggest that worldwide between 5 and 10 million individuals were infected with the virus by the end of 1988. At that time, in the United States more than 80,000 cases of AIDS had occurred, and nearly 50,000 of these individuals had died. Projections by the U.S. Public Health Service Centers for Disease Control estimate that between 1.5 and 2.0 million Americans are infected with HIV but are currently asymptomatic. Although the "cofactors" that may determine the onset of symptoms remain unknown, all current evidence suggests that HIV-infected individuals will eventually develop AIDS.

Researchers have identified three epidemiological patterns of HIV transmission, which roughly follow geographic boundaries. Pattern I includes North America, Western Europe, Australia, New Zealand, and many urban centers in Latin America. In these industrial, highly developed areas, transmission has been predominantly among homosexual and bisexual men. Since the introduction of widespread blood screening, transmission via blood now occurs principally among intravenous drug users who share injection equipment in these areas. Although there is no evidence of widespread infection among the heterosexual population in these countries, het-

erosexual transmission of the virus from those infected via intravenous drug use has increased, leading to a rise in pediatric cases resulting from perinatal transmission.

Within the United States the distribution of AIDS cases has been marked by a disproportionate representation of the poor and minorities. As the principal mode of transmission has shifted to intravenous drug use, AIDS has increasingly become an affliction of the urban underclass, those at greatest risk for drug addiction. Serum surveys reveal that 50 percent or more of the intravenous drug users in New York City are infected with HIV. Blacks and Hispanics, who comprise 20 percent of the U.S. population, accounted in 1988 for more than 40 percent of all AIDS cases. Women, who account for more than 10 percent of new AIDS cases, are typically infected by intravenous drug use or by sexual contact with a drug user; in 70 percent of all infected newborns, transmission can be traced to drug use. By 1991, between 10,000 and 20,000 children in the United States are expected to have symptomatic HIV infections.

In pattern II countries, comprised of sub-Saharan Africa and, increasingly, Latin America, transmission of HIV occurs predominantly through heterosexual contact. In some urban areas in these countries, up to 25 percent of all sexually active adults are reported to be infected, and a majority of female prostitutes are seropositive. In addition, transfusion continues to be a mode of transmission because universal screening of blood is not routine. Unsterile injections and medical procedures may also be contributing to the spread of infection. In these areas, perinatal transmission is an important aspect of the epidemic; in some urban centers at least 5 to 15 percent of pregnant women have been found to be infected.

Pattern III countries, which include North Africa, the Middle East, Eastern Europe, Asia, and the Pacific, have thus far experienced less morbidity and mortality from the pandemic. Apparently, HIV-1 was not present in these areas until the mid-1980s; therefore, fewer than 1 percent of all cases have been found in pattern III countries. Infection in these areas has been the result of contact with infected individuals from pattern I and II countries, or importation of infected blood. The nature of world travel, however, has diminished the significance of geographic isolation as a means of protecting a population from contact with a pathogen.

In 1985, a related virus, HIV-2, was discovered in West Africa. Although early reports have suggested that HIV-2 may be less pathogenic, the natural history of infection with this agent remains unclear, as does its prevalence.

Immunology

HIV cripples the body's immunologic system, making an infected individual vulnerable to other disease-causing agents in the environment. The most common of these opportunistic infections in AIDS patients has been pneumocystis pneumonia, an infection previously seen principally among patients receiving immunosuppressive drugs. In addition to pneumocystis, AIDS patients are prone to other infectious agents such as cytomegalovirus (CMV), *Candida albicans* (a yeastlike fungus), and *Toxoplasma gondii* (a protozoan parasite). There is also evidence that infection with HIV makes individuals more vulnerable to infection with tuberculosis. A resurgence of tuberculosis has been reported in nations with a high incidence of AIDS.

Immunologic damage occurs by depletion of a specific type of immune cell, a white blood cell known as a helper T4 lymphocyte. Destruction of these cells accounts for the vulnerability to many normally harmless infectious agents. In some cases, infection of the central nervous system with HIV may cause damage to the brain and spinal column, resulting in severe cognitive and motor dysfunction. In its late manifestations, AIDS causes severe wasting. Death may occur from infection, functional failure of the central nervous system, or starvation.

Clinical Manifestations and Treatment

HIV infection has a wide spectrum of clinical manifestations and pathological abnormalities. After infection, an individual may remain free of any symptoms for years, perhaps even a decade or longer. Some individuals do experience fever, rash, and malaise at the time of infection when antibodies are first produced. Patients commonly present with general lymphadenopathy, weight loss, diarrhea, or an opportunistic infection. Diagnosis may be confirmed by the presence of antibodies for HIV or by a decline in T4 helper cells. Most experts now agree that HIV infection itself should be considered a disease regardless of symptoms.

Research efforts to develop effective therapies have centered on antiviral drugs that directly attack HIV, as well as drugs likely to enhance the functioning of the immune system. Because the virus becomes encoded within the genetic material of the host cell and is highly mutable, the problem of finding safe and effective therapies has been extremely difficult, requiring considerable basic science and

clinical knowledge. Studies are currently being conducted to determine the anti-HIV properties of many drugs, but the ethical and economic obstacles to clinical trials with experimental drugs are formidable. Given the immediacy of the epidemic, it is difficult to structure appropriate randomized clinical trials, which often take considerable time, to assess the safety and efficacy of a drug. At present, the U.S. Food and Drug Administration has licensed only one drug for the treatment of HIV infection, AZT (azidothymidine) which, according to clinical studies, delays but does not prevent death. Since the beginning of the epidemic, clinical reasearch has refined the treatment of opportunistic infections. Recent studies, for example, have demonstrated the effectiveness of aerosolized pentamidine, an antibiotic, in preventing the development of pneumocystis pneumonia. Despite these advances, expected survival currently (as of 1988) averages 2 years after the onset of symptoms. With anticipated improvements in antiviral treatments, length of survival is likely to increase.

History and Geography

In its first decade, AIDS has created considerable suffering and has generated an ongoing worldwide health crisis. During this brief period, the epidemic has been identified and characterized epidemiologically, the basic modes of transmission have been specified, a causal organism has been isolated, and effective tests for the presence of infection have been developed. In spite of this remarkable progress, which required the application of sophisticated epidemiological, clinical, and scientific research, the barriers to controlling AIDS are imposing and relate to the most complex biomedical and political questions. AIDS has already sorely tested the capabilities of research, clinical, and public health institutions throughout the world.

Because HIV is related to other recently isolated primate retroviruses such as simian T lymphotropic virus (STLV)-III, which has been isolated in wild African green monkeys, there has been considerable speculation that HIV originated in Africa. Antibodies to HIV were discovered in stored blood in Zaire dating back to 1959, and it seems likely that evidence of the organism will be identified in even earlier specimens. According to Robert Gallo and Luc Montagnier, who have been credited with the identification of HIV, it is likely that the virus has been present for many years in isolated groups in central Africa. Because outside contacts were minimal, the virus was rarely spread, and an epidemic

could not be sustained. Once a sizable reservoir of infection was established, however, HIV became pandemic. As with other sexually transmitted diseases, such as syphilis, no country wished to be associated with the stigma of the "origin" of the virus.

The epidemic began at a moment of relative complacency, especially in the developed world, concerning epidemic infectious disease. Not since the influenza epidemic of 1918–20 had an epidemic appeared with such devastating potential. The Western, developed world had experienced a health transition from the predominance of infectious to chronic disease and had come to focus its resources and attention on systemic, noninfectious diseases. Thus AIDS appeared at a historical moment in which there was little social or political experience in confronting a public health crisis of this dimension. The epidemic fractured a widely held belief in medical security.

Not surprisingly, early sociopolitical responses were characterized by denial. Early theories, when few cases had been reported, centered on identifying particular aspects of "fast track" gay sexual culture that might explain the outbreak of cases of immune-compromised men. Additional cases among individuals who had received blood transfusions or blood products, however, soon led the U.S. Centers for Disease Control to the conclusion that an infectious agent was the likely link among these individuals. Nevertheless, in the earliest years of the epidemic, few wished to confront openly the possibility of spread beyond these specified "high-risk" groups. During this period, when federal and state interest and funding lagged, grassroots organizations, especially in the homosexual community, were created to meet the growing needs for education, counseling, patient services, and in some instances, clinical research. Agencies such as the Gay Men's Health Crisis, founded in New York City in 1982, and the Shanti Project, established in San Francisco in 1983, worked to overcome the denial, prejudice, and bureaucratic inertia that limited governmental response.

As the nature and extent of the epidemic became clearer, however, hysteria sometimes replaced denial. Because the disease was so powerfully associated with behaviors characteristically identified as either immoral or illegal (or both), the stigma of those infected was heightened. Victims of disease were often divided into categories: those who acquired their infections through transfusions or perinatally, the "innocent victims"; and those who engaged in high-risk, morally condemnable behaviors, the "guilty perpetrators" of disease. Since the early recognition of behavioral risks for infection, there has been a ten-

dency to blame those who became infected through drug use or homosexuality, behaviors viewed as "voluntary." Some religious groups in the United States and elsewhere saw the epidemic as an occasion to reiterate particular moral views about sexual behavior, drug use, sin, and disease. AIDS was viewed as "proof" of a certain moral order.

People with AIDS have been subjected to a range of discriminatory behavior including loss of job, housing, and insurance. Since the onset of the epidemic, incidents of violence against gays in the United States have risen. Despite the well-documented modes of HIV transmission, fears of casual transmission persist. In some communities, parents protested when HIV-infected schoolchildren were permitted to attend school. In one instance, a family with an HIV-infected child was driven from a town by having their home burned down.

By 1983, as the potential ramifications of the epidemic became evident, national and international scientific and public health institutions began to mobilize. In the United States, congressional appropriations for research and education began to rise significantly. The National Academy of Sciences issued a consensus report on the epidemic in 1986. A presidential commission held public hearings and eventually issued a report calling for protection of people with AIDS against discrimination and a more extensive federal commitment to drug treatment. The World Health Organization established a Global Program on AIDS in 1986 to coordinate international efforts in epidemiological surveillance, education, prevention, and research.

Despite the growing recognition of the significance of the epidemic, considerable debate continues regarding the most effective public health responses to the epidemic. Although some nations such as Cuba have experimented with programs mandating the isolation of HIV-infected individuals, the World Health Organization has lobbied against the use of coercive measures in response to the epidemic. Given the lifelong nature of HIV infection, effective isolation would require lifetime incarceration. With the available variety of less restrictive measures to control the spread of infection, most nations have rejected quarantine as both unduly coercive and unlikely to achieve control, given current estimates of prevalence. Traditional public health approaches to communicable disease including contact tracing and mandatory treatment have less potential to control infection because there are currently no means of rendering an infected individual noninfectious.

Because biomedical technologies to prevent trans-

mission appear to be some years away, the principal public health approaches to controlling the pandemic rest upon education and behavior modification. Heightened awareness of the dangers of unprotected anal intercourse among gay men, for example, has led to a significant decline in new infections among this population. Nevertheless, as many public health officials have been quick to note, encouraging the modification of risk behaviors, especially those relating to sexuality and drug use, present no simple task, even in the face of a dread disease.

The burden of AIDS, in both human suffering and its demands on resources, is likely to grow in the years ahead. Projections now estimate expenditures totaling nearly $70 billion per year in the United States by 1991. Ensuring quality care for those infected will become even more difficult, especially in the epidemic's epicenters, where those infected are increasingly among the minorities and poor. In the developing world, AIDS threatens to reverse advances in infant and child survival in recent decades. The epidemic is likely to have a substantial impact on demographic patterns. Because the disease principally affects young and middle-aged adults, 20 to 49 years of age, it has already had tragic social and cultural repercussions. Transmitted both horizontally (via sexual contact) and vertically (from mother to infant), the epidemic has the potential to depress the growth rate of human populations, especially in areas of the developing world. In this respect, the disease could destabilize the work force and depress local economies.

AIDS has clearly demonstrated the complex relationship of biological and behavioral forces in determining patterns of health and disease. Altering the course of the epidemic by human design has already proved to be no easy matter. The lifelong infectiousness of carriers; the private, biopsychosocial nature of sexual behavior and drug use; and the fact that those at greatest risk are already stigmatized – all have made effective public policy interventions even more difficult. Finally, the very nature of the virus itself – its complex and mutagenic nature – makes a short-term technological breakthrough unlikely.

The remarkable progress in understanding AIDS is testimony to the sophistication of contemporary bioscience; the epidemic, however, is also a sobering reminder of the limits of that very biotechnology. Any historical assessment of the AIDS epidemic must be considered provisionary. Nevertheless, it already has become clear that this epidemic has forced the world to confront a new set of biological imperatives.

VIII.2
African Trypanosomiasis (Sleeping Sickness)

African trypanosomiasis, or sleeping sickness, is a fatal disease caused by a protozoan hemoflagellate parasite, the trypanosome. It is transmitted through the bite of a tsetse fly, a member of the genus *Glossina*. Sleeping sickness is endemic, sometimes epidemic, across a wide band of sub-Saharan Africa, the so-called tsetse belt that covers some 11 million square kilometers. Although the disease was not scientifically understood until the first decade of the twentieth century, it had been recognized in West Africa from the fourteenth century.

The chemotherapy to combat trypanosomiasis has remained archaic, with no significant advances made and, indeed, very little research done between the 1930s and the 1980s. Most of the victims are poor, rural Africans, which has meant that there is little or no economic incentive for pharmaceutical firms to devote research resources to the disease (Goodwin 1987). However, in the mid-1980s field trials of a promising new drug, D1-alpha-difluoromethylornithine (DFMO), demonstrated the drug's efficacy in late-stage disease when there is central nervous system involvement. In addition, there have been exciting recent developments in the field of tsetse eradication with the combined use of fly traps and odor attractants (Hall et al. 1984). And, the World Health Organization's Special Program on Tropical Disease is trying to overcome the research problem resulting from the reluctance of pharmaceutical firms to get involved.

Etiology

There are two forms of human sleeping sickness in Africa. An acute form caused by *Trypanosoma brucei rhodesiense* with a short incubation period of 5 to 7 days occurs in eastern and southern Africa. The chronic form, *Trypanosoma brucei gambiense*, of western and central Africa can take from several weeks to months or even years to manifest itself. Both diseases are transmitted by tsetse flies. There are many species of *Glossina*, but only six act as vectors for the human disease. The *palpalis* group, or riverine tsetse, is responsible for the transmission of *T. b. gambiense* disease. Riverine tsetse include *Glossina palpalis* (see Figure VIII.2.1), *Glossina fuscipes,* and *Glossina tachinoides;* these inhabit the
Figure VIII.2.1. *Glossina palpalis.*

two large blocks of lowland rain forest in western and central Africa as well as the fringing gallery forests along waterways, which extend into neighboring savanna regions. The *morsitans* group, or savanna tsetse, is the vector for *T. b. rhodesiense,* the cause of the rhodesiense form of sleeping sickness; it includes *Glossina morsitans* (see Figure VIII.2.2), *Glossina pallidipes,* and *Glossina swynnertoni,* which live in the savanna woodlands of eastern and southern Africa (see Maps VIII.2.1 and VIII.2.2). Although tsetse flies are not easily infected with trypanosomes, once infected they remain vectors of the disease for life.

After being bitten by an infected fly, most victims experience local inflammation, or the trypanosomal chancre; and parasites migrate from this site to multiply in blood, lymph, tissue fluids, and eventually the cerebrospinal fluid. The blood trypanosome count oscillates cyclically, with each successive wave, or *parasitemia,* manifesting different surface antigens. In this manner, trypanosomes evade antibodies raised by the host to their previous surface coats. (This antigenic variability has helped to make

the trypanosome one of the most researched pathogenic parasites and a particular favorite with molecular biologists today [Warren, personal communication].) Eventually, all organs are invaded, with central nervous system involvement ultimately leading to death.

Epidemiology

The epidemiology of African sleeping sickness is far from being fully understood (Jordan 1986). A complex epidemiology makes it most difficult to analyze and predict, thereby necessitating analysis of the total context of the disease pattern. In addition, the epidemiological pattern varies considerably from place to place. Nevertheless, two features are well-recognized. First, trypanosomiasis is exceptionally focal, occurring at or around specific geographic locations; and second, the number of tsetse flies is apparently not as important for disease incidence as is the nature of the human–fly contact.

The focal nature of sleeping sickness means that the ecological settings in which it occurs are of vital importance for understanding its epidemiology. Seemingly impossible to destroy, many historical foci tend to flare up in spite of concentrated efforts since the 1930s on the part of surveillance and prevention personnel (Duggan 1970; Janssens, personal communication). This means that very often the villages and regions that were affected decades ago remain problem areas today. The disease involves

humans, parasites, tsetse flies, wild and domesticated animals, and the ecological setting that they share. Although foci remain at varying levels of endemicity, increasing population movements have complicated the epidemiology (Lucasse 1964; Ruppol and Libala 1977). Moreover, disease incidence is not necessarily related to fly density. Research has shown that a small number of flies with good human–fly contact can sustain an endemic, even as epidemic, incidence.

The average life-span of tsetse flies is 1 to 6 months, during which they require shade, humidity, and a temperature range between 20° and 30°C. Tsetse species have varying food preferences, ranging from the blood of wild and domestic animals to that of humans, but they require a daily blood meal, thereby making a single fly potentially highly infective.

Gambiense sleeping sickness is classically a disease of the frontier of human environment, where human-created habitat meets sylvan biotope. Humans are the principal reservoir of *T. b. gambiense*, and they maintain the typical endemic cycle of the disease. It is now known, however, that some animals, including domestic pigs, cattle, sheep, and even chickens, can act as reservoirs. The key to understanding the *gambiense* form is its chronicity and the fact that there are usually very low numbers of parasites present in the lymph and other tissue fluids. *Gambiense* disease can be maintained by a mere handful of *peridomestic* flies—that is, those

that have invaded bush or cultivations near human settlements. This is known as close human–fly contact. Cultivation practices such as the introduction of banana groves, shade trees, new crops like tobacco and lantana hedges, or the creation of new farms can provide fresh ecological niches into which tsetse flies may spread, introducing sleeping sickness through peridomestic transmission.

Riverine *G. palpalis* are most commonly found near the low-level brush bordering smaller waterways and pools; during dry seasons, when humans and flies are brought together through their shared need for water, the flies become particularly infective. Activities such as fishing, bathing, water collection, and travel bring humans into daily contact with the insects, and in this way an endemic level of the disease can be maintained over long periods. Other common foci for the disease are sacred groves, which are often small clearings in the forest where the high humidity allows the flies to venture farther from water sources.

The virulent *rhodesiense* form of the disease is a true zoonosis maintained in wild animal reservoirs in the eastern African savannas. In the case of *T. b. gambiense,* humans are probably the normal mammalian hosts, with wild and domestic animals as adventitious hosts, whereas in the case of *T. b. rhodesiense* the usual mammalian hosts are wild ungulates, with humans as adventitious hosts. Transmission of *rhodesiense* disease is more haphazard and directly relates to occupations such as searching for firewood, hunting, fishing, honey gathering, poaching, cultivation, cattle keeping, and being a game warden or a tourist. Whereas the *gambiense* form of the disease is site related, the *rhodesiense* form is occupation related, which helps to explain why the latter characteristically affects many more men and boys than women and girls. However, when a community moves near bush infested with infected flies, the entire population is at risk.

The wild and domestic animal reservoir of trypanosomes is an important factor in the epidemiology and history of sleeping sickness. The paleogenesis of human trypanosomiasis has been much studied, and it is well established that the trypanosomiases are ancient in Africa. Indeed, it is conjectured that the presence of sleeping sickness may explain why the ungulate herds of the African savanna have survived human predators for so long; the wild-animal reservoir of trypanosomes firmly restricted the boundaries of early human settlement (McNeill 1977). Although the wild

ungulate herds became trypo-tolerant, with few exceptions domestic cattle still succumb to the disease, and the vast majority of research and funding has been aimed at solving the problem of animal – *not* human – sleeping sickness.

In evolutionary terms, the presence of trypanosomes in Africa may perhaps have precluded the development of some ground-dwelling faunas, thus encouraging certain more resistant primates, including the early ancestors of humankind, to fill the empty ecological niches (Lambrecht 1964). If so, then humans were exposed to the possibility of trypanosomal infection at the time of their very remote origin. The parasites are, on the whole, poorly adapted to humans, which accounts for the variety of clinical symptoms and ever-changing epidemiological patterns. The fact that the parasitism of human beings is still evolving helps us to understand the unpredictable nature of the disease. A perfectly adapted parasite does not kill its host – at least in the short run.

Distribution and Incidence

An estimated 50 million people in 42 countries are at risk for trypanosomal infection (Molyneux and Smith, personal communication), while it is estimated that only about 5 to 10 million people have access to some form of protection against or treatment for the disease (World Health Organization 1985). Sleeping sickness is endemic across the wide band of sub-Saharan Africa known as the "tsetse belt" lying roughly between 20° north and 20° south of the equator (see Maps VIII.2.1 and VIII.2.2), where it can attain epidemic proportions for a variety of natural and sociopolitical reasons.

The actual numbers of cases will never be known, as it is a disease of remote rural areas, and even today people in such places often die undiagnosed and uncounted. Most national statistics are grossly underreported, with the World Health Organization being notified of about only 10 percent of the new cases. Based upon data from reporting countries, the current estimate of incidence is 20,000 to 25,000 cases annually, which is alarming because most of the victims are concentrated in Zaire, Uganda, and southern Sudan, the most important foci of the disease in the 1980s. In 1987, Busoga (Uganda) reported around 7,000 new cases, whereas the same region reported 8,500 to 9,000 cases in 1979–80. Some villages had infection rates of up to 25 percent (Smith, personal communication). In the late 1970s and 1980s, severe outbreaks occurred in Cameroon, Angola, Central African Republic, the Ivory Coast,

Tanzania, as well as the Sudan, Zambia, Uganda, and Zaire.

Clinical Manifestations and Pathology

Although trypanosomiasis has been studied for over 80 years, much is still unknown about the pathology of the disease. Three phases follow the bite of an infected fly: first the chancre itself; then the hemolymphatic or "primary stage"; and finally the meningocephalitic or "secondary stage." On average, people infected with *T. b. gambiense* live 2 or 3 years before succumbing, although there are recorded cases of infection spanning as much as 2 decades. In contrast, infection with the more virulent *T. b. rhodesiense,* if untreated, usually leads to death within 6 to 18 weeks.

The disease manifests a bewildering, sometimes startling, array of clinical symptoms, which can vary from place to place. Progressing through the two stages, there is increasing parasitemia with eventual involvement of the central nervous system. Clinical symptoms can include fever, headache, and psychiatric disorders such as nervousness, irascibility, emotionalism, melancholia, and insomnia, which reflect neuronal degeneration. Other symptoms include loss of appetite, gross emaciation, sleep abnormalities, stupor, and the characteristic coma from which sleeping sickness derives its name. Some of the initial symptoms of sleeping sickness are also characteristic of early malaria, which can make differentiation between the two diseases difficult in the field. A common, easily recognizable symptom is swelling of lymph nodes, especially those of the cervical, subclavicular, and inguinal regions. Another common symptom is called "moon face," an edema caused by leaking of small blood vessels. A most common complication during trypanosomiasis is pneumonia, which is a frequent cause of death. A disturbing aspect of the chronic *gambiense* form can be its long period of development, sometimes as long as 15 years after the victim has left an endemic area.

Immunology

The prospect of a vaccine for human trypanosomiasis is bleak. This pessimism is occasioned in part by the trypanosome's ability to alter rapidly surface antigens, apparently to evade the host's humoral immunity. Nevertheless, immune mechanisms may be involved in several aspects of the disease. This is probably the case for endemic *gambiense* disease in western and central Africa, where sleeping sickness is known to be an ancient disease, and where early field workers sometimes observed the phenomenon

of asymptomatic carriers. During *gambiense* infection, trypanosomes multiply, and, with increased parasitemia, the victim suffers fever after which the parasitemia recedes in apparent response to the production of antibodies. Soon the parasites again multiply, but this generation produces antigenic material against which the previous antibodies are ineffective. It is this phenomenon of "antigenic variation" that greatly reduces the prospect of producing an effective vaccine, and at present very little research is underway on vaccine development (Boothroyd 1985).

History and Geography

The history of sleeping sickness in Africa is long and complex, stretching across millennia to threaten millions today. The complicated ecology of the trypanosomiasis, involving the human host, trypanosome, tsetse fly, wild and/or domestic animal reservoir, climate, and geography has dramatically affected demographic patterns in sub-Saharan Africa. The parameters and density of human settlement have been limited in many regions until the present time, while the trypanosomiasis have prevented cattle-keeping across vast regions of the continent, thereby seriously affecting the nutrition of entire populations.

The "African lethargy," or "sleepy distemper," was well known to Europeans in West Africa from as early as the fourteenth century, through good descriptions given by Portuguese and Arab writers. For centuries slave traders rejected Africans with the characteristic swollen cervical glands, for it was common knowledge that those with this symptom sooner or later died in the New World or North Africa (Hoeppli 1969). In 1734 an English naval surgeon described the disease along the Guinea coast, and in 1803 another English doctor described the symptom of swollen cervical glands, which came to be called "Winterbottom's sign" (Atkins 1735; Winterbottom 1803). As European exploration and trade along the West African coast increased between 1785 and 1840, the disease was reported in Gambia, Sierra Leone, and western Liberia, whereas between 1820 and 1870, it was also commonly noted along the Liberian coast.

Colonial Period

Certainly the disease was an important factor in the history of colonial Africa. In the beginning, colonial administrators were concerned mainly with the health of Europeans and those few Africans in their service. But the threat of epidemics of sleeping sickness eventually forced colonial authorities to take

much more seriously the health of entire African populations.

For many Africans the disease occasioned their first, often traumatic, encounters with their new political masters, while epidemics enabled many colonial authorities to increase their political hegemony through public health measures. In those colonies affected by sleeping sickness, medical services often developed in direct response to this one disease, which resulted in the development of "vertical" health services – programs aimed at controlling a specific disease, while neglecting other crucial public health issues. Although the colonial powers have departed, as recently as the 1970s the World Health Organization urged developing countries to move toward "horizontal" health services that take into account the multifactoral nature of disease and health.

Research in Parasitology and Tropical Medicine.
Sleeping sickness, along with malaria and yellow fever, played an important role in the development of the new specialties of parasitology and tropical medicine. In 1898, Patrick Manson, the "father of tropical medicine," published the first cogent discussion of the new scientific discipline. He explained that tropical diseases, those present in warm climates, were very often insect-borne parasitical diseases, the chief example being trypanosomiasis (Manson 1898).

Trypanosomiasis at the time was very much on the minds of colonial officials. In the decade between 1896 and 1906, devastating epidemics killed over 250,000 Africans in the new British protectorate of Uganda, as well as an estimated 500,000 residents of the Congo basin. Understandably, the new colonial powers, including Britain, France, Germany, Portugal, and King Léopold's Congo Free State, perceived sleeping sickness to be a grave threat to African laborers and taxpayers, which in turn could dramatically reduce the utility of the new territories. Moreover, the fears were not limited to the continent of Africa; the British also speculated that sleeping sickness might spread to India, the "jewel" of their empire (Leishman 1903).

Thus ensued one of the most dramatic campaigns in the history of medicine, as scientific research teams were dispatched to study sleeping sickness. They began with the Liverpool School of Tropical Medicine's expedition to Senegambia in 1901 and the Royal Society's expedition to Uganda in 1902; other expeditions followed until World War II.

Many of these were sent by new institutions espe-cially designed to investigate the exotic diseases of warm climates. The British, for example, opened schools of tropical medicine at Liverpool and London in 1899, while other such schools came into being in Germany, Belgium, France, Portugal, and the United States. This new field of scientific endeavor, tropical medicine ("colonial medicine" for the French), offered the opportunity for bright young men to gain international acclaim and a place in the history of medicine. According to John L. Todd of the Liverpool School of Tropical Medicine in 1903, "Tryps are a big thing and if we have luck, I may make a name yet!" (Lyons 1987).

It should be noted that sleeping sickness was not the only disease to receive such attention as Europeans sought to establish themselves permanently in regions of the globe where health conditions were difficult and mortality was high (Carlson 1984; Bradley 1986). There were major discoveries by Manson, who was the first to demonstrate insects as vectors of human disease (filariasis); and by Ronald Ross, who found that the malaria parasite was transmitted by the *Anopheles* mosquito. Yet, despite the fact that endemic malaria was probably the cause of far more morbidity, the trypanosome and trypanosomiases attracted much attention in the new field of tropical medicine for the next 2 or 3 decades. Indeed, obsession with it dominated the first issue of the *Transactions of the Society of Tropical Medicine and Hygiene* in 1907.

Quite literally, sleeping sickness captured the colonial imagination (Martin 1923). International meetings were convened to discuss sleeping sickness, beginning with one at the British Foreign Office in 1907. As the number of "tryps" specialists increased, sleeping sickness became a key factor in the international exchange of research findings in tropical medicine. The Sleeping Sickness Bureau was opened in London in 1908 to facilitate communication of research findings on all aspects of the disease. Its work continues to the present time as the important *Tropical Diseases Bulletin.*

After World War I and the formation of the League of Nations' Health Organization (the antecedent of the World Health Organization), two major conferences in 1925 and 1928 were convened to focus on African sleeping sickness. These conferences, following the pattern of the nineteenth-century sanitation and hygiene conferences, sought international collaboration and cooperation in implementing public health solutions. In Africa, special research centers on tsetse flies and sleeping sickness appeared in many colonies including Uganda, Kenya, Tangan-

yika (now Tanzania), Belgian Congo (Zaire), Nigeria, Ghana, and French Equatorial Africa (Chad, Central Africa Republic, Congo-Brazzaville, and Gabon). Sleeping sickness thus became an important catalyst for cooperation among the colonial powers in Africa, which in turn aided the rapid growth of tropical medicine as a field. In fact, sleeping sickness early in the twentieth century attracted international attention to Africa with an urgency that was repeated in the early 1980s with AIDS (Kolata 1984).

Response to the disease occurred within the private sector as well. Concerned at the possible loss of increasingly important African markets, the European business and commercial community encouraged and sometimes initiated research into tropical diseases. For example, the principal founder of the Liverpool School of Tropical Medicine in 1899 was the influential and powerful capitalist Alfred Lewis Jones, chairman of a Liverpool-based shipping line that plied a lucrative trade along the West African coast (Morel 1968). He was also a personal friend of the notorious King Léopold of the Congo Free State. The businessman shared the imperialist's dismay at the potential devastation that could be caused by sleeping sickness, and together they were keen to support attempts to prevent the decimation of African populations.

Politics and Epidemiology. The politics of colonialism often reflected contemporaneous perceptions of the epidemiology of sleeping sickness. By 1900, for example it was widely accepted that the disease had been endemic in West Africa for centuries but had only recently begun spreading into the Congo basin and eastward. H. H. Johnston, the English colonial expert, popularized this view by arguing that sleeping sickness had been spread eastward across the Congo basin in 1888–9 by H. M. Stanley's Emin Pasha Relief Expedition (Morris 1963; Lyons 1987).

From the earliest days of colonial settlement, it was not uncommon to blame sleeping sickness for the abandoned villages and depopulated regions that Europeans encountered during their push into the interior. It usually did not occur to the intruders that in many cases Africans were withdrawing from areas because of the brutal nature of colonial conquest, and half a century would pass before researchers began to examine the deeper socioeconomic and political causes of the dramatic changes in the African disease environment that had resulted in the spread and increased incidence of sleeping sickness.

The word "epidemic" is a relative term that in-

volves many factors. The declaration of an epidemic is most often made by an authority with the sanction of the state. Epidemics are social and political, as well as medical, events and their declaration can serve a variety of needs (Stark 1977). Early in the twentieth century, the declaration of an epidemic could provide a pretext by which to control unruly populations suffering the traumas of colonial conquest. For example, in response to threatened epidemics of disease, African populations could be recognized and relocated for ease of political control and administration. On the other hand, declarations of sleeping sickness epidemics also enabled public health and medical service personnel to implement measures designed to contain the incidence and spread of the disease.

Medical experts at the turn of the nineteenth century tended to favor the theory of circumstantial epidemiology, which held that diseases were spread mainly through human agency within specific sets of circumstances. Lacking effective treatments, the principal methods of control of epidemic disease consisted of segregation or isolation and disinfection with acrid smoke or strong fumes such as sulfur and vinegar. Disease was perceived as an invader to be demolished. This view accounts for much of the imagery and idiom of war used in early public health campaigns. A major adjunct to this theory was the belief that once the circumstances had been identified, most diseases in Africa could and would be controlled, even eliminated, with techniques and technology developed in Europe. The European colonials assumed that they would succeed where Africans had failed and that they would transform the continent by conquering the problems of tsetse and the trypanosome, among others. Most colonists believed that much of the backwardness they saw in African society was attributable, at least in part, to endemic diseases such as sleeping sickness that could, they thought, help to explain the lack of the use of the wheel and the attendant need for human porterage, as well as the lack of animal-powered plows, mills, and the like.

Powerful notions of the potential of Western technology for solving health problems in Africa, sleeping sickness among them, have survived until quite recently. Rarely, if ever, did colonial authorities consider the possibility that Africans not only possessed some ideas about the ecology of sleeping sickness but had gained fairly effective control of their environment. An example of one such African strategy was the warnings to early European travelers not to travel through certain regions during daylight

hours when tsetse flies were active and might infect their transport animals. Moreover, throughout the tsetse-infested regions, there were instances of African residence patterns that allowed coexistence with the ubiquitous tsetse flies yet avoided population concentrations conducive to epidemic outbreaks. It was, according to John Ford (1971),

a curious comment to make upon the efforts of colonial scientists to control the trypanosomiases, that they almost entirely overlooked the very considerable achievements of the indigenous peoples in overcoming the obstacle of trypanosomiasis to tame and exploit the natural ecosystem of tropical Africa by cultural and physiological adjustment both in themselves and [in] their domestic animals.

European colonizers, by contrast, often disrupted – or destroyed – indigenous practices and survival strategies with the result that endemic sleeping sickness spread and sometimes became epidemic with disastrous effects. For example, from the late 1880s through the 1920s, the Belgians forced Congolese individuals to spend ever-increasing amounts of time searching farther and farther afield for sources of wild rubber with which to meet tax demands. In northern Zaire, rubber vines proliferated in the gallery forests, and such galleries were, and remain, superb ecological niches for the vector of *gambiense* sleeping sickness, *G. palpalis.*

The colonial powers, however, held their own version of the history of sleeping sickness and its evolution (Morris 1963; Burke 1971). Prior to their arrival, ancient, intractable foci of the disease had existed in West Africa and in the Congo basin around which, from time to time, the disease would flare into epidemic proportions. Colonials believed that it really began to spread only after the European newcomers had suppressed local wars and slave raiding among African peoples and established law and order. This in turn allowed many Africans, for the first time ever, to move freely and safely away from their home regions. Protected by Pax Brittannica, Belgica, and the like, the increased movements of Africans carried sleeping sickness from old endemic foci to new populations. There was some basis for this hypothesis, especially in West Africa such as in Ghana and Rukuber of Nigeria (cf. Duggan 1970). This widely accepted notion of the spread of sleeping sickness had an important consequence in the enormous effect expended by the Europeans in trying to regulate African life at every level, and especially to limit strictly any freedom of movement.

Ford, the British entomologist who spent over 25

years researching sleeping sickness, was one of the first to challenge this "classical view" of the pacification of Africa and the spread of the disease. He argued that it was not the pacific character of European colonization but, on the contrary, its brutal nature, that greatly disrupted and stressed African populations (Kjekshus 1977). In particular, the balanced ecological relationships among humans, tsetse flies, and trypanosomes were disrupted by European activities with the result that endemic sleeping sickness flared into epidemic proportions. Vivid examples of the results of such ecological upheaval were the sleeping sickness epidemics in Uganda and the Congo basin that had killed hundreds of thousands.

Public Health Initiatives.   Epidemics continued throughout much of the colonial period, especially prior to World War II when there were serious outbreaks in both West and East Africa, which occasioned a great deal of morbidity and mortality (Duggan 1970). Public health regulations proliferated to control the disease that affected other areas of administration such as taxation, labor supply, and freedom of movement across international frontiers. In some colonies, sleeping sickness programs became so extensive and bureaucratic that they came into conflict with other colonial departments, exacerbating competition for scarce staffing and financial resources within colonial administrations. In addition, sleeping sickness regulations were often responsible for confrontations between the private and state sector as members of the former found themselves increasingly hindered in their attempts to exploit the people and resources of Africa.

Two major patterns emerged in the colonial campaigns against sleeping sickness. In one, the focus was on tsetse eradication, whereas in the other, the focus was on the medicalization of victims. Both approaches, however, involved varying degrees of brush clearance as a prophylactic measure, and in reality, most campaigns were a combination of features from each approach. For instance, it was pointless to think of successfully destroying tsetse habitat in the rainforest conditions of the Congo basin or much of French Equatorial Africa. Nevertheless, in some areas combined campaigns of brush clearance, resettlement, and medicalization were carried out.

Within this framework, national variations emerged in the colonial campaigns. The British took a more broadly ecological approach to control of the disease, whereas the French and the Belgians took a more "medical" approach to the problem of human infection. British policy was to break the

chain of sleeping sickness transmission by separating people from flies. Thus, while British administrators implemented social policies aimed to protect people from disease, the scientific community, especially the new entomologists, searched for solutions to the "tsetse fly problem" in Africa (Ford 1971). The compulsory mass resettlement of Ugandans, which probably helped save lives, from lakeshore communities in Buganda and Busoga in 1908, and the huge Anchau (northern Nigeria) scheme begun in 1936 are good examples of breaking transmission chains. Likewise, in some regions where it was ecologically feasible, Belgians resettled groups of people such as those along the Semliki River in eastern Congo.

Unfortunately, in the context of recently conquered and colonized Africans, who had rural subsistence economies, and whose culture and tradition were intricately linked to locale, compulsory relocation sometimes had calamitous effects on those it was meant to protect. In the Belgian Congo an extraordinary amount of legislation and effort was directed at the control of populations in relation to sleeping sickness. In some places people found themselves forbidden to go near rivers that were designated "infected" with the disease. They could not fish, cross the rivers, use their rivercraft, or even attend to cultivations along the banks. It is not surprising that many Africans regarded sleeping sickness as *the colonial disease* because of the sometimes overwhelming amount of administrative presence it elicited (Duggan, personal communication; Lyons 1985).

French and Belgian efforts were directed chiefly at "sterilizing the human reservoir" of trypanosomes through mass campaigns of medicalization, or injections. To achieve this, they conducted systematic surveys of entire populations, hoping to locate, isolate, and treat all victims. Eugène Jamot, a French parasitologist, developed this method in Ubangui-Chari (French Equatorial Africa), and later introduced it to affected parts of Cameroon and French West Africa (Jamot 1920). In 1916, he organized an ambitious sleeping sickness campaign based upon mobile teams, which systematically scoured the country for victims of the disease to be injected.

A grid system was devised to ensure complete surveys, and the mobile teams worked with true military efficiency. Between July 1917 and August 1919, over 90,000 individuals had been examined, and 5,347 victims were identified and treated. Jamot's design for a sleeping sickness service was soon adopted by the Belgians in the Congo, and by 1932 there were five such teams operating annually in northern Congo alone. Admirable as it was for its sheer scale of organization, the policy of mass medicalization did not affect the fundamental ecology of the parasites; indeed, this approach had the effect of removing the store of antibodies from humans that had been built up through long contact with the parasites (Lyons 1987).

Sterilization of the human reservoir was made possible in 1905 when the first trypanocidal drug became available in the form of an arsenical compound, atoxyl. Discovered by the German chemist Paul Ehrlich, and adapted for use with sleeping sickness by Wolferstan Thomas of the Liverpool School of Tropical Medicine, atoxyl, alone or in combination with other compounds, remained the only chemotherapy for 2 decades. Atoxyl was toxic for 38 percent of patients, with dreadful side effects suffered by those whom it did not kill outright, among them the blinding of 30 percent of those injected. By the early 1920s, new drugs – suramin (1916–20) and tryparsamide (1919–25), and later in the early 1940s, pentamidine – were in use for early-stage *rhodesiense* and *gambiense* disease. Melarsoprol, a most problematic arsenical with serious side effects, including up to 5 percent mortality, was and is used for second-stage disease. Together with suramin and pentamidine, these three have remained the drugs of choice since the 1940s.

Postcolonial Period

In the early 1960s, which saw independence for many African territories, colonial rulers concurred that human sleeping sickness was under control in Africa. But political upheavals in many countries following independence, accompanied by the breakdown of medical infrastructures and large-scale population displacements, once again seriously affected the epidemiology of sleeping sickness. Some countries – Zaire, Uganda, Sudan, and Ivory Coast, for instance – witnessed epidemics of sleeping sickness, and it has been estimated that by 1969 there were up to 1 million sleeping sickness victims in the Congo alone (Mulligan 1970).

Sleeping sickness continues to afflict unknown numbers of Africans. Epidemics occurred in the 1980s in old, well-known foci located in those regions of Africa experiencing disorder and decay of public service brought about by socioeconomic and political conditions. In fact, some areas are experiencing a disheartening replay of events earlier this century, while other areas are experiencing the introduction of the disease for the first time.

Tsetse flies and the trypanosomes that cause sleeping sickness will continue actively to shape the future of humankind in Africa. Because the most effective means of control is continual and thorough surveillance and treatment with available chemotherapy, present-day health planners and administrators must be aware of the history of this disease and the ease with which that history can repeat itself.

VIII.3
Ainhum

The name *ainhum* is derived from a word in the Nagos language of East Africa meaning "to saw." It describes the development of constricting bands about digits, almost always the fifth, or smallest, toe, which ultimately undergoes self-amputation. Typically the disease is bilateral (i.e., affecting both small toes).

Ainhum is ordinarily a disease of middle-aged black Africans of both sexes accustomed to going barefoot. The disease is common in Nigeria and East Africa, and has been reported less frequently in other tropical areas, including India, Burma, Panama, the Antilles, and Brazil (Burgdorf and Goltz 1987).

Ainhum was noticed frequently among slaves in Brazil and was first described in detail in 1867 by Brazilian doctor J. F. da Silva Lima who also named the disease. Silva Lima's description is outstandingly accurate, and has not been bettered. In one case he wrote that the toe had taken the shape of a small oval potato; the covering skin had become coarse and scabrous, and very tender to touch. As the disease progressed, wrote Silva Lima, a strong constriction appeared at the base of the toe, and, as the blood flow to the toe was impeded, the bones ceased to exist. In time, spontaneous amputation of the toe occurred (Cole 1965; Silva Lima 1867).

The cause of ainhum is unknown. According to Walter Burgdorf and Robert Boltz, chronic trauma, infection, hyperkeratosis, decreased vascular supply, and impaired sensation may alone or in combination produce excessive fibroplasia, and lead to ainhum. It is an acquired condition, although a hereditary pre-

disposition has not been ruled out (Curban and Moura 1965). Surgery is the mainstay of therapy, for in most cases prompt amputation may allow the patient to escape pain and infection.

VIII.4
Alzheimer's Disease

In 1906, Alois Alzheimer first described a neurological disorder of the brain associated with global deterioration of cognitive functioning and resulting in severe social impairment. Once thought rare, senile dementia of the Alzheimer's type is the most commonly acquired progressive brain syndrome. Alzheimer's disease begins with insidious intellectual and memory loss as the brain becomes shrunken from nerve cell loss and advances over 5 to 15 years to a chronic vegetative state. Progressive cognitive, psychological, and social dysfunction has a profound effect on family and friends. Alzheimer's disease is associated with significant morbidity, and it may be the fourth leading cause of death in the United States (Katzman 1976). D. K. Kay and colleagues (1964) showed the average survival for demented men to be 2.6 years after the diagnosis of illness, whereas the survival period for nondemented men of the same age was 8.7 years. However, there is great variability in survival statistics from different studies.

Although Alzheimer's disease is the leading cause of dementia, its etiology remains unknown, and treatment is supportive. The illness is a major problem among the elderly. Approximately 4 percent of the population over the age of 65 is affected, and by age 80, prevalence reaches 20 percent (Brodie 1982). As the elderly population of the United States increases, the number of persons with Alzheimer-type dementia will also increase. Alzheimer's disease exists in the presenium, but it has been difficult to document a bimodal distribution with regard to age. Even though pathological changes in presenile and senile forms of the illness are similar, there is evidence that early- and late-onset Alzheimer-type dementia differ clinically (Seltzer and Sherwin 1983).

Clinical Manifestations and Diagnosis

Clinical Manifestations

Alzheimer-type senile dementia is associated with behavioral signs and symptoms that divide into corresponding stages. In the early stage, subjective memory deficit may be difficult to differentiate from benign senile forgetfulness. However, elderly persons with benign forgetfulness are unable to recall unimportant details, whereas patients with Alzheimer-type senile dementia forget important and unimportant information randomly (Kral 1962).

Typically, patients with Alzheimer's disease forget where things are placed, become lost easily, and have difficulty remembering appointments. Both recent and remote memory are affected, which may be documented by neuropsychological testing. When patients recognize their cognitive and social losses, many develop feelings of hopelessness and despondency. As Alzheimer-type senile dementia progresses, the patient enters a confusional phase with more global impairment of cognitive functioning (Schenk, Reisberg, and Ferris 1982). Changes in higher cortical functions, such as language, spatial relationships, and problem solving, become more apparent.

During the confusional phase, obvious denial begins to replace anxiety, and cognitive deficits are noticeable to family and friends. In the final phase, the patient becomes aimless and may hallucinate or be restless and agitated. Language disorders such as aphasia occur in late stages. Abnormal neurological reflexes, indicative of loss of higher neural inhibition, are common. Not all patients with Alzheimer-type senile dementia demonstrate the classic evolution of symptoms. Although almost all patients have some memory impairment, other focal cortical defi-

cits may predominate initially. Spatial relationship impairment is common early. The patient may also complain of word-finding difficulty or demonstrate mild problems in speaking and understanding. In cases where damage to the frontal lobes of the brain predominates, the patient presents with judgment problems.

Diagnosis

Diagnosis of Alzheimer's disease remains a diagnosis of exclusion. In the absence of biological markers for the illness, it is not surprising that clinical diagnosis may be less than accurate and, in fact, may be correct in as few as one-half of Alzheimer-type senile dementia cases (Alafuzoff et al. 1987). Not only do cognitive changes associated with normal aging overlap those found in the early stages of dementia, but also a wide spectrum of conditions may produce dementia. In any given patient, several conditions leading to progressive cognitive decline may occur simultaneously. Even neuropathologists may encounter diagnostic difficulty and may be reluctant to make the diagnosis without the proper clinicopathological correlation (Khachaturian 1985).

The clinical diagnosis of Alzheimer-type senile dementia always requires documentation of progression (McKhann et al. 1984). Reports from family and friends provide the most valid measures of cognitive decline in elderly persons and support the clinician's judgment that global intellectual deterioration has occurred.

Clinical Staging and Evaluation

Progression is usually gradual but with fluctuation of symptom severity. The patient may react very dramatically to changes in the living situation, to losses of friends or relatives, or even to admission to the hospital for evaluation. These acute changes probably represent withdrawal of orienting stimuli and emotional distress rather than progression of the disease process.

A number of clinical staging strategies have been developed, but there is no entirely satisfactory technique as yet. Simplified rating scales (such as the Folstein Mini-Mental) may be efficiently administered, but only identify the presence or absence of cognitive impairment. Other cognitive scales are more accurate, but they are also more complex and may take an hour to administer. The Blessed Scale (Blessed, Tomlinson, and Roth 1968) obtains information from collateral sources and has the advantage of documented correlation with pathological lesions at autopsy. Unfortunately, it provides little

information about cognitive performance. Other behavioral scales rely solely on the interviewer's interpretation of the patient's performance on several activities (Salzman, Kochansky, and Shader 1972).

Psychometric tests may be useful in delineating patterns of cognitive deficit at various stages of severity and in identifying the qualitative aspects of performance deficit. Although laboratory tests are sometimes used to support the diagnosis of Alzheimer's disease, the laboratory is actually more useful in excluding other causes of cognitive deterioration. Atrophy of the cerebral cortex is often seen on computed tomography, but it is frequently overinterpreted. There is a poor correlation between size of the brain ventricles, widened cerebral sulci, and severity of dementia (Fox, Topel, and Huckman 1975). Attempts have been made to correlate dementia with brain density (Albert et al. 1984). Unfortunately, results have been inconsistent, and there is a pressing need for quantitative computed tomographic studies that correlate the scanning images with clinical and pathological findings.

Differential Diagnosis

Alzheimer's disease may be difficult to distinguish from other untreatable progressive dementias, which include Pick's disease, demyelinating diseases, slowly progressive brain tumors, inflammatory diseases, arteriosclerotic vascular diseases, toxic exposures, repeated metabolic insults, deficiency diseases, late sequelae of head trauma, Creutzfeldt–Jakob disease, and viral and fungal infections. Dementia is common in patients with terminal cancer and may result from a variety of causes.

The evaluation of a patient presenting with dementia often reveals untreatable causes, but treatable dementia is discovered in 20 to 25 percent of such patients (Wells 1977).

Treatable causes of dementia include pernicious anemia, thyroid disorders, chronic central nervous system infections, toxic exposures, surgically correctable mass lesions, inflammatory vascular disease, certain forms of arteriosclerotic vascular disease, and normal-pressure hydrocephalus. Occasionally, iatrogenic dementia, related to the inappropriate use of medication or to idiosyncratic drug effects, is identified. Multi-infarct dementia may be the most difficult progressive dementia to differentiate from Alzheimer's disease despite the fact that specific diagnostic criteria for each have been promulgated in the official nomenclature. There is an obvious need for a valid and reliable set of clinical criteria to distinguish the two conditions. Nonetheless, risk fac-

tors for stroke should be evaluated and controlled when possible in every patient with early dementia.

J. L. Cummings and D. F. Benson (1983) suggest that all forms of dementia other than Alzheimer's and Pick's disease show signs of subcortical dysfunction in addition to more obvious cortical signs. This is especially true of dementia associated with basal ganglia disease, which regularly produces the characteristic subcortical pattern of slowed thinking, attention deficit, memory impairment, and apathy. Subcortical dementia occurs in 20 to 40 percent of patients with Parkinson's disease (Marttila and Rinne 1976) and is also observed in progressive supranuclear palsy, Huntington's chorea, and Wilson's disease. Symptomatic treatment of basal ganglia disease occasionally improves the associated dementia. Antidepressants may improve cognition as well as any associated depression (Albert, Feldman, and Willis 1974).

Depression is the most common treatable illness that may masquerade as Alzheimer-type senile dementia. Cognitive abilities return to baseline levels when depression is treated. Because some patients with early dementia have secondary depression, dementia and pseudodementia may be difficult to differentiate. The depression that occurs in the early stages of Alzheimer-type senile dementia tends to resolve as the disease progresses. Pseudodemented, depressed patients are apt to have poor attention, inconsistent cognitive changes, absence of cortical signs, weight loss, sleep disturbance, guilt, poor self-esteem, a past personal family psychiatric history, and a more rapid onset.

In contrast, patients with cortical dementia of Alzheimer-type often show insidious onset, slow progression, early loss of insight, amnesia for remote and recent events, spatial disorientation, reduction in spontaneous speech, and occasionally aphasia. Agnosia, apraxia, increased muscular tension, and abnormal neurological reflexes may also be present (Gustafson and Nilsson 1982).

Epidemiology and Etiology

Alzheimer's disease is ultimately a neuropathological diagnosis. A wide variety of gross morphological and microscopic changes occur in the brain of patients with Alzheimer's disease. Unfortunately, many of these changes are difficult to distinguish from alterations that occur in the brain of normal elderly persons, who also show some atrophy of white matter and, to a lesser extent, gray matter.

Neurochemically, Alzheimer's disease has been associated with a decrease in the activity of the en-

zyme choline acetyltransferase, which synthesizes acetylcholine (Coyle, Price, and DeLong 1983). Acetylcholine is the neurotransmitter most involved in memory circuits. Levels naturally decrease with age, but in patients with Alzheimer-type dementia, choline acetyltransferase may decline to 20 percent of that in age-matched control subjects. Other neurochemical changes associated with Alzheimer's disease include a decrease in gamma-aminobutyric acid, substance P, and somatostatin-like activity in the brain of patients with Alzheimer-type dementia. The significance of these findings is unclear.

Although it is generally recognized that genetic influences are important in Alzheimer's disease, the exact nature of these genetic influences also remains unclear. There are some families that have a large number of members with the clinical or pathological diagnosis of Alzheimer's disease (Cook et al. 1979). The most important practical point regarding these kindreds is that most of them meet criteria for autosomal dominant inheritance. Penetrance of the gene exceeds 90 percent in most of these families. As a result, the children of an affected person have a 50 percent risk of developing dementia if they survive to the age at which dementia begins in that family. The exact proportion of familial cases is unknown, but they may account for as many as 10 percent of all cases of Alzheimer-type dementia (Kokmen 1984). There is some familial clustering in families without dominant inheritance. It would appear that concordance for dementia is somewhat higher in monozygotic versus dizygotic twins, suggesting genetic factors. On the other hand, concordance is not 100 percent, so environmental factors must have a role. Since age of onset varies within a twin pair, it may be difficult to be certain whether a given pair is truly discordant.

An association has been shown also between Alzheimer's disease and families that produce children with Down syndrome (Heston and Masri 1966). Further support for a link between Down syndrome and Alzheimer's disease is provided by the fact that patients with Down syndrome tend to demonstrate neuropathological findings consistent with Alzheimer-type senile dementia if they live to adult life. Since Down syndrome represents a disorder of chromosome 21, a point of origin for the search for the genetic determinants of Alzheimer's disease is suggested. The amino acid sequence for the amyloid that accumulates in the brains of patients with Alzheimer's disease is called the *A4 beta-pleated amyloid*. The gene for the precursor has been identified, cloned, and mapped to the proximal long arm

of chromosome 21 (St. George-Hyslop et al., 1987). Recent data favor the hypothesis of a genetically induced overproduction of amyloid protein as a factor in the cause of Alzheimer's disease.

When families request genetic counseling, one can only explain what is known about the genetic factors. In a family with a single Alzheimer victim, the lifetime risk for a close relative also to develop dementia is approximately 10 percent. Since most dementia develops over the age of 70, this is a relatively small probability. In families with dementia occurring over several generations, an autosomal dominant inheritance is probable, and the risk for children of an affected parent may approach 50 percent. In these families, optimum health management indicates the suspicion of dementia in every elderly person with altered environmental–social interactional skills, multiple physical complaints in the absence of objective disease, or vague and unclear history. Autopsy can be suggested to confirm diagnosis to trace the pedigree more accurately.

Environmental causes for Alzheimer's disease have also been suggested. Some investigators have linked focal intranuclear accumulation of aluminum to the presence of neurofibrillary degeneration in hippocampal neurons. The relationship of aluminum to Alzheimer-type senile dementia, however, is not well accepted (Markesbery et al. 1981). General decline of immunologic competence with aging suggests an autoimmune mechanism. Although elevated levels of brain antibody have been demonstrated in Alzheimer's disease, antineuronal antibodies have not been demonstrated in the central nervous system (Watts, Kennedy, and Thomas 1981). Serum protein abnormalities have been demonstrated, notably changes in haptoglobin functions. Finally, a viral cause has been proposed but not substantiated (Wisniewski 1978).

Treatment

Although the cause of this disease remains unclear, good clinical management is nonetheless critical. Every effort should be made to maintain the patient's independence within the limits of safety. Measures to maintain orientation, such as memory aids, eyeglasses, hearing aids, calendars, diaries, adequate lighting, and organization of the patient's personal items, are helpful (Eisdorfer and Cohen 1981). Appropriate locks to prevent unsafe wandering, and suitable safeguards on dangerous household appliances must be utilized. Of course, the patient should not be permitted to drive.

Providing quality care, however, requires an un-

derstanding of the health care delivery system in which physicians and patients find themselves. Psychosocial management is based on enhancing the function of the care system that surrounds the patient. This usually involves several family caregivers, who should receive accurate information concerning the disease and the prognosis. Caregivers must take care of themselves and may benefit substantially from referral to a support group of the Alzheimer's Disease and Related Disorders Association. Caregivers should be made aware of the factor that most insurance does not cover either community services or long-term care in nursing homes. A competent legal adviser and appropriate financial counselor can be of substantial help. Even though many families want to keep elderly individuals in the home, in-home support services are expensive and often not available.

Alzheimer's disease remains a major challenge not only to modern medicine but also to the health care delivery system, and to society at large. Not only is further research necessary in the diagnosis and management of the disease itself, but also major changes are necessary in the health care delivery system if patients afflicted with this illness are to get the care that they need.

History

Although Alzheimer's disease only recently "has exploded into public and scientific consciousness" (Rabins 1988), it doubtlessly has a long history under such rubrics as "senility," "hardening of the arteries," and "dementia," to name but a few. Certainly senility and dementia are conditions that have been recognized for millennia. The Assyrians, Greeks, and Romans all knew and described them. Peter V. Rabins (1988) credits J. E. D. Esquirol, however, for the first modern description, in 1838, of what seems to have been Alzheimer's disease. Esquirol wrote of a "senile dementia" that increases with age (Beach 1987). Seven years later, Wilhelm Griesinger published a textbook on mental disease that clearly recognized the condition of "presenile dementia" caused by brain atrophy found at autopsy. Neither of these reports, however, seems to have had much influence on investigators at the time (Wisniewski 1989).

It was during the latter half of the nineteenth century that public as well as scientific concern for problems of the elderly increased considerably. With that concern came the birth of the field of geriatrics and increasing attention paid to dementia in the elderly (Beach 1987). Much of the effort during these decades focused on whether it was an inevitable product of aging, or rather an actual disease. Emil Kraepelin, one of the founders of modern psychiatry, pointed out the difficulty in separating normal senility from senile dementia. In applying the new technique of silver staining, Alzheimer, his student, identified a new neuropathological marker of dementia in the brain of a patient who had died at age 55 after a 4-year illness. This marker was the neurofibrillary tangle, which he speculated was the marker of a dead cell. Alzheimer thus made the first correlation between clinical characteristics of dementia in a patient and pathological lesions in the brain. Kraepelin later named the illness Alzheimer's disease in honor of his former pupil.

The question then became one of determining if this disease was the same as senile dementia. It revolved around the ancient problem of what pathological changes can be attributed to aging as opposed to other causes. Kraepelin had emphasized the presenile nature of Alzheimer's disease, yet because of its similarity to senile dementia some investigators suggested that Alzheimer's disease might be caused by "a premature onset of the aging process" (Beach 1987). Also confusing the picture was the nineteenth-century notion which extended also into the twentieth century: that cerebral arteriosclerosis might be the cause of senile dementia. By the late 1920s, there had been a sufficient accumulation of case descriptions of dementia among the elderly that statistical analysis could be brought to bear on the problem. It was found that most of the cases did in fact occur between the ages of 50 and 60, sustaining the notion of its presenile nature. In 1955 Martin Roth showed that mental changes could be triggered by a variety of both "functional" and "organic" diseases, and by the 1960s two major groups of researchers were at work on Alzheimer's disease. One, headed by Robert Terry, was based at Albert Einstein University, and the other, headed by Bernard Tomlinson, Gary Blessed, and Roth, was located at Newcastle-upon-Tyne. From their work and from other studies, it became apparent, among other things, that the changes in the brain found in cases of presenile dementia were the same as those in senile dementia (Katzman 1986; Vannoy and Greene 1989).

The discovery broadened the definition of Alzheimer's disease and thereby increased enormously the number of individuals viewed as victims of it. It also created major semantic problems. Previously the *presenile* nature of Alzheimer's disease was a defining factor. Now the illness shown to be a major

affliction of the elderly population was called *senile dementia of the Alzheimer type* (SDAT), which psychiatrists call "primary degenerative dementia." *Senile dementia* (SD) has been used to mean either SDAT or Alzheimer's disease (AD), but it may also refer to other forms of dementia in the elderly (Reisberg 1983). In addition, Alzheimer's disease and senile dementia were often lumped together as senility or as cerebral arteriosclerosis. This latter concept proved to be so tenacious that even as late as the middle 1970s it was called "probably the most common medical misdiagnosis" of the cause of mental deterioration in the elderly (Beach 1987).

In the early 1980s, Alzheimer's disease was defined as an "age-associated cognitive decline of gradual onset and course, accompanied by Alzheimer-type neuropathologic brain changes" with "no distinction with respect to age of onset" (Reisberg 1983), and was thought to be responsible for 50 percent or more of all dementias (Vannoy and Greene 1989).

This definition is essentially the working one as we enter the last decade of the twentieth century. Experts at a 1990 conference on the illness believe that Alzheimer's disease is being diagnosed correctly in about 80 percent of cases, even though such diagnoses can be confirmed only after death, and even though the etiology and epidemiology of the disease remain obscure.

It may well be determined that Alzheimer's disease is not a single disease but, rather, many different diseases with multiple causes ranging from genetics to exogenous toxins. The extent to which age and aging will rank among those causes remains a subject of debate. Reports of the condition among individuals in their 30s have been used to support the contention that the disease is unrelated to aging. On the other hand, there is a rising prevalence with age, such that by age 85 and over, some 20 percent or more are demented. If, of course, Alzheimer's disease is a specific disease or diseases (as opposed to an inevitable product of the aging process for some 5 to 7 percent of the population over age 65), then, of course, there is hope for a cure.

The question, however, of why Alzheimer's disease has been called the disease of this century – one that has only recently burst upon the developed world in epidemic proportions – is certainly bound up with advancing age for many and with the demographic changes that this has wrought. In 1900, there were only 3 million Americans aged 65 or older. Today there are 27 million, and it has been estimated that in the year 2030 there will be 50 million. Given the fact that an individual who lives to be 80 has an almost 1:4 chance of developing Alzheimer's disease or a related disorder, estimates suggest that the number of these victims will increase from some 2.5 million in the late 1980s to about 4 million by the turn of the century. As the 1990s began, it was further estimated that fully half of all nursing home patients in the United States are Alzheimer victims.

The implications of the growing number of these victims for health care delivery systems are staggering. In 1967 a White House conference on aging resulted in the creation of the National Institute on Aging, which greatly facilitated research on Alzheimer's disease. In 1983, a Task Force on Alzheimer's Disease was created by the Department of Health and Human Services, which has emphasized the need for increased research and increased research funding, and in 1987 the journal *Alzheimer's Disease and Associated Disorders – An International Journal* was founded to report such research. As more and more resources are brought to bear, the outlook for breakthroughs in understanding the causes of Alzheimer's disease and treating it are more optimistic than in former times. But at the time of writing, it remains a devastating disease whose etiology is unknown.

VIII.5
Amebic Dysentery

Amebiasis is an infection of the colon caused by a parasitic protozoan, the ameba *Entamoeba histolytica.* Several species of ameba inhabit the large intestine. Most are harmless commensals or minor parasites, usually causing little or no clinical damage. The closely related species *Entamoeba coli* and *Entamoeba hartmanni* are commensals, and infection with *E. histolytica* is also often asymptomatic. *E. histolytica* is probably a species complex, with a number of morphologically similar forms with varying degrees of invasiveness. *E. hartmanni,* formerly believed to be a "small race" of *E. histolytica,* is now recognized as a separate nonpathogenic species. Pathogenic amebas cause light to severe intestinal damage (amebic dysentery) and sometimes spread to the liver, lungs, brain, and other organs.

Etiology

The parasite exists in two forms during its life cycle. Active adults, trophozoites, multiply in the lumen of the colon. They frequently live there harmlessly, feeding on the contents of the intestine. Some strains are generally commensal; others are highly pathogenic. Under conditions of stress, lowered host resistance, or when a particularly pathogenic strain is involved, amebas invade the intestinal wall and cause abscesses. As they pass lower into the large intestine, the drier environment stimulates them to form a cyst wall. The original cell nucleus divides twice, producing four daughter nuclei. Cysts are passed with the feces and are infective when swallowed. Excystation takes place in the small intestine, and the young trophozoites, four from each cyst, are carried in the fecal stream to the large intestine. When dysentery occurs, trophozoites are

swept out too rapidly to encyst. Even though huge numbers of amebas may be passed, they die quickly and are not infective. Persons with mild or no symptoms produce infective cysts, and it is they, not the patients with dysentery, who spread the disease.

Epidemiology

Infection is by the fecal–oral route. Direct infection can take place in circumstances of extreme crowding among children, as well as inmates of institutions for the mentally retarded and insane, and among male homosexuals. Indirect spread, however, by fecal contamination of food and water, is more common. Waterborne epidemics of amebic dysentery are not so frequent as those of bacillary dysentery, but the former do occur when sewage contaminates wells or water pipes. Fruits and vegetables can become covered with cysts when human feces are used as fertilizer, or when fruits are washed in contaminated water or are handled by a symptomatic or asymptomatic carrier. Flies and cockroaches can mechanically transmit cysts from feces to food. The disease thus flourishes in poor sanitary conditions but is rare where good personal hygiene is practiced and where water and sewer systems function properly. Dogs, cats, and monkeys can be infected in the laboratory, but there is no evidence that animal reservoirs have an epidemiological significance.

Distribution and Incidence

Infection with *E. histolytica* occurs around the world, although both commensal and pathological amebiasis is more common in poor, tropical countries. Prevalence rates vary greatly, as does the proportion of infections that result in clinical disease.

Amebiasis, especially clinical disease, is rare today in developed countries and is confined largely to specific groups such as residents of institutions, male homosexuals, travelers, and immigrants. In the United States from 3,000 to 4,000 cases were reported annually in the 1960s through the late 1970s. However, a spurt to roughly twice that level occurred in 1979–84. The disease was concentrated in Texas and California and was probably due to increased immigration from Mexico and Southeast Asia.

On the other hand, cases may be significantly underreported. One recent estimate suggests that the real annual total probably exceeds 100,000, and, in a 1970 study, 4 percent of military recruits had positive serologic tests. As recently as the early 1950s, infection rates of 10 to 20 percent were found in some rural southern counties. In Britain the carrier rate is between 2 and 5 percent; 31 amebiasis deaths were recorded from 1962 to 1971.

Asymptomatic and clinical amebiasis is much more common in Third World countries. Surveys have shown prevalence rates of from 2 to 60 percent, reflecting real differences as well as technical difficulties. It is clearly a major public health problem in much of South and Southeast Asia, China, Africa, and parts of Latin America. Mexico appears to have an unusually high prevalence. In the early 1980s it was estimated that 5 to 6 million clinical cases and 10,000 to 30,000 deaths took place annually in a population of some 70 million. Men in their 20s and 30s were most likely to die. In 1981, it was estimated that there were about 480 million infected people in the world: 290 million in Asia, 80 million in Africa, 90 million in the Americas, and remarkably, 20 million in Europe. Serious disease struck 10 million in the Americas, 15 to 30 million Asians, 10 million Africans, and few if any Europeans. The global death toll was between 40,000 and 110,000.

Diagnosis, Clinical Manifestations, and Pathology

Diagnosis depends on microscopic examination of stools, serologic tests, and clinical symptoms. The classic method, discovery of trophozoites or cysts in stools, is tedious and requires considerable skill, even with modern equipment and staining techniques. Trophozoites remain active only in fresh specimens and must be distinguished from commensal species and white blood cells. Preserved fecal specimens may be concentrated and stained, but detecting the adults and cysts and identifying them accurately are still difficult procedures. Furthermore, since trophozoites and cysts are not continually passed, more than one sample must be examined. Three or more specimens collected on separate days will find 80 to 90 percent of infections; fewer will be needed in symptomatic cases, as trophozoites are most readily detected in bloody patches in stools. Serologic tests also have limitations. Antibodies do not form unless amebas reach the bloodstream. It has been estimated that antibodies circulate in 85 to 90 percent of patients with liver abscess but in only 50 to 80 percent of those with severe dysentery. Serologic tests detect antibodies from recovered as well as active cases, which further limits the use of such methods in prevalence surveys.

Amebas cause disease when they invade the mucosal and submucosal layers of the large intestine, producing characteristic flask-shaped lesions. In severe cases the lesions become large and conflu-

ent, resulting in substantial tissue destruction, bleeding, loss of fluids, and sloughing of patches of mucosa. Damage to the intestinal wall reduces water absorption, and loose stools with blood and mucous are passed. In addition to severe and perhaps fatal damage to the gut, amebas sometimes penetrate through the muscular coat of the bowel, where they enter the bloodstream and are carried to other organs, especially the liver. Intestinal perforation may result in fatal peritonitis. Large abscesses may form in the liver, with grave and sometimes fatal consequences. Amebas may also migrate from the liver through the diaphragm to the lungs and cause new abscesses there. Brain abscesses are rare, but lethal. Very destructive skin ulcerations can also occur, especially around the anus.

Clinical symptoms of intestinal amebiasis range from mild diarrhea and abdominal discomfort to frequent loose stools with blood mucus, severe pain, emaciation, and prostration. Onset is generally insidious. Liver involvement may develop without evidence of intestinal disease. Symptoms include severe, continuous pain, enlarged and tender liver, fever, and weakness. Diagnosis is by biopsy or serology. Chronic amebiasis, both intestinal and hepatic, is sometimes very difficult to identify.

Differential diagnosis must rule out bacillary dysentery. Amebic dysentery tends to be a chronic disease with a gradual onset and little or no fever. The stools tend to be more abundant but less frequent and not to be bright red with blood, as is common in bacillary dysentery. Amebic dysentery has a longer incubation period, 20 to 90 days or more, compared to 7 days or less for the bacillary form. Finally, with its shorter incubation period and greater probability of water transmission, bacillary dysentery is more likely to occur in dramatic epidemics.

Prevention

Prevention is achieved with improved sanitation, especially good water and sewer systems and proper washing of fruits, vegetables, and hands. Routine chlorination of water does not destroy cysts. A Brazilian root, ipecacuanha, and its active ingredient, emetine, have been given orally to treat dysentery since the seventeenth century. It was first given by injection in 1912 and, despite its toxicity, is sometimes still employed for both intestinal and extraintestinal amebiasis. Safer drugs, such as metronidazole, are usually employed but must be given over 10- to 20-day periods and relapses are frequent. Infection does not produce immunologic protection against reinfection with the same or another strain.

History

Little is known of the early history of amebiasis. The disease probably did not become a serious problem until people began to adopt a sedentary, agricultural way of life. Dysentery has been described in the early medical writings of Europe and Asia, and outbreaks were frequent in military units, on slave ships, and in prisons. It is generally impossible, however, to determine whether amebic or bacillary dysentery was involved in any particular outbreak of the "flux."

British doctors in India provided good clinical accounts of amebiasis in the early nineteenth century. In 1828 James Annesley published an important study, based on clinical and pathological work, which clearly linked the intestinal and hepatic aspects of the disease. The pathogen was described in 1875 by a Russian physician, Fedor A. Lösch. Lösch, working in St. Petersburg with a patient from northern Russia, noted the clinical course of the disease, identified the ameba, and was able to produce similar lesions in dogs by feeding them ameba-rich stools from his patient. Lösch, however, believed that something else initially caused the disease and that the ameba merely "sustained" it. Technical problems, especially in identifying amebas and determining which were pathogenic and which were harmless, greatly impeded further research.

Stephanos Kartulis kept interest in the subject alive in the 1880s. Working in Cairo, he established that an ameba was the probable cause of tropical dysentery and managed to transmit infection to kittens. Then in 1890, a Canadian, Henri Lafleur, and an American, William Councilman of Johns Hopkins, published a definitive study of the pathology of the disease. Two German investigators, H. Quincke and E. Roos, distinguished between a pathogenic and a commensal ameba of humans, on clinical and morphological grounds, as well as by infection experiments on kittens. Still, the situation remained confused, as ameba identification and taxonomy was controversial and many research results could not be replicated. Doubts about the significance of pathogenic amebas were widespread in the early 1900s, despite painstaking studies like those of Leonard Rogers in Calcutta. Even Sir Patrick Manson, perhaps the single most important figure in tropical medicine, expressed skepticism about the role of amebas in dysentery as late as 1909. Ernest L. Walker (1913), an American scientist working in the Philippines, established the basic outline of the life cycle of *E. histolytica* and cleared some of the confusion about nonpathogenic forms with a series of feed-

ing experiments on volunteer Filipino convicts. The discovery of methods to raise amebas in culture in 1925 has contributed to further clarification. Many mysteries still remain, however, as to distinctions between pathogenic and nonpathogenic strains, and factors such as diet, stress, and concomitant infections that trigger invasiveness in longstanding, asymptomatic infections.

VIII.6
Anemia

</div>

Anemia, an insufficiency of red blood cells (RBC) and hemoglobin for oxygen-carrying needs, results from a variety of disease processes, some of which must have existed since ancient times. It was defined in quantitative terms in the mid-nineteenth century, but before that the evidence of anemia is found in the descriptions of pallor or in the occurrence of diseases that we now know cause anemia. For example, lead poisoning decreases RBC production and was apparently widespread in Rome. Intestinal parasites cause iron deficiency anemia and were known to exist in ancient times. Parasites found in paleopathological specimens include *Ascaris lumbricoides*, *Trichiuris trichiuria*, and various species of *Taenia* (*ovis*, *globosa*, *solium*, and *saginata*), all of which can cause intestinal blood loss and anemia. *Diphyllobothrium latum*, which leads to malabsorption of vitamin B_{12} and a megaloblastic anemia, has been found in mummies in Prussia and Peru.

Congenital abnormalities in RBC metabolism, including glucose 6-phosphate dehydrogenase (G6PD) deficiency and various forms of thalassemia and sickle-cell disease, were probably present also in ancient times. Thalassemia protects against malaria, and the incidence of the relatively mild, heterozygotic form of thalassemia (thalassemia minor) probably increased in the Mediterranean region after the appearance of falciparum malaria, the most fatal form of the disease.

Iatrogenic anemia was also common throughout most of recorded history, because bleeding was considered therapeutic from Greek and Roman times until the mid-nineteenth century.

Quantitation of Hemoglobin

The first quantitation of blood elements is attributed to Karl Vierordt of Tübingen, who published his method for counting RBC in 1852. The method was laborious, however, requiring some 3 hours, and other methods for diluting the blood and the use of pipets and counting chambers were subsequently developed. George Hayem of the University of Paris introduced a diluting solution in 1875. (It was the same saline solution he used intravenously to treat cholera.) Hayem observed that the average size of erythrocytes in chlorosis was smaller than normal (6 μm vs. 7.5 μm in diameter) and that the amount of

hemoglobin per RBC was decreased in chlorosis (Wintrobe 1985).

The quantitation of hemoglobin specifically was introduced in 1899 by Theodur W. Tallquist of Finland. The results, reported as percentages of "normal," had a wide margin of error, but the method was used well into the mid-twentieth century. Other physicians had measured the hematocrit in centrifuged, anticoagulated blood, or had used the size of red blood cells and a color index as measures of hemoglobin concentration. In 1903 the "volume index" was introduced. It was clear that in various forms of anemia, the red cell size and concentration of hemoglobin in the red blood cells varied (Wintrobe 1985).

Classification

There are many conditions or deficiencies that result in anemia. This section will identify several types of anemia prevalent today.

Pernicious Anemia (PA)

Awareness of this type of anemia appears in the second half of the nineteenth century. Thomas Addison of Guy's Hospital described a severe, usually fatal form of anemia in 1855. Macrocytes were recognized by Hayem in 1877; he also noted a greater reduction of hemoglobin than of red blood cells in pernicious anemia. In 1880, Paul Ehrlich found large nucleated RBC in the peripheral blood containing dispersed nuclear chromatin; he called them *megaloblasts,* correctly concluding that they were precursors of Hayem's giant red cells that had escaped from the marrow (Castle 1980).

In 1894, T. R. Fraser of Edinburgh became the first physician reported to have fed liver to patients with PA. Although he achieved a remission in one patient, others could not immediately repeat his success (Castle 1980). But in 1918, George H. Whipple bled dogs and then fed them canned salmon and bread. After the dogs became anemic, he needed to remove very little blood to keep the hemoglobin low, although when the basal diet was supplemented, he found that he needed to bleed them more often. It turned out that liver was the most potent supplement, but it was not until 1936 that hematologists realized that the potency of liver was due to its iron content (Whipple and Robsheit-Robbins 1925).

George Richards Minot of Harvard University became interested in the dietary history of his patients following the first reported syndromes due to deficiency of micronutrients. He focused attention on liver after Whipple's observations in dogs; in trying to increase the iron and purines in the diet of

patients with pernicious anemia, he fed them 100 to 240 grams of liver a day. He observed that the reticulocytes (an index of bone marrow activity) started to rise 4 to 5 days after the liver diet was begun. In fact, patients showed a consistent rise in RBC count and hemoglobin levels whenever they consumed liver in adequate amounts. In the attempt to purify the protein in liver, it was found that extracts were effective, and subsequently, cyanocobalamin – vitamin B_{12} – was identified. It was purified in 1948 and synthesized in 1973 (Castle 1980; Wintrobe 1985).

The possible role of the stomach in PA was pointed out by Austin Flint in 1860, only 5 years after Addison's description of the ailment appeared. In 1921, P. Levine and W. S. Ladd established that there was a lack of gastric acid in patients with PA even after stimulation. William B. Castle established that gastric juice plus beef muscle was effective in treating pernicious anemia, although either alone was not. An autoimmune basis for development of pernicious anemia has been established in recent years (Doniach, Roitt, Taylor 1963; Castle 1980).

Iron-Deficiency Anemia

Iron-deficiency anemia is by far the most common cause of anemia in every part of the world today (Davidson and Passmore 1969). It undoubtedly existed in ancient times as well. In this condition, fingernails develop double concave curvature, giving them a spoon shape (*koilonychia*). A Celtic temple at Nodens, in Gloucestershire, England, built in Ascelpian style after the Romans had left Britain in the fourth century A.D., contains a votive offering of an arm fashioned crudely proximally but with increasing detail distally; it shows characteristic koilonychia (Hart 1980).

Pallor, the hallmark or cardinal sign of anemia, is seen especially in the face, lips, and nails, often imparting a greenish tint to Caucasians, a presenting sign that led to the diagnosis of *chlorosis* or the "green sickness" in the sixteenth century. In the seventeenth century, pallor became associated in the popular mind with purity and femininity, and chlorosis became known as the "virgin's disease" (Hart 1980). Constantius I, father of Constantine the Great, was called Constantius Chlorus, because of his pale complexion (Hart 1980), and it seems most likely that he had a congenital form of chronic anemia. (He came from an area known today to have a relatively high frequency of thalassemia.)

Preparations containing iron were used therapeutically in Egypt around 1500 B.C. and later in Rome,

suggesting the existence of iron deficiency. In 1681, Thomas Sydenham mentioned "the effect of steel upon chlorosis. The pulse gains in strength and frequency, the surface warmth, the face (no longer pale and death like) a fresh ruddy coulour.... Next to steel in substance I prefer a syrup ... made by steeping iron or steel filings in cold Rhenish wine...." In 1832 P. Blaud described treatment of chlorosis by use of pills of ferrous sulfate and potassium carbonate that "returns to the blood the exciting principle which it has lost, that is to say the coloring substance" (London 1980).

Children have increased needs for iron during growth, as do females during menstruation, pregnancy, and lactation. Chronic diarrhea, common in the tropics where it is often associated with parasitism, decreases iron absorption whereas parasitism increases iron losses. Estimates indicate that the needs of pregnant and lactating women in tropical climates are about twice those of women in temperate zones. In the tropics high-maize, low-iron diets are common, and soils are iron deficient in many areas (Davidson and Passmore 1969).

Glucose 6-Phosphate Dehydrogenase (G6PD) Deficiency

Favism, or hemolytic anemia due to ingestion of fava beans, is now known to occur in individuals deficient in G6PD. The Mediterranean type of G6PD deficiency is found in an area extending from the Mediterranean basin to northern India, an area corresponding to Alexander's empire. Sickness resulting from ingestion of beans was probably recognized in ancient Greece, forming the basis for the myth that Demeter, Greek goddess of harvest, forbade members of her cult to eat beans. Pythagoras, physician and mathematician of the fifth century B.C. who had a great following among the Greek colonists in southern Italy, also seems to have recognized the disorder, since he, too, forbade his followers to eat beans. It is in that area of southern Italy that the incidence of G6PD deficiency is highest (Hart 1980).

In 1956, the basis for many instances of this type of anemia was recognized as to a hereditary deficiency of the enzyme glucose-6-phosphate dehydrogenase within the red cell. Inheritance of G6PD is now recognized to be a sex-linked characteristic with the gene locus residing on the X chromosome.

It is estimated that currently over 100 million people in the world are affected by this deficiency. Nearly 3 million Americans carry the trait for G6PD deficiency; about 10 to 14 percent of black American males are deficient in G6PD. The defect is not limited to blacks; it is found among Sephardic and Kurdish Jews, Sardinians, Italians, Greeks, Arabs, and in the Orient among Filipinos, Chinese, Thais, Asiatic Indians, and Punjabis. It has not been found among North American Indians, Peruvians, Japanese, or Alaskan Eskimos.

The first documented report of drug-induced (as opposed to fava bean-induced) hemolytic anemia appeared in 1926 following the administration of the antimalarial drug pamaquine (Plasmoquine). During World War II, after the world's primary sources of quinine were captured by the Japanese, about 16,000 drugs were tested for antimalarial effectiveness. In 1944, an Army Medical Research Unit at the University of Chicago studying these potential antimalarial drugs encountered the problem of drug-induced anemia. Research by this group over the next decade elucidated the basic information on G6PD deficiency (Keller 1971).

Pamaquine was found to cause hemolysis in 5 to 10 percent of American blacks but only rarely in Caucasians, and the severity of the hemolysis was observed to be dependent on the dose of the drug (Keller 1971; Beutler 1980). Although similar sensitivity to the related drug primaquine and many other related drugs was demonstrated, the term "primaquine sensitivity" came to be used to designate this form of hemolytic anemia. It was subsequently demonstrated that the hemolysis was due to an abnormality in the erythrocytes of susceptible individuals and that it was self-limited even if administration of primaquine was continued (Dern et al. 1954). Several biochemical abnormalities of the sensitive red cells, including glutathione instability, were described. In 1956, Paul E. Carson and colleagues reported that G6PD deficiency of red cells was the common denominator in individuals who developed hemolysis after one of these drugs was administered, and the term G6PD deficiency became synonymous with primaquine sensitivity (Carson et al. 1956). It was soon found that this deficiency was genetically transmitted (Beutler 1980).

Sickle-Cell Disorders

Sickle-cell disorders have existed in human populations for thousands of years. However, the discovery of human sickle cells and of sickle-cell anemia was first announced in the form of a case report by James Herrick at the Association of American Physicians in 1910. In 1904, Herrick had examined a young black student from Grenada who was anemic; in the blood film he observed elongated and sickle-cell-shaped RBC (Herrick 1910).

By 1922 there had only been three cases of this type of anemia reported. But in that year Verne R. Mason, a resident physician at Johns Hopkins Hospital, described the first patient recognized to have that disease at that institution. He entitled his report "Sickle Cell Anemia," thus introducing the term that would become the standard designation (Mason 1922).

In 1923 C. G. Guthrie and John Huck performed the first genetic investigation of this disease and developed a technique that became an indispensable tool for the identification of sickle trait in later investigations, population surveys, and genetic studies (Guthrie and Huck 1923).

Virgil P. Sidenstricker, of Georgia, recorded many of the clinical and hematologic features of sickle-cell disease. He introduced the term "crisis," was the first to suggest that the anemia was hemolytic, and reported the first autopsy describing the typical lesions of the illness including a scarred, atrophic spleen. He was also the first to describe sickle-cell anemia in childhood, noting the peculiar susceptibility of victims to infection with a high mortality rate (Sidenstricker et al. 1923).

The first case of sickle-cell anemia to be reported from Africa was described in 1925 in a 10-year-old Arab boy in Omdurman, and the first survey of the frequency of sickle-cell trait in the African population was reported in 1944 by R. Winston Evans, a pathologist in the West African Military Hospital. In a study of almost 600 men of Gambia, the Gold Coast, Nigeria, and the Cameroons, he found approximately 20 percent to have the trait, a sickling rate about three times that in the United States (Evans 1943–4).

In East Africa, E. A. Beet found a positive test for sickling in 12.9 percent of patients in the Balovale district of Northern Rhodesia. He also reported striking tribal differences in the prevalence of sickle-cell trait. By 1945 H. C. Trowell had concluded that sickle-cell anemia was probably the most common and yet the least frequently diagnosed disease in Africa. He noted that in his own clinic in Uganda no cases had been recognized before 1940, but 21 cases were seen within the first 6 months of 1944 when he began routine testing for sickling (Trowell 1945; Beet 1946).

For many years, it was thought that sickle-cell anemia was rare in Africa in contrast to the greater prevalence observed in America, and some thought that interbreeding with white persons brought out the hemolytic aspect of the disease. It was not until the mid-1950s that it was understood that few homozygous sickle-cell cases came to medical attention because of a high infant mortality rate from that disease. This was demonstrated in Léopoldville when J. and C. Lambotte-Legrand found that only two cases of sickle-cell anemia had been reported among adults in the Belgian Congo although sickling occurred in about 25 percent of the black population. They subsequently followed 300 infants with sickle-cell anemia. They found that 72 died before the end of the first year of life, and 144 had perished by the age of 5 (Lambotte-Legrand and Lambotte-Legrand 1955).

Subsequent research by others, however, established the fact that sickle-cell anemia patients who did survive to adolescence came from the higher social groups, and that the standard of living, the prevalence of infection and nutritional deficiency, and the level of general health care were the principal factors affecting the mortality rate from sickle-cell anemia in young children. By 1971, as improved health care became available, the course of the disease was altered; and, at the Sickle Cell-Hemoglobinopathy Clinic of the University of Ghana, it was reported that 50 percent of the patients with sickle-cell anemia survived past age 10 (Conley 1980).

Geographic distribution of sickle-cell gene frequency was mainly charted by the mid-twentieth century. The prevalence of sickling in black populations of the United States was well established by 1950. Numerous studies performed in central and South Africa also revealed that although the frequency of sickling varied, the occurrence of the gene that caused it was confined mostly to black populations.

In Africa, after World War II, surveys established that across a broad belt of tropical Africa, more than 20 percent of some populations were carriers of the sickle-cell trait. Significantly, a high frequency of sickle trait was also found among whites in some areas of Sicily, southern Italy, Greece, Turkey, Arabia, and southern India. Yet by contrast, sickling was virtually absent in a large segment of the world extending from northern Europe to Australia. These observations led to several hypotheses about where the mutant gene had had its origin and how such high frequencies of a deleterious gene are maintained (Conley 1980).

Hermann Lehmann presented evidence that sickling arose in Neolithic times in Arabia, and that the gene was then distributed by migrations eastward to India and westward to Africa. He and others have speculated that the frequency of the gene increased significantly in the hyperendemic malarial areas of Africa and spread northward across the Sahara

along ancient trade routes, particularly along the routes that led to Mecca in Arabia. Since the eastern and western Arabian types of sickle-cell disease are different, spread must have occurred along sea trade routes, accounting for similarities in sickle-cell anemia in eastern Africa, eastern Arabia, and southern India (Lehmann and Huntsman 1974).

Obviously then, there was much interest generated in the cause of the very high frequency of the sickle-cell gene in Africa. In 1946, Beet in Rhodesia noted that only 9.8 percent of sicklers had malaria, whereas 15.3 percent of nonsicklers were affected (Beet 1946). P. Brain, of Southern Rhodesia, suggested that RBC of sicklers might offer a less favorable environment for survival of malarial parasites (Brain 1952). In 1954, J. P. Mackey and F. Vivarelli suggested that "the survival value [of the trait] may lie in there being some advantage to the heterozygous sickle cell individual in respect of decreased susceptibility of a proportion of his RBC to parasitization by P. falciparum" (Mackey and Vivarelli 1954).

A relationship between sickle-cell trait and falciparum malaria was reported by A. C. Allison in 1954. He noted that the frequency of heterozygous sickle-cell trait was as high as 40 percent in some African tribes, suggesting some selective advantage or else the gene would be rapidly eliminated because most homozygotes die without reproducing. He decided that a high spontaneous mutation rate could not account for the high but varying frequencies of the gene, and postulated that sickle-cell trait occurs as a true polymorphism and that the gene is maintained by selective advantage to the heterozygous. Comparing the distribution of falciparum malaria and sickling, Allison found that high frequencies of the trait were invariably found in hyperendemic malarial areas. He also found that people with sickle-cell trait suffer from malaria not only less frequently but also less severely than other persons, and concluded that where malaria is hyperendemic, children with the sickle-cell trait have a survival advantage (Allison 1954).

Previously in 1979, Linus Pauling and Harvey Itano had reported the aberrant electrophoretic mobility of sickle hemoglobin, and ascribed the altered hemoglobin of patients with sickle-cell anemia to a change in the globin portion of the molecule. It was shown that the red cells of sickle-cell anemia patients contain the abnormal hemoglobin almost exclusively, whereas those with sickle-cell trait contain other normal and abnormal components. These findings supported the theory of the genetic basis of

sickle-cell anemia, proposed earlier by James Neel – that the person with sickle-cell trait is a heterozygous carrier of the sickling gene – and supplied a direct link between defective hemoglobin and molecules and the pathological consequences (Pauling et al. 1949).

Thalassemia

Thalassemia, an inherited form of anemia, results from the deficient synthesis of a portion of the globin molecule and is thought by some also to have stabilized in the face of malaria. A variety of forms exist, based on the chain and site within a specific chain at which the genetically determined defect exists. It has been suggested that thalassemia originated in Greece and spread to Italy when it was colonized by Greeks between the eighth and sixth century B.C. At present, it is most frequent in areas where ancient Greek immigration was most intense: Sicily, Sardinia, Calabria, Lucania, Apulia, and the mouth of the Po (Ascenzi and Balistreri 1977).

Skeletal Changes in Anemia: Porotic Hyperostosis

Chronic anemia from any cause results in bone changes, which can be recognized in archaeological specimens. These changes, called porotic or symmetrical hyperostosis, result from an overgrowth of bone marrow tissue, which is apparently a compensatory process. The cancellous zone between the cortical layers or tables of the skull is enlarged and the trabeculae become oriented perpendicular to the inner table, giving a radial pattern described as "hair standing on end." The inner table is unchanged, but the outer table is displaced externally and may be thinned or completely atrophied and often has a spongy appearance. The process varies in location in different individuals; frontal, parietal, temporal, occipital, and maxillary bones can be affected. A similar process is also seen in the metaphysical ends of long bones and anterior superior and acetabular areas of the ilium.

Today porotic hyperostosis is seen classically in X-rays of patients with congenital hemolytic anemias, as well as in children with chronic iron deficiency anemia. This is especially the case when the iron deficiency occurs in premature infants or is associated with protein malnutrition or rickets (Lanzkowsky 1968).

Porotic hyperostosis has been observed in archaeological specimens from a variety of sites, including areas of Greece, Turkey, Peru, Mexico, the United

States, and Canada. In most areas, the findings are considered evidence of iron-deficiency anemia, although thalassemia was apparently responsible in some areas. Around the shores of the Mediterranean, malaria was probably the most frequent cause of chronic anemia at certain times.

Archaeological specimens from the Near East show an incidence of anemia of only 2 percent in early hunters (15,000–8000 B.C.) who ingested a lot of animal protein and thus took in reasonable amounts of dietary iron. By contrast, farming populations of 6500 to 2000 B.C. showed an anemia incidence of 50 percent.

Many New World natives whose diet consisted primarily of corn (maize) and beans had a diet deficient in iron and protein. Moreover, when cooked in water for long periods of time, the food in the diet was also low in ascorbate and folate. Ascorbate helps convert dietary ferric to ferrous iron, which is more easily absorbed; therefore, deficiency of this vitamin increased the problem of deficient dietary iron. A high incidence of iron deficiency has been demonstrated by modern studies of infants and children in populations living on a diet consisting mostly of maize and beans (El-Najjar and Robertson 1976). It is not surprising then, in North America, that porotic hyperostosis was found in 54 percent of skeletons in the canyons of northern Arizona and northern New Mexico, among a population that ate little meat and subsisted mainly on maize. By contrast, plains dwellers in southern Arizona and southern New Mexico, who used more animal foods, had an incidence of only 14.5 percent. Absence of evidence for malaria or hemoglobinopathies in the New World before the arrival of the Europeans argues against these possible causes of porotic hyperostosis (Hart 1980).

VIII.7
Anorexia Nervosa

Anorexia nervosa is a psychophysiological disorder especially prevalent among young women and is characterized by prolonged refusal to eat or to maintain normal body weight, an intense fear of becoming obese, a disturbed body image in which the emaciated patient feels overweight, and the absence of any physical illness that would account for extreme weight loss. The term *anorexia* is actually a misnomer, because genuine loss of appetite is rare, and usually does not occur until late in the illness. In reality, most anorectics are obsessed with food and constantly struggle to deny natural hunger.

Clinical Manifestations and Pathology

In anorexia nervosa, normal dieting escalates into a preoccupation with being thin, profound changes in eating patterns, and a weight loss of at least 25 percent of the original body weight. Weight loss is usually accomplished by a severe restriction of caloric intake, with patients subsisting on fewer than 600 calories per day. Contemporary anorectics may couple fasting with self-induced vomiting, use of laxatives and diuretics, and strenuous exercise.

The most consistent medical consequences of anorexia nervosa are amenorrhea (ceasing or irregularity of menstruation) and estrogen deficiency. In most cases amenorrhea follows weight loss, but it is not unusual for amenorrhea to appear before noticeable weight loss has occurred. The decrease in estrogens

causes many anorectics to develop osteoporosis, a loss of bone density that is usually seen only in postmenopausal women (Garfinkel and Garner 1982).

By the time the anorectic is profoundly underweight, other physical complications due to severe malnutrition begin to appear. These include bradycardia (slowing of the heartbeat), hypotension (loss of normal blood pressure), lethargy, hypothermia, constipation, the appearance of "lanugo" or fine silky hair covering the body, and a variety of other metabolic and systemic changes.

In addition to the physical symptoms associated with chronic starvation, anorectics also display a relatively consistent cluster of emotional and behavioral characteristics, the most prominent of which grows out of the anorectic's distorted perception of food and eating. Unusual eating habits may include monotonous or eccentric diets, hoarding or hiding food, and obsessive preoccupation with food and cooking for others.

Emotionally, anorexic patients are often described as being perfectionistic, dependent, introverted, and overly compliant. Although studies have failed to find a consistent psychiatric symptom pattern for the disorder, frequently reported neurotic traits include obsessive compulsive, hysterical, hypochondriacal, and depressive symptoms. A decrease in or disappearance of sexual interest is also a frequent concomitant of anorexia nervosa, according to the 1987 *Diagnostic and Statistical Manual (DSM)* of the American Psychiatric Association.

A distorted body image is an almost universal characteristic of anorectics, with many patients insisting that they are overweight even when their bodies are extremely emaciated. As a result, most individuals with anorexia nervosa deny or minimize the severity of their illness and are thus resistant to therapy. The anorectic's refusal to acknowledge her nutritional needs, and her steadfast insistence that nothing is wrong, make anorexia nervosa one of the most recalcitrant disorders in contemporary medicine.

Distribution and Incidence

Once considered to be extremely rare, the reported incidence of anorexia nervosa has more than doubled during the 1970s and 1980s (Herzog and Copeland 1985). The disorder is especially prevalent among adolescent and young adult women. Indeed 90 to 95 percent of anorectics are young and female, and as many as one in 250 females between 12 and 18 years of age may develop the disorder. Onset of anorexia nervosa occurs almost exclusively during

the teens, although some patients have become anorectic as early as age 11 and others as late as the sixth decade of life. Patients are typically from middle- or upper-class families.

Anorexia nervosa is comparatively rare in men: Approximately 5 to 10 percent of anorectics are male. The clinical picture for male anorectics is also much different from that for women. In general, male anorectics tend to display a greater degree of psychopathology, are often massively obese before acquiring the disorder, are less likely to be affluent, and are even more resistant to therapy than their female counterparts (Garfinkel and Garner 1982).

Among American blacks, Chicanos, and first- and second-generation ethnic immigrants, there are few reported cases. However, this racial and ethnic distribution reflects socioeconomic status rather than racial characteristics (Herzog and Copeland 1985). Similarly, anorexia nervosa is confined to the United States, Canada, Western Europe, Japan, and other highly industrialized areas. The absence of the disorder in developing nations, and its high incidence among affluent social groups in Westernized countries have led many clinicians to classify anorexia nervosa as a "culture-bound" syndrome (i.e., a disorder that is restricted to certain cultures primarily because of their distinctive psychosocial features) (Prince 1985).

Etiology and Epidemiology

Although the etiology of anorexia nervosa is an area of intense investigation, researchers have yet to reach a consensus about the origin of the disorder. The most sophisticated thinking on the subject regards anorexia nervosa as a disorder that involves an interplay of biological, psychological, and cultural factors. Advocates of this model view these three etiologic factors as reciprocal and interactive, and believe that it is simplistic to isolate one component as the single underlying cause of the disorder (Garfinkel and Garner 1982; Brumberg 1988a; Brumberg and Striegel-Moore 1988).

Joan Brumberg (1988a) has developed a multi-determined etiologic model based on a two-staged conceptualization of anorexia nervosa, which delineates the relative impact of sociocultural influences and individual biological and psychological variables in precipitating the disorder. In the first stage – the "recruitment" phase of the illness – sociocultural factors play the dominant role. During this period, cultural assumptions that associate thinness with female beauty lead certain women into a pattern of chronic dieting. Indeed, research on the sociocultural causes of anorexia nervosa has linked the increased incidence of anorexia nervosa and other eating disorders with the tremendous cultural attention given to dieting and food, standards of beauty increasingly based on thinness, and the fitness movement (Chernin 1985; Schwartz, Thompson, and Johnson 1982; Orbach 1986). Yet sociocultural variables alone cannot explain why some women but not others move from chronic dieting to anorexia nervosa. Therefore, other individual factors must be implicated in the final development of the illness.

Brumberg's model of anorexia nervosa relies on a second stage – career or acclimation – to correct the shortcomings of sociocultural explanations of the disorder. During the career phase, specific biological and psychological features determine which individuals develop the full-blown psychopathology of anorexia nervosa. In order to explain the transition between the recruitment and career phases of anorexia nervosa, Brumberg relies on recent research in the biological and social sciences that has sought to uncover the unique physiological and psychological characteristics of anorexic patients.

Since the early 1900s, a number of different endocrinological and neurological abnormalities have been postulated as underlying biological causes of anorexia nervosa: hormonal imbalance, dysfunction in the satiety center of the hypothalamus, lesions in the limbic system of the brain, and irregular output of vasopressin and gonadotropin (Herzog and Copeland 1985). The search for a biomedical cause of anorexia nervosa is made difficult, however, by the fact that chronic starvation itself produces extensive changes in hypothalamic and metabolic function. Researchers in this area have yet to find a common biological characteristic of the anorectic population that is unmistakably a cause rather than a consequence of extreme weight loss and malnutrition (Brumberg 1988a).

A more satisfactory explanation of the biological factors that contribute to the "career" phase of anorexia nervosa is the "addiction to starvation" model proffered by the British psychiatrists George I. Szmukler and Digby Tantum (1984). According to Szmukler and Tantum, patients with fully developed anorexia nervosa are physically and psychologically dependent on the state of starvation. Much like alcoholics and other substance abusers, anorectics find something gratifying or tension-relieving about the state of starvation, and possess a specific physiological substrate that makes them more susceptible to starvation dependence than individuals who merely

engage in chronic dieting. Szmukler and Tantum add, however, that starvation dependence is not the total explanation of anorexia nervosa. Rather, they believe that starvation dependence acts in conjunction with a range of sociocultural, psychological, and familial factors that encourage certain individuals to use anorexic behavior as a means of expressing personal anguish.

Current psychological models of anorexia nervosa fall into three basic categories: psychoanalytic, family systems, and social psychology. In both the psychoanalytic and family systems models, anorexia nervosa is seen as a pathological response to the development crisis of adolescence. Orthodox psychoanalysts, drawing on the work of Sigmund Freud, view the anorectic as a girl who fears adult womanhood, and who associates eating with oral impregnation (Brumberg 1988a). Family systems theory, however, offers a more complex explanation of the relationship between adolescence and anorexia nervosa. On the basis of clinical work with anorectics and their families, family systems therapists have found that the majority of anorexic patients are "enmeshed," meaning that the normal process of individuation is blocked by extreme parental overprotectiveness, control, and rigidity. Anorexia nervosa is therefore seen as a form of adolescent rebellion against parental authority (Minuchin, Rosman, and Baker 1978; Bruch 1988).

Research in social psychology and the field of personality has devised several psychological tests to distinguish the psychological characteristics of anorectics from others in their age group. One study has shown that whereas many of the psychological traits of anorectics and other women are indistinguishable, anorectics display a markedly higher degree of ineffectiveness and self-esteem. Other studies have proposed that anorectics have actual cognitive problems with body imaging, whereas others suggest a relationship between anorexia nervosa and sex-role socialization (Garfinkel and Garner 1982).

Finally some researchers have attempted to fit anorexia nervosa within other established psychiatric categories such as affective disorders and obsessional neurosis. Many anorectics in fact display behavior patterns associated with obsessive-compulsive disorders: perfectionism, excessive orderliness and cleanliness, meticulous attention to detail, and self-righteousness. This correlation has led a number of researchers to suggest that anorexia nervosa is itself a form of obsessive-compulsive behavior (Rothenberg 1986). Depressive symptoms are also commonly seen in many patients with anorexia nervosa. Various family, genetic, and endocrine studies have found a corre-lation between eating disorders and depression. However, the association between anorexia nervosa and other psychiatric disorders remains controversial (Garfinkel and Garner 1982; Herzog and Copeland 1985).

History

Pre–Eighteenth Century

The existence of anorexia nervosa in the past has been a subject of much historical debate. Some clinicians and medical historians have postulated that anorexia nervosa was first identified in 1689 by the British doctor Richard Morton, physician to James II (Bliss and Branch 1960; Silverman 1983). The medieval historian Rudolph Bell has dated the origins of anorexia nervosa even earlier, claiming that certain medieval female saints, who were reputed to live without eating anything except the eucharist, actually suffered from anorexia nervosa (Bell 1985).

Other historians, however, have argued that attempts to label all historical instances of food refusal and appetite loss as anorexia nervosa are simplistic, and maintain that the historical record is insufficient to make conclusive diagnoses of individual cases (Bynum 1987; Brumberg 1988a). Although these historians agree that the final physiological stage of acute starvation may be the same in contemporary anorectics and medieval ascetics, the cultural and psychological reasons behind the refusal to eat are quite different. Thus, to reduce both to a single biomedical cause is to overlook the variety of social and cultural contexts in which certain individuals have chosen to refuse food.

Nineteenth Century

The modern disease classification of anorexia nervosa emerged during the 1860s and 1870s, when the work of public asylum keepers, elite British physicians, and early French neurologists partially distinguished anorexia nervosa from other diseases involving loss of appetite (Brumberg 1988a). In 1859, the American asylum physician William Stout Chipley published the first American description of *sitomania,* a type of insanity characterized by an intense dread or loathing of food (Chipley 1859). Although Chipley found sitomania in patients from a broad range of social and age groups, he identified a special form of the disease that afflicted adolescent girls. Chipley's work was ignored by his contemporaries, however, and it was not until the 1870s, when two influential case studies by the British physician William Withey Gull (1874) and the French alienist

Charles Lasègue (1873) were published, that physicians began to pay significant attention to anorexia in girlhood. Gull's primary accomplishment was to name and establish anorexia nervosa as a coherent disease entity distinct from either mental illnesses in which appetite loss was a secondary feature, or physical "wasting" diseases such as tuberculosis, diabetes, or cancer. Despite widespread acclaim for Gull's work with anorectic patients, however, clinicians during the late nineteenth century generally rejected the conception of anorexia nervosa as an independent disease. Instead, they conceptualized it either as a variant of hysteria that affected the gastrointestinal system, or as a juvenile form of neurasthenia (Brumberg 1988a).

Nineteenth-century physicians also tended to focus on the physical symptom of not eating, and ignored the anorectic patient's psychological reasons for refusing food. An important exception was Lasègue, who was the first to suggest the significance of family dynamics in the genesis and perpetuation of anorexia nervosa. Because of the somatic emphasis of nineteenth-century medicine, however, most nineteenth-century medical practitioners disregarded Lasègue's therapeutic perspective. Instead, they directed medical intervention toward restoring the anorectic to a reasonable weight and pattern of eating rather than exploring the underlying emotional causes of the patient's alleged lack of appetite (Brumberg 1988a).

Early Twentieth Century

In the twentieth century, the treatment of anorexia nervosa changed to incorporate new developments within medical and psychiatric practice. Before World War II, two distinct and isolated models dominated medical thinking on anorexia nervosa. The first approach was rooted in late-nineteenth-century research in organotherapy, a form of treatment based on the principle that disease resulted from the removal or dysfunction of secreting organs and glands (Brumberg 1988a). Between 1900 and 1940, a variety of different endocrinologic deficiencies were proposed as the cause of anorexia nervosa. In 1914, Morris Simmonds, a pathologist at the University of Hamburg, published a clinical description of an extreme cachexia due to destruction of the anterior lobe of the pituitary. Because patients with anorexia nervosa and those with Simmonds' disease shared a set of common symptoms, many clinicians assumed that a deficiency in pituitary hormone was the cause of both conditions (Brumberg 1988a).

Other researchers implicated thyroid insuffi-

ciency as the cause of anorexia nervosa. Research conducted at the Mayo Clinic in Rochester, Minnesota, during the period between the two world wars established a relationship between thyroid function and body weight, and led many physicians to regard anorexia nervosa as a metabolic disorder caused by a deficiency in thyroid hormone. Throughout the 1920s and 1930s, insulin, antuitrin, estrogen, and a host of other hormones were also employed in the treatment of anorexia nervosa (Brumberg 1988a).

The second major approach to anorexia nervosa in the early twentieth century grew out of the field of dynamic psychiatry, which emerged during the 1890s and early 1900s. Beginning in the last decade of the nineteenth century, practitioners in dynamic psychiatry increasingly focused on the life history of individual patients and the emotional sources of nervous disease. Two of the leading pioneers in this new field – Freud and Pierre Janet – were the first to suggest a link between the etiology of anorexia nervosa and the issue of psychosexual development. According to Freud, all appetites were expressions of libido or sexual drive. Thus, not eating represented a repression of normal sexual appetite (Freud 1918–59). Similarly, Janet asserted that anorectic girls refused food in order to retard normal sexual development and forestall adult sexuality (Janet 1903; Brumberg 1988a).

Because of the enormous popularity of endocrinologic explanations of disease, the idea of anorexia nervosa as a psychosexual disturbance was generally overlooked for more than 30 years. By the 1930s, however, the failure of endocrinologic models to establish either a predictable cure or a definitive cause of anorexia nervosa, the growing reputation of the Freudian psychoanalytic movement, and increased attention to the role of emotions in disease led a number of practitioners to assert the value and importance of psychotherapy in the treatment of anorexia nervosa. Although biomedical treatment of the disorder continued, most clinicians realized that successful, permanent recovery depended on uncovering the psychological basis for the anorectic's behavior. Following on the work of Freud and Janet, orthodox psychiatrists during this time postulated that refusal to eat was related to suppression of the sexual appetite, and claimed that anorectic women regarded eating as oral impregnation and obesity as pregnancy (Brumberg 1988a).

Post–World War II

After World War II, a new psychiatric view of eating disorders, shaped largely by the work of Hilde

Bruch, encouraged a more complex interpretation of the psychological underpinnings of anorexia nervosa. Although Bruch agreed that the anorectic was unprepared to cope with the psychological and social consequences of adulthood and sexuality, she also stressed the importance of individual personality formation and factors within the family to the psychogenesis of anorexia nervosa. Here, Bruch revived Lasègue's work on the role of family dynamics in anorexia nervosa. According to Bruch, the families of most anorectic patients were engaged in a dysfunctional style of familial interaction known as "enmeshment": Such families are characterized by extreme parental overprotectiveness, lack of privacy of individual members, and reluctance or inability to confront intrafamilial conflicts. Although superficially these families appeared to be congenial, said Bruch, this harmony was achieved through excessive conformity on the part of the child, and undermined the child's development of an autonomous self. Anorexia nervosa, according to Bruch, was therefore a young woman's attempt to exert control and self-direction in a family environment in which she otherwise felt powerless (Bruch 1973, 1988).

Bruch was also primarily responsible for the tremendous growth in the popular awareness of anorexia nervosa and other eating disorders in the 1970s and 1980s. Through her book, *The Golden Cage: The Enigma of Anorexia Nervosa* (1978), which sold over 150,000 copies, and numerous articles in popular magazines, Bruch brought anorexia nervosa into common American parlance (Brumberg 1988b).

At the same time that the American public was becoming increasingly aware of anorexia nervosa, the number of reported cases of the disorder grew tremendously. This phenomenon has led some clinicians and social commentators to suggest that the popularization process itself may promote a "sympathetic host environment" for the disorder (Striegel-Moore, Silberstein, and Rodin 1986; Brumberg 1988b). As Bruch (1988) herself observed:

Once the discovery of isolated tormented women, it [anorexia nervosa] has now acquired a fashionable reputation, of being something to be competitive about. . . . This is a far cry from the twenty-years-ago anorexic [*sic*] whose goal was to be unique and suggests that social factors may impact the prevalence of the disorder.

VIII.8
Anthrax

Anthrax is an acute zoonotic disease, primarily of herbivorous animals, which is transmissible to human beings. The causative organism is *Bacillus anthracis,* often referred to in earlier, and especially in French, texts as *bactéridie,* the name first bestowed on it by Casimir Davaine in 1863. Humans are infected only secondarily through contact with animals or animal products, and thus the disease in human beings must be considered in relation to anthrax in animals.

The species of domestic animals most commonly affected are cattle, sheep, and goats; pigs, dogs, and cats are less susceptible. Since an enlarged spleen is a classic observation in animals with anthrax, the disease has also been known as *splenic fever* or *splenic apoplexy.* In humans the cutaneous form is known as *malignant pustule,* and the pulmonary or intestinal, industrial type, as *woolsorters' disease* or *industrial anthrax.* In French the equivalent of splenic fever is *sang de rate,* in German *Milzbrand;* other French synonyms include *charbon* and *pustule maligne.*

Etiology and Epidemiology

Because *B. anthracis* produces resistant spores in suitable soils, the disease has long been endemic in many areas throughout the world, with a majority of the outbreaks occurring in Europe and Asia. The Americas, Africa, and Australasia are less affected. Once contaminated with anthrax spores, an area can be extremely difficult to clear, as has been demonstrated on the island of Gruinard off the west coast of Scotland, which was experimentally contaminated during World War II. This is of prime importance for the eipdemiology of the disease because it is rarely spread directly from animal to animal, but almost always through ingestion of contaminated food, either by grazing or, in cooler climates, through imported winter foodstuffs. Humans are accidentally infected either by contact with infected animals or by contaminated animal products. The infectivity of the anthrax bacillus for people is low, and therefore, even where large numbers of spores and bacilli are found in an industrial environment, only relatively few cases occur.

The nonindustrial type of anthrax in humans affects those in professions such as veterinary surgery, pathology, farming, butchery, and the like and takes the form of malignant pustule – a lesion due to contamination of the skin with material from infected animals. The industrial type may present as either malignant pustule or pulmonary disease and is acquired in the woolen industries especially through contaminated air. The disease approached an epidemic situation in the late eighteenth and nineteenth centuries in France and in England in factories processing imported horsehair and sheep's wool.

Distribution and Incidence

Anthrax is widely distributed throughout the world, but there are distinct differences in incidence and in species affected among the various continents and countries. Outbreaks in animals in Europe (mainly cattle) and in Asia (sheep and goats) heavily outweigh those in the United States and Africa, whereas Australia and Canada are rarely affected. Extensive enzootic areas with a constant presence of infection include China, Ethiopia, and Iran, and, in the Americas, Mexico and some South American countries. Available data suggest an annual average total of some 10,000 outbreaks throughout the world; for Great Britain the annual total between the two world wars ranged from 400 to 700, mostly very minor outbreaks. Since then there appears to have been a gradual reduction in incidence, helped in Great Britain by the introduction in 1919 of the Anthrax Prevention Act, forbidding importation of certain types of potentially contaminated material. Since World War II the number of fatal cases in human beings has been substantially reduced following the introduction of antibiotic therapy.

In countries such as Italy and Russia, a close correlation has existed between the seasonal incidence of the disease in people and in animals, with a rise during the hot summer months reflecting the sea-

sonal changes in temperature, humidity, and vegetation favoring spread and reproduction of the bacillus.

Immunology

The immunogenic behavior of the anthrax bacillus is complex, and it is not certain whether or to what extent immunity develops in cases of recovery from infection. The existence of an extracellular toxin produced by *B. anthracis,* which in part determines its virulence was demonstrated only during the 1980s. Certain strains of certain animal species possess a high degree of natural resistance, a fact that introduced confusion and fed much of the controversy surrounding the early work on the etiology of and immunity in anthrax. The live attenuated vaccines used by Louis Pasteur have undergone continued development and improvement over the years, but early results claiming reductions in incidence and fatality rates following their use were not readily sustained. Thus, the early vaccines have gradually been replaced by spore-based vaccines and methods combining active and passive immunization using prepared antiserum. Until recently, vaccines have not been considered safe for use in human beings, but serum treatment has been used extensively for prophylactic and therapeutic purposes.

For occupational reasons women are less liable to exposure than men, but the disease, when established, is more commonly fatal in females.

Clinical Manifestations and Pathology

In its principal animal hosts, anthrax may take one of three forms: (1) a *peracute* type (*splenic apoplexy*), where sudden death occurs almost simultaneously with the first symptoms; (2) an *acute* type characterized by an acute fever, usually followed by death after 2 to 12 days; and (3) a *subacute* type often followed by recovery. Classical signs include fever, stupor, spasms, convulsions, intestinal disturbances, and respiratory or cardiac distress. Death follows septicemia and accompanying severe toxic manifestations. Characteristic enlargement of the spleen is reflected in the name of splenic fever.

Anthrax in people may take the form of a malignant pustule (cutaneous anthrax), where the bacilli enter through the skin, producing a primary lesion developing into a characteristic area of inflammation surrounding a dark necrotic center; or it may take the form of the pulmonary or – less commonly – the intestinal type, which follows inhalation of dust containing anthrax spores, as has occurred in the woolen industries. Monkeys exposed to artificially generated aerosols of anthrax spores develop symptoms mimicking woolsorters' disease. Postmortem find-

ings include hemorrhages in the lung, hemorrhagic mediastinitis and lymphadenitis, and sometimes hemorrhagic meningitis.

History and Geography

In the past, outbreaks of anthrax (along with other epizootic diseases) among animals have undoubtedly helped to prepare the way for major outbreaks of epidemic disease in human beings. When anthrax has decimated herds of cattle or sheep, for example, human populations have faced starvation which, in turn, has lowered their ability to resist those epidemics. Anthrax has been known from antiquity, although until relatively recently it was not clearly separated from other diseases with similar manifestations. Possibly sudden death of animals at pasture, blamed by Aristotle (and subsequently by his followers over the centuries) on the shrewmouse and its "poisonous bite," may in many cases have been due to the peracute form of anthrax commonly referred to as *splenic apoplexy.*

Nineteenth-century authors speculated that the fifth and sixth plagues of the Egyptians as described in *Exodus,* which struck their herds and the Egyptians themselves, might have been anthrax. Evidence that this may have been the case centers on the Israelites, who were installed on sandy ground above the level of the Nile. They escaped the plagues, whereas those who did not lived in areas subject to flooding by the rising of the Nile, which could have provided perfect conditions for growth of the anthrax bacillus. Three decades before the birth of Christ, Virgil, in the *Georgics,* vividly described an animal plague that had much in common with anthrax, and warned against its transmission to people through contact with infected hides.

Through the centuries since Biblical times there are many records of animal plagues that almost certainly were anthrax but were often confused with a number of other complaints. By 1769, when identification of epidemic diseases of animals and human beings had become more precise, Jean Fournier in Dijon classified a number of different lesions as a single disease entity (anthrax), which he called *charbon malin.* More importantly, he recognized the transmission of the disease to people, and drew attention to cases occurring in workers who handled raw hair and wool, a theme developed in several accounts published in France during the following decade. These were all concerned with workers who had contracted anthrax while opening and sorting bales of horsehair imported from Russia. From the mid-nineteenth century, the disease became a problem in English facto-

ries as well, and subsequently in those of Scotland. At about the same time, the woolen industries began experiencing the problem as wool and hair from the East were introduced to the British trade. Wool-sorting, until then considered a particularly health-ful occupation, suddenly began to show an alarming increase in the number of deaths and the extent of disease among the workers. The workers themselves suspected an association between the disease and the growing proportion of wool and hair imported from the East. By the late 1870s, concern in the Yorkshire factories was acute, but by then the new bacteriology had led to the identification of the cause of anthrax. J. H. Bell in Bradford had demonstrated that both woolsorters' disease and malignant pustule in humans derived from anthrax in animals.

Bell's work had been made possible by the work of Davaine and that by Robert Koch in the 1860s and 1870s. During the nineteenth century, the study of anthrax and the use of animal models in its pursuit had become an important part of the framework for the emergence of bacteriology as an academic discipline. In France, Eloy Barthélemy established the transmissibility of anthrax in feeding experiments with horses in 1823. From 1850 onward, study of the putative agent was pursued by workers in Germany and in France, beginning with the results obtained by Aloys Pollender, then by Pierre Rayer, and finally by Davaine who, during extensive work with guinea pigs in the 1860s, bestowed on it the name of *bactéridie,* which survived in the literature for a long time. From 1876 onward, the anthrax bacillus became a cornerstone of both Koch's theories and his development of pure culture methods; in the late 1870s, W. S. Greenfield at London's Brown Institution and H. Toussaint in Lyons published the first studies of acquired immunity against anthrax in animals, before Pasteur took over the field and was able to demonstrate, at Pouilly-le-Fort in 1881, that immunity could be produced through vaccination of sheep.

In Great Britain, industrially acquired anthrax became a notifiable disease in the Factory and Workshops Act of 1895; the incidence was reduced when the Anthrax Prevention Act of 1919 prohibited importation of certain types of potentially contaminated material. Since World War II, following the introduction of antibiotic therapy, the number of fatal human cases has been substantially reduced.

VIII.9
Apoplexy and Stroke

Apoplexy

The old, very popular and quite international term *apoplexy* (or its equivalents *apoplectic attack, attack, apoplectic ictus* or *ictus*) today generally means stroke. The word "apoplexy" comes from the Greek *apoplexia,* which is derived from the verb *apoplessein,* meaning, respectively, "stroke" and "to strike." To define apoplexy is therefore to relate the history of the word and of its different successive significations. The history of apoplexy, from the Greeks to the twentieth century, will be presented first, followed by the medical details of stroke.

History

In the Hippocratic corpus, "apoplexy" appears as an obviously clinical term. For many centuries after Galen's writings of the second century A.D., it was thought that apoplexy involved brain matter, whereas epilepsy represented a disturbance of brain function. From the invention of the printing press to the late nineteenth century, several hundred monographs were devoted to apoplexy. Indeed the medical history of A. Dechambre (1866) listed some 150 such references between 1611 and 1865.

The first autopsies involving postmortem examinations of the brain were performed in the seventeenth century. Many more were done, however, after the publication of *De Sedibus, et Causis Morborum per*

Anatomen Indagatis, Libri Quinque by Giovanni Battista Morgagni in 1761. Morgagni reported numerous cases of postmortem examinations of apoplexy cases, which he separated into serous apoplexy (*apoplexia serosa*) and sanguineous apoplexy (*apoplexia sanguinea*).

In his 1820 treatise *On Apoplexy,* John Cooke considered that hemorrhagic lesions were commonest and that the other types of lesions (e.g., tumors, suppuration, cysts) were questionable cases of apoplexy. In his volume *Cases of Apoplexy and Lethargy with Observations upon the Comatose Diseases* published in 1812, John Cheyne thought that apoplexy might be "serous" or "sanguineous," but he was skeptical of the former entity. The periodic apnea, now known as the Cheyne–Stokes respiration, was first described by Cheyne in an 1818 article. "A case of apoplexy in which the fleshy part of the heart was converted into fat." For John Abercrombie, writing on *Pathological and Practical Research on Diseases on the Brain and Spinal Cord* in 1828, the cerebral lesion of apoplexy might be either a hemorrhage or a serous effusion, but sometimes there seemed to be no apparent anatomic lesions.

In his well-known *L'Anatomie pathologique du corps humain . . .,* Jean Cruveilhier, professor of morbid anatomy in Paris, used the word "apoplexy" as a synonym for "hemorrhage" (in its anatomic, pathological meaning). He distinguished "apoplexy without loss of consciousness" from "apoplexy with loss of consciousness" and wrote of pontine or spinal apoplexies as well as cerebral ones. This pathological point of view was strengthened by Richard Bright who, in his book *Diseases of the Brain and Nervous System* (1831), described and illustrated under the term "apoplexy" several cases of cerebral hemorrhage.

This association of apoplexy with hemorrhage in the central nervous system led gradually to the use of apoplexy as a synonym for hemorrhage and to the creation of expressions such as "spinal apoplexy" (in place of "spinal hemorrhage"), "pulmonary apoplexy" (in place of "hemorrhagic pulmonary infarct"), "abdominal apoplexy" (in place of "massive abdominal hemorrhage"), "renal apoplexy" (in place of "renal hemorrhage"), "splenic apoplexy" (in place of "hemorrhage of the spleen"), and so forth.

From the second half of the nineteenth century to the beginning of the twentieth century, the semantic confusion between apoplexy and hemorrhage continued. J. Russell Reynolds, for example, in his *Diagnosis of Diseases of the Brain, Spinal Cord, Nerves and Their Appendages* (1866), stated that an apoplectic attack could result from congestion, hemorrhage, tumor, uremia, or vascular obstruction. A. Trousseau, a professor in Paris, however, had attacked this problem of confusion in his famous *Clinique médicale de l'Hôtel-Dieu de Paris* (1865), and the French neurologist J. M. Charcot later (1881) emphasized that apoplexy was a clinical syndrome that unfortunately had often been used synonymously with cerebral hemorrhage.

Thus, Trousseau and Charcot, along with individuals such as Dechambre (1866), E. Bouchut and A. Desprès (1889), and J. Déjerine (1914), concluded that apoplexy could arise from conditions other than intracerebral hemorrhage, and that the use of the term should be restricted to the clinical syndrome that involved a "sudden and simultaneous loss of all the brain functions, consciousness, feeling and movement, without conscpicuous change of respiration and blood circulation" (Déjerine 1914). Surprisingly, in 1921, J. Lhermitte, in his well-known *Traité de pathologie médicale,* nonetheless persisted in the use of apoplexy as a synonym for hemorrhage and opposed the "hemiplegy of the apoplexy" and "the hemiplegy of the infarctus."

The term "apoplexy" has since become obsolete and disappeared from the indices of most contemporary textbooks of neurology and neuropathology and from the usual vocabulary of the modern physician. Nevertheless, it remains widely used in popular language and literature. Its proper use, however should be restricted to the field of the history of medicine, from Hippocrates to the beginning of the twentieth century. In the present medical vocabulary, the term "apoplexy" must be replaced either by "stroke" or by "hemorrhage" according to the context.

Stroke

According to World Health Organization diagnostic criteria, a stroke consists of "rapidly developing clinical signs of focal (at times global) disturbance of cerebral function, lasting more than 24 hours or leading to death with no apparent causes other than that of vascular origin." "Global" refers to patients in deep coma and those with subarachnoid hemorrhage (SAH). This definition excludes transient ischemic attacks (TIA), a condition in which signs last less than 24 hours.

Distribution and Incidence

Strokes are the most common life-threatening neurological disease and the third leading cause of death, after heart disease and cancer, in Europe and the United States. Death rates from strokes vary with age and sex; for example, in the United States, the

rates for males are 11.9 per 100,000 for those aged 40 to 44, and 1,217 per 100,000 for those aged 80 to 84. For females the rates are 10.9 (aged 40 to 44) and 1,067 (aged 80 to 84). In France, in the 30- to 34-year-old group, fully 2½ times more men than women die of the disease. The differential, however, declines progressively with increasing age so that at over age 84 the sex ratio is equal. Large differences in cerebrovascular disease (CVD) mortality have been noted among races. For example, in the United States, mortality is 344 per 100,000 for nonwhites but just 124 per 100,000 for whites. Among countries differences in mortality due to stroke ranged from 70 in Switzerland to 519 per 100,000 in Japan. Within the same region, mortality from stroke is higher in Scotland than it is in England and Wales.

Decline in CVD deaths has occurred in all developed countries since 1915, and the decline has accelerated during the last two decades. The acceleration seems related to decline in incidence, because 30-day case fatality rates were unchanged over this 20-year period. Interestingly, this decrease in incidence was demonstrated in a Rochester study (Schoenberg 1978).

The incidence in Rochester, New York, in 1983 was 103 per 100,000. The 3-week mortality rate was within the range of 25 to 35 percent. But strokes are more disabling than lethal: 20 to 30 percent of survivors became permanently and severely handicapped. Moreover, recurrent strokes have been observed in 15 to 40 percent of stroke survivors.

Risk Factors

Apart from age, the most important risk factor for CVD is arterial hypertension. Control of severe and moderate, and even mild, hypertension has been shown to reduce stroke occurrence and stroke fatality. Cardiac impairment ranks third, following age and hypertensive disease. At any level of blood pressure, people with cardiac disease, occult or overt, have more than twice the risk of stroke. Other risk factors are cigarette smoking, increased total serum cholesterol, blood hemoglobin concentration, obesity, and use of oral contraceptives.

Etiology and Pathology

Strokes are a heterogeneous entity caused by cerebral infarction or, less commonly, cerebral hemorrhage. Cerebral infarction accounts for the majority of strokes (63 percent, as documented by the New York Neurological Institute, in 1983–4). When perfusion pressure falls in a cerebral artery below critical levels, brain ischemia (deficiency of blood) develops, progressing to infarction if the effect per-

sists long enough. In most cases, ischemia is caused by occlusion of an intracerebral artery by a thrombus or an embolus arising from extracranial artery disease or cardiac source. The main cause of ischemic strokes (40 to 56 percent of the cases) is atherosclerotic brain infarction, the result of either intracerebral artery thrombosis or embolism arising from stenosed (narrowed or restricted) or occluded extracranial arteries. Lacunar infarction (14 percent of the ischemic strokes) is a small, deep infarct in the territory of a single penetrating artery, occluded by the parietal changes caused by hypertensive disease. Cerebral embolism from a cardiac source accounts for 15 to 30 percent of ischemic strokes. The main cause is atrial fibrillation related to valvular disease or ischemic heart disease. Other causes of cerebral infarction are multiple, resulting from various arterial diseases (fibromuscular dysplasia, arterial dissections, arteritis), hemopathies, systemic diseases, or coagulation abnormalities. However in 20 percent of the cases, the cause of cerebral infarction, despite efforts to arrive at a diagnosis, remains undetermined.

Intracranial hemorrhages (ICH) account for 37 percent of strokes. The main cause of ICH is the rupture of miliary aneurysms that have developed in the walls of interior arteries because of hypertensive disease (72 to 81 percent of the ICH). Nonhypertensive causes of ICH are numerous and include substance abuse, cerebral amyloid angiopathy, intracerebral tumors, and coagulation abnormalities.

Clinical Manifestations and Classification

Clinical manifestations of strokes depend on both the nature of the lesion (ischemic or hemorrhagic) and the part of the brain involved. In the early 1960s, a classification of strokes according to their temporal profile was proposed to promote the use of common terminology in discussion of natural history and treatment programs.

The term *incipient stroke* (TIA) was defined as brief (less than 24 hours), intermittent and focal neurological deficits due to cerebral ischemia, with the patient normal between attacks. The term "reversible ischemic neurological deficit" (RIND) was coined for entirely reversible deficits occurring over more than 24 hours.

The term *progressing stroke* (stroke-in-evolution) is applied to focal cerebral deficits observed by the physician to progress in the severity of the neurological deficit over a period of hours or, occasionally, over a few days.

The term *completed stroke* is used when the neuro-

logical signs are stable and no progression has been noted for 18 to 72 hours. *Major stroke* is a term applied when immediate coma or massive neurological deficit occurs. In these cases, hope of recovery and of effective treatment are minimal. *Minor stroke,* by contrast, is a term applied to cases where the deficits relate to only a restricted area of a cerebral hemisphere, or where the symptoms experienced are of only moderate intensity. With minor strokes, diagnosis and institution of treatment should be rapidly combined to avoid further deterioration and, if possible, facilitate the regression of deficit.

These definitions contain some obvious uncertainties, particularly in categorizing a stroke during the early hours. However, they underscore the fact that the management of a stroke often depends more on its temporal profile and on the severity of the neurological deficit than on the nature of the lesion.

VIII.10 Arboviruses

Arbovirus is a truncated term for arthropod-borne viruses, all of which require multiplication in their vectors for transmission. Arboviruses diseases may be simpler to understand when viewed solely from the position of the end product, which is disease in humans or other vertebrates. The diseases fall into a few recognizable sets: (1) encephalitides; (2) diseases with fever and rash, often fairly benign; (3) diseases with hemorrhagic manifestations, often fatal; and (4) mild fevers, quite undiagnosable except through laboratory study. A common feature of all of these is periodic outbreaks, with dozens, hundreds, or thousands of cases. A second common feature is lack of specific treatment. In addition, only for very few of the diseases do vaccines exist. Possibility of disease control is real, however, and is based on a knowledge of the epidemiology of arbovirus infections in general, the role that vectors play, and the particular features in regard to the transmission of the specific disease in question.

Etiology

Arboviruses, numbering at latest count 512 separate and identifiable agents, are placed in 11 families, with a few as yet unclassified agents. Table VIII.10.1 presents a listing of family and subfamily groupings, limited to those viruses of major importance in human and veterinary diseases.

It is evident from the table that there is no simple delimiting definition of an arbovirus on a taxonomic basis, or even on a biochemical basis. There are 511 RNA viruses, and then there is African swine fever virus (ASF), a DNA virus. ASF belongs to the Iridoviridae and is the only Iridovirus (so far as is yet known) with an arthropod vector and a vertebrate host. There are numerous Iridoviridae, incidentally, with arthropod vectors and plant or arthropod hosts.

Viruses must qualify in several important points in order to be considered as arboviruses. The life cycle of an arbovirus involves an arthropod (usually insect, tick, or mite) that is capable of becoming infected itself when it imbibes the virus from an infected host. The arthropods serve as vectors of the virus, from an infected vertebrate host to an uninfected one. The virus must multiply in the arthropod, a process requiring several days, and reach a concentration suffi-

cient to be passed, in a later feeding, to the host, and to induce an infection in that host. The host, in turn, must have a viremic phase in order to pass the virus back to a biting or sucking arthropod.

This rigid definition gives rise to confusion (e.g., recent misconceptions about putative arthropod vectors of measles, hepatitis B virus, and human immunodeficiency (HIV) virus), but the definitions are uncompromising. The confusion is compounded when it is realized that although an arthropod, with mouth parts freshly contaminated by feeding on an infected host, may possibly transmit virus mechanically, a defined vector must be capable of multiplying the virus internally over a period of several days and of transmitting it by then biting a susceptible host in later feedings. This is referred to as the *biological transmission cycle*. Mechanical transmission must be quite unusual and with respect to arboviruses has never been observed in nature, but has been achieved in the laboratory under controlled conditions. In the case of HIV (not an arbovirus), mechanical transmission by needle is thought to be a dominant mode of transmission in the subset of drug users in some societies. The malaria parasite similarly can be transmitted by infected needle.

Again, from the point of view of the virus, it must be capable of multiplying in one or more vertebrate hosts, usually over a period of several days, reaching a level in the bloodstream adequate to infect a foraging vector.

The above considerations define (1) the interval between the arthropod ingestion of infected blood and the ability to transmit virus biologically, again by biting, to a susceptible host (the *extrinsic incubation period*), and (2) the period, in the host, before the viremia level rises to a height necessary to infect the biting arthropod (the *intrinsic incubation period*). The minimum interval between infection in one vertebrate host and acquisition of infection by the next vertebrate host is the sum of the extrinsic and intrinsic incubation periods. It is frequently about a week or more, and the maximum interval from one infection to the next may be weeks or months.

Virus Morphology, Size, Structure, and Characteristics

Arboviruses from selected families or subgroupings that contain viruses of importance to humans or other vertebrates are compared in Table VIII.10.2. Size varies considerably; shapes range from spherical to rhabdoform (bullet-shaped) to icosahedral.

Structurally, some entire groupings of viruses are enveloped, some are not. There are other differential characteristics, as indicated in the table. Again, the common bond is biological transmission by arthropod to vertebrate. How, in the evolution of viruses, this ability to exploit two phyla of living creatures arose again and again in such widely different taxa, is not known.

Virus morphology is not totally explicated by reference to arboviruses subsumed in such groups as alphaviruses, flaviviruses, bunyaviruses, rhabdoviruses, orbivirus (see Table VIII.10.1). More detailed references (e.g., Theiler and Downs 1973; Field 1985) must be consulted for further information. Almost the entire grouping of arboviruses consists of RNA viruses that are readily degradable by lipid solvents, ribonucleases, or heat and freezing (at temperatures above −70°C). The viral agents can be vacuum-desiccated satisfactorily, permitting greatly lengthened periods of storage with minimal loss in titer. Wet or desiccated material in glass-sealed ampoules can be stored in dry-ice containers or, better yet, in liquid nitrogen containers for long periods of time.

Epidemiology

When the science of epidemiology of the nineteenth century was applied to the study of yellow fever, the epidemiologist was hampered by a lack of knowledge of infectious agents and of vector arthropods in the transmission cycle. Consequently, there was great confusion and an endless diatribe surrounding various hypotheses on how infection could travel so mysteriously from place to place, with infections occurring in people who apparently never had had contact with a case. With Theobald Smith's demonstration in cattle of transmission of the Texas redwater fever organism by ticks, Ronald Ross's demonstration of transmission of the parasite of malaria by mosquitoes, and Walter Reed's demonstration of transmission of the virus of yellow fever by mosquitoes, came the dawn of modern epidemiological studies on arthropod-transmitted diseases.

As can be seen in Table VIII.10.3, a mysterious specificity exists between certain feeding arthropods and certain viruses; furthermore, a preferential feeding of certain arthropods (mosquitoes, for example) on certain food sources is shown. Some vertebrates react to a specific virus with severe disease. Yellow fever, for example, produces severe illness in humans, laboratory white mice, rhesus monkeys, and *Alouatta* monkeys. On the other hand, yellow fever

Table VIII.10.2. *Size, morphology, structure, and composition of selected virus families or genera that contain arboviruses*

Family	Genus	Size	Morphology	Composition	Structure
Bunyaviridae		80–120 nm	spherical	RNA	Lipid bilayer or envelope that anchors external surface projections of 5–10 nm, arranged regularly Uukuniemi has hexagonal arrays of surface structure
Togaviridae					
	Alphavirus	60–65 nm	spherical	RNA	Enveloped; symmetrical surface filaments, 6–10 nm; icosahedral with 42-subunit symmetry
	Flavivirus	43 nm (mean diam.)	spherical	RNA	Enveloped with surface projections
Reoviridae					
	Orbivirus	50–65 nm (inner core)	spherical	RNA	Double-protein capsid shell; nonenveloped; icosahedral symmetry
Rhabdoviridae		60–85 nm wide; approx. 180 nm long (animal rhabs)	"bullet shape"	RNA	Enveloped; intricate internal structure
Coronaviridae		100–150 nm	spherical	RNA	No envelope; 20-nm surface projections
Iridoviridae					
	African swine fever	175–215 nm	icosahedral	DNA	Capsid has dense outer shell; central nucleoid, 72–80 nm

may infect dogs, cats, *Cebus* monkeys, cows, and horses without producing overt disease. Among the encephalitides, eastern equine encephalitis (EEE) virus (endemic strains) can produce severe disease and death in human beings, laboratory mice, certain other vertebrates, and very specifically equines. But cattle do not develop illness with this agent, nor do sheep, goats, dogs, or cats. By contrast, the South American EEE strain that kills horses produces no illness in human beings but does produce detectable antibodies.

The resistance of various vertebrates to various arboviruses can be of use to the investigator because it permits the production of large quantities of immune sera in such vertebrates. Such immune sera are of minimal importance in treating disease in human beings, but are of cardinal importance in the design of specific serologic tests for virus identification. With the advent of cell culture techniques, leading to the preparation of monoclonal antibodies to specific portions of a virus genome, identification work has been greatly broadened in scope and much narrowed in specificity, often providing in a matter of hours identification of a virus that would have required days or weeks for identification using older techniques.

Modern techniques, founded on studies carried out over a period of half a century, involving basic laboratory techniques of complement fixation, precipitation, electrophoresis, centrifugation, hemagglutination inhibition, and virus neutralization, have been extended by later advances such as "tagged"

Table VIII.10.3. *Twenty-nine selected arboviruses important in causing human and/or animal diseases, with data on vectors, hosts, and geographic distributions*

Family	Subfamily or group	Virus (abbr.)	Vector(s)	Principal host(s) involvement	Geographic range

antibodies – that is, the use of monoclonal antibodies in combination with "tagged probes" in electron microscopy. Such new techniques, involving the use of specific "probes," are presently a fertile area of research, from which is emerging a more rational and complete knowledge of the virus particle itself and its interactions with vertebrate and invertebrate hosts.

Dengue

Geographic distribution of viruses and disease is determined by the characteristics of the vectors, rather than by the characteristics of the viruses. Taking dengue viruses (*Flavivirus* genus) as an example, the limits of their distribution are defined by the limits of the distribution of the principal vector, *Aedes aegypti*. This mosquito, originally found in Southeast Asia, spread worldwide, traveling wherever humans traveled and established itself in tropical and subtropical and often temperate regions, but not in Arctic and Antarctic polar extremes. The dengue viruses moved with the vectors and became established worldwide, particularly in tropical and subtropical regions. The viruses may have had, in their original territories of Southeast Asia, cycles involving *A. aegypti* and/or *Aedes albopictus* and subhuman forest primates, but as the virus left their original home, they adapted to a vector–human–vector cycle, allowing them to exist in endemic form wherever humans exist, and to appear in epidemic form at intervals.

The other Southeast Asian vector, *A. albopictus*,

has of recent years established itself in other countries such as the United States, with as yet unknown potential for involvement in the life cycles of still other viruses such as yellow fever. There are also other aedine vectors of dengue in Polynesia. The dengues are placed in four serotypes, one or more of which are associated with often fatal manifestations of dengue hemorrhagic fever and dengue shock syndrome. These are important causes of mortality in small children in countries of Southeast Asia, scattered cases being seen elsewhere. It is hypothesized that sequential infections in the same individual by different serotypes of dengue may lead to these serious complications.

Yellow Fever

Yellow fever, a *Flavivirus* serologically related to the dengues, is also capable of being transmitted from human to human by *A. aegypti* and can maintain itself endemically in a human population by such means. This mode of transmission occurred a century and more ago but has not been observed recently. The virus is found in Africa, south of the Sahara, and in the equatorial South American jungle regions. In both Africa and South America (here including Central America, and the West Indies), and even in the United States, Spain, France, Gibraltar, and England, periodic outbreaks of the disease, often explosive and devastating, have been observed since *A. aegypti* may establish itself in subtropical and even temperate locales. Although *A. aegypti* (and *A. albopictus*) is prevalent in Asia and

Australia, yellow fever has never established itself in these regions. With vectors present, as well as millions of nonimmune humans, there is a continuing threat of its introduction.

A reason yellow fever has been able to maintain itself in tropical South America and Africa is that the virus can utilize a different set of vectors: the forest canopy-frequenting *Haemagogus* mosquitoes of the New World, as well as *A. aegypti* and *Aedes africanus, Aedes simpsoni, Aedes taylori, Aedes furcifer,* and other aedines in Africa, often with and often without *A. aegypti.* Using the endemic *Haemagogus* or *Aedes* species, the virus remains established as an endemic virosis in various subhuman primates of these regions. This maintenance cycle is referred to as "sylvan" or "jungle" yellow fever. The sylvan *Haemagogus* or *Aedes* can and often does bite humans, and thus can transfer the virus out of the mosquito–monkey–mosquito cycle into a mosquito–human–mosquito cycle. An infected forest worker in the early stage of illness (and circulating virus in high titer) can migrate to an urban setting infested with *A. aegypti* and establish the dreaded urban mosquito–human–mosquito cycle. Recently, several large outbreaks of this type have occurred in Africa and in South America, some of them involving the deaths of thousands of people such as in the Nigeria epidemic in 1986.

A completely effective attenuated yellow-fever vaccine (17D) has been available since 1935, but governments in regions where yellow fever is endemic have as yet failed to react adequately in getting the population at risk immunized. The blame for this rests not on technical failure (the vaccine itself), nor on difficulties in administration of same, but in the inability of governments to establish adequate bureaucratic–administrative procedures to protect the health of the people. *Aedes* control projects, often employed for disease control, again suffer from a bureaucratic inability to maintain effective programs at a high level of efficiency over periods of years.

Encephalitides

Another group of the arboviruses, the encephalitides (Venezuelan, eastern, western, St. Louis, Japanese, Murray Valley, Russian spring–summer encephalitis), present mechanisms quite different from the dengue or yellow fever models. The vectors in question – mosquitoes or ticks – are of themselves geographically delimited, and therefore, the specific viruses associated with specific vectors are geographically delimited, with little chance of spread beyond natural ecological barriers. The viruses themselves have a basic vertebrate cycle in birds or small mammals. Certain of the viruses, such as Venezuelan equine encephalitis, eastern equine encephalitis, and western equine encephalitis, can escape from the mosquite–small vertebrate–mosquito cycle and spread like wildfire in one or another of the larger vertebrates, causing widespread mortality, and humans may be thus involved. These epidemics are sporadic and unpredictable. The endemic cycles are present continuously, but unobserved unless specifically sought for. Others of the viruses are associated particularly with birds and mosquitoes. These viruses include St. Louis encephalitis virus of the Americas, Japanese encephalitis virus of the Orient, Murray Valley encephalitis of Australia and New Guinea, Ilheus virus of South America and Trinidad, Rocio virus of southeast Brazil, and West Nile virus of Africa, the Middle East, and India. The viruses are often very prevalent in a region, in birds, with the disease usually being uncommon in human beings, but sometimes occurring in large epidemics. Heron rookeries and pig farms in the Orient have been shown to be Japanese encephalitis virus-amplifying localities, providing opportunities for infection of large numbers of mosquito vectors and thus facilitating large-scale transmission of virus to human beings. Immunity rates in populations are often high (bespeaking inapparent infections), and encephalitis rates low.

In the central United States, a recent arrival on the virus scene, La Crosse virus, a member of the California virus group, has established its position as the commonest arboviral cause of encephalitis. This endemic disease has some unusual features. It is transmitted by woodland aedine mosquitoes, and has as vertebrate hosts certain small mammals of the region. It has been further established that the virus can be transmitted transovarially (TOT) from mosquito to mosquito, vertically, through the egg, and laterally, from female to male or from male to female during copulation. This mechanism has been hypothesized to explain the long persistence of virus in a vector, serving to carry it over periods of inclement weather or drought. Similar TOT has been shown for dengue, Japanese encephalitis, and yellow fever.

Tick-borne encephalitis (Russian spring–summer encephalitis, RSSE) in the Eurasian continent and Powassan virus encephalitis in America are delimited by the range of specific tick vectors; these viruses are endemic in small mammals and present themselves in humans as sporadic cases, often not distinguished from encephalitis caused by other vi-

ruses or of unknown etiology except by special laboratory studies.

Epidemiology of arboviruses can be conceptualized as a huge, multidimensional matrix, involving many viruses on one axis, many vectors on another, many vertebrate hosts on another, and yet another axis for ecological, ethological, meteorological, cultural, and edaphic influences impinging on vectors and hosts.

Clinical Manifestations and Diagnosis

The early days of onset of most arboviral infections are usually accompanied by fevers, aching, and general malaise, and cannot be distinguished from early stages of other very common diseases such as influenza, malaria, measles, pneumonias, meningitis, other respiratory afflictions, and even Lassa fever and smallpox. As diseases progress in their course, specific later manifestations may provide aid in differential diagnosis. Such specific manifestations include rashes, eruptions, nausea and vomiting, diarrhea, cough, and encephalitis.

Sporadic cases in a population may be quite impossible to diagnose specifically. But as epidemics progress, specific features may appear and provide the clue to diagnosis. Malaria in the tropics and influenza in temperate regions and the tropics serve as "coverup" or "umbrella" diagnoses that often block out recognition of arbovirus illness.

Definitive diagnosis demands the assistance of experienced virologists working in adequate laboratory diagnostic facilities. There exist only a few dozen such facilities in the world, supported by the World Health Organization, governments, armed forces military establishments, and, in a few instances, private philanthropy. Such laboratories usually combine laboratory diagnostic methodology and facilities for carrying out field epidemiological studies.

Specific diagnosis can only rarely benefit the patient, but is of vital importance in alerting health departments of the presence of a potentially threatening epidemic. Appropriate control procedures directed at the vectors can then be applied on an emergency basis. In the special case of yellow fever, mass immunization of exposed populations can successfully halt an epidemic in its tracks. Such an immunization campaign is usually combined with emergency mosquito control.

Treatment and Control

Aside from provision of nursing care, and maintaining nutrition and fluid balance, there are no specific remedies for infections. Nonspecific measures, particularly treatment of shock (maintaining fluid and electrolyte balance) may be life-saving in dengue-shock syndrome cases.

Vector control is applicable in certain situations. Fred Soper and co-workers in the 1930s eradicated *A. aegypti* from all of Brazil, thus eliminating the risk of urban yellow fever. The mosquito has reinvaded much of the territory formerly freed, and the threat of yellow fever has returned. Short-term vector control is widely practiced, particularly when epidemics threaten. This may include airplane spraying of insecticides, treatment of interior walls of buildings with residual insecticides, insecticide treatment of mosquito breeding places, destruction or drainage of mosquito breeding places, screening of dwellings, use of insecticidal fogs in and around dwellings, use of insect repellents, and wearing of protective clothing.

The attenuated live yellow fever virus vaccine (17D) has been used for over 50 years in the successful immunization of millions of people. A live attenuated dengue virus vaccine is being tried. A killed Japanese encephalitis virus vaccine is given to millions of people in the Orient. A killed RSSE virus vaccine is used extensively in parts of the former Soviet Union. Killed virus vaccines against eastern equine encephalitis, western equine encephalitis, Venezuelan equine encephalitis, and Rift Valley fever virus are used primarily to protect livestock. Laboratory workers studying these viruses are routinely immunized.

VIII.11
Arenaviruses

The Arenaviridae are a small group of viruses, containing several of considerable importance as human disease agents. They are listed in the *Catalogue of Arthropod-Borne Viruses,* not because they are arboviruses but because they have been discovered in large part by arbovirologists, working on details of arthropod-transmitted viruses. Most of the 14 members of the group have rodents as reservoir hosts, but they occasionally infect humans who imbibe or ingest the virus when accidentally consuming rodent-contaminated food and drink, or are otherwise in contact with an environment contaminated by rodent excreta. At least one of the viruses, however, Lassa virus, can pass directly from person to person. This happens particularly in hospital settings. Other Arenaviruses important in human disease are Junin (Argentine hemorrhagic fever), Machupo (Bolivian hemorrhagic fever) from South America, and the virus causing lymphocytic chorio-meningitis (LCM). Six of the viruses – Junin, Machupo, Pichinde, Tacaribe, Lassa, and LCMs – have infected laboratory workers. (Because Lassa fever is covered elsewhere in this work, it will not be treated here in any detail.)

Virus Morphology, Size, and Structure

Electron micrographic studies of infected cells reveal round, oval, or pleomorphic budding particles with mean diameters of 110 to 130 nanometers. The envelopes, which have spikes, are derived from the plasma membranes of the host cell by budding. The interior contains variable numbers of electron-dense granules measuring 20 to 25 nanometers and resembling ribosomes. These sandy grains gave rise to the name *Arenavirus* because *arena* means "sand" (Rowe et al. 1970). The exact composition of this core material and its derivation are as yet uncertain. The virions are enveloped RNA-containing nucleocapsids. The genome consists of two single-stranded RNA molecules (Lehmann-Grube 1988).

History

The first arenavirus to be discovered was the one causing LCM in mice and monkeys; it was reported in 1934 by C. Armstrong and R. D. Lillie. Later studies showed that the virus was present in feral *Mus musculus* (the common house mouse) and accounted for a scattering of human cases annually in Europe and America. More commonly, those cases were seen in personnel who were handling laboratory animals, particularly white mice and hamsters. The agent itself was characterized morphologically by electron microscopy, and later investigated in serologic, biochemical, and biophysical studies. No serologic relatives were found, and over several decades, only scattered cases and outbreaks have been reported in America and Europe.

In 1957, a virus named Tacaribe was recovered from a fruit-eating bat in Trinidad, West Indies (Downs et al. 1963). This agent remained unclassified. Meanwhile a disease was observed among field workers in the northern provinces of Argentina that occurred at harvest time and caused considerable mortality. A virus subsequently named Junin (Parodi et al. 1958) was recovered from these patients, and the disease was named Argentinian hemorrhagic fever (AHF). Cases occur annually, and there have been epidemics of the disease over the past 30 years.

A particularly virulent infection broke out in the small town of San Joaquin, Beni Department, in the Amazonian lowlands of Bolivia. In due course it was

called Bolivian hemorrhagic fever (Johnson et al. 1965). The outbreak was checked, however, once the rodent host of the Machupo virus that caused the disease was implicated and rodent control mechanisms were instituted. Since then Machupo virus has "gone underground"; no further outbreaks have been reported and little further epidemiological work is being done on the disease.

In January 1969, another of the arenaviruses was forcefully brought to the attention of Western medicine, with an outbreak among medical personnel in Lassa, northeastern Nigeria (Buckley, Casals, and Downs 1970). At least seven more outbreaks of the disease subsequently named Lassa fever have taken place since then, involving about 450 patients and almost 125 deaths. The virus appears to have a natu-

ral cycle of transmission in rodents but, as previously mentioned, can spread from human to human.

Epidemiology (and Phylogenetic Considerations)

Table VIII.11.1 lists the 16 members of the Arenaviridae, their known vertebrate hosts' geographic distribution, date of first finding, and author(s) and dates of first description. Four of these are important agents in human disease: LCM, Junin, Machupo, and Lassa. In addition, 10 other members of the group are apparently nonpathogenic (for human beings). Epidemiological information about these is scanty, although several – particularly Tacaribe and Pichinde – have been studied intensively in the laboratory.

Table VIII.11.1. *History and natural occurrence of arenaviruses*

Virus	First finding	Natural Occurrence		First description
		Principal host	Geographic distribution	
LCM	1933	*Mus musculus*	America, Europe	Armstrong and Lillie 1934
Quaranfil	1953	*Bubulcus ibis:* pigeon *Argas* ticks	Egypt, S. Africa, Afghanistan, Nigeria	Taylor et al. 1966
Tacaribe[a]	1956	*Artibeus literatus Artibeus jamaicensis*	Trinidad, West Indies	Downs et al. 1963
Junin	1958	*Calomys laucha Akodon azarae*	Argentina	Parodi et al. 1958
Amapari	1964	*Oryzomys* sp. *Neacomys guianae*	Brazil (Amazonas)	Pinheiro et al. 1966
Araguari	1964	opossums	Brazil	USPHS 1988
Johnston Atoll	1964	*Ornithodorus capensis*	Johnston Atoll (Pacific)	Taylor et al. 1966
Machupo	1965	*Calomys callosus*	lowland Bolivia	Johnson et al. 1965
Parana	1965	*Oryzomys buccinatus*	Paraguay	Webb et al. 1970
Tamiami	1965	*Sigmodon hispidus*	Florida (U.S.A.)	Calisher et al. 1970
Pichinde	1965	*Oryzomys albigularis Thomasomys lugens*	Colombia	Trapido and Sanmartin 1974
Latino	1965	*Calomys callosus*	Brazil, Bolivia	Webb et al. 1973
Lassa	1969	*Praomys natalensis*	Nigeria, Liberia Sierra Leone	Buckley et al. 1970
Flexal	1975	*Oryzomys bicolor*	Edo. de Para, Brazil	Pinheiro et al. 1977
Mopeia	ca.1976	*Praomys natalensis*	Southeast Africa	Wulff et al. 1977
Mobala	ca.1982	*Praomys jacksoni*	Central African Republic	Gonzalez et al. 1983

Note: Three of these viruses are already named in the International Catalogue of Arboviruses (1975 and 1988 update): Araguari, Quaranfil, and Johnston Atoll are considered possible Arenaviridae, the latter two on basis of electron microscopic studies (Zeller, personal communication, 1989). None of these three viruses has rodent hosts.

[a]The isolation of Tacaribe from mosquitoes is considered doubtful, and due to a possible laboratory numbering error (Downs et al. 1963).

In regard to the Tacaribe group viruses, beginning with LCM, and continuing with other members of the group, a rodent association is usually found. Exceptions are Tacaribe, a virus isolated several times from bats in Trinidad in 1957 (and never reisolated there or elsewhere), and the two recently associated agents, Quaranfil and Johnston Atoll, found in birds and tick ectoparasites of birds (learned from personal communication with wife of H. Zeller in 1989).

A fascinating feature is the geographic–ecological–natural host range of the Arenaviridae. Each rodent species involved with an individual virus has its ecologically determined range, and thus delimits the territory of distribution of the virus. As can be seen in Table VIII.11.1, the exception to the limited-host-range rule is the house mouse, *M. musculus*. The genus *Mus* is an Asiatic and European genus. *Mus musculus* is well adapted to the human environment and now has worldwide distribution but is found particularly in the temperate regions of America, Europe, and Asia. It moves where humans move, and communication by sea has opened the world to it, although in the tropics it has remained more restricted to coastal or riverine settlements.

Praomys natalensis, the multimammate mouse, is also very common; commensal with humans, it is widely distributed in Africa, and is associated with Lassa virus and Mopeia virus. *Praomys jacksoni,* another member of the genus, which holds 14 species, is associated with Mobala virus in the Central African Republic. The literature is confusing because *Praomys* is often referred to as *Mastomys*. Currently, however, *Mastomys, Myomys,* and *Myomyscus* are all considered to be synonymous with *Praomys* (Honacki, Kinman, and Koeppl 1982). *Praomys* is placed in the rodent family Muridae.

The New World rodents associated with arenaviruses are all placed in the family Cricetidae, with several genera involved. It is likely that there have been many opportunities for virus dispersal as well as adaptation of viruses to new rodent hosts, when one considers (1) the number of viruses, such as LCM, Lassa, Junin, Machupo, and others; (2) the diversity of rodents; and (3) the rise (and later enormous development) of intracontinental and intercontinental traffic; and (4) the recently recognized pair of viruses Quaranfil and Johnston Atoll (provisionally placed in the Arenaviridae on the basis of electron microscopic studies), which are associated with birds that disperse widely. Thus it seems evident that the whole world is at risk for species radiation of Arenaviridae.

Immunology

The various arenaviruses have been shown to be related principally via complement fixation reactions to the glycoprotein gp44 in the viral envelopes. The nucleoproteins of the viruses demonstrate relationships through virus neutralization tests. The fatal infection induced in adult mice experimentally inoculated with LCM has been shown to be associated with a T cell-mediated immune response. Studies of the several viruses of the Tacaribe group have extended knowledge of this phenomenon. When newborn mice are infected intracerebrally with LCM, their immune response is deficient, and they go into a lifetime chronic carrier state. This same response can be induced in adult mice that have been immunosuppressed.

Clinical Manifestations, Diagnosis, Treatment, and Control

Lymphocytic Choriomeningitis (LCM)

LCM has been found in the Americas, Europe, and Asia, but not in Africa or Australia. Outbreaks are sporadic and often associated with experimental animal colonies. The disease in humans is usually benign, with symptoms resembling influenza. Inapparent cases (determined by serologic changes) are frequent during outbreaks. Meningitis (with 90 to 95 percent lymphocytes in the cerebrospinal fluid) may occur as a primary symptom of disease, or more usually as a relapse several days after apparent recovery from the acute illness. In some cases there may be meningoencephalitic signs and symptoms, with reflex changes, paralyses, cutaneous anesthesias, and somnolence. Fatal cases are rare. When infections occur in pregnancy, complications of encephalitis, hydrocephaly, and chorioretinitis in the fetus and the newborn may be seen. Treatment is limited to supportive care. Control is limited to control of mouse populations in houses and to vigilant supervision of laboratory colonies of mice and hamsters.

Argentine Hemorrhagic Fever (Junin)

The disease occurs in the heavily agricultural moist pampas provinces to the west of Buenos Aires. It is seen in the rural regions, mostly in farm workers, including migrant workers. Several hundred cases are seen annually, occurring mainly in the harvest season between April and July. Infection in humans results from contact with field rodents. The incubation period is from 10 to 14 days, with an insidious onset beginning with malaise, fever, chills, head and back pains, nausea, vomiting, and diarrhea or constipation.

In progressive cases, hemorrhagic manifestations begin about the fourth day of illness, and may proceed to death (in about 10 percent of confirmed cases). In some cases, neurological symptoms may predominate.

Laboratory findings include leukopenia, thrombocytopenia, albuminuria, and cylindruria. Serologic testing is an aid to diagnosis, but as is the case with many virus diseases, virus isolation and identification are recommended. Convalescence lasts several weeks after severe illness, and recovery is then usually complete. There are no proven specific antiviral agents; but there are recent reports of successful treatment with immune plasma. When it has been given before the eighth day of illness, marked reduction in mortality has been observed. Rodent control would appear to be an obvious prevention measure, but it is not practical, given the vast areas where the virus is endemic. Much attention has been given to development of a vaccine, and at present a live attenuated vaccine shows promise of becoming useful in preventing disease in human beings. Another vaccine possibility being explored utilizes the avirulent Tacaribe virus to induce immunity against Junin.

Bolivian Hemorrhagic Fever (Machupo)

This disease is localized to several provinces of the Department of Beni, in the Amazonian lowlands, and is endemic in the local rodent (*Calomys*) populations. Exposed human beings have an incubation period of about 2 weeks. Patients have a high fever for at least 5 days; myalgia, headache, conjunctivitis, cutaneous hyperesthesia, nausea, and vomiting are features of the illness. Hemorrhagic manifestations occur in some 30 percent of patients, and there may be serious bleeding. Hypotension in the second week of illness is seen in about 50 percent of patients, and in many patients it proceeds to hypovolemic shock and death. Symptoms indicative of central nervous system involvement, among the tremors of tongue and extremities, convulsions, and coma, appear in almost half the patients. The death rate in several epidemics has been about 25 percent. Convalescence is protracted. Laboratory findings include leukopenia, hemoconcentration, and proteinuria. Pathological findings include generalized adenopathy and focal hemorrhages in various organs. No specific therapy is known. Treatment is limited to supportive measures. Rodent control in homes and villages has proven to be an effective means of controlling epidemics, and also of preventing sporadic cases of disease.

VIII.12
Arthritis (Rheumatoid)

Rheumatoid arthritis, the major crippling illness among chronic rheumatic disorders, is a systemic disease that affects many joints with an inflammatory reaction lasting months or years. Frequently, the small joints of the hands and feet are affected first, although often the larger peripheral joints of the wrists, hips, knees, elbows, and shoulders are involved as well. Some remissions do occur, but the illness progresses to produce damage and deformity. There is no known etiology.

In 1961, the American Rheumatism Association developed a set of eight diagnostic criteria for rheumatoid arthritis suitable for epidemiological surveys. They are as follows:

1. Morning stiffness
2. Pain on motion or tenderness in at least one joint
3. Swelling (soft tissue) of at least one joint
4. Swelling of at least one other joint
5. Symmetrical joint swelling
6. Nodules under the skin, typically on the surface of muscles that extend or stretch the limbs
7. Observable changes identified by X-rays, typically erosions of bone
8. Positive serologic test for rheumatoid factor

In a given patient, a definite diagnosis of rheumatoid arthritis would depend on the presence of at least five of these criteria and the absence of evidence for other rheumatic conditions.

Distribution and Incidence

When using the above definition, a number of researchers have indicated that rheumatoid arthritis is worldwide, affecting all ethnic groups. A summary of prevalence data in rheumatoid arthritis has been provided by P. D. Utsinger, N. J. Zvaifler, and E. G. Ehrlich (1985). Fifteen studies were cited from countries such as the United States, United Kingdom, Finland, Puerto Rico, Canada, Japan, Bulgaria, and Jamaica. The authors have concluded that the prevalence of rheumatoid arthritis, as defined above, is consistently between 1 and 2 percent of the adult population in all parts of the world. In general, females suffer the illness about two and a half times more frequently than males; however, prevalence increases for both females and males over age 35, making it normally a disease of the

middle years. The number of new cases per 1,000 population per year ranges from 0.68 to 2.9. The prevalence of chronic arthritis in children among Caucasians is 5 percent that of adults. The mode of onset in children may vary more than that in adults, in that the simultaneous involvement of four or more joints – seen in 93 percent of the adult cases – occurs in only 30 percent of those children in whom diagnosis of rheumatoid arthritis is subsequently established.

Epidemiology and Etiology

Despite the years of intensive study of endocrine, metabolic, and nutritional factors as well as geographic, occupational, and psychological variables, the etiology of rheumatoid arthritis has not been elucidated. A genetic predisposition is suspected (because certain histocompatibility markers are found frequently); however, bacterial and viral infections are often associated with acute polyarthritis in humans, and thus an infection followed by an altered or sustained immunologic response could be instrumental for development of the disease. Certainly, immunologic abnormalities appear to play a role in both the aggravation and perpetuation of the inflammatory process. Cellular and humoral immunologic reactions occur at the local site (joints) and often systemically. The production of antiimmunoglobulins or rheumatoid factors occurs initially in the inflammatory tissue of the joint and can subsequently be detected in the serum of 80 percent of the patients treated for the condition. Those patients with rheumatoid arthritis who are seropositive for rheumatoid factor show a more marked progression of the disease than do those who are seronegative.

Clinical Manifestations and Diagnosis

The onset and course of rheumatoid arthritis are particularly variable. Usually, fatigue, weight loss, and generalized aching and stiffness, especially on awakening in the morning, precedes localization of symptoms and the development of joint swelling. These symptoms at times develop explosively in one or more joints, but more often there is progression to multiple joint involvement. The disease may remit spontaneously in the first year or diminish in intensity, only to recur in the same or additional joints at intervals. The more troublesome cases usually continue to affect many joints with sustained inflammatory reactions for months or years. In these latter cases, marked bone and joint damage often develop, with drift of the ulna (outer bone of the forearm) and consequent deviation of the fingers, leading to lim-ited function and instability. Signs of systemic involvement may also be seen, for example, nodules at the elbows, cutaneous degeneration at the fingertips (which appear as small, 1- to 2-millimeter infarcts in the nail fold) or at the elbow tip, pulmonary fibrosis, inflammation of the sac enclosing the heart, anemia, fever, rash and peripheral ulcers in the lower limbs, disease of the nervous system, and wrist weakness occasioned by the carpal tunnel syndrome. In addition, there is usually a gradual weight loss as well as the loss of muscle volume and power.

Treatment

Although there is no cure, the principles of treatment are, first, to minimize the swelling, pain, and damage; and second, to maintain joint function as closely to normal as possible. To this end, a number of medical and surgical modalities are available to manage patients over the course of their disease. Drug therapy is an important part of this management as it is directed toward controlling the destructive inflammatory processes within the joint.

The antiinflammatory agents commonly used for this control include aspirin and similar compounds referred to as nonsteroidal antiinflammatory agents. Whereas some symptoms and signs of the disease can be improved by these drugs, additional agents may be required for those patients who have continuing progressive damage. This treatment might include gold salts and antimalarial, antitumor, and immunosuppressive agents. Corticosteroid derivatives are recognized to be potent antiinflammatory agents with some immunomodulating effect. Although they may dramatically improve the most troublesome symptoms, they have not been proven to alter significantly the progression of the disease. Moreover, the side effects of these drugs may be hazardous over the many years needed to treat chronic conditions such as rheumatoid arthritis.

History and Geography

The clinical term "rheumatoid arthritis" was first introduced in the medical literature by A. B. Garrod in 1859. It was not in common usage until "officially recognized" in the United Kingdom by the Department of Health in 1922 and by the American Rheumatism Association in 1941. Until recent times many names were used to describe what we currently recognize as rheumatoid arthritis: rheumatic gout, chronic rheumatic arthritis, goutte asthenique primative, rheumatismus nodosus, and rheumatoid osteoarthritis. Broader terms such as gout, arthritis, and rheu-

matism would also have encompassed rheumatoid arthritis as well as numerous other conditions.

Evidence for the existence of rheumatoid arthritis in earlier times, however, must be gleaned from literature, from art, and from paleopathological studies of ancient bones, and to date that evidence has been far from overwhelming. Indeed the lack of early descriptions of this disease led authors such as E. Snorrason (1952) to suggest that the disease is recent in origin (i.e., since the seventeenth century) and is evolving to develop a peak incidence during the twentieth century before ultimately disappearing (Buchanan and Murdoch 1979).

By contrast, other arthritic disorders such as ankylosing spondylitis, osteoarthritis, and spinal hyperostosis have been recognized in skeletons thousands of years old and appear to be unchanged from the present condition. In fact, given the lack of evidence of the existence of rheumatoid arthritis until relatively recent times, L. Klepinger (1979) and others have suggested that rheumatoid arthritis has evolved from ankylosing spondylitis. Suffice it to say that the uncertainty about the antiquity of rheumatoid arthritis is at least partly due to the methods by which we have examined the evidence of a disease whose current definition includes a combination of clinical, radiological, and serologic criteria. Nonetheless, a search for evidence of rheumatoid arthritis in the literature, art, and bones of the past is an intriguing one.

Literature

In 1800, A. J. Landré-Beauvais wrote an account of a disease that is today universally accepted as representing rheumatoid arthritis. Earlier European descriptions of rheumatoid arthritis, which C. L. Short (1974) and the present authors find convincing, were written by Thomas Sydenham in 1676, W. Heberden in 1770, and B. Brodie in 1818. These observers each described long-term, chronic, debilitating diseases affecting multiple joints, which included descriptions of typical hyperextension deformity of the interphalangeal joints of the fingers. Before these dates, there are several descriptions of disease that *could* represent certain phases of rheumatoid arthritis, ranging from the acute explosive attack to one of chronic sustained disability. This is particularly so in the case of the Emperor Constantine IX (ca. 980–1055) who, at the age of 63, suffered from polyarthritis in the feet, and subsequently the hands, shoulders, and knees, leading to a nodularity and residual deformity in the fingers, and flexion and swelling of the knees. However, the

absence of currently applied diagnostic criteria based on skeletal X-rays and serologic information does not absolutely exclude a diagnosis of polyarticular gout or some other erosive joint disease in an otherwise very suggestive report.

In the thirteenth century, a less complete description was written in Britain by Bartolemeus Anglicus who, after describing several types of arthritis, stated that "one form of the disease is worse for it draws together tissues and makes the fingers shrink and shrivels the toes and sinews of the feet and of the hands."

Perhaps the earliest known description suggestive of rheumatoid arthritis is in the Eastern literature (India) and discussed in the *Caraka Samhita,* written about A.D. 123. In this work, the disease in question was said to manifest itself as swollen, painful joints initially in the hands and feet and then affecting the whole body. The ailment was reported to be protracted, difficult to cure, and associated with anorexia. Although ultimate proof is lacking, these descriptions may represent the earliest written record of rheumatoid arthritis.

Art

Although there is no unequivocal illustration of symmetrical polyarthritis, attention has been drawn to some presentations of deformities of the hands in the Flemish painters (1400–1700) who otherwise painted the ideal, unaffected limb with considerable accuracy (Klepinger 1979). Some works of Peter Paul Rubens show changes typical of rheumatoid arthritis, suggesting to T. Appelbloom and colleagues (1981) that Rubens, who himself suffered from rheumatoid arthritis, painted the progressive phases of his own disease in the hands of his subjects during the years 1609–38.

Paleopathology

Of the thousands of mummies and whole skeletons from the distant past that have been observed, there are surprisingly few specimens that show features compatible with rheumatoid arthritis. The reader will recall that the definition of the disease requires a symmetrical pattern commonly affecting the small joints. This poses a problem when the determination of symmetry is not possible because one or more long bones are absent or because the small bones of the hands and feet are frequently lost.

Although rheumatoid arthritis, at the present time, is a major cause of symmetrical erosive polyarthritis, other causes do exist, and thus it seems appropriate to employ the term "erosive joint

disease," which may or may not have been rheumatoid arthritis when describing the arthritis seen in ancient bones.

The description by W. P. May (1897) of an Egyptian mummy 5,500 years old indicates a case of possible rheumatoid arthritis: a male, 50 or 60 years of age with hands, wrists, elbows, and knees, and feet affected. Particular note was made of the fingers – "small joints of the hands are swollen and fusiform" – while the metatarsophalangeal joints were markedly involved with some peripheral fusion. The author emphasized the unequal symmetry, and no erosions were described. Studies by J. Rogers and colleagues (1981) and A. K. Thould and B. T. Thould (1983) in the United Kingdom have identified only two or three cases of erosive arthritis compatible with rheumatoid arthritis in some 816 skeletons dating from the Saxon to Roman and British medieval times.

A detailed analysis of a well-preserved 34-year-old female Eskimo mummy from the Kodiak Islands is described by D. Ortner and C. S. Utermohle (1981); in this instance evidence of erosive inflammatory polyarthritis compatible with juvenile rheumatoid arthritis is clearly presented. More recently, reports of erosive polyarthritis occurring in ancient bones ranging from 5,000 years to 1,000 years old in North America have been identified by B. M. Rothschild's group (1987). In fact, Rothschild and colleagues have speculated that rheumatoid arthritis could have had a viral origin in North America and then migrated to Europe in the post-Columbian period, where it manifested itself as a more severe disease in subsequent centuries. This, they argue, might account for the apparent relative infrequency of the disease in Europe prior to the seventeenth century.

Today the disease is identified in most ethnic groups and in all parts of the world. Thus only detailed studies and precise reports on skeletal remains can establish whether erosive arthritis, which may have been rheumatoid arthritis, was more prevalent in the past than it is presently. These findings could impact considerably upon our understanding of the pathogenesis of the disease and perhaps also suggest whether it is likely to disappear as some have argued.

VIII.13
Ascariasis

The giant intestinal roundworm, *Ascaris lumbricoides,* is a very common parasite with a worldwide distribution. The adult worms are 15 to 35 cm (6 to 14 inches) long and reside in the lumen of the small intestine. Sometimes, however, they are passed in the feces and, if vomited into the oral cavity, may exit from the host's mouth or nostrils; thus they have been known to medical observers for millennia. Female worms produce up to 200,000 fertilized eggs daily, which are passed in the feces. Eggs incubate in the soil for at least 2 to 3 weeks to produce an infective larval stage within them. The eggs are very resistant to chemicals, desiccation, and extreme temperatures, but they mature or "embryonate" most rapidly in warm, moist, shady conditions in clay soils. People become infected by eating embryonated eggs in food or water contaminated with feces; or, in the case of toddlers, infection occurs by direct ingestion of eggs with dirt. Poor rural sanitation and the use of human feces for fertilizer obviously favor transmission. Mature eggs hatch in the small intestine, and the larvae then undergo a remarkable series of migrations in the host. They penetrate the intestinal wall and are carried in blood or lymph vessels to the liver and heart, and then the lungs. Here they break out into the air sacs, develop, and molt for about 3 weeks, and then climb up the trachea to the throat, where they are subsequently swallowed to establish themselves as adults in the small intestine.

Distribution and Incidence

This nematode was known to ancient writers in China, India, Mesopotamia, and Europe, and was present in pre-Columbian America. The World Health Organization estimated in the early 1980s that between 800 and 1,300 million people harbored an average of six worms each. The true figure may be even higher. Surveys have demonstrated infection in more than 50 percent of sampled populations in such countries as Bangladesh, Brazil, China, Colombia, India, Iran, Kenya, Mexico, Tanzania, and Vietnam, and the rate approaches 100 percent in many rural areas. In China, it was estimated that the 1947 *Ascaris* population produced 18,000 tons of eggs a year; they may be even more productive today. The worm is also common in developed countries, although improved sanitation has greatly reduced prevalence in recent decades. During the 1960s, surveys conducted in school children and other groups showed infection rates of 2.5 to 75 percent in Italy, 21 percent in Spain, 40 to 80 percent in Portugal, 18 percent in Romania, 2 to 5 percent in urban Japan, and up to 20 percent in the Japanese countryside. Foci still exist in some rural areas in the southern United States.

Clinical Manifestations, Diagnosis, Treatment, and Control

Symptoms of ascariasis vary widely. As is often true for helminthic infections, low worm loads may cause few or no symptoms. Large numbers of larvae in the lungs may produce ascaris pneumonitis, with symptoms resembling pneumonia. Allergic reactions can cause asthma attacks. Larvae can reach atypical (ectopic) sites such as the brain, eye, or kidney, where they may produce grave, life-threatening conditions, but such events are fortunately rare. Adult worms in the intestine can cause fever, abdominal discomfort, diarrhea, and allergic reactions to their proteins. Fever may induce worms to wander to the larynx, where they can cause suffocation, or to exit the mouth or nostrils. Heavy infections rob the host of nutrients, and tangled masses of worms can result in fatal intestinal obstruction if not treated promptly. Intestinal ascariasis is especially serious in young children. A study in Kenya showed that ascariasis produced signs of protein–energy malnutrition in many children and often retarded their growth; similar results have been reported from other Third World countries. Even if severe effects occur in only a small percentage of cases, the ubiquity of the worm makes it an important cause of morbidity in many countries.

Diagnosis is made by detecting eggs in microscopic examination of the feces. Drug treatment is usually safe and effective, but care must be taken to keep the adult worms from wandering about in response to therapy. Intestinal obstruction is treated by inducing vomiting or by surgery. Preventive measures include sanitary latrines, composting feces to be used as fertilizer, and careful washing of fruits and vegetables that are eaten raw. Mass treatment may also reduce the danger of continued reinfection.

VIII.14
Bacillary Dysentery

Bacteria from several genera, including *Campylobacter, Salmonelle,* and *Yersinia,* as well as some strains of the common intestinal bacillus *Escherichia coli,* can invade the mucosa of the large intestine and cause dysentery, but members of the genus *Shigella* are by far the most important agents. Shigellosis is a common disease that occurs worldwide and afflicts persons of all races and age groups. In addition, *Campylobacter* appears to be an emerging pathogen, at least in the United States. It lives in the small intestine and produces a dysentery-like condition that is usually self-limiting.

Etiology and Epidemiology

Four species or subgroups of *Shigella* cause human disease. *Shigella dysenteriae* (subgroup A), the first to be discovered, is the most virulent. *Shigella flexneri* (B), *Shigella boydii* (C), and *Shigella sonnei* are less dangerous. More than 40 serotypes are recognized and are useful in tracing the spread of outbreaks.

Shigella organisms are passed in the feces and spread from person to person by the fecal–oral route. Bacteria are excreted during the illness and for about 4 weeks after recovery, but some asymptomatic individuals may act as carriers for a year or more. Contaminated food and water are the most common modes of transmission. Direct fecal contamination or mechanical carriage by flies can introduce bacteria into food, milk, or water. Sick, convalescent, or even healthy food handlers who have poor hy-

gienic practices are especially dangerous; proper handwashing after defecation is a simple but effective preventive measure. Crowding and poor sanitation favor transmission, and outbreaks are common in jails and institutions for the retarded and mentally ill.

Epizootics have been reported in colonies of captive primates, and two species have been isolated from dogs, but animal reservoirs have no known epidemiological significance.

Distribution and Incidence

Shigellosis occurs worldwide, but is especially common in countries with poor water and sewage systems. The virulent *S. dysenteriae* is mostly confined to the tropics and East Asia; a much less pathogenic form, *S. sonnei,* is the most abundant species in the United States. All age groups are vulnerable, but severe disease is most common in children and among the elderly. There appears to be no racial or ethnic immunity, although populations can acquire considerable resistance to locally prevalent strains. Travelers may become ill when they encounter unfamiliar strains. Accurate incidence rates are impossible to obtain, but shigellosis is a serious health problem in most underdeveloped countries and a major cause of infant and child mortality. The disease is commonly endemic in poor countries, but great epidemics can also take place. During World War II, acute dysentery, apparently introduced by Japanese and/or Allied troops, attacked many indigenous groups in western New Guinea, causing thousands of deaths despite the efforts of Australian authorities. In 1969 an epidemic of *S. dysenteriae* caused 110,000 cases and 8,000 deaths in Guatemala.

Shigellosis is also a constant threat in developed countries, especially when sanitary standards are weakened. For example, two important *S. sonnei* outbreaks occurred in the United States in 1987. One took place among Orthodox Jews in New York, New Jersey, Ohio, and Maryland, with the majority of cases occurring among small children in religious schools. Patterns of spread were consistent with person-to-person transmission among religious communities in the four states. The first outbreak was in New York City, where 132 cases were reported and at least 13,000 were suspected. Smaller epidemics in upstate New York and other states appeared to be linked with Passover visits to relatives in the city. The second epidemic began with the annual meeting of a counter-culture group, the Rainbow Family, in a national forest in North Carolina in early July. Poor hygiene and inadequate latrines

allowed infection to spread among the campers, who caused at least four clusters of cases in Missouri and Pennsylvania when they dispersed. Shigellosis rates in the United States ranged from about 5 to 11 per 100,000 from 1955 to 1986; the disease is almost certainly seriously underreported.

Diagnosis, Clincial Manifestations, and Pathology

Diagnosis is by clinical signs, cultivation of *Shigella* or other bacteria from tissue swabs and feces, and serologic tests to determine species and strains. Differential diagnosis must exclude other agents of dysentery, including other bacteria, viruses, and amebas.

Bacteria invade the mucosa of the large intestine, where they cause mucus secretion, edema, and, usually, superficial ulceration and bleeding. The watery diarrhea is probably caused by a toxin that increases the secretions of the cells of the intestinal wall.

The incubation period is from 1 to 4 days. Onset is sudden in children, with fever, drowsiness or irritability, anorexia, nausea, abdominal pain, tenesmus, and diarrhea. Blood, pus, and mucus appear in the diarrheal stools within 3 days. Increasingly frequent watery stools cause dehydration, and death can occur as early as 12 days. If the patient survives, recovery usually begins after about 2 weeks. In adults, there is usually no fever, and the disease generally resolves itself after 1 to 6 weeks. Symptoms in both children and adults may vary from simple, transient diarrhea to acute dysentery and death.

It is not always possible to differentiate amebic and bacillary dysentery on clinical grounds, but shigellosis generally has a more sudden onset and more acute course, is more likely to occur in explosive epidemics, and is not a chronic disease. Tenesmus is a much more common symptom in shigellosis, and the stools are generally less abundant and contain more bright red blood than in typical cases of amebic dysentery.

Control and Treatment

Sanitary measures are crucial for the prevention of bacillary dysentery and other diseases that are spread by fecal–oral route. Proper waste disposal, postdefecation handwashing, and safe water supplies are essential. Chlorination of water kills *Shigella* and other bacterial agents of dysentery. Sanitary food preparation, control of flies, and pasteurization of milk are also important. In areas with inadequate sanitation, avoidance of raw foods and use of bottled water can help to protect the traveler.

Patients may require rehydration and replacement of lost electrolytes, as well as symptomatic care for cramps and discomfort. Bed rest is important. After a day or two of fasting, soft, easily digestible food should be given in small, frequent meals. In most cases, such supportive therapy is sufficient. A variety of antibiotics can be effective against various *Shigella* species, but drug resistance is a growing problem. Many strains of *S. sonnei* in the United States have developed resistance to ampicillin and tetracycline; thus, in cases where drug therapy is essential, newer agents must be employed.

History

Medical writers have described dysentery or "the flux" since ancient times, but the bacterial form of the disease was not clearly distinguished until late in the nineteenth century. Dysentery ravaged Persian armies invading Greece in 480 B.C., and the disease has always been a companion of armies, often proving much more destructive than enemy action. This disease was, and remains, common among both rural and urban poor people around the world. An epidemic of what must have been shigellosis swept France in 1779, causing especially severe damage in some rural areas of the western part of the country. Troop movements for a planned invasion of England helped spread the disease. At least 175,000 people died, with some 45,000 deaths in Brittany alone. Children constituted the majority of the fatalities. During the U.S. Civil War, Union soldiers had annual morbidity rates of 876 per 1,000 from dysentery, and annual mortality rates of 10 per 1,000. Dysentery outbreaks were problems for all belligerents in World War I, especially in the Gallipoli and Mesopotamian campaigns.

Bacterial dysenteries took a heavy toll among infants and young children in Western countries until very recent times. During the late nineteenth and early twentieth centuries, the decline in breast feeding and the growing use of cows' milk in European and American cities exposed infants and toddlers to a variety of bacterial and other agents of dysentery and diarrhea. As milk is an excellent growth medium for *Shigella* and many other pathogens, contaminated milk and lack of refrigeration led to especially high death rates in hot weather. Milk-borne shigellosis was a significant contributor to the "summer complaint," which took thousands of young lives annually in cities like Paris and New York. Infant health movements, public health education, and pas-

teurization of milk largely eliminated the problem in western Europe and North America by about 1920. Shigellosis, however, still contributes to the "weanling diarrhea," which afflicts tens of millions of Third World children every year.

The Japanese bacteriologist Kiyoshi Shiga isolated *S. dysenteriae* in 1898, and confirmed its role as a pathogen by showing that the organism reacted with sera of convalescing patients. The other species were discovered early in the twentieth century, and much research has been directed to immunologic studies of various strains. The role of *Campylobacter* species as common human pathogens has been recognized only since the 1970s.

VIII.15
Beriberi

Beriberi is a disease caused by a deficiency of thiamine, or vitamin B_1, that is expressed in three major clusters of symptoms, which vary from person to person. It involves edema, or swelling, of the legs, arms, and face. The nerves may be affected, causing, first, a loss of sensation in the peripheral nerves and, later, paralysis. The cardiovascular system may be involved, evidenced by enlargement of the heart and extremely low diastolic blood pressure. Beriberi may be chronic and so low-grade that it cannot be detected by clinical examination; in its chronic form, it may alternatively result in disability for months or years; or it may be acute and result in death in a few weeks. Until major tissue damage occurs, it is curable and reversible by consumption of thiamine.

The name "beriberi" derives from a Sinhalese word, meaning weakness. As *kakke,* it has been known in Japan since antiquity and is described in the earliest Chinese medical treatises. The several forms of beriberi have often been considered as separate diseases. In "wet" beriberi, swelling and heart complications occurred, although often with loss of the sense of touch, pain, or temperature. In "dry" beriberi, there was little swelling, but instead a progressive loss of those senses and then of motor control followed by atrophy of the muscles of the paralyzed limbs and a general wasting syndrome. Today it is thought that dry beriberi was partly due to a deficiency of vitamin B_2. *Shoshin* beriberi was a term used to denote a fulminating, or acute form with severe heart complications. "Infantile" beriberi was the last form to be recognized; in addition to swelling, heart enlargement, and other cardiovascular complications, indicative of beriberi, suckling infants also had such symptoms as loss of voice and gastrointestinal disturbances, neither of which occurred in adults.

The discovery that beriberi was caused by a nutritional deficiency led to the identification and study of vitamins. The isolation and later synthesis of thiamine led to the enrichment of key foods as a public health intervention. Beriberi was not only a cause of enormous human suffering and death, but also one of the most important diseases in the development of medical science.

Etiology and Epidemiology

Thiamine is vital to every living thing, both plant and animal. It is an essential component of dozens of

enzymes that metabolize food. In particular, thiamine is necessary to derive energy from glucose, the preferred food of nerve cells, and from other carbohydrates. It is more indirectly involved in the metabolism of the amino acids isoleucine, leucine, and valine.

An enzyme is a catalyst for chemical reactions. It consists of a protein and a coenzyme that attaches to the target substance, activates the chemical change, and then detaches to be ready again for the target substance. In its most important role, thiamine, as thiamine pyrophosphate, is the coenzyme of carboxylase. Among other things, it causes carboxyl (COOH) groups to be oxidized into carbon dioxide and water, releasing energy to body cells. Because it functions as part of a reusable enzyme catalysis system and is not an integral part of tissue structure itself, thiamine is needed in only small amounts of 1 to 3 micrograms a day.

Thiamine is a water-soluble vitamin that is found widely in foods. It is most concentrated in whole grains, yeast, and legumes; in liver, heart, and kidneys of most mammals; and in oysters. It is available also in most green vegetables and pork. An antagonistic enzyme produced by bacteria – *thiaminase* – is found in a few diverse foods such as raw fish and tea. The symptoms of beriberi are caused by a deficiency of thiamine, which may be slight or severe, temporary or long term. The deficiency usually results from the shortage of thiamine in a restricted and monotonous diet, but it can sometimes be exacerbated by the consumption of large amounts of foods high in thiaminase.

The epidemiology of beriberi follows from the role of thiamine in energy metabolism and its deficiency in restricted diets. The population at highest risk for beriberi have been (1) people engaged in heavy labor, such as farmers plowing their fields and soldiers and construction workers; (2) pregnant women; and subsequently, (3) their nursing infants. The populations in which beriberi has been most prevalent have been of two kinds: people confined to institutions, such as prisons, asylums, and naval ships, who are limited to monotonous and restricted diets such as bread and water or fish and rice; and people who derive a large portion of their calories from rice from which milling has removed most of the bran in which the thiamine is found.

Rice Cultures

Beriberi is in large part a disease of rice culture. When rice is the staple food, it is eaten in very large quantities and commonly provides 80 percent or more of the caloric energy. When the hull is removed with a mortar and pestle at home, enough bran remains on the rice to provide the necessary thiamine. When the rice is milled efficiently in modern plants, however, it is polished into white rice and thiamine is almost entirely eliminated.

Cooking methods are also important in the etiology of the disease. In northern China, Korea, and Japan, the rice hulls were traditionally removed before shipment in order to reduce bulk. When the rice reached the cities, it was so crawling with weevils that the subsequently highly-milled rice was covered in weevil juices and thus often treated with talc. Cooking procedures called for the rice to be thoroughly washed several times. The first washing alone removed half of the thiamine. In Burma and other parts of Southeast Asia, the custom has been to cook rice with excess water and throw away the water that is not absorbed, which contains most of the thiamine. Other peoples either cook the rice so as to absorb all the water, or use the extra water for drinking purposes or for other cooking. In the lower Ganges Valley in India, in Bihar and Bengal, the custom has been to parboil rice. Steaming the rice for partial cooking before drying it and then milling it for distribution preserves most of the thiamine in white rice, and is protective against beriberi. However, the labor or costs required in the process and the different taste and texture produced have not been widely acceptable among other peoples in Asia.

Numerous cultural beliefs and practices are involved in the regional etiology of beriberi. In northeastern Thailand and Laos, for example, people usually steam their glutinous variety of rice – a protective behavior. But, unlike other people in Thailand, they have very limited supplies of fresh fruit or vegetables or of meat for consumption. They eat fish, most of which is in the form of a fermented raw paste and is high in thiaminase, the destroyer of thiamine. Throughout the region, rice is so central to the cultures that it is synonymous with food itself. One result is that invalids, weanlings, and other susceptible people may eat nothing except rice. As milling spreads throughout the region, beriberi has resulted.

Other At-Risk Groups

There is now indication that in eighteenth- and nineteenth-century Brazil, the disease was endemic among slaves and members of the working classes. The deficiency was usually the result of diets consisting mainly of manioc flour and a little dried meat. This flour actually contains less thiamine than does

milled rice, and the preparation of the lean dried meat not only eliminated most of its natural thiamine but also increased the body's need for the vitamin (Kiple 1989).

A new population at risk has recently been recognized. In urbanized and industrial countries, beriberi occurs most frequently among alcoholics. At the same time that chronic alcohol consumption impairs the absorption of thiamine by the intestine and its storage and utilization in the liver, it increases the metabolic rate and requires relatively enormous amounts of thiamine for metabolism of the alcohol. When the alcoholic substitutes alcohol for other foods in his or her diet and curtails consumption of thiamine, Wernicke's encephalopathy and other neuropsychiatric disorders may occur, involving loss of motor coordination, loss of feeling in the hands and feet, and inability to remember or learn.

There are a few other specific groups of individuals at risk of beriberi. These include people suffering from renal failure and under long-term dialysis, and people under long-term intravenous feeding.

Because beriberi is a deficiency disease, it is entirely preventable by the consumption of adequate amounts of thiamine. In the United States, enrichment of white bread – replacing the thiamine that had been removed in the milling and bleaching of wheat – caused clinical disease virtually to disappear except among alcoholics. More recently, rice enrichment has also proved beneficial.

Distribution and Incidence

Within recent centuries, beriberi has occurred among institutionalized populations and military forces all over the world. Although the disease has afflicted poor Americans subsisting mainly on white bread and poor Europeans consuming a monotonous diet of potatoes without meat or vegetables, beriberi is and has been most prevalent among the large Asian populations who consume white rice. In the first decade of the twentieth century, mortality from beriberi in Japan averaged 20 per 100,000, and in 1920 reached 70 per 100,000 among the urban population (Shimazono and Katsura 1965). In that same first decade, an estimated 120 per 1,000 people in the Straits Settlements (what is now Malaysia and Singapore) had beriberi, and in the Philippines, 120 per 1,000 of Filipino military scouts were admitted to a hospital for the disease (Williams 1961). Jacques May (1977) reported that in recent times beriberi still occurred in southern China, Vietnam, the Philippines, Indonesia, parts of Burma, southern India, Sri Lanka, Madagasgar, central Africa, local areas

in west Africa, and Venezuela, northwestern Argentina, and Brazil.

The true contemporary incidence of beriberi cannot be determined. Since it is so easily treated upon detection by the administration of thiamine, it has almost ceased to be fatal. As a nutritional deficiency, it is rarely reportable at any governmental statistical level. At the subclinical level, however, it probably still occurs widely. In a study in Australia, one in five healthy blood donors and one in three alcoholics at a hospital were found by biochemical assay to be deficient in thiamine (Wood and Breen 1980).

There was an epidemic of beriberi in the decades following World War II. Before the war, hand milling of rice was universal except for the largest cities. With independence and economic development, power milling spread along the railroads and, via new highways, to the rural hinterland and eventually even to the remote hill country. In the late 1950s, beriberi was thought to be responsible for a quarter or more of the infant mortality in parts of Burma and the Philippines (Postumus 1958) and to be the tenth highest cause of overall mortality in Thailand (May 1961). Enrichment of rice at the mills has greatly reduced clinical beriberi, but even in southern China it still occurs (Chen, Ge, and Liu 1984).

Clinical Manifestations and Pathology

The beriberi clinical triad consists of edema and neurological and cardiovascular manifestations. The complex of symptoms resulting from thiamine deficiency, however, has often been confused by the common occurrence of other vitamin deficiencies at the same time. Thus, some of the symptoms that distinguished "dry" beriberi were indicative of riboflavin deficiency. A diet deficient in thiamine would usually be deficient in other B vitamins as well. Some of the differences in the manifestation of thiamine deficiency disease among laboring adults, suckling infants, and alcoholics are due to such complications.

A person with beriberi classically entered the medical system when he or she developed symptoms of the weakness that gave the disease its name. There was malaise, a heaviness in the lower limbs, loss of strength in the knee joint and wrist, and usually some loss of sensation. There was tightness in the chest, palpitations, restlessness, loss of appetite, and often a full feeling in the epigastrium. Infants also vomited, had diarrhea, and had difficulty breathing.

Edema is one of the important signs and is always present in the early stages. Edema, or dropsy, com-

monly progresses until the lower extremities and the face are swollen. Pain and sensitivity in the calf muscles is an early sign as muscles begin to swell, degenerate, and atrophy. Swelling of the lining of the intestines can also congest them. Edema of the lungs often causes sudden respiratory distress and, with heart failure, death.

Heart palpitations, even at rest, and a diastolic blood pressure below 60 millimeters of mercury are usually diagnostic. There is enlargement of the heart, particularly the right ventricle. A heart murmur may be heard. An EKG may be normal in a mild case but shows abnormal waves of sinus origin in advanced ones.

First the autonomic, then the sensory, and finally the motor nerves are affected. On autopsy, there is proliferation of Schwann's cells in the sciatic nerves. In chronic beriberi, there is progressive degeneration of nerve fibers. There is loss of coordination, sometimes even of the eyes. Sensibility to tactile stimulation, then to pain, and finally to temperature is lost. The motor nerves are next affected, with paralysis beginning in the lower extremities. Then the fingers are affected, the hand drops limp at the wrist, and the fingers contract into a claw hand. Eventually, even the intercostal muscles, diaphragm, and speech control muscles are affected.

Other symptoms that commonly occur include a full sensation or cramping of the epigastrium, heartburn, constipation, and mental confusion. B. Wood and K. J. Breen (1980) define clinical thiamine deficiency to consist of beriberi heart failure and Wernicke's encephalopathy. The latter is a dysfunction of the brain that is characterized by confusion and by a loss of coordination and independent movement of the eyes that is commonly found in alcoholics. Thiamine reverses most of the symptoms, but many patients are left permanently with an inability to form new memories (Korsakoff's psychosis).

In classic beriberi, death results eventually from severe disturbances of the circulatory system and paralysis of the respiratory muscles ending in heart failure.

History and Geography

Most historical studies of beriberi have been concerned not with its occurrence or impact, but with the developments in medical science that led to an understanding of its etiology, treatment, and prevention. The geography of the disease has been closely bound to the rice-eating peoples of Asia, although the disease has never been limited to them.

In the nineteenth century, beriberi was common among troops and institutionalized people around the globe. What appeared to be epidemics occurred on British ships in the Bay of Bengal, Dutch ships in the East Indies, Norwegian whalers, ships plying the China trade in the Sea of Japan, and ships bringing "coolies" home to India from labor in the French Antilles (Hirsch 1885). The broader epidemiology was very puzzling.

The Search for the Etiology

August Hirsch (1885) noted many contradictions as he described the changing pattern of beriberi in the latter half of the nineteenth century. In a few places, notably Japan and the Malay archipelago and the state of Minas Gerais in Brazil, the disease was endemic. The disease had first appeared in Bahia in Brazil in 1866, and then had spread to São Paulo and Rio Grande do Sul by 1874, along the Brazilian seacoast, and into the interior provinces and on into Paraguay. Similarly, the disease had been known on the coast of Japan, but had now spread into interior towns. Earlier opinion had held that a distance of 40 to 60 miles from a seacoast or great river was enough to give immunity, but the disease now occurred hundreds of miles into the interior of Burma and India as well as Brazil. Its appearance in new places showed that it was not caused by climate, which had not changed, and yet it was associated with the rainy season and hot, humid weather. It seemed associated with a period of acclimatization, since people from the interior who moved to the coast as well as new troops usually did not develop the disease for 8 months to a year. It afflicted people in the prime of life, and wealth and high position did not grant immunity. People who led sedentary lives, such as scholars and teachers, were prone to the disease but so were soldiers and laborers. Tainted water was contraindicated. Clearly people who lived in crowded and poorly ventilated quarters were at risk. The evidence for a dietary cause was confusing. There seemed to be an association with insufficient diet, especially lack of fat and albumin, and with preponderance of rice and dried fish in the diet. Rice, however, was eaten widely in places where beriberi did not occur, and cases had been observed in Borneo where troops eating beef and eggs contracted the disease whereas laborers on a diet of rice and fish did not. Hirsch concluded from the global evidence that the cause of beriberi was *sui generis,* a peculiar and specific poison and not the climate, weather, soil, manner of living, or diet. It is instructive to contemplate the complexity of the disease, which was not clarified until the concept of a nutri-

tional *deficiency,* lack of a vitamin, (or mineral) was developed and replaced the idea of a positive poison, in the twentieth century. Then three factors could explain Hirsch's observations quite simply: the monotonous, restrictive diets of certain populations such as prisoners, troops, and coolies; the metabolic needs of heavy labor; and, notably, the spread of steam-driven milling to supply the urban grain needs. The power mills, first established along coasts and at great ports, then spread along transportation routes through the urban system. They intensified and spread an ancient problem in East Asian populations, and introduced it to plantation societies and booming cities in Latin America and Africa. Power milling practices continued to widen and to cause beriberi in Asia especially until into the 1970s.

Ship beriberi was serious among the fishing fleets of New England, Norway, Great Britain, and Canada. There were epidemics in the asylums of Arkansas, and among convicts in South Carolina. It was reported along the entire coast of South America from Venezuela to Argentina, but was especially serious in Panama City and among the Brazilian navy. In Africa, where there was little rice consumption, it affected troops in Senegal, Sierra Leone, Gabon, the Congo, and Angola. Seven epidemics along the Ivory Coast killed 80 percent of 1,100 known afflicted. It afflicted especially those who ate diets based on bananas, corn, and yams.

Robert R. Williams (1961) has best described the importance of the disease as he first encountered it in the Philippines in 1910 (25 years after Hirsch's description) by summarizing some of the numerous papers and presentations of Edward B. Vedder. In Asia, beriberi was one of the leading causes of death. In what is now Malaysia, British doctors estimated that in 20 years they had treated 150,000 hospitalized cases, of whom 30,000 had died out of a total population of 1,250,000. In the hospitals of Kuala Lumpur between 1895 and 1910, 8,422 admissions out of 33,735 were for beriberi; 20 percent died (Williams 1961). In Japan, where white rice was popular, mortality increased from 20 per 100,000 to over 30 per 100,000 in the early 1920s (Shimazono and Katsura 1965). General morbidity among the Japanese population is not known, but in the Russo-Japanese War of 1904–5 more than 20,000 cases among the troops made beriberi "the only ravaging epidemic."

There were early suspicions that diet was responsible. K. Takaki observed as a student in Europe the low incidence of beriberi among European navies. In 1885, as surgeon general of the Japanese navy, he altered the diet on the ship where sailors had previously been much afflicted with beriberi, and in so doing provided convincing evidence of beriberi's nutritional etiology. He subsequently ordered the protein ration increased for all naval personnel, and barley was added to their diet.

By the late nineteenth century, the Dutch in Indonesia had also become convinced that diet was somehow to blame for beriberi. Experiments were carried out among the penitentiaries of Java in which locally hand-milled rice was substituted for white rice, and beriberi almost disappeared among the prisoners. In 1890, Christian Eijkman, a Dutch officer in Java, discovered that a paralytic disease with nerve damage characteristic of beriberi could be induced in chickens fed polished rice. He and his successor, Gerrit Grijns, demonstrated in 1900 that this condition could be prevented or cured by feeding rice bran. Later Grijns extracted the water-soluble factor from the bran and used it to treat people.

These Dutch efforts were the first experimental characterization of nutritional deficiencies, and they developed an animal model that was essential for later nutritional work. Their immediate impact was limited, however, because American and Japanese physicians did not read Dutch. The belief continued across much of the globe that beriberi must be due to some toxin or microbe, although none could be found, or to food spoilage. After the work of Louis Pasteur, the assumption was that every disease must have a positive etiology, an active cause.

Isolation of the Active Factor

In 1910 in the Philippines, Vedder, a U.S. Army captain, began treating beriberi cases with an extract from rice bran, and enrolled the efforts of Williams, a new scientist at the Bureau of Science in Manila, to isolate the active factor. A Filipino doctor, Jose Albert, was then able to identify infantile beriberi: Recognizing that in Europe, breast feeding was protective compared to artificial feeding of babies, but that in the Philippines two-thirds of the mortality occurred in breast-fed infants, he made the connection linking the mothers' eating habits to the disease.

In 1911, Casimir Funk at the Lister Institute in London isolated a crystalline substance, which he erroneously thought was the active antiberiberi factor and called it a "vitamine" after its amine function. In 1926, two Dutch chemists in Java, B.C.P. Jansen and W. F. Donath, succeeded in isolating and crystallizing the active substance from rice bran.

They mischaracterized it, however, by missing its sulfur atom, and other scientists were unable to repeat the isolation.

Williams, now a chemist at Bell Laboratories working on marine cables, continued on his own time and money at home to isolate the active factor and succeeded in 1933. He and those working with him characterized it chemically, and finally, in 1936, completely synthesized it and proved their active synthetic material to be biologically and chemically identical to the antiberiberi factor. Williams named it *thiamin,* to which research councils later added a final *e*. Taking out a patent whose royalties funded the Williams–Waterman Fund for the Combat of Dietary Disease, Williams interested Merck & Company in developing a commercial process. Production of thiamine increased from 100 kilograms in 1937 to 200,000 in 1967 (Gubler 1984) until, as Williams remarked with satisfaction, synthetic thiamine was cheaper than that which could be extracted from any natural source (Williams 1961).

Prevention of Beriberi

In the final stage, from his position on the Food and Nutrition Board of the National Academy of Science's National Research Council, Williams pioneered and supported the enrichment of grain with synthetic thiamine. Russell M. Wilder led the effort to enrich flour, which General Mills supported, and in 1941, the first definitions and standards for enrichment were established. The principle espoused was to raise thiamine to "high natural levels" in the milled flour. Because it was a standard and not a requirement, enrichment of bread in the United States was not fully accomplished until a popular movement was organized during World War II.

Other methods of preventing beriberi had been practiced for decades in Asia. There was considerable success in both Japan and Indonesia in limiting the extent of milling so that bran remained on the rice. These efforts involved the large, central mills of major cities rather than isolated rural enforcement. Professionals involved in public health generally believed in the importance of educating the public and improving diet to prevent beriberi. Williams, who repeatedly traveled to Asian countries campaigning for the prevention of beriberi, noted that there was opposition on the part of British nutritionists and their Asian pupils to any artificial enrichment of cereals because of a viewpoint that "any commercial intent is suspect with respect to any public health measure" (Williams 1961). The result was that even as beriberi spread through the Southeast Asian countryside as an epidemic following the spread of power rice milling and development, the United Nations and its Food and Agriculture Organization continued to ignore efforts at rice enrichment. Finally, in the 1970s the government of Thailand undertook heavy investments, and others followed their example until the agencies of the United Nations became supportive. It was difficult to treat rice grains with synthesized vitamins (locally deficient) and seal them with a protective coating against washing and excess cooking water, let alone to distribute tons of the enriched rice to be mixed with deficient rice at thousands of small mills extending into the most remote areas, and then to regulate and enforce the system. Nonetheless the success of recent efforts portends that, although marginal and subclinical beriberi may persist forever, the scourge of beriberi is ended.

Black Death

The "Black Death" is the name given by modern historians to the great pandemic of plague that ravaged parts of Asia, the Middle East, North Africa, and Europe in the middle of the fourteenth century. Contemporaries knew it by many names, including the "Great Pestilence," the "Great Mortality," and the "Universal Plague." This epidemic was the first and most devastating of the second known cycle of widespread human plague, which recurred in waves, sometimes of great severity, through the eighteenth century. Some of the later and milder "plagues" in this period seem to have also involved other diseases, including influenza, smallpox, and dysentery. Nonetheless almost all historians agree, on the basis of contemporary descriptions of its symptoms, that the Black Death should be identified as a massive epidemic of plague, a disease of rodents, caused by the bacillus *Yersinia pestis,* that can in the case of massive epizootics be transmitted to human beings by fleas. Although the Black Death manifested itself most commonly as bubonic plague, it also appeared at various times and places in its primary pneumonic and septicemic forms.

History and Geography

The geographic origins and full extent of the Black Death are still unclear. The earliest indisputable evidence locates it in 1346 in the cities of the Kipchak Khanate of the Golden Horde, north and west of the Caspian Sea. Until recently, most historians have claimed, based on Arabic sources, that the epidemic originated somewhere to the east of the Caspian, in eastern Mongolia or Yunnan or Tibet, where plague is enzootic in various populations of wild rodents. From there it was supposed to have spread along the Mongol trade routes east to China, south to India, and west to the Kipchak Khanate, the Crimea, and Mediterranean. Recently, however, John Norris (1977) has contested this account, pointing out that the sources describing Chinese epidemics of the 1330s and 1340s and the inscriptions on the graves at Issyk Kul (1388–9), south of the Aral Sea, are too vague to allow us to identify the disease(s) in question as plague, and that there are no reliable records of Indian epidemics in the mid-fourteenth century. Although Norris's own theory that the Black Death originated to the south of the Caspian in Kurdistan or Iraq is highly speculative (Dols 1978; Norris 1978), he is certainly correct that much more work needs to be done with Chinese and Mongol sources before we can say anything definite about the course of the Black Death before 1346 and its eastern geography and chronology after that date.

The epidemic's westward trajectory, however, is well established. It reached the Crimea in the winter of 1346–7 and Constantinople shortly afterward. From there it followed two great, roughly circular paths. The first swirled counterclockwise south and east through the eastern Mediterranean and the Middle East. The Black Death reached lower Egypt in the autumn of 1347 and moved slowly up the Nile over the next 2 years. By early 1348, it had also hit Cyprus and Rhodes, and during the late spring and summer it moved through the cities of the Mediterranean littoral and Palestine – Gaza, Jerusalem, Damascus, Aleppo – and then east to Mecca, Armenia, and Baghdad, where it appeared in 1349.

The second circle described by the plague was greater in length and duration and moved clockwise, west and north and finally east again, through the western Mediterranean and Europe. According to Italian chroniclers, Genoese ships brought the disease to Sicily from the Black Sea in the autumn of 1347, at about the same time it appeared in Alexandria. From there it spread to Tunisia, the Italian mainland, and Provence. By the summer of 1348 it had moved westward into the Iberian peninsula and as far north as Paris and the ports of southern England. During 1349 it ravaged the rest of the British Isles and northern France, parts of the Low Countries and Norway, and southern and western Germany. In 1350 it was in northern and eastern Germany, Sweden, and the Baltics, and in 1351, in the eastern Baltics and northern Poland. During the following 2 years, it attacked Russia, reaching as far east as Moscow in the summer of 1353.

Although the Black Death lasted in all at least 7 years, from its first clearly recorded appearance in the Caspian area to its final devastation of Moscow, no single city or region suffered for more than a small fraction of that period. The plague moved like a wave through the Middle East and Europe, and the average duration of the epidemic in any given place seems to have been about 5 to 6 months. The reasons for this are complicated. The ecology of plague means that it is a seasonal phenomenon; in its dominant, bubonic form, it flourishes in warm weather, whereas its rarer, primary pneumonic form is most common in winter. Thus the Black Death was above all a disease of spring, summer, and early autumn, typically receding in the last months of the year. For this reason, areas first affected in early spring, like Tunis or the cities of central Italy, in general suffered longer and more severely than those, like northern France and Flanders, affected in August or September. The most unfortunate regions were those such as Lower Egypt, the Veneto, Provence, or Ireland, which experienced successive pneumonic and bubonic epidemics (lasting as long as 9 or 10 months, spanning both winter and summer) or were reinfected in successive years.

Transmission and Mortality

There is considerable debate over the ways in which the Black Death was transmitted from person to person and place to place. Plague is an ecologically complex disease, depending on the mutual interaction of bacilli, rodents, fleas, and humans; the lack of detailed evidence about the experience and behavior of animals and insects in the mid-fourteenth century forces us to rely on indirect and therefore ambiguous evidence derived from the speed and pattern of the epidemic's spread.

The disease was clearly propagated by humans; rather than moving slowly across fields and forests from one group of rodents to another, it progressed quickly along major routes of trade and communication, traveling faster by sea than by land. Thus in virtually every area in which its trajectory is known (the Black Sea, the Mediterranean, the North Sea, the Baltic), it appeared first in ports and then spread more slowly along roads and rivers to inland cities and from there into the surrounding countryside. A number of extremely remote areas, including parts of the Pyrenees, the central Balkans, and the sub-Atlas region, seem to have escaped largely or entirely.

Historians differ, however, about the ways in which humans acted to spread the plague. Virtually all agree that ships carried colonies of diseased ro-

dents from port to port, where they could infect the local rat population, and that sick rats also traveled overland hidden in shipments of cloth and grain. Some also emphasize the autonomous role of the oriental rat flea, *Xenopsylla cheopis,* which could survive independently and be transported in cloth and bedding. Others add to that the role of the human flea, *Pulex irritans,* arguing that in severe epidemics such as the Black Death with a high incidence of septicemic plague, fleas could transmit the disease between humans with no need for a rodent intermediary (Biraben 1975; Ell 1980). In addition, on the basis of detailed contemporary descriptions, it is now almost universally accepted that in both Europe and the Middle East, the Black Death also included numerous pockets of primary pneumonic plague, a highly contagious airborne disease. It seems likely that all of these forms of transmission were involved, although their relative importance varied according to local conditions.

It is difficult to judge mortality rates during the Black Death with any precision, except in a few areas. Contemporary chroniclers tended to give impossibly high estimates, whereas other records – necrologies, testaments, hearth taxes, and so forth – are incomplete or reflect only the experience of particular groups or require extensive interpretation. Nonetheless, historians generally agree that death rates most commonly ranged between about 30 and 50 percent in both Europe and the Middle East, with the best records indicating a mortality in the upper end of that range. Some areas are known to have suffered more than others. It is frequently claimed that central Italy, southern France, East Anglia, and Scandinavia were most severely affected, although the evidence for this claim is uneven. Clearly, however, certain regions were relatively fortunate; Milan, for example, Bohemia, and parts of the Low Countries seem to have experienced losses of less than 20 percent, whereas Nuremberg, for some reason, escaped entirely. In general, however, the trend in recent research is to move the estimated mortality rates upward. It now appears that many remote and rural areas suffered as much as the larger cities and that a number of regions previously thought largely to have escaped the epidemic, such as parts of the Low Countries, were in fact clearly affected. The Black Death seems to have been more universal and more virulent than many historians a generation ago believed.

Some groups also suffered more than others, even within a single city or region. A number of contemporary observers in various parts of Europe com-

mented on the relatively high death rates among the poor. These assertions are plausible; the poor lived in crowded and flimsy houses, which would have allowed the easy transmission of plague from rats to humans and from person to person, and they did not have the luxury of fleeing, like the rich, to plague-free areas or to their country estates. Conversely, death rates seem to have been somewhat lower than average among the high European aristocracy and royalty, who lived in stone buildings and were relatively mobile. People whose occupations brought them into contact with the sick, such as doctors, notaries, and hospital nurses, appear to have suffered disproportionately, at least in some areas, as did people who lived in large communal institutions, such as the Mamluks of Egypt and Syria or members of Christian religious orders. For all these groups, the main factor seems to have been increased exposure rather than susceptibility.

Attempts at Control and Prevention

The Black Death was in many ways a completely unprecedented experience for those who suffered through it. Plague had virtually disappeared from the Middle East and Europe during the centuries between the end of the first pandemic in the eighth century and the beginning of the second pandemic, and although the first half of the fourteenth century had been marked by a number of epidemics of other diseases, none approached the Black Death in destructiveness and universality. Contemporaries reacted vigorously against the disease, attempting to halt its spread, mitigate its virulence, and alleviate the suffering it provoked. For the most part, however, their responses took traditional forms: Rather than developing new strategies for managing the crisis, they fell back on established measures, though in many cases they applied these with unprecedented rigor.

For those who could afford it, the most common reaction sanctioned by established medical authorities was flight; even in the Islamic world, where religious authorities inveighed against the practice and exhorted believers to accept the mortality as a martyrdom and a mark of divine mercy, people abandoned infected cities in search of more healthful territory. Those who remained sought spiritual remedies. In both Islamic and Christian countries, religious leaders organized prayers, processions, and special religious services, supplicating God to lift the epidemic. The European reaction, however, had a unique perspective, which was lacking for the most part among Muslims for whom the epidemic was a morally neutral event: Drawing on traditional teachings concerning sin and penance, Christians on every level of society interpreted the plague as a mark of divine wrath and punishment for sin and, in some cases, even as a sign of the approaching apocalypse.

In many Italian cities, private individuals engaged in acts of piety and charity in an attempt to ensure the safety and salvation of themselves and their communities, while public authorities released poor prisoners and passed temporary laws against concubinage, swearing, sabbath-breaking, and games of chance. But public reaction often took more extreme forms – among them, groups of flagellants, who professed publicly, whipping themselves and preaching repentance, in order to ward off God's wrath and the Black Death. This movement seems to have begun in Italy, where it drew on thirteenth-century precedents, but it reached its height in northern and central Europe, in Austria, Thuringia, Franconia, the Rhineland, and the Low Countries. In Thuringia it was associated with a radical critique of ecclesiastical authorities, which led Pope Clement VI to condemn the practice as heretical.

The most extreme and shocking example of Christian religious reaction to the Black Death, however, was directed against Jewish communities in Provence, Catalonia, Aragon, Switzerland, southern Germany, and the Rhineland. Jews in these areas were accused of spreading the plague by poisoning Christian springs and wells. This kind of scapegoating was not unprecedented – earlier fourteenth-century epidemics had provoked similar accusations against lepers, foreigners, and beggars as well as Jews – but the violence of the popular reaction was extraordinary, in some places resisted and in some places abetted by rulers and municipal governments.

Despite the protests of the pope, hundreds of Jewish communities were completely destroyed in 1348 and 1349, their members exiled or burned en masse, while the residents of many others were imprisoned and tortured, with their property confiscated. The destruction was great enough to shift the center of gravity of the entire European Jewish population significantly eastward. Like the flagellant processions, with which they were occasionally associated, many of these pogroms had a prophylactic intent; some of the most violent episodes took place before the plague had actually reached the areas in question. There is no evidence for practices of this sort in Islamic communities, which could boast both a long tradition of religious pluralism and tolerance and a less morally loaded theological interpretation of the epidemic.

A second set of defensive reactions belonged to the realm of medicine and public health. Although both Muslims and Christians identified Divine Will as the ultimate cause of plague, most accepted that God worked through secondary causes belonging to the natural world, and this allowed them to interpret the epidemic within the framework of contemporary medical learning. Both societies shared a common medical tradition based on the works of Greek writers such as Hippocrates and Galen, which explained epidemics as the result of air corrupted by humid weather, decaying corpses, fumes generated by poor sanitation, and particular astrological events. Thus both Muslim and Christian doctors recommended (with some differences in emphasis) a similar set of preventive and curative practices that included a fortifying diet, rest, clean air, and moderate bloodletting for the healthy, together with salves, internal medication, and minor surgery for the sick.

Where Europe and the Islamic world clearly diverged was in their attitudes toward public health. There is little evidence that Islamic communities (where theological teachings combined with the classical medical tradition to deemphasize contagion as a cause of infection) engaged in large-scale social measures to prevent plague, beyond religious ceremonies and occasional public bonfires to purify the air. From the very beginning of the epidemic, however, the populations of a number of European cities – above all, in central and northern Italy, which boasted a highly developed order of municipal and medical institutions – reacted aggressively in a largely futile attempt to protect themselves from the disease. Initially they fell back on existing sanitary legislation, most of it dating from the thirteenth and early fourteenth centuries; this emphasized street cleaning and the control of particularly odoriferous practices like butchery, tannery, dyeing, and the emptying of privies. As the plague moved closer, however, a number of Italian governments instituted novel measures to fight contagion as well as corrupt and fetid air. They imposed restrictions on travel to and from plague-stricken cities and on the import and sale of cloth from infected regions and individuals. They passed laws against public assemblies and regulated the burial of the dead. They hired doctors to study the disease and treat its victims (many physicians had fled the cities along with others of their class), and they appointed temporary boards of officials to administer these measures. In Milan the ducal government boarded up the houses of plague victims, and in Avignon, the pope created a settlement of wooden huts outside the city walls to receive the sick and isolate them from the rest of the community.

These measures against contagion were unprecedented in the context of both contemporary medical theory and municipal practice; they seem initially to have been a response to the experience of pneumonic plague, which ravaged the cities of Italy and southern France in the winter and spring of 1347–8. The ecology of plague and problems of enforcement made such measures largely ineffective, although it is striking that Milan, which applied anticontagion practices most drastically, was the least affected of all major Italian cities. Nonetheless, such measures represent the beginnings of large-scale public health organizations in Europe; succeeding epidemics saw their elaboration and their spread to other parts of the continent, where they eventually became the basis for widespread practices such as quarantines and cordons sanitaires.

Black and Brown Lung Disease

Black and brown lung are the names given by workers in the coal and textile industries, respectively, and by some physicians and public officials, to symptoms of respiratory distress associated with dusty work. Most physicians and epidemiologists have, however, preferred to categorize these symptoms as they relate to findings at autopsy and studies of pulmonary function and to name their appearance in particular patients as, respectively, *coal workers' pneumoconiosis* and *byssinosis*. The terms "black lung" and "brown lung" are historical legacies of intense negotiations about the causes of respiratory distress and mortality among workers in the coal and textile industries of Europe and North America, especially since the nineteenth century. (For the conventional medical definitions of the pathology subsumed under the terms black lung and brown lung, see the extensive bibliographies in papers by Fox and Stone [1981] and Corn [1980]).

History and Geography
For many centuries, medical observers, and workers and their employers, have recognized respiratory distress and its consequences as an occupational hazard among underground miners and employees of industries that generate considerable dust (notably refineries, foundries, and the manufacturing of cotton, flax, and hemp). Pliny described the inhalation of

"fatal dust" in the first century. In the sixteenth century, Agricola observed that miners, physicians, and engineers were aware of shortness of breath and premature death. In the early nineteenth century, pathologists observed that some miners in Scotland had black lesions on the lung at autopsy. The term *pneumoconiosis* appears to have been invented in 1867. *Brown lung* seems to have been named by analogy with *black lung*, apparently in the 1960s.

The contemporary, imprecise medical synonym for black lung is *coal workers' pneumoconiosis* (CWP). CWP occurs in two forms: simple CWP and progressive massive fibrosis. Both forms have characteristic lesions. Agencies awarding compensation for disability usually use the designation "black lung" as a rough synonym for pathologically defined CWP and for obstructive airways disease among coal miners.

Most medical authors, epidemiologists, and agencies awarding compensation usually use "brown lung" as a popular synonym for byssinosis or *chronic dust-induced respiratory disease* (CDIRD). The pathology in these descriptions resembles that of chronic bronchitis.

The rich literature on the history and geography of black and brown lung cannot be summarized in conventional terms. Many authors have attempted to describe the history of these conditions, but they have almost invariably done so on the basis of the precise definition of symptomatology accepted at the time they were writing. The reported geography of the conditions is consistent with the distribution of industries in which dust is a by-product, but the perception of the conditions in particular places (and by later observers) has determined what is said, in retrospect, about their geography.

Distribution and Incidence
Each condition has been described among workers exposed to coal dust (CWP) and cotton dust (byssinosis). Perhaps 1 million workers worldwide are currently exposed to both coal and cotton dust. The most reliable statistical accounts of the conditions, both contemporary and historical, are available in British and American sources. The historical and geographic incidence of each condition (and of the particular diseases defined at each time of writing) has been influenced by public policy and regulations for dust suppression, by the characteristics of the mining and manufacturing process (and, for black lung, by the type of coal itself), by the workers' general state of health, and by their exposure to other causes of respiratory disease, notably cigarette smoke, and by the availability of publicly supported

programs of disability compensation and medical care.

Opinions about the distribution and incidence of the conditions have been linked to competing views about their clinical manifestations and pathology. For many years and in many communities, physicians did not differentiate the symptoms of black and brown lung from those of other common respiratory disorders. In the early stages of both diseases, workers are frequently asymptomatic and without functional impairment. For black lung defined medically as CWP, the progression of symptoms often includes chronic cough and phlegm, shortness of breath, and then functional impairment; but some workers with lesions of CWP at autopsy remained free of symptoms. The initial symptoms of byssinosis are tightness in the chest, dyspnea, and a cough following a return to work after a weekend or holiday. Later symptoms extend to other workdays and include a chronic stage, with severe continuous dyspnea, chronic cough, and permanent ventilatory insufficiency.

Epidemiology and Etiology

Both black and brown lung (and their medically named partial synonyms) have been the focus of many studies – and are highly controversial. Early epidemiological studies established an association between occupation and respiratory disease. Studies of both conditions in the United States were, in general, initiated later than those in Britain for reasons that include the political roles of manufacturers and unions and the structure of public regulation as well as different perceptions of the relative importance of silica and coal dust and the amount of dust that constituted a dangerous exposure in textile manufacturing. Moreover, many epidemiological, clinical, and pathological investigations have yielded uncertain results.

Aspects of coal miners' lung distress that remain controversial include the following: (1) the mechanisms by which coal dust acts on the lungs; (2) the significance of the correlation, or lack of it, between clinical evidence of respiratory impairment and X-ray findings; and (3) the absence, in some studies, of strong, independent correlations between respiratory disorders in mining communities and work in the mines. Caplan's syndrome is an example of the complexity and controversy surrounding coal miners' lung conditions. This syndrome, first described among Welsh coal miners in 1953, appears to be a consequence of the interaction of characteristics of rheumatoid arthritis with a residue of silica in the lungs; yet the syndrome seems extremely rare in the United States, dispite the high incidence of both dust exposure and arthritis among miners.

For byssinosis, areas of uncertainty include the following: (1) the substance in cotton dust that causes respiratory distress; (2) lack of clear evidence linking levels of dust exposure to findings indicative of clinically defined disease; and (3) the absence of widely agreed upon findings from clinical and pathological examinations that are sufficiently specific to permit a diagnosis of disease.

Nevertheless, the contemporary literature on both conditions is widely regarded as offering considerable guidance for public action. Most investigators agree that the relatively high incidence of respiratory distress in mining and textile workers is evidence of exposure to toxic agents in industrial dust. Many authors have hypothesized mechanisms by which these agents could operate in the lung. There is considerable agreement about clinical manifestations and pathology. And there is overwhelming consensus that reducing dust levels in the workplace contributes to reducing the incidence of both black and brown lung and the symptoms, signs, and findings defined by medical scientists as diseases among workers in dusty industries.

Throughout their histories, black and brown lung have been matters of controversy involving people and institutions beyond the medical profession. The definitions of the conditions have been matters of intense political concern. Generalizations about their incidence and distribution depend on how they are defined, and defining them has long been controversial. Etiology and epidemiology remain in dispute in part because of scientific uncertainty but also because involved as well are significant amounts of money and fundamental issues about the relationship between employers and employees and the public interest in workplace health and safety. Laws and regulations are often more important sources than medical texts for understanding what clinical manifestations and pathological findings mean for treatment, compensation, and control of the environment of the workplace.

VIII.18
Bleeding Disorders

The existence of a hereditary tendency to excessive bleeding was recognized in the second century A.D. by Rabbi Judah, who exempted from circumcision the son of a woman whose earlier sons had bled to death after this rite. But only in this century has expanding knowledge of the physiology of *hemostasis* – the arrest of bleeding – made evident the diverse nature of inherited bleeding disorders. In addition, only recently has it been recognized that a tendency to thrombosis might likewise be due to an inherited hemostatic defect.

Physiology of Hemostasis

The mechanisms by which blood loss in mammals is stopped after vascular disruption are complex. Small vascular injuries are sealed by platelets that adhere to the site of damage, where they attract other circulating platelets, so as to form an occlusive aggregate or plug that can close small gaps. Larger defects in vessel walls are occluded by coagu-lation of blood – that is, by its transformation from a fluid to a gel-like state. Uncontrolled bleeding and its antithesis, thrombosis (the formation of a clot within a blood vessel), are important pathogenetic factors for human disease, including a large variety of hereditary disorders.

The basic structure of both the occlusive clots that halt blood loss and pathological intravascular clots (or *thrombi*) is a meshwork of fibrous protein (*fibrin*) that entraps blood cells. Plato and Aristotle both described the fibers found in shed blood. When the blood vessel wall is disrupted, whether by trauma or disease, a soluble plasma protein, *fibrinogen (factor I)*, is transformed into the insoluble strand of fibrin. Fibrin formation takes place through three steps: First, a plasma proteolytic enzyme, *thrombin,* cleaves several small peptides from each molecule of fibrinogen. Molecules of the residue, called *fibrin monomers,* polymerize to form the fibrin strands. Finally, these strands are bonded covalently by a plasma transamidase, *fibrin-stabilizing factor (factor XIII),* itself activated by thrombin, increasing their tensile strength.

Thrombin is not found in normal circulating plasma, but evolves after vascular injury from its plasma precursor, *prothrombin (factor II)*, via either or both of two interlocking series of enzymatic events, the extrinsic and intrinsic pathways of thrombin formation. The steps of the extrinsic pathway begin when blood comes into contact with injured tissues (such as the disrupted vascular wall). The tissues furnish a lipoprotein – *tissue thromboplastin* or *tissue factor (factor III)* – that reacts with a plasma protein, *factor VII*. Factor VII then converts a plasma proenzyme, *Stuart factor (factor X),* to its active form. Thus activated, *Stuart factor (factor Xa),* acting in conjunction with a nonenzymatic plasma protein, *proaccelerin (factor V),* releases thrombin from prothrombin, and in this way initiates the formation of fibrin.

The intrinsic pathway of thrombin formation is launched when vascular disruption brings plasma into contact with certain negatively charged substances, such as subendothelial structures or the oily sebum layer of skin. Exposure to negative charges changes a plasma protein, *Hageman factor (factor XII),* to an enzymatic form, *activated Hageman factor (factor XIIa),* that participates in both clotting and inflammatory reactions. In the latter role, activated Hageman factor converts a plasma proenzyme, *prekallikrein,* to *kallikrein,* an enzyme that releases small peptides from a plasma protein, high molecular weight *kininogen.* These peptides, notably

bradykinin, increase vascular permeability, dilate small blood vessels, and induce pain.

The role of activated Hageman factor in the intrinsic pathway is to initiate a series of proteolytic reactions that lead ultimately to the release of thrombin from prothrombin. These reactions involve the sequential participation of several plasma proteins, including *plasma thromboplastin antecedent* (PTA, *factor XI*), high molecular weight kininogen, plasma prekallikrein, *Christmas factor (factor IX), antihemophilic factor (factor VIII),* Stuart factor (factor X), and proaccelerin (factor V). Of these various proteins, PTA, plasma prekallikrein, Christmas factor, and Stuart factor are the precursors of proteolytic enzymes, whereas high molecular weight kininogen, antihemophilic factor, and proaccelerin serve as nonenzymatic cofactors. The ultimate product, activated Stuart factor (factor Xa), releases thrombin from prothrombin through the same steps as those of the extrinsic pathway. Hageman factor also enhances clotting via the extrinsic pathway by augmenting the activity of factor VII, whereas factor VII in turn can directly activate Christmas factor. Thus, the steps of the extrinsic and intrinsic pathways are intertwined.

Certain steps of both the extrinsic and intrinsic pathways require the presence of calcium ions and phospholipids, the latter furnished, in the extrinsic pathway, by tissue thromboplastin and, in the intrinsic pathway, by platelets and by plasma itself.

Antihemophilic factor (factor VIII) is of peculiar interest as it circulates in plasma loosely bound to another plasma protein, *von Willebrand factor* (vWf), which fosters hemostasis by promoting adhesion of platelets to injured vascular walls. The plasma proteins participating in coagulation are synthesized at least in part by the liver, except for von Willebrand factor, which is synthesized in vascular endothelial cells and megakaryocytes.

Synthesis of certain of the plasma clotting factors – namely prothrombin, factor VII, Stuart factor (factor X), and Christmas factor (factor IX) – is completed only in the presence of *vitamin K,* furnished by leafy vegetables and by bacterial flora in the gut.

The clotting process is modulated by inhibitory proteins present in normal plasma. *Plasmin,* a proteolytic enzyme that can be generated from its plasma precursor, *plasminogen,* can digest fibrin clots as well as certain other plasma proteins. *Antithrombin III* inhibits all of the plasma proteases of the clotting mechanism, an action enhanced by *heparin,* a glycosaminoglycan found in various tis-

sues but not in plasma. *Heparin cofactor II,* a protein distinct from antithrombin III, also inhibits clotting in the presence of heparin. *C1 esterase inhibitor* (C1-INH) originally detected as an inhibitor of the activated form of the first component of the immune complement system (C1), also blocks the activated forms of Hageman factor and PTA as well as plasmin. *Alpha-1-antiproteinase (alpha-1-antitrypsin)* is an inhibitor of activated PTA. *Protein C,* when activated by thrombin, blocks the coagulant properties of antihemophilic factor (factor VIII) and proaccelerin (factor V), an action enhanced by *protein S;* proteins C and S both require vitamin K for their synthesis. Activated protein C also enhances the conversion of plasminogen to plasmin. *Alpha-2-macroglobulin* is an inhibitor of plasma kallikrein, and plasmin can be inhibited by several plasma proteins, notably by *alpha-2-plasmin inhibitor.*

Human disorders due to the functional deficiency of each of the factors needed for the formation of a clot have been recognized and extensively studied. In some instances, the patient's plasma appears to be deficient or totally lacking in a specific clotting factor or inhibitor. In others, plasma contains a nonfunctional variant of the normal plasma protein.

Classic Hemophilia

Clinical Manifestations

The best known of all the bleeding disorders is classic hemophilia (hemophilia A, the hereditary functional deficiency of factor VIII), which is the prototype of an X chromosome-linked disease, limited to males but transmitted by female carriers. Necessarily, all daughters of those with the disease are carriers, as are half the daughters of carriers. In turn, half the sons of carriers inherit the disease. A typical family history of bleeding inherited in the manner described is found in about two-thirds of cases; in the rest, the disorder appears to arise de novo, either because a fresh mutation has occurred or because cases were unrecognized in earlier generations.

Classic hemophilia varies in severity from family to family. In the most severe cases, in which plasma is essentially devoid of factor VIII, the patients may bruise readily and bleed apparently spontaneously into soft tissues and joints, with the latter resulting in crippling joint disease. Trauma, surgical procedures, and dental extractions may lead to lethal bleeding. The life expectancy of those with severe classic hemophilia is foreshortened, death coming from exsanguination, bleeding into a vital area, or infection. The prognosis of classic hemophilia has

been greatly improved by modern therapy in which episodes of bleeding are controlled by transfusion of fractions of normal plasma containing the functionally missing proteins. This therapy is not without hazard, for transfusion of concentrates of factor VIII derived from normal plasma has been complicated by transmission of the viruses of hepatitis and the acquired immunodeficiency syndrome (AIDS).

In those families in which classic hemophilia is milder, bleeding occurs only after injury, surgery, or dental extraction. The severity of clinical symptoms is paralleled by the degree of the deficiency of antihemophilic factor (factor VIII), as measured in tests of its coagulant function.

Geography

Classic hemophilia appears to be distributed worldwide but geographic differences in its incidence have been described. In the United States, Great Britain, and Sweden, estimates of the prevalence of classic hemophilia range from about 1 in 4,000 to 1 in 10,000 males; a somewhat lower prevalence has been estimated in Finland. Whether classic hemophilia is less prevalent in blacks than in other groups, as has been suggested, is uncertain since milder cases may not be brought to medical attention for socioeconomic reasons.

Christmas Disease

Clinical Manifestations

Christmas disease (hemophilia B), the hereditary functional deficiency of Christmas factor (factor IX), is clinically indistinguishable from classic hemophilia, and can be differentiated only by laboratory tests. It is inherited in the same way as an X chromosome-linked disorder and is therefore virtually limited to males. As is true of classic hemophilia, the disorder varies in severity from family to family in proportion to the degree of the clotting factor deficiency. Christmas disease is heterogeneous in nature, for in some families the plasma is deficient in Christmas factor, whereas in others the plasma contains one or another of several nonfunctional variants of this clotting factor. Therapy for hemorrhagic episodes in Christmas disease is currently best carried out by transfusion of normal plasma, which contains the factor deficient in the patient's plasma. An alternative therapy, infusion of concentrates of Christmas factor separated from normal plasma, may be needed in some situations, but its use may be complicated by the transmission of viral diseases as well as by other problems.

Geography

Worldwide, Christmas disease is perhaps one-eighth to one-fifth as prevalent as classic hemophilia. Most reported cases have been in individuals of European origin, but in South Africa and in the United States, as reflected by Ohio data, Christmas disease is relatively as common in blacks as in whites. Christmas disease of moderate severity is particularly prevalent among inhabitants of the village of Tenna, in Switzerland, and among Ohio Amish. This disorder is said to be rare in Japan.

Von Willebrand's Disease

Clinical Manifestations

Classic hemophilia is not the only hereditary deficiency of antihemophilic factor. Von Willebrand's disease is a bleeding disorder of both sexes which in its usual form is present in successive generations; thus, it is inherited as an autosomal dominant trait. The plasma of affected individuals is deficient in both parts of the *antihemophilic factor complex* – that is, the coagulant portion (factor VIII) and von Willebrand factor (vWf). The *bleeding time* – the duration of bleeding from a deliberately incised wound – is abnormally long, distinguishing von Willebrand's disease from classic hemophilia or Christmas disease. The disorder is usually mild, although variants have been observed in which severe bleeding episodes are frequent. Inheritance in these cases is probably recessive in nature.

Geography

The prevalence of von Willebrand's disease is uncertain because mild cases are easily overlooked. Using Ohio as something of a proxy for the United States, von Willebrand's disease is about one-fourth as prevalent as classic hemophilia, meaning about 2 or 3 cases per 100,000 individuals. Estimates of 3 to 6 cases per 100,000 have been made in the United Kingdom and Switzerland, whereas the prevalence is somewhat higher in Sweden, about 12 per 100,000. A study conducted in northern Italy on a population of school children revealed that 10 of 1,218 had laboratory evidence of the disease as well as a family history of hemorrhagic problems. By contrast, the disorder is relatively uncommon in blacks. Similarly, although the severe, autosomal recessive form of von Willebrand's disease is unusual in most individuals of European extraction (perhaps 1 per 1 million), it is particularly prevalent among Israeli Arabs, in whom it can be detected in about 5 individuals per 100,000, and in Scandinavia.

Unusual Disorders of Hemostasis

Functional deficiencies of Hageman factor (Hageman trait), plasma prekallikrein (Fletcher trait), and high molecular weight kininogen (Fitzgerald, Flaujeac, or Willimas trait) are all asymptomatic, although in each case a major defect in clotting is found in the laboratory. These disorders occur with equal frequency in both sexes, and are recessive traits, meaning that they must be inherited from both parents. Hageman trait and deficiencies of plasma prekallikrein and high molecular weight kininogen are all rare, and data concerning their prevalence are available only for Hageman trait, which, in Ohio, occurs in about 1 in 500,000 individuals. By contrast, a disproportionately high number of cases of Hageman trait have been reported from the Netherlands. No racial predilection for Hageman trait or deficiency of high molecular weight kininogen had been described, but deficiency of plasma prekallikrein appears to be more frequent in blacks and in individuals of Mediterranean extraction.

Hageman trait is a heterogeneous disorder; in most families, the plasma appears to be deficient in Hageman factor, but plasma in a few contains a nonfunctional variant of this clotting factor. A similar heterogeneity had been observed in plasma prekallikrein deficiency, with the plasma of those patients of Mediterranean origin containing a nonfunctional variant of plasma prekallikrein.

The hereditary deficiency of plasma thromboplastin antecedent (PTA or factor XI deficiency) is also inherited in an autosomal recessive manner. The hemorrhagic symptoms are usually mild; in women, excessive menstrual bleeding may be troublesome. Nearly all reported cases have been those of Ashkenazi (i.e., eastern European) Jews or Japanese, although cases in individuals of American black, Arabic, Italian, German, Yugoslav, Dutch, Scandinavian, English, Korean, and Asiatic Indian heritage have also been recognized. In Israel, as many as 0.1 to 0.3 percent of Ashkenazi Jews may be affected, and 5.5 to 11 percent may be heterozygous carriers. Similarly, in Ohio, at least 0.3 percent of Ashkenazi Jews have PTA deficiency, and at least 3.4 percent are heterozygotes.

Hereditary deficiencies of factor VII, Stuart factor (factor X), proaccelerin (factor V), and prothrombin are rare, and no racial or geographic distribution is yet apparent. An estimate of one case of factor VII deficiency per 100,000 has been made. A still rarer syndrome, the combination of factor VII deficiency and Dubin–Johnson syndrome (the latter a disorder of billirubin metabolism) has been described in Is-

raeli Jews of Sephardic origin, the patients coming from Iran, Iraq, and Morocco.

In each of these disorders, the deficiency appears in both sexes and is inherited as a recessive trait, and in a number of instances the parents have been consanguineous. In general, the basic nature of these functional deficiencies is variable. In some instances, the plasma of the affected individuals appears to be deficient in the factors, as shown in functional assays. In others, the plasma contains an incompetent variant of the supposedly missing factor. For example, patients functionally deficient in prothrombin may either be truly deficient in this protein, or their plasma may contain one or another variant, nonfunctional form of prothrombin (congenital dysprothrombinemia). A similar variability in the nature of functional deficiencies of factor VII and Stuart factor (factor X) has been detected. In one variant of factor X deficiency, first observed in patients in the village of Friuli in northeast Italy, Stuart factor could not be detected in the usual functional assays, but behaved normally when the venom of Russell's viper was added to the patients' plasma.

The symptoms of deficiencies of factor VII, Stuart factor, and proaccelerin (the last called parahemophilia) are variable, some individuals having hemorrhagic episodes comparable to those of severe hemophilia, whereas others are spared except in the event of severe trauma. In women, excessive menstrual bleeding may be a serious problem.

Disorders of fibrin formation are of peculiar interest. Patients with congenital afibrinogenemia (who have no detectable fibrinogen in plasma) may bleed excessively from the umbilicus at birth, and thereafter from injuries or surgical procedures. In addition, they may exsanguinate from relatively minor vascular injuries, and menorrhagia may be disastrous; yet they may have little in the way of spontaneous bleeding. Fortunately, cogenital afibrinogenemia is a rare recessive disorder, detected in both sexes, and only about 150 cases have been recorded to date. Often the parents are consanguineous. A milder form, congenital hypofibrinogenemia (in which the plasma contains small but measurable amounts of fibrinogen), has also been described in about 30 families, and some investigators believe that this is the heterozygous state for congenital afibrinogenemia, meaning that these individuals have inherited the abnormality from but one parent. In still other families, the concentration of fibrinogen in plasma is normal or only moderately decreased, but the fibrinogen is qualitatively abnormal. This disorder,

congenital dysfibrinogenemia, occurs in both sexes and in successive generations; that is, it is inherited as a dominant trait. The affected individuals may be asymptomatic, detected only by chance, or they may suffer mild bleeding problems. Paradoxically, they may also sustain thrombosis. Over 100 families with dysfibrinogenemia have been described, and the molecular defect in each family is almost always unique.

Fibrin-stabilizing factor (factor XIII) deficiency is similarly rare; perhaps 100 cases have been described thus far. In some, plasma appears to be deficient in fibrin-stabilizing factor, and in others, plasma contains a nonfunctional variant of this agent. Patients with fibrin-stabilizing factor deficiency have severe bleeding problems beginning with the umbilicus at birth. The patients may die of central nervous system hemorrhage, and in women spontaneous abortion is frequent. Some evidence suggests that affected males are sterile.

Little information is available concerning a racial or geographic predilection for any of these disorders of fibrin formation, but the prevalence of fibrin-stabilizing factor deficiency in the United Kingdom is said to be 1 in 5 million.

Another disorder of great interest is the hereditary deficiency of alpha-2-antiplasmin. In this disease, which is inherited as a recessive trait, patients may have symptoms suggestive of severe classic hemophilia. Bleeding apparently results from the rapid dissolution of clots by plasmin, whose proteolytic activity is unchecked because of the deficiency of alpha-2-plasma inhibitor. Too few cases have been recognized to determine whether there is a geographic predilection for this disorder, but it has been reported in Japan, the Netherlands, Norway, the United States, and Argentina.

Hereditary Thrombotic Disorders

In contrast to the deficiency states described to this point, a hereditary deficiency of certain of the inhibitors of clotting results in an increased tendency to thrombosis. Thus, familial recurrent thrombosis has been observed in individuals of both sexes, with inherited partial deficiencies of antithrombin III, protein C, protein S, or heparin cofactor II. The affected individuals, most of whom are heterozygotes (i.e., they have inherited an abnormal gene from but one parent), have about half the concentration of the inhibitory proteins of normal individuals. Only a handful of cases of deficiencies of heparin cofactor II, protein C, or protein S have been recorded, but a deficiency of antithrombin III is relatively common.

In Massachusetts, the prevalence is said to be about 50 per 100,000. No geographic or racial predilection has been reported.

Most of the reported cases of deficiencies of these several inhibitors have been in individuals of European origin. Additional instances of antithrombin III deficiency have been recognized in Japanese, Algerians, and American blacks; protein C deficiency has been seen in Jordanian and Israeli Arabs, and in Japanese; and protein S deficiency has been reported in Japan.

History

The earliest record of the existence of hereditary hemorrhagic disease is in the Babylonian *Talmud*. Recurrent descriptions of what was probably hemophilia were recorded thereafter, but it was only in 1803 that John Otto, a Philadelphia physician, recognized that this disorder was limited to males and transmitted by certain of their asymptomatic female relatives. During the nineteenth century, the mode of inheritance of hemophilia was delineated, and in their 1911 review of all the published cases of hemophilia, W. Bulloch and P. Fildes were unable to find a single authentic case of hemophilia in a female.

The mechanism underlying the defect in classic hemophilia was elucidated by A. J. Patek, Jr., and R. H. Stetson in 1936, who determined that the patients were functionally deficient in what is now called antihemophilic factor (factor VIII). Only later was it realized independently by P. N. Aggeler, I. Schulman, and R. Biggs that an essentially identical disorder, inherited in the same way, resulted from a deficiency of Christmas factor (factor IX). In 1926, E. A. von Willebrand recognized the disease that now bears his name among inhabitants of the Åland Islands in the Gulf of Rothnia. This hereditary hemorrhagic disorder affects both sexes and was detected in succeeding generations; these characteristics, along with the presence of a prolonged bleeding time, distinguishes von Willebrand's disease from hemophilia. In 1953, several independent groups of investigators found that the titer of antihemophilic factor (factor VIII) was abnormally low in patients with von Willebrand's disease, and some years later T. S. Zimmerman reported a deficiency also in the concentration of what is now called von Willebrand factor.

With few exceptions, the existence of the various clotting factors required for normal coagulation of blood was detected by the study of patients with unusual hemorrhagic disorders. In each instance, a protein extracted from normal plasma corrected the

specific defect in the patient's plasma. Thus, current knowledge about the physiology of blood clotting has been derived from the interplay between the clinic and the laboratory.

VIII.19
Botulism

Botulism is an uncommon, potentially fatal paralytic disease caused by a protein neurotoxin that is produced by the bacterium *Clostridium botulinum.* The disease is most frequently seen as a foodborne intoxication first clearly documented in the early nineteenth century; however, two other forms of the disease have been identified in the latter part of the twentieth century: wound botulism and infant botulism.

Etiology

Botulism is caused by very powerful neurotoxins that are elaborated during the growth and multiplication of the bacterium *C. botulinum.* The bacterium, which exists in nature as a spore, multiplies and produces its toxin in oxygen-deprived or anaerobic conditions, such as may occur in canned or hermetically sealed foods or unclean wounds. Spores of *C. botulinum* are found naturally in soil and marine sediments, and thus may readily occur as normal contaminants of many vegetable and animal sources of food. The spores and their toxins are inactivated by boiling canned foods according to food industry specifications.

Table VIII.19.1. *Types of* Clostridium botulinum, *susceptible species, and sites of outbreaks*

Type	Species	Site of outbreaks
A	Humans	U.S., former U.S.S.R.
B	Humans, horses	Northern Europe, U.S., former U.S.S.R.
C	Birds, turtles, cattle, sheep, horses	Worldwide
D	Cattle, sheep	Australia, South Africa
E	Humans, birds	Canada, Northern Europe, Japan, U.S., former U.S.S.R.
F	Humans	Denmark, U.S.
G	No outbreaks recognized

To date, seven immunologically distinct forms of botulinum toxins, labeled A through G, have been identified. Botulism in humans has generally been associated with A, B, E, or F toxins, whereas the C and D toxins have been identified in botulism outbreaks among various animal species, as shown in Table VIII.19.1.

Clinical Manifestation and Pathology

The onset of disease usually occurs within 12 to 36 hours of ingestion of food contaminated with botulinum toxin. Botulism typically presents with an array of distressing signs of motor nerve dysfunction, including double or blurred vision and difficulty with speech and swallowing. The unabated disease progresses to generalized paralysis and death from respiratory muscle involvement.

Diagnosis is confirmed by detecting botulinum toxin in the blood, feces, or wound site of the patient. Depending on the dose of toxin, untreated botulism carries a high fatality rate. Early treatment with antitoxin accompanied by respiratory assistance and other supportive intensive care may be life-saving.

The pathophysiology involves inhibition of release of the neurotransmitter substance acetylcholine at the neuromuscular junction, thus preventing the initiation of the electrical impulse needed for muscle contraction. Electromyography shows a characteris-

tic decrease in amplitude of the evoked muscle action potential in response to an electrical stimulus.

Infant botulism, a condition confined to babies between 2 weeks and 9 months of age, typically presents with listlessness and generalized weakness ("floppy baby") and has been shown to cause some cases of sudden infant death syndrome (SIDS). It has been associated with ingestion of various processed infant foods – honey in particular – that contain botulinum spores. First described in the United States in 1976, where the majority of cases have been reported, infant botulism has also been documented in Europe, Australia, Asia, and South America.

History

Botulism derives its name from the Latin word, *botulus* (sausage), based upon observations in the late 1700s and early 1800s by physicians in southern Germany who noted the occurrence of an unusual but frequently fatal disease following ingestion of spoiled sausage. Justinius Kerner, a district health officer in Württemberg, compiled these reports in official documents, with the result that botulism has at times been called "Kerner's disease." A similar illness seen in nineteenth-century Russia in association with eating smoked or pickled fish was labeled "ichthiosismus."

In 1896, Emile von Ermengem, student of Robert Koch and professor of bacteriology at the University of Ghent, established that the disease was caused by a neurotoxin produced by an anaerobic bacterium. This discovery emerged from his laboratory investigation of the cause of a dramatic outbreak of the disease that occurred at a gathering of musicians in a small Belgian village.

Following initial recognition of the disease in the United States in 1899, the repeated occurrence of botulism outbreaks associated with commercially canned foods led to extensive applied research in the 1920s. Sponsored by the National Canners Association, these studies established the safe food processing practices that are now in widespread use by the industry.

Geographic Distribution

A low incidence and sporadically occurring disease, botulism has been well documented in many parts of the world, as indicated in Table VIII.19.2. Although completeness of official reporting varies among countries, hence preventing reliable estimates of true distribution and incidence, it is clear that botulism is a disease with significant case fatality rates wherever reported.

Table VIII.19.2. *Reports of botulism from various countries in recent years*

Country	Average cases (per year)	Average deaths (per year)	Case fatality rate (%)
Poland (1959–69)	310	31	10
Germany (1962–71)	66	3	5
U.S.S.R. (1958–64)	47	14	29
United States (1950–73)	21	7	31
Japan (1951–9)	19	5	27
France (1956–70)	9	1	5
China (Sinkiang) (1949–57)	9	4	44
Canada (1961–7)	8	3	35
Belgium (1946–71)	4	NA[a]	–
Norway (1957–71)	4	NA[a]	–
Denmark (1958–72)	1	NA[a]	–
Hungary (1950–65)	1	1	9

[a]NA = not available.

Foods primarily responsible for botulism vary considerably among countries, reflecting differing dietary and food preservation practices. In Poland, Germany, and France, canned meats have accounted for the vast majority of outbreaks, whereas in Japan and Russia home-preserved and pickled fish have been most commonly incriminated. In the United States, low-acid canned vegetables, particularly beans, peppers, and mushrooms, have been the most common sources of botulism, with relatively few outbreaks traced to meat or fish. Most instances in all parts of the world are associated with improper home canning or pickling, though the far more serious public health problem of botulism associated with faulty commercial canning does continue to occur.

Brucellosis

Brucellosis, or *undulant fever,* is a zoonotic infection caused in humans by organisms of three main species of the genus *Brucella: Brucella melitensis,* whose natural host is the goat; *Brucella abortus,* transmitted largely from cattle; and *Brucella suis,* transmitted from pigs. Clinically, all three types cause similar infections in humans characterized by intermittent waves of fever that may persist for weeks, often with subsequent relapses and prolonged periods of ill health. The causal relationship between organism and disease was first recorded by David Bruce in Malta in 1887; the name *Malta fever,* which reflects its prevalence among civilians and British troops in that island in the nineteenth century, has been in general use for most of the present century. More recently, other *Brucella* species have been found to be implicated in the human disease, which has been shown to be widespread around the globe. The terms "Malta fever" and "Mediterranean fever" have been gradually replaced by undulant fever, or brucellosis.

Etiology and Epidemiology

The type of brucellosis originally studied in Malta and described by Bruce in 1887 is caused by *B. melitensis.* It is transmitted to human beings by consumption of milk from infected goats; occasional cases due to contamination of skin with infective material have also been observed. The mode of transmission became established only during the first decade of the twentieth century. In Malta and elsewhere around the Mediterranean littoral, the disease was endemic rather than epidemic during the nineteenth century, its highest incidence occurring during the summer months. Officers of the services, and their wives and children, appeared to be more susceptible than the lower ranks; and likewise among civilians, the professional classes suffered more than the laborers. Records going back to the mid-nineteenth century show very high annual morbidity rates, but low case-fatality rates.

Other areas traditionally affected by undulant fever due to *B. melitensis* show variations in epidemiological patterns. For example, in southeast France where sheep and goats also vastly outnumber cattle, the disease was still widespread in the 1930s. There it had more the character of an occupational disease than of a consumers' disease. The majority of cases occurred in the farming communities and resulted from direct contact with infected animals and manure, although consumption of goats' milk and of fresh cheese prepared from goats' or ewes' milk also played some part.

Present in all countries around the Mediterranean, brucellosis, caused by *B. melitensis,* is also known in India, China, South Africa, and South America. In 1918 Alice Evans suggested that the agent of the cattle disease known as contagious abortion was very similar to *B. melitensis* and might be capable of causing a similar disease in human populations. This was soon confirmed, and cases of brucellosis caused by *B. abortus* transmitted to human beings by consumption of raw cows' milk have occurred worldwide, especially in areas of high incidence of epizootic abortion in cattle.

The third major type of undulant fever is due to *B. suis.* As the name suggests, its natural host is the pig, and the human variety of the disease attacks mainly slaughterers and packers infected by handling contaminated carcasses. In most cases, *B. suis* invades the human host through skin lesions, although airborne infection is also thought to be possible. The disease in pigs, and in human beings, is far less common than its counterparts in goats and in cattle, and therefore, undulant fever in human beings due to *B. suis* has been observed mainly in hog-raising areas of the American Midwest, Brazil, and the Argentine. Sporadic cases of undulant fever in

Alaskan Eskimos have resulted from a type of *B. suis* infecting wild reindeer.

Distribution and Incidence

The three main types of *Brucella* infection in human populations are widespread around the globe in areas dependent in one way or another on those domestic animals that are the main hosts of the respective organisms. Undulant fever caused by *B. melitensis* follows the distribution of goats all along the Mediterranean littoral (Malta or Mediterranean fever) as well as in parts of China, India, South Africa, and South America, although pasteurization of milk has substantially reduced its incidence during the second half of the twentieth century. The same applies to *B. abortus* infections. Contagious abortion of cattle, and with it the disease in humans, has been almost completely eradicated from several countries in northern Europe where the incidence is now very low. The true incidence of *B. abortus* is difficult to assess because it has low pathogenicity and often causes latent infections.

In the United States, brucellosis is still not uncommon, the causative organism being, in order of importance, *B. abortus, B. suis,* and lastly *B. melitensis.* Most cases occur sporadically, although occasional minor outbreaks have been reported. Also, the situation is constantly changing as a result, in part, to various eradication programs.

Bruce's discovery of the causal agent had no immediate impact on the incidence of Malta fever; only after identification of the mode of transmission was there a dramatic fall in number of cases, first in the British armed services in Malta where supplies of goats' milk to the troops were curtailed by 1906. In an island where goats are the almost exclusive source of milk, control of the disease in the civilian population was a much greater problem. It was achieved, in Malta and elsewhere, only after World War II, when pasteurization became generally accepted.

Immunology

The failure of the immune systems of both animals and humans to deal quickly and decisively with *B. melitensis* and *B. abortus* accounts for the persistence of infection and thus frequent cases of long duration. Evans, who first drew attention to the similarities between the two organisms, contracted a laboratory infection with the disease in 1922 and suffered recurring episodes of debilitating undulant fever, alternative with periods of apparent recovery, for more than 20 years (in spite of this she lived, after final recovery, until the age of 94).

B. abortus, in particular, can give rise to latent infection, leading to latent immunity, which occurs more frequently in persons exposed to milk infection over a period of time than in those suddenly exposed to heavy doses of infective material. This may help to explain the low rate of clinical disease in veterinarians, who as a group show immunologic evidence of exceptionally high levels of response to erstwhile infection.

Vaccination is possible against *B. abortus* in cattle and against *B. melitensis* in sheep and goats, but in human beings it is still at an experimental stage. Some knowledge of the immunogenic constituents of the bacillus has become available since the 1960s, but the animal vaccines developed thus far are too toxic for use in humans. In Britain a free calf vaccination service was introduced by the Ministry of Agriculture in 1962.

Clinical Manifestations and Pathology

Undulant fever due to *B. melitensis* is essentially a septicemia or blood poisoning characterized by an irregular temperature curve with intermittent waves of fever, usually lasting for 10 to 30 days. Although case fatality rates are low, the protracted character of many cases makes it a serious and debilitating illness. Its duration varies; it may be only a few days, or it may last as long as a year. Subsequent relapses may occur over a period of several years, accompanied by general ill health alternating with periods of apparent recovery. Symptoms included weakness, muscular pain, nocturnal sweats, anorexia, chills, and nervous irritability. Recorded postmortem appearances include congestion and enlargement of the liver and hypertrophy of the spleen; cultures taken from both these organs have been found to be positive for *B. melitensis* in 100 percent of cases.

B. abortus appears to be less capable than *B. melitensis* of producing clinical cases in humans, but more likely to give rise to latent infection, especially in veterinarians. Once established, however, the clinical disease seems to develop in similar fashion. It lasts an average of 13 weeks and may become chronic. *B. abortus* can also cause a short influenza-like illness, and sometimes a persistent low intermittent fever. In rare cases, infection in pregnant women has been followed by abortion.

Undulant fever caused by *B. suis* is clinically similar to the above types.

History and Geography

Among the fevers plaguing the Mediterranean peoples since antiquity, a low type with regular remis-

sions or intermissions has been recorded since the time of the Hippocratic writings. Its geographic origins are indicated by many synonyms of which the best known are Malta fever and Mediterranean fever, although other variants involve Naples, Constantinople, Crete, and Gibraltar. A differential description of Malta fever as distinct from other fevers was first given by J. A. Marston in 1863; he called it "gastric remittent fever" and described several cases including his own ("a mild case of gastric remittent fever"). In 1887, Bruce, a surgeon attached to the Malta garrison like Marston before him, recorded his discovery of a small microorganism in the spleen of fatal cases. He proceeded to establish its causal role and called it *Micrococcus melitensis,* although in the 1920s it was changed to *Brucella melitensis* in his honor. Returning from duty in Malta, Bruce taught at the Army Medical College at Netley; among his students was Matthew Louis Hughes who, posted to Malta in 1890, enthusiastically embraced Bruce's interest in the prevailing fever. He wrote, both alone and in collaboration with Bruce, several papers dealing with the disease during the next decade, until he died under enemy fire while tending casualties in South Africa at Ladysmith in December 1899. It was Hughes (1897) who published a definitive clinical description of Malta fever, which is still quoted today as a model of its kind.

Since the time of Bruce, and because of the presence of British troops in the island, the disease and its epidemiology have received particular attention in Malta, culminating in the work of the British Mediterranean Fever Commission, which began reporting in 1905. During this work, Themistocles Zammit was able to establish the presence of the disease in local goats and the role of goats' milk in transmitting the disease to the human population. The results of his research caused the British army and navy to prevent troops from drinking goats' milk; within a year the disease had all but disappeared from the British forces in Malta (see Figure VIII.20.1). As already mentioned, for social and economic reasons control of the disease in the civilian population proved far more difficult to achieve; only the advent of pasteurization could eventually solve this problem, although it should be noted that the disease in goats is still resisting control.

B. melitensis infections had been observed and described in the late 1800s, following Robert Koch's epoch-making demonstration of the methods for isolating and identifying specific disease agents. It was Bruce, however, who isolated the causal microorganism in 1887. Nearly two more decades were to elapse
Figure VIII.20.1. Graphs illustrating the dramatic reduction in the incidence of brucellosis in the British garrison in Malta from 1905 to 1907, following the ban on the use of goat's milk. (From D. Bruce 1908.)

before the goat was identified as the natural host of *B. melitensis* and the mechanism of transmission to humans became clear. In the case of *B. abortus* infections, the historical sequence of events was rather different. The disease in cattle had been described by several authors during the first half of the nineteenth century. In the context of the times some considered it contagious, others not. Its transmissibility was demonstrated in pregnant cattle in 1878; and just before the turn of the century Bernhard Bang in Copenhagen was able to isolate and identify the causal agent. It was only in 1918, however, that Evans noted a close morphological and biochemical similarity between *B. melitensis* and *B. abortus;* within a few years *B. abortus* had been shown to be pathogenic for human beings and to give rise to cases of undulant fever in many areas around the world where raw cows' milk rather than goats' milk was consumed, and where epizootic abortion of cattle was a common occurrence.

Last of the major types of undulant fever to attract attention was that caused by *B. suis.* The first case to be diagnosed appears to have been in the United States in 1922, although even then the identity of the agent was not immediately recognized. Clinically (and bacteriologically) the disease is similar to

the two other major types although it is less extensively distributed in either pigs or humans. *B. suis* infection of swine first began to cause concern in the large hog-raising areas of the midwestern United States in the 1930s. The disease has since been reported to be present in a number of other countries, but cases appear to be mostly sporadic, with only a few recognized outbreaks in the United States, and one in Denmark in 1929.

VIII.21

Bubonic Plague

Plague has often been used as a synonym for *pestilence,* which refers nonspecifically to any acute epidemic accompanied by high mortality. But the term also refers to the recurrent waves of bubonic plague punctuating European history from 1348 to 1720. Bubonic plague epidemics occurred when *Yersinia pestis,* a rodent disease, was communicated to humans through the bite of infected fleas. Humans have exceedingly poor immune defenses to this organism, and within 6 days of infection most victims develop a grossly swollen lymph node, a bubo, signifying the body's attempt to contain and arrest multiplication of *Y. pestis.* On the average, around 60 percent of those infected died within a week after the appearance of the bubo. Thus bubonic plague brought high and dramatic rates of mortality when it extended into human communities.

Distribution and Incidence

With the historically ironic exception of western Europe, *Y. pestis* today occurs naturally throughout the world among the wide variety of rodents and lagomorphs (i.e., rabbits and related species). Some of the more than 300 rodent species affected are relatively resistant to disease from *Y. pestis* and can survive and reproduce while technically infected by the organism. *Y. pestis* infects new animals either because fleas transmit it or because the microbe is shed and survives in the protective microclimate of warm rodent burrows. Some literature refers to this part of the plague cycle as "sylvatic" plague, or "enzootic" plague.

The "disease," then, is not always a disease, and it is ecologically very complex. Indeed, it is occasional ecological change or disturbance that brings susceptible rodents into contact with *Y. pestis.* Historically the most important of these rodents is considered to be *Rattus rattus,* the common, commensal black or brown house rat, that literally "shares man's table." When infected by *Y. pestis* these susceptible animals die quickly of an overwhelming infection, with blood levels of the microbe so high that their rat fleas imbibe large numbers of organisms.

The oriental rat flea *Xenopsylla cheopis* and the human flea *Pulex irritans* are thought to be historically important arthropod vectors transmitting "epizootic" plague to humans. *X. cheopis* is an effi-

cient vector because a bend in its feeding tube, or proventriculus, creates a location for growth of *Y. pestis,* such that the flea becomes "blocked," unable to swallow a full blood meal. Attempting to dislodge this bolus or wad, the flea infects new mammalian hosts. Other fleas clear *Y. pestis* more quickly, so that only the excreta of the flea, or the crushing of its body, will infect. *P. irritans* had an important historical role because it is a flea that feeds indifferently upon both humans and the common house rat.

Human plague usually arises after an epizootic plague has produced high mortality among susceptible rodents, when infected fleas, deprived of rodent hosts, begin to feed on humans. Although some historians speak of "endemic plague," no such phenomenon can exist. Humans do not normally carry the *Y. pestis* organism, and thus cannot infect fleas or otherwise pass the disease to new hosts. For human communities, plague is an acute infection ultimately derived from infected rodents.

In areas of the world today where plague routinely infects resistant rodents, ecologists and public health officials try to monitor the passage of the disease to susceptible species. In these regions – the American southwest, south central Eurasia, and Southeast Asia – humans who are likely to encounter infected animals or their fleas must be revaccinated often, for human immunity to *Y. pestis* is short-lived.

Immunity

Yersinia pestis was once called *Pasturella pestis,* a name that has persisted because it was used in much of the older, widely consulted, historical literature about European plagues. In 1971, the name was changed in part to honor Alexandre Yersin, a French microbiologist and student of Louis Pasteur, who, working in Southeast Asia during the late nineteenth century outbreak of plague, successfully cultured the microorganism.

Other members of the *Pasturella* family are rarely pathogenic in humans and do not provide cross-immunization with *Y. pestis.* Two organisms, however, have been added to the *Yersinia* group: *Yersinia pseudotuberculosis,* which causes a mild respiratory infection, and *Yersinia enterocolitica,* which causes a gastroenteritis that can be life-threatening in very young children. Infection with either of the other *Yersinia* species establishes some cross-immunity with *Y. pestis,* because they have shared antigens.

The antigens, or components of the organism, which stimulate an immune response, can vary in virulence, such that vaccines can be created that are very mild plague strains. *Y. pestis* causes severe human disease when it contains an envelope protein facilitating its entry into cells and other antigens that impede the body's white blood cells' attempt to kill infected cells. *Y. pestis* can liberate both endotoxins and exotoxins, leading to circulatory collapse. These combined activities stimulate, and can defeat, both cellular and humoral immunity to plague, and explain why the disease can carry extremely high-case fatality rates. With a typical virulent strain of the bacterium, over 60 percent of all infected humans untreated will die within 10 days of infection. If the organism reaches the lungs, there is even less chance the person will survive. A victim whose lungs become infected during the course of bubonic plague can cough out highly virulent, encapsulated organisms, which are rapidly absorbed on the mucous membranes of any nearby, susceptible person. This can lead to "primary" pneumonic plague in which the bubonic plague of disease is bypassed and spreads directly from human to human. When this has occurred, case fatality rates have been close to 100 percent.

Clinical Manifestations and Diagnosis

Once a human is infected with *Y. pestis,* the organism rapidly replicates at the site of the flea bite. This area can subsequently become necrotic, where dead tissue blackens to produce a carbuncle or necrotic pustule often called a "carbone" in many historical accounts. But in many cases the progress of infection is too rapid for this to happen. The lymphatic system attempts to drain the infection to the regional lymph node, where organisms and infected cells can be phagocytized (ingested by macrophages and white blood cells). That node becomes engorged with blood and cellular debris, creating the grossly swollen bubo. Because infected fleas usually bite an exposed area of the body, often a limb or the face, the location of the subsequent bubo is often visible. Frequent sites are the groin, the axilla, or the cervical lymph nodes.

But drainage can occur to an internal lymph node, or the infection can proceed too rapidly for the lymphatic system to effect a defense. In the latter case, "septicemic" or blood-borne plague has occurred, seeding the organism quickly in many organs. Victims of septicemic plague become rapidly moribund and often develop neither eschar nor bubos, although the more usual clinical course is the formation of a bubo, described in historical accounts as reaching the size of an egg, orange, or even grapefruit. The area is inflamed, boggy or doughy to the

touch, and exquisitely painful. Patients often demanded that a physician or surgeon incise and drain the bubo, a process that could have liberated infective organisms.

The bubo often appears within 4 to 6 days after infection, and because of the multiple ways in which *Y. pestis* is virulent to humans, disease progresses quickly after this point. In about 5 to 15 percent of the cases the lungs are infected, but more often a high fever with headache and mental disorientation are characteristic symptoms. Occasionally circulatory collapse and hemorrhagic sepsis occurs, blackening the surface of the body. Death typically occurs within 4 to 6 days after the onset of symptoms. In the past, a diagnosis of plague might have been made on the basis of this rapid clinical progression from health to death alone, although clearly this could have been caused by countless other conditions. But the acute formation of a bubo, visible in 60 percent of bubonic plague victims, is pathognomonic of plague, meaning that no other disease commonly causes this reaction.

History and Geography

Most of the historical literature of plague identifies three lengthy time periods when bubonic plague repeatedly assaulted human communities. The first known cycle of widespread human plague occurred during late Greco-Roman antiquity. Byzantine historian Procopius of Caesarea described the acute lymphadenopathy well: "Those in whom the bubo grew to the largest size and suppurated while ripening usually survived, no doubt because the malignant property of the already weakened boil was annihilated" (quoted in Biraben and Le Goff 1975). Procopius described the devastating epidemic of 542 in Constantinople, which was dubbed the "Plague of Justinian" because of his dramatic account. The wave of epidemic reached western Europe by 547, which was also powerfully described by Bishop Gregory of Tours. Virulent, epidemic plague recurred throughout the Mediterranean for the next 200 years.

The second cycle of plague, at least in its early stages, is often referred to as the Black Death and is treated in this work as a separate entry, for certainly it is the most heavily studied of the plague cycles. Beginning about 1300, the cycle is generally considered to have ended at about 1800, although the ending date can be disputed. This manifestation of the disease took a very heavy toll in the Middle East as well as in Europe and appears to have also invaded Asia. It has held a special fascination for Europeans,

however, and any bibliography assembled on important European works dealing with this second cycle would contain several hundred listings.

This is the case because the plague has been viewed as pivotal in so many areas of historical inquiry. Surely it was to some significant extent responsible for the stagnant demographic performance in Europe prior to the mid-eighteenth century, and surely, too, the plague stimulated new and important public health efforts in the great urban centers of Europe. In addition, the continued presence of the disease in Europe presents a mystery because at no other time in history was the disease able to survive in northern Europe without constant reintroduction from the Middle East. Finally, over the course of a half millennium the plague was the source of inspiration for numerous literary works, and more than a few on medicine.

Historians frequently credit public health measures devised during the fifteenth through the seventeenth centuries to combat the plague with some mitigation of the disease and its ultimate disappearance. However, in the light of modern medical knowledge of bubonic plague, it is clear that such measures — quarantine of well individuals, isolation of the sick and their household contacts, large pesthouses or lazarettoes, and even the elaboration of a theory of contagion — would have little effect on its course.

Certainly the most important questions about these 500 years of plague in Europe have to do with its disappearance and demographic consequences. In the latter case, it is important to realize that much of the mortality credited to the plague was due to its indirect impact, rather than infection. When an epidemic struck, panic ensued and this alone, by bringing an end to normal sanitary and social services while precipitating headlong flight, would have taken a significant number of lives, as would isolating both ill and well in hospitals and pesthouses. Chief among these victims would have been the very young, the very old, and the economically disadvantaged.

Beginning in the early eighteenth century, Europe was increasingly protected from plague invasions from Ottoman lands by a staunch Austrian barrier. Manned by over 100,000 men and featuring numerous quarantine and checkpoint stations, this famous sanitary cordon limited both trade and human traffic, which may have helped to spare Europe from the third or most recent cycle of the plague that seems to have had its beginning in central Asia about the middle of the eighteenth century (Benedict 1988).

From there the plague spread to the Yunnan region of China and simultaneously to northern India and, then, aided by rapid sea transportation, radiated globally from Hong Kong, Bombay, and Calcutta.

But if Europe was bypassed, the Americas were not. Rather, along with Australia and eastern Africa, North and South America were infected for the first time, and by the early years of the nineteenth century some regions of the Western Hemisphere were experiencing relatively minor, but nonetheless panic-inspiring, epidemics. Those that struck San Francisco are among the best documented in this pandemic cycle, although the disease killed millions in India and in African countries.

If the Americas and Australia did not suffer greatly from this third cycle of the plague, one consequence was that the disease did establish itself among the rodents and lagomorphs of these New Worlds. In North America the geographic extent of the plague has subsequently widened each year, and sporadic cases of human plague claim 8 to 15 victims annually despite the effectiveness of therapy with antibiotics such as tetracycline and streptomycin. In the Americas, as elsewhere, smoldering enzootic foci of plague demand a constant global effort in surveillance and control.

Carrión's Disease

Carrión's disease is an infectious disease caused by a microorganism of the genus *Bartonella*. Two species have been described, the *bacilliformis* type and the *verrugiformis* type. These bacteria are parasites of human red blood and histiocytic cells. The *bacilliformis* type produces two stages of the disease, a febrile acute hemolytic anemia known as "Oroya fever," followed by a granulomatous mucocutaneous eruption known as "Verruga Peruana." The *verrugiformis* type produces only the verrucose stage.

Etiology and Epidemiology

B. bacilliformis are pleomorphic bacteria, well stained with the Romanovsky stain. In the red blood cells and in the histiocytic cells, the bartonella assumes a rodlike (bacillus) or coccoid shape, 1 to 3 microns in size (Figure VIII.22.1). The electron microscope shows the flagella of the bartonella. It grows well in liquid and in semisolid blood media. The human bartonella is closely related to the animal bacteria *Hemobartonella, Eperythrozoon,* and *Grahamella.*

In 1913 Charles Townsend identified the sandfly *Phlebotomus verrucarum* as the insect vector of the disease. The female is the only transmitter, and the transmission occurs during the night. Carrión's disease is a rural disease, and, like yellow fever, it does not need a human reservoir because the bartonella lives in the small animals in the area.

Immunology (Experimental Transmission)

Between 1948 and 1950, the author and collaborators conducted a series of experimental transmission on human volunteers. Thirty healthy men were inoculated with parasitic blood through subcutaneous, intramuscular, and intravenous routes. None of the volunteers developed the disease, and the blood culture remained negative after more than 120 days. Another four volunteers who had been splenectomized for other reasons were infected with the same inoculum. All of them developed the disease, with bartonellas evident in the erythrocytes and blood cultures positive. Antibiotics halted the parasitism, and the volunteers recovered immediately.

After our experiments, three of the former healthy volunteers were exposed to the bite of the insect in the verrucogenous zone. None of them developed the disease. They appeared to have developed immunity as a result of the previous live inoculation. Later on, 10 workers out of a group of 100 were inoculated with attenuated live bartonellas in order to test a vaccine against the disease. None of them developed any symptoms, and the blood cultures remained negative. Meanwhile 45 of their companions who were not vaccinated developed the disease.

Our conclusions were as follows: First, the natural infection of the bartonellosis occurs only through the sandfly vector. Second, the inoculation from a sick person to a healthy person does not effect transmission of the disease. Rather the inoculation of a live germ appears to produce immunity. Third and last, direct inoculation of the *B. baciliformis* into a splenectomized patient produces the disease, with bartonellas evident within the erythrocytes and blood cultures testing positive.

Clinical Manifestations

There are two stages in Carrión's disease: the "anemic stage," characterized by an acute febrile anemia with bartonellas in the red blood cells; and the "verrucose stage," characterized by a disseminated verrucous eruption in the skin and mucous membranes. The anemia is of the macrocytic and hypochromic types, and, in severe infection, erythrocyte levels plummet to less than a million in a few days. The parasitic index in these cells reaches 80 to 100 percent.

The onset is abrupt, with fever, chills, and generalized osteal pain. Bone marrow hyperplasia, reticulocytosis, and jaundice are observed, with an increase of bilirubin in the blood and urine. The blood culture is positive, even in the earliest days of the anemia. The verrucose stage is characterized by a diffuse generalized granulomatous eruption on the mucocutaneous integument. Usually this phase is separated from the anemic stage by an asymptomatic interval of several months to a year or more. There are several types of eruption. The first, called the "miliary form," is a profuse, homogeneous, small intradermic eruption, which resembles multiple disseminated hemangioma. In the second, the "nodular form," nodules appear primarily on the arms and the legs; they can be deep in the dermis or prominent on the surface of skin; some are ulcerated and bloody. The third type, the "mular form," has pseudotumoral lesions ½ to 1 inch in diameter which are seated in the deep tissue. The eruption become painful only when a secondary infection develops or with increased bleeding (Figure VIII.22.2A–C).

In the *verrugiformis* type, the clinical picture is that of a diffuse granulomatous eruption similar to the *baciliformis* type, but less intense. One special feature of the *verrugiformis* type is that the eruption can recur two or more times during a lifetime; some of these patients of endemic areas become latently infected.

Pathology

The main pathogenic feature is the intracellular reproduction of the bartonella inside the cytoplasm of
Figure VIII.22.2. Verrucose eruptions: (top) miliary form, diffuse and generalized; (middle) nodular form, two intradermic nodules; (bottom) mular form. In the pseudotumoral eruption (bottom), the granulomatous lesions are seated in the deep tissue; sometimes the eruption becomes painful when a secondary infection develops or when bleeding increases. (From O. Urteaga-Ballón and J. Calderón. 1972. *Dermatología Clínica,* by permission of the author.)

Figure VIII.22.3. Intracellular reproduction cycle of the *Bartonella bacilliformis* (top) the cytoplasm of a histiocytic bone marrow cell, and (bottom) the endothelial cells of a lymph node. (From O. Urteaga-Ballón and J. Calderón. 1972. *Dermatología Clínica,* by permission of the author.)

the endothelial cell. Microscopically these cells are swollen with tremendous numbers of bacteria, which push the nucleus of the cell eccentrically (Figure VIII.22.3A,B). The pressure resulting from the multiplication of the bartonellas causes the cell membrane to rupture, releasing millions of bacteria,

which then start a new intracellular colonization in other endothelial cells. Also, the bartonellas act as parasites on the peripheral erythrocytes, inducing the anemia syndrome.

Histopathological study of the anemia of Carrión's disease reveals massive hyperplasia of the phagocytic reticuloendothelial cells in the spleen, lymph nodes, liver, and bone marrow. Erythrophagocytosis is responsible for the anemia. The macrophages initiate the destruction of the parasitized erythrocytes. The extraordinary phagocytic hyperplasia characterizes the cellular immunoresponse of this disease. The macrophages contain, in their cytoplasm, 2 to 10
Figure VIII.22.4. Erythrophagocytosis of parasitized erythrocytes in (top) peripheral blood; and (bottom) spleen. Bottom panel, showing extraordinary phagocytic hyperplasia, and macrophages containing more than 10 erythrocytes, illustrates the mechanism responsible for the anemia. (From O. Urteaga-Ballón and J. Calderón. 1972. *Dermatología Clínica*, by permission of the author.)

erythrocytes with bartonellas (Figures VIII.22.4 A,B). Severe cases show thrombosis and infarction in the spleen, centrolobular necrosis of the liver, and lung congestion.

At the end of the anemia stage, an immunoresponse is mounted against the active basilar bartonellas, which then are converted to the resistant coccoid stage. This is the most dangerous period of the disease. The "anoxemia" is extremely severe, with the red blood cell count falling to below 1 million. In at least 30 percent of the cases, the untreated patient dies after physical collapse. Another 40 percent die from secondary complications. The nonspecific immunoreaction decreases to the "anergic stages," but some quiescent chronic infection in the patient will exacerbate to an acute stage. The most frequent complications are salmonellosis, tuberculosis, malaria, and amebiasis in carrier cases.

From the clinical point of view, the patient has recovered. He or she appears to be normal, but the bartonellas still live in the adventitial cells surrounding the subcutaneous capillaries. Blood and bone marrow cultures are still positive. There is an unstable balance between the intracellular bacteria and the immune response. In time, when this equilibrium breaks down, the bartonellas start a new cycle of reproduction in the histiocytes. The second stage of the disease appears as a disseminated verrucose eruption. This histiocytic proliferation, with the in situ presence of the microorganism, is a clear example of cellular immunity. Sometimes the histiocytic proliferation is so great that the lesion appears like a tumor, a histiocytic lymphoma.

The histopathology of the granulomatous phase shows an angioblastic proliferation with large, pale histiocytes and endothelial cells, some filled with coccobacillus bartonellas. The rupture of these cells results in the dissemination of the bartonellas through the skin, with the appearance of new verrucose eruptions. The eruptive phase tends to heal spontaneously without scars.

Diagnosis and Treatment

The diagnosis is made upon a finding of bartonellas within the red blood cells in acutely anemic patients. Blood and bone marrow cultures are the most useful diagnostic test for carrier cases in the endemic zones. The eruptive phase is easily identified with some clinical experience, but surgical biopsy is required to show the bartonella inside the histiocytes in the Giemsa stain. The cultured tissue is positive.

Before the advent of antibiotics the mortality rate from Carrión's disease was very high. In acute severe cases, 30 to 70 percent of patients died in the anemic phase, either directly from the bartonella infection or from secondary complications. Antibiotics have a powerful antibactericidal effect; the anemia is arrested, and blood regeneration starts immediately. Until now, chloromycetin has been the most effective antibiotic in the anemic stage, because it is also specific for salmonellosis, the most serious complication. Streptomycin is the ideal antibiotic during the eruptive phase. In 4 to 5 days, the eruption

shrinks and the verrucose nodes subside without any scar.

According to our experiments a specific vaccine must be prepared with attenuated live bartonellas. However, it must be kept in mind that the live germ vaccine will produce the acute anemic phase in splenectomized patients.

History and Geography
Carrión's disease was probably depicted thousands of years ago in the pottery of the ancient Peruvian civilization. The disease flourished jointly with malaria and cutaneous leishmaniasis in the inter-Andean valleys of western South America. The focus of the endemic transmission is in Peru, although some cases exist in Colombia and Ecuador. The endemic areas of the disease are confined to rural areas in narrow valleys where the elevation is 2,100 to 7,500 feet.

The disease in both its forms was probably noticed and described during the Spanish Conquest. It attracted worldwide attention only in 1870, when an epidemic of the acute febrile form of the disease killed thousands of workers during the construction of a railroad from Lima to Oroya. In 1885, Daniel Carrión, a Peruvian medical student, contracted the disease by self-inoculation with verruga and died of Oroya fever; thus establishing the connection between the two conditions. In 1909 Alberto Barton, a Peruvian physician, described the presence of live organisms in the red blood corpuscles of victims of Oroya fever, and a decade later these findings were confirmed by R. P. Strong and his colleagues (1913). They, however, felt that despite the work of Carrión, Oroya fever and verruga peruana were caused by two distinct agents. The controversy was resolved by H. Noguchi and T. Battistine (1926), who reported the pair to be different manifestations of the same disease. M. Hertig in 1942 definitively described both the disease and its vector.

VIII.23
Catarrh

Catarrh is now regarded as inflammation of the mucous membranes, especially of the air passages, together with the production of a mucoid exudate. Simple though this definition is, it bears evident traces of the history of the disease.

History
The name derives from Hippocrates' use of *katarrhoos,* "a flowing down" of humors from the head. In that use, the term was probably not yet technical, and so akin to such a Latin word as *defluxio.* In commenting on Hippocrates, however, Galen distinguishes from a general "downflowing" a more precise meaning of "catarrh" – that is, a defluxion from the head *to the lungs,* producing a hoarseness of voice and coughing.

The Greek word became *catarrhus* in Latin and a technical term with, increasingly, Galen's meaning attached to it. Although it is tempting to identify *catarrhus* and catarrh, we have to remember that for Galen and doctors down to the seventeenth century, *catarrhus* could not be defined without reference to Galenic pathology. *Catarrhus* was a process in which the brain, preternaturally affected by cold, produced a qualitatively unbalanced humor in excessive quantity that passed down through the pores in the palate and by way of the trachea to the lungs. This unspoken assumption behind the name is paralleled by that behind the modern definition: We make the assumption that the "inflammation" of the definition is due to infection by an organism. It is the

identity of the organism that gives us the ontology of the disease. A similar situation existed in all historical periods; that is to say, definitions of disease have always carried with them some part of a theory of causation. (Purely empirical accounts of disease are descriptions of symptoms.) To put it another way, disease in Western medicine has traditionally been seen as disordered function. But function is a process, and knowledge of it depends on knowledge of how the body works.

In the eighteenth and nineteenth centuries, there were a number of different so-called systems of physiological knowledge, in each of which what was indicated by a single disease-name was seen differently. For example Franciscus de Le Boë (F. Sylvius), as an iatrochemist, divided catarrhs into groups distinguished by the chemical qualities of the humor produced. As a hydraulically inclined mechanist, Hermann Boerhaave thought of catarrh in terms of obstruction of the small vessels, which caused swelling. Indeed, his most frequent use of the term was as an adjective to describe angina. "Angina" was any difficulty in breathing, and catarrhous angina was the result of swollen membranes. Although membranes also played an important part in the new tissue-pathology of early nineteenth-century Paris, the Parisian view of the body, and therefore disease, was again different. Marie François Bichat had stressed the sympathies between membranes and their ability to secrete and imbibe the fluids of the cavity they lined. To this were added the new techniques of physical diagnosis by percussion and stethoscope.

Catarrh again became a disease of membranes, of excessive secretion, and of fluids moving audibly in their cavities. Some Bichatian sympathy of membranes seems to lie behind the early nineteenth-century notion of a catarrh of the urinary bladder. This opinion is recorded in R. Hooper's *Lexicon Medicum,* which also distinguishes sharply common catarrh, which is a cold and particularly a cold in the head, from epidemic catarrh, which is identified with influenza. The modern meaning is derived from the former.

VIII.24
Cestode Infections

Cestodes or tapeworms are a class of flatworms in the phylum Platyhelminthes. The adult stages of four species and the larval stages of two are important parasites of humankind. Several other species, most of which normally parasitize other vertebrates, can also cause human disease.

K. David Patterson

VIII.25
Chagas' Disease

Chagas' disease (American; trypanosomiasis, trypanosomiasis cruzi) is an illness of the Americas which can take the form of either an acute, febrile, generalized infection or a chronic process. The cause is a protozoan, *Trypanosoma cruzi,* which is harbored by both domesticated and wild animals. When it is transmitted to humans by insects, this essentially untreatable disease is associated with fever, edemas, and enlargement of the lymph nodes and can cause dilation of parts of the digestive tract leading to megacolon and megaesophagus as well as cardiac enlargement and failure. In fact, Chagas' disease is the leading cause of cardiac death of young adults in parts of South America.

Distribution and Incidence
The disease, which probably had its origins in Brazil, is limited to the Western Hemisphere, with heavy concentrations in Brazil, Argentina, Chile, and Venezuela. Cases are also reported in Peru, Mexico, and most other Central and South American countries along with the Caribbean islands and the United States.

Epidemiology and Etiology

T. cruzi, a member of the class Mastigophora, family Trypanisomidae, has over 100 vertebrate hosts including dogs, cats, armadillos, opossums, monkeys, and humans. Unlike other trypanosomes it does not multiply in the bloodstream, but rather lives within various tissues of the host and multiplies by binary fission. It is transmitted by reduvid bugs that ingest the trypanosome during a blood meal from a vertebrate host. The trypanosomes in turn develop in the intestines of the bug, and, while they neither enter its saliva nor are injected when the bug bites, they do pass out in its feces.

Thus the infection is transmitted when the infected insect breaks the skin to draw blood and then defecates following its meal, thereby contaminating the site of the bite. Infection can also occur when the feces is rubbed into the eyes or reaches the mucosa of the mouth, and possibly through contaminated foods as well. The trypanosomes can also be transmitted via the placenta, maternal milk, and blood transfusions.

The insect vector, which is the principal means of transmission, flourishes in huts in poor rural areas where it lives in cracks in the walls and in thatching and mats used as roofing. Cases may be few in spite of large numbers of infected bugs, if the bugs are not domesticated – that is, adapted to living in houses.

Clinical Manifestations and Pathology

There are a number of different forms of the disease, which will be considered separately. In all cases, however, the prognosis is poor because there is no effective treatment. The acute form ends in death in 10 percent of the cases, and although the chronic form may last from 10 to as long as 40 years, few individuals remain asymptomatic for life. Chronic cardiac disease as well as megacolon and megaesophagus all can shorten life.

The acute form, occurring primarily in young children, is most commonly a febrile illness; other symptoms are normally those of generalized lymph node enlargement as well as enlargement of the liver and spleen, and edema of the face. When death occurs, it is generally due to acute inflammation of the muscular walls of the heart (myocarditis) or to a complicating bronchopneumonia.

The latent form of the disease is seen in patients who have recovered from the acute form, as well as others who have harbored the parasite but have not displayed symptoms of the illness. Multiple examinations, however, often reveal changes in esophageal and peristaltic motility as well as electrocardiographic changes.

The subacute form of Chagas' disease is normally seen in young adults who suffer a rapidly progressive cardiac failure.

The chronic form of the illness is the leading cause of death in endemic areas. The heart becomes tremendously enlarged, and in about 30 percent of the cases, parasites may be found within pseudocysts in muscle fibers. Although survival may be as long as 5 years, death usually intervenes within 6 to 12 months.

The digestive form of Chagas' disease presents as megacolon or megaesophagus in endemic areas. The afflicted suffer the degeneration and diminution of nerve cells in the muscular layers of these organs, leading to their enlargement. The condition by itself is normally not fatal, but patients often experience difficulty in swallowing because of the enlarged esophagus, and constipation that normally accompanies megacolon. These difficulties in turn can promote other illnesses that are life-threatening.

The congenital form of the disease has long been known. The fetus is infected transplacentally, and the result can be premature fetal death or a newborn with Chagas' disease in its acute stage.

History and Geography

Chagas' disease is unusual in that its etiological agent, vector, and the major features of its epidemiology were described before the first human case was ever reported. All this was done by Carlos Chagas, a Brazilian physician, in a series of publications beginning in 1909, with the result that the disease appropriately bears his name.

The illness, however, is not new. Studies undertaken of mummies from the Tarapaca Valley in northern Chile have revealed megacardia, megacolon, and megaesophagus in a number of individuals who lived more than 2,000 years ago, and although the etiological agent was not discovered, the valley today is an endemic area of Chagas' disease (see Figure VIII.25.1).

According to L. J. da Silva (1985), nineteenth-century visitors to Brazil reported instances of megaesophagus and the presence of the cone-nosed bug vectors of Chagas' disease. Most interesting is the case of Charles Darwin, who wrote that he was bitten by a huge *Triatoma* carrier of the infection while in South America. Frank Burnet (1962) reported that Darwin's mysterious chronic illness, from which he always suffered, dated from this time, and cited a distinguished protozoologist who believed that Darwin was infected with Chagas' disease.

The disease, although similar to the African form

and lassitude in the legs and feet, dyspnoea, palpitation of the heart, headache, febrile pulse, somnolence, pica, and suppression of the menses. (Sydenham 1850)

The actual clinical entity was only defined later, by Friedrich Hoffmann in 1731.

After centuries of nosologic confusion, chlorosis was associated almost entirely with Caucasian girls encountering puberty. Still, from clinical observations alone, the etiology remained obscure. Inconsistencies abounded. Not all young women developed the disease at the age of menarche. It struck the rich as well as the poor. Some, but not all, suffered a morbid appetite termed pica (the consumption of stones, clay, chalk, and other substances of no nutritional value). Even into the nineteenth century, confusion permeated medical thinking about chlorosis. The ailment has been likened to a lion in elephant grass; all physicians heard its roar, but none could delineate it with absolute certainty. S. Ashwell opened his lengthy analysis in 1836 by saying. "Disease of menstruation, *especially chlorosis and amenorrhea,* are, in this country, of very frequent occurrence.... They are too *greatly neglected in their early stages, when they are most curable; and lastly, there is by no means an agreement of professional opinion as to their exact nature.*"

By the time of William Osler later in the century, medical opinion was far more confident. The clinical features of chlorosis had been distilled to the point that in many instances the condition could be "recognized at a glance" (Osler 1893).

Etiology and Treatment

Developments in laboratory medicine brought physicians to something approaching consensus regarding the pathophysiology of chlorosis. By the mid-nineteenth century, reasonably accurate methods were available to determine the number of red blood cells and their hemoglobin content. With this it became apparent that the *sine qua non* of chlorosis was an iron deficiency anemia. In the minds of many physicians, chlorosis could now be separated from earlier mimics such as love-sickness, hypochondriasis, and neurasthenia.

The natural history of chlorosis, whether treated with iron or not, remained a matter of dispute. In part, this undoubtedly related to frequent misdiagnoses. Using iron, some physicians reported that a single cure was lasting (Thomson 1886; Faber and Gram 1924). For others the disease progressed to phthisis, many cases of which probably were tuberculosis as such, rather than chlorosis. After iron became a standard treatment, there was general agreement that the disease recurred when treatment was stopped, but responded when iron was reinstituted and continued.

Ralph Stockman wrote the most comprehensive and effective accounts of the nature and treatment of chlorosis (Stockman 1893, 1895a, 1895b). In his series of 63 cases, 27 were suffering their first attack, 11 their second, and 22 several attacks. Of the last group, some were chronically anemic. If patients remained on the prescribed iron long enough, the chronic cases responded as well as the newly diagnosed (Stockman 1895c). From what we now know of iron deficiency anemia, those receiving proper doses of iron should have done well, whereas the improperly or untreated cases would have ended badly, even fatally.

Some observers might look on the use of iron in treating chlorosis before an iron deficiency had been demonstrated as sheer luck, and one more example in the history of medicine where physicians did the right thing for the wrong reason. Yet although there are many examples of right thing–wrong reason in medicine's past, iron for chlorosis probably is not one of them. For when physicians employed proper iron compounds in correct doses, the clinical results were dramatic and altogether convincing. The failures, when iron was used, might more properly be thought of as doing the right thing with the wrong regimen.

Even if it was correct that the central feature of chlorosis was an iron deficiency anemia, a good deal of confusion remained. Still to be elucidated were a host of diseases marked by pallor, wasting, and lassitude, some of which had anemia as a secondary manifestation. These included nephritis, hypothyroidism, subacute bacterial endocarditis, mitral stenosis, and tuberculosis. What did subside was the focus on many factors once thought of as central, but which were now relegated to a contributory role at most. These included lack of fresh air and exercise, corsets, love sickness with its related sexual frustration, Rudolph Virchow's notion of hypoplasia of the arterial system, and a variety of uterine disorders.

Chlorosis reminds us of the complex interaction between physiology and social elements in the genesis of human disease. This interplay is better understood in light of our current notions of iron metabolism. To protect the body against the destructive effects of excessive iron, intestinal absorption is fixed at a rate that barely replaces the small amount lost normally. This balance is so exquisite that the prolonged loss of 2 teaspoons of blood daily will ex-

ceed the body's ability to absorb iron from a normal diet, and anemia follows. Iron deficiency anemia can result from a decrease in dietary iron, an increase in bodily demand for iron, or a loss of blood.

In chlorosis the decrease in iron intake came about either from poverty that precluded the intake of iron-rich foods or from cultural influences that led young women to avoid meat, eggs, and even milk because of the belief that animal foods increased the sexual drive, a very undesirable state of affairs in Victorian times. The increase in bodily demands for iron, for our purposes, resulted simply from the rapid growth associated with adolescence. For the historian of disease seeking physiological explanations for chlorosis, these factors would combine to produce an iron deficiency anemia.

Historical Interpretations

Clinical Manifestations and Diagnosis

The green skin color of chlorosis, from which it may have derived its name, remains, like the origin of syphilis, one of the more fascinating problems in the history of disease. The conundrum appeared when chlorosis was equated with iron deficiency; yet greenish skin in Caucasians was rarely observed in the many cases of hypochromic anemia then being diagnosed. Some of these cases undoubtedly related to the conditions just mentioned in which a hypochromic anemia appeared secondarily. Another possibility is that chlorosis was a misnomer, that the word "green" was used metaphorically. In this sense the word can be traced back to the *Oxford English Dictionary* to mean "of tender age, youthful . . . immature, raw, inexperienced."

Significantly, the green skin was included only sporadically in clinical descriptions of chlorosis over the years. Lange made no mention of it in his original description. In one study, of 27 authors who listed the usual signs of chlorosis, only 16 mentioned greenish skin as characteristic of the disease (Hudson 1977b). In another analysis, of 19 descriptions only 3 were considered definitely green, 3 possibly so, and 2 yellowish green (Loudon 1980). In 1915 Richard Cabot, author of a popular textbook of physical diagnosis, concluded that "it takes the eye of faith to see any justification for the title of the disease." On the other hand, the 1975 edition of a prominent textbook of dermatology averred that "the skin may have a green or brown tint in the iron deficiency syndrome" (Siddall 1982). Yet recent work on the nature of chlorosis has done nothing to alter this author's conclusion of a decade ago: "In the question

of the green skin of chlorosis, the available historical evidence permits us to go no further than a suspension of judgment" (Hudson 1977b). At the very least, it is now reasonable to remove green skin as the outstanding characteristic that the designation chlorosis implied.

Distribution and Incidence

The incidence of chlorosis in earlier times is impossible to determine. From the attention it received in medical and other literature as well as in art, one may infer that the condition was not rare. By the end of the nineteenth century, it was viewed as extremely common. Clifford Allbutt (1909) observed, for example, that "the chlorotic girl is well-known in every consulting room, public or private." This conclusion is all the more striking in light of the rapid exit of chlorosis from center stage. By 1915 medical observers were commenting on the disappearance of the green disease (Osler and McCrae 1915; Campbell 1923). Between 1924 and 1930 only seven cases of chlorosis were diagnosed in Guy's Hospital (Witts 1930). By 1936 W. M. Fowler was asking "What disease . . . can compare with chlorosis in having occupied such a prominent place in medical practice only to disappear spontaneously while we are speculating as to its etiology?"

He was premature, in his use of the words "disappear" and "spontaneously," but he was not alone. Others concluded that chlorosis had never been anything but a simple iron deficiency anemia brought on by an inadequate diet and a loss of menstrual blood (Patek and Heath 1936). With this understanding another physician wrote that "this disease about which so much has been written and disputed has finally ended its stormy career" (Bloomfield 1960). Again the optimism was premature. Physicians continued to find chlorosis very much alive. In 1969 it was listed as one of the five major categories of hypochromic anemia that were considered diseases *sui generis* (Witts 1969). In 1980 Irvine Loudon concluded that chlorosis was a functional disease intimately related to anorexia nervosa; that although chlorosis, like the Cheshire cat, "faded from sight, it is, in this story, still there under another name." Current medical dictionaries still carry the term and define it as an iron deficiency anemia of young women.

Owing perhaps to its ephemeral nature, chlorosis has been particularly alluring to revisionist historians. Recent work has emphasized the importance of the general perception of women and their role in

what physicians thought and did about disease, although there is surprisingly little about chlorosis as such in this literature (Hartman and Banner 1974).

Marxist and social historians have also become interested in chlorosis. These revisionist approaches, to varying degrees, tend generally to diminish the importance of pathological physiology in explaining the rise and decline of chlorosis. The more committed the revisionists are to their historical biases, the more difficulty they have squaring their interpretations with those of others as well as with more purely medical explanations. The Marxist, for example, must construct social and political conditions that produced chlorosis in young women of the capitalist class as well as the oppressed poor, because the evidence is incontrovertible that the condition affected both, as one of them readily acknowledges (Figlio 1978).

The feminists who would argue that nineteenth-century physicians mistreated women consciously on the basis of gender must account for the fact that many of the treatments accorded women by male physicians at the time derived from an inadequate understanding of reproductive physiology, and that masculine sexual conditions were also mistreated. The historian who argues that chlorosis was nothing more than a cultural construction of Victorian family life, that physicians diagnosed the condition simply because they expected to encounter it, and that young women simply learned to manifest the clinical picture of chlorosis (Brumberg 1982) must explain the well-documented existence of the disease in young men as well (Fox 1839; Evans 1845; Witts 1930).

Enthusiasm for new historical approaches to disease should not obscure the importance of the final common pathway of social, political, and cultural forces. And that common denominator for chlorosis in the nineteenth and early twentieth centuries was an iron deficiency anemia. Social and cultural factors certainly predisposed individuals to chlorosis, but persons became patients ultimately because they had red blood cells that were too small and lacked the normal amount of hemoglobin. Poor nutrition – whether due to poverty or cultural preferences – certainly contributed. Physicians, with their heavy reliance on blood-letting, even prophylactically in pregnant women, undoubtedly played a part as well (Siddall 1980). Chlorotic women gave birth to iron-deficient children – "larval chlorotics" they were called. Chlorosis, at bottom, was a deficiency disease. Explaining it historically demands an eclectic historiography. The biopsychosocial model emerging as

the proper paradigm for health professionals dealing with disease in our time has always operated historically. Ockham's razor may be useful in logic, but it may slice too narrowly in history. Plethora rather than parsimony more often illuminates the complexities of humanity's interaction with society at any given time and place. Chlorosis is a case in point. There remains ample reason to recall L. J. Witt's remark (1969) that "however one looks at it, one is left with the uneasy feeling that the mystery of chlorosis, like that of Edwin Drood, remains unsolved."

│ Cholera   │
└─────────────────────────────────┘

Cholera is an acute diarrheal disease usually accompanied by vomiting and resulting in severe dehydration or water loss and its consequences. The disease, in the strict sense of the term cholera, is caused by a specific, comma-shaped bacterium, *Vibrio cholerae,* first isolated in Egypt and Calcutta by Robert Koch and colleagues in 1883. Mortality rates have reached up to 50 percent and even 70 percent of those with the disease during epidemics. It has apparently been long endemic in the Ganges Delta of India and Bangladesh from which it has spread in periodic epidemics to other parts of India, the East, and eventually to much of the rest of the world. Most of this spread has occurred since 1817, when the modern history of the disease outside India begins; it is now generally agreed that some seven pandemics have occurred since its initial spread. The most recent began in 1961 and is only now receding. The bacterium is disseminated by the so-called fecal–oral route as a consequence of sewage and fecal contamination of water supplies and foodstuffs. This indirect transmission long made its spread difficult to understand.

In the course of history, the term "cholera" has been variously applied. In order to understand the literature of cholera in the past, the reader must also understand these varying usages. The word "cholera" appears first in the Hippocratic corpus and there refers to sporadic diarrheal disease. It has been suggested that it derives from the Greek word for "bile" and for "flow" (difficult to accept since cholera excreta are singularly free of bile), or from a Greek work for "spout" or "gutter." Later classical writers including Celsus, Aretaeus, and Caelius Aurelianus described a condition under the same name. By late 1669, Thomas Sydenham employed the term in describing an epidemic in London. The term was also widely used to describe endemic or sporadic diarrhea throughout the nineteenth century and earlier in western Europe and the Americas. This is sometimes specifically designated as *cholera nostras.*

The term *cholera morbus* has also been widely used in a manner that can cause confusion because it has been applied to indicate both epidemic and sporadic or endemic forms of illness marked by diarrhea. Today the term is applied as defined above and thus is limited to the disease caused by *V. cholerae.* Synonyms have included *Asiatic cholera* or *cholera*

asiatica, epidemic cholera or *cholera epidemica, malignant cholera, cholera asphyxia,* and *cholera spasmodica.* It is now generally accepted that all cholera in the West prior to the nineteenth-century epidemics was endemic or sporadic – and not caused by *V. cholerae.* It is also generally accepted that the cholera of India prior to 1817 was an earlier expression of the epidemic cholera, with the first reference appearing in Western literature in the *Lendas da India,* published in 1543 by the Portuguese explorer Gaspar Correia. He describes an outbreak occurring in 1503 in the army of the Sovereign of Calicut. Cholera was also described in 1563 by Garcia da Orta in one of the earliest books printed in Goa. Its Portuguese name was *mordexim,* from which the French *mort de chien* is derived. Other Eastern terms were *hyza* (Arabic and Hindustani), *tokhmu* (Persian), *bisoochtau* (Sanskrit), and *fural* (Mahratta). That the differentiation is not universally accepted can be seen in the 1961 writings of the Indian bacteriologist S. N. De, who includes all types of conditions under one disease entry and therefore objects to the implications of the term "Asiatic" cholera. Nonetheless, this survey will be limited to the epidemic of Asiatic cholera, unless specifically indicated to the contrary.

Etiology

As noted already the etiologic agent of Asiatic or epidemic cholera is a comma-shaped bacterium, *V. cholerae.* It is gram-negative, made motile by means of a single terminal or polar *flagellum* – or motility organ. This bacterium was seen in the excreta and intestinal contents of cholera victims by Filippo Pacini and described by him so accurately in a report he published in Florence in 1854 that it still carries the name he gave it, although the finding made little impact at the time.

The bacterium can be grown in the laboratory in simple media and in an alkalinity greater than that tolerated by most other bacteria. This latter characteristic is of significance for its growth in the human small intestine, as will be duly noted. On the other hand, it is more sensitive to acidity. This bacterium survives and multiplies in the environment outside the human body, notably in any relatively uncontaminated alkaline environment. It does not regularly infect animals; its host range is limited to humans. And it can be carried and spread by humans, especially convalescents, in the absence of overt disease. The bacteria produce and secrete a toxin, which is the actual cause of the symptoms that constitute the disease.

Control and Distribution

The infection is spread solely by infected humans, whose excreta may contaminate drinking water and food. This is not the direct contact that contagionists in earlier generations expected from experience with readily transmittable infections such as smallpox. Thus communicability was a highly controversial matter until its bacterial etiology was established. With this in mind one can state that the appearance and spread of cholera in a community or country depend first on the appearance of a person, either ill or well, who is discharging the cholera vibrio from his or her intestinal tract, and second on the state of hygiene, water supply, and sewage disposal in promoting or impeding the transmission of the bacterium to a potential victim. In endemic areas such as the Ganges Delta, a water table hardly below the surface of the ground has posed almost insurmountable problems. In the past, unsatisfactory sanitary facilities have been necessary conditions for cholera outbreaks in Europe and the Americas. Indeed, the history of the control of cholera is the history of improved sanitation.

Current distribution of epidemic cholera is largely limited to areas in the Indian continent and the tropical Far East, where it persists and occasionally breaks out in low-lying wet areas of contaminated water supply and sewage disposal. Since the Second World War, it has made sporadic forays into the Middle East and Far East, often associated with social disruption. In the early 1970s, cholera appeared briefly in Europe, with outbreaks in Mediterranean ports especially Naples (over 30 deaths), Barcelona, and the Atlantic port of Lisbon with over 2,000 cases. Some cases were carried by rapid transportation to the north, but resulted in no further extension of the disease. One small area of persistent infection appears to be the lower bayou country outside of New Orleans, the origin of these recurring cases.

Immunology

A natural immunity or resistance to cholera seems to exist because not all persons ingesting infected material contract the infection. C. Macnamara (1870) noted that of 19 persons accidentally drinking infected water on shipboard in 1861, only 5 contracted the infection. This resistance might well be nonspecific; the natural acidity of the stomach could act as a barrier to infection (a possibility well appreciated by Macnamara). On the other hand, one infection does not produce the solid immunity against repeated infections in survivors as in other infec-

tions such as smallpox and measles. When post-infection immunity does arise, it is of relatively short duration. Extensive experimental and clinical trials with immunization against cholera have not been convincing. Such measures have been mandated at times for travelers, nevertheless. The weakness of postinfection immunity is consistent with the weakness of the case for immunization.

Clinical Manifestations and Pathology

The bacterial infection is limited to the intestinal tract; no microbes are found to invade the body tissues. The low bacterial population normally in the small intestine as well as its high alkalinity contribute to the cholera vibrio's ability to survive and grow there, usually in massive numbers. They adhere to the intestinal wall and secrete a toxin that inhibits the absorption of water and electrolytes (salts) from the intestine into the circulation. Since the blood delivers large amounts of water and salts into the intestinal tract, which are then normally reabsorbed back into the bloodstream, failure of this reabsorption results in the loss and excretion of many liters of fluid in the course of a single day. This loss presents as a massive, debilitating diarrhea, which is the major clinical feature of cholera. All other symptoms of the disease are attributable to this water and salt depletion. These symptoms and clinical findings include weakening and finally loss of palpable pulse, thickening of the circulating blood, suppression of urination, loss of tissue fluids giving the face a sunken appearance, cyanosis, muscular spasms, and a disastrous fall in blood pressure leading to profound shock, which represents the fatal conclusion of the disease. The mind is ordinarily clear throughout the course of the disease. Recovery, when it occurs, is marked by the return of the capacity to reabsorb and retain fluids and salts, and a reversal of the signs and symptoms discussed above.

Pathological changes observed in the past on examination of the body at autopsy can now be attributed to postmortem changes. Early reports describe an erosion of the intestinal wall leading to the fluid loss mentioned, with the intestinal lining being found shed into the excreta. But in 1960, Eugene J. Gangarosa of the Walter Reed Hospital was able to observe the intestinal walls of cholera patients directly and found no evidence of any structural damage to cells in this area. Thus was research directed toward damage at an enzymatic or molecular level, pathologically caused by the cholera toxin already discovered by De in 1959.

Treatment

Norman Howard-Jones (1972) described the earlier treatment of cholera as follows: "In the whole of the history of therapeutics before the twentieth century there is no more grotesque chapter than that on the treatment of cholera, which is largely a form of benevolent homicide."

Modern therapy consists simply of replacing the lost water and salts. This may be done by intravenous therapy, or by oral administration in milder cases or as an adjunct to the intravenous therapy in more serious cases. This has greatly facilitated the treatment of diarrhea patients, especially in resource-poor countries. Thus cholera is essentially curable. Antibiotics play only a minor role, in that they may shorten the duration of disease and reduce the massive amounts of necessary fluid replacement.

History and Geography

Consideration of the historical literature under the rubric "cholera" requires appreciation of what disease is being treated. Literature on cholera in western Europe and the Americas that was written prior to about 1830 and that described an endemic or sporadic disease called "cholera" is excluded from the following account. There is a relatively sparse literature on the disease in India, which serves as a prelude to the modern history of true cholera. The modern literature on cholera starts slowly in 1817 and accelerates with its appearance in Russia in 1829, eastern Europe in 1831, and western Europe and North America in 1832.

Antiquity

There have been conflicting opinions concerning the possible references to cholera in the early Hindu literature. James Annesley (1825) stated: "I have not been able to obtain any information from those acquainted with the writings of the Hindoos, favouring the inference that cholera has prevailed in former ages as a wide-spreading epidemic." Robert Pollitzer (1959) makes only a brief and doubtful reference to the matter. Jan Semmelink (1885), formerly principal physician of the army of the Netherlands East Indies, in the French translation and condensation of his much more heavily documented Dutch edition of the same year, reviewed available English, French, and German translations very critically and rejected all references to possible early epidemic cholera in the Far East.

Sixteenth Through Eighteenth Century

Reference has already been made to the explorer Correia, who stated that in the spring of the year 1503, 20,000 men died in the army of the Sovereign of Calicut, some of a "disease, sudden-like, which struck with pain in the belly, so that a man did not last out eight hours time." Correia also met cholera in an epidemic form in Goa in the spring of 1543, called by the natives *moryx,* where the mortality was so great that it was very difficult to bury all of the dead. The disease was marked "by vomiting, with drought of water accompanying it, as if the stomach were parched up, and cramps that fixed the sinews of the joints" (Macnamara 1870). Garcia da Orta's report from Goa in 1563 called the disease *hachaiza* or *haiza* as the Arabs did, and also *colerica passio* and *morxi.*

The Netherlander Jan Huygen van Linscoten described what he called *mordexijn* in Goa in 1584, as did the Frenchman Vincent Le Blanc also in Goa in 1585. Reports followed through the rest of the 1500s and 1600s, including that of the well-known Jacobus Bontius in the earlier 1600s, who extended his observations to Batavia, now Indonesia. Notices of the disease continued to appear into the eighteenth century when they were joined by those of Englishmen. Thomas Percival in 1788 reported that a ship surgeon from Chester was treating cholera morbus with *radix Columbo* in the East Indies during the 1750s, and provided a fair description of the disease. The Scotsman James Lind described cholera throughout the East Indies and in India in the 1760s as a "constant vomiting of a tough white pellucid phlegm, accompanied by a constant diarrhea, [which] was deemed the most mortal symptom." He used the term *mordechin.*

Macnamara (1870) recorded that the "earliest account of the occurrence of cholera in India, from the pen of an English physician (Dr. Paisley), is dated Madras, February 1774, and is to be found in Curtis's *Works on Diseases of India,* published in Edinburgh in 1807." Although nothing further seems to be known of this Paisley, his letter forms a cornerstone in the history of the disease in British India. Annesley (1825), in an early English classic on cholera, quotes the following passage: "Thus," Paisley wrote from Madras, in 1774, "there can be no doubt that their (the troops') situation contributed to the frequency and violence of this dangerous disease, which is, as you have observed, a true cholera morbus." In 1781, it ravaged the troops in the district of Ganjam, requiring the admission to the hospi-tal on March 22 alone of no less than 500 men of a division of 5,000. It is curious to note that the report cited calls the disease a "pestilential disorder" and does not name it cholera, although later writers (including Macnamara) assumed that it was.

This outbreak is reported to have reached Calcutta. In April of 1783, "cholera burst out at Hurdwar, and in less than eight days is supposed to have cut off 20,000 pilgrims." Fragmentary observations continued to appear, some from travelers, describing the following:

[D]isease broke out with terrible ferocity, and destroyed an enormous number of people. During the month of October, 1787, epidemic cholera committed terrible ravages at Arcot and Vellore. With regard to this outbreak, Mr. Davis, a member of the Madras Hospital Board, remarks: "I found in what was called the Epidemic Hospital, three different diseases, viz., patients labouring under cholera morbus; an inflammatory fever with universal cramps; and a spasmodic affection of the nervous system, distinct from cholera morbus. I understood, from the Regimental Surgeon, that the last disease had proved fatal to all who had been attacked with it, and that he had already lost twenty-seven men of the regiment in a few days. Five patients were then shown to me with scarce any circulation whatever to be discovered; with their eyes sunk within the orbits; jaws set, bodies cold, and extremities livid."

Nineteenth Century: The Pandemics

Cholera, or cholera-like disease, continued to be observed during the rest of the eighteenth and into the nineteenth century. Then, in the year 1814, outbreaks of cholera occurred in a number of Indian provinces, including the crowded barracks of Fort William at Calcutta among recruits just arrived from England.

Macnamara, who evaluated all these many reports of the appearance of the disease, concluded that "we are, . . . I think justified in arriving at the conclusion that it was nothing new for cholera to spread over India in an epidemic form prior to 1817 and 1819." At this point, something drastically "new" did occur, as cholera escaped the bounds of India and initiated the waves of pandemics that were to engulf the world. This change in cholera's pattern of activity has led a few to conclude that a new disease arose in Bengal in 1817, a contention Pollitzer (1959) regards as untenable, observing the following:

Incomplete or even fragmentary though the evidence brought forward . . . often is, it leaves no room for doubt

that cholera, present in India since ancient times, not only continued to exist but was apt to manifest itself periodically in wide spread conflagrations.

Dissenting views do, however, exist, including those of Annesley (1825) who, writing within a decade of the 1817 outbreak, states "[t]hat we have no proof of the prevalence of cholera in India, as a widespreading epidemic in former times." Again the skeptical Semmelink devotes a whole work to the observations of cholera in the East before 1817, providing detailed criticism of what must be essentially every report in the European literature. And again he is vehement in his judgment that the accounts refer to other than the epidemic cholera of 1817 and after, although his nosology is sometimes archaic and difficult to follow. It has also been suggested in this age of genetic engineering that a genetic modification in the microbe was responsible for this supposed change in cholera's nature.

The First Pandemic. In any event, in March 1817, a death from cholera took place in Fort William, but because it was a solitary case no notice was taken of it. By July, however, outbreaks occurred in several districts in the Province of Bengal. The first notice of this in the *Proceedings of the Bengal Medical Board* was a letter from Robert Tytler, civil surgeon of Jessore, dated August 23, 1817. He wrote:

An epidemic has broken out in the bazaar, the disorder commencing with pain or uneasiness in different parts of the body, presently succeeded by giddiness of the head, sickness, vomiting, griping in the belly, and frequent stools. The countenance exhibits much anxiety, the body becomes emaciated, the pulse rapidly sinks, and the patient, if not speedily relieved with large doses of calomel, followed by one of opium, . . . [is carried off] within four and twenty hours.

In July and the following months, Calcutta was affected; 25,000 of its inhabitants were under medical treatment for the disease of whom 4,000 died. Thus begins the modern history of Asiatic or epidemic cholera, although none of the documents immediately surrounding the event make reference to the name "cholera," until a letter dated September 16 specifically refers to "cholera morbus."

Within 3 months the disease had spread throughout the Province of Bengal, and in November it reached the camp of the Marquis of Hastings in Bundelcund. During 1818, it moved over the greater part of India including Delhi and Bombay, with estimated attack rates of up to 7.5 percent of the exposed population. It continued to rage

through 1819 and 1820, extending into Ceylon and Burma, Siam, Malacca and Singapore, and the Philippines. By 1821, it had invaded Java, Batavia, and China to the east and Persia to the west, reaching Baghdad with a besieging Persian army, and extending from there to Aleppo. By 1823, it was in Egypt, Astrakhan, and the Caspian shores and throughout Syria along the shores of the Mediterranean. But it receded for a number of years, thereby terminating the First Pandemic.

The Second Pandemic. By 1824, cholera had retreated to its endemic area in Bengal, where it remained active in the Ganges Delta through 1826. But in 1827, it spread out again in the so-called Second Pandemic into the Punjab, and by 1829 extended through Persia to the shores of the Caspian Sea. In Orenburg in 1829 (August 26), it soon expanded north and west into Russia. By September of 1830, cholera was in Kharkov and Moscow, and began spreading west into Bulgaria. During the winter of 1830–1, it persisted in the Russian army in Poland, and then in the spring it invaded Warsaw and soon after, Riga. Meanwhile, cholera was also raging through Mecca and Turkey, reaching Constantinople and Alexandria by July and August. On August 3, it entered Berlin and Vienna, and reached Hamburg by the beginning of October. Around the end of October, if not before, it appeared in England at Sunderland, supposedly imported from Hamburg or Riga. Late fall and early winter brought a brief respite, during which teams of observers were sent to infected areas from as yet unaffected areas, while commissions at home were trying to prepare for the coming onslaught and arguments about such matters of quarantine, sanitation, contagiousness, and treatment.

The opening of the year 1832 was soon followed by a reawakening of cholera. In February, it appeared in Newcastle, Edinburgh, and London, as well as places in between. Next it reached France, bursting on Paris on March 24, and soon engulfing all districts of the city. Within 18 days no fewer than 7,000 persons were dead. Next, cholera hurdled the Atlantic Ocean to appear on June 8 in Quebec and on June 19 in Montreal. Presumably, it arrived with emigrants on the brig "Carricks," which left infected Dublin in April and lost 42 of its 173 passengers before reaching Quebec on June 3. On June 23, cholera invaded the United States, appearing in New York on that date and in Philadelphia on July 5. From these ports of entry, it marched westward across both North American countries.

Entry into Spain, Portugal, and the Caribbean and Latin America was delayed until 1833, and into Italy until 1835. Havana lost 8,253 persons in a population of 65,000 between February 26 and April 20, 1833, and by August no less than 15,000 had perished in Mexico.

Yet by 1834, the disease was beginning to recede, and while it persisted in a number of Mediterranean and Central American areas for a few more years, it retreated once again in 1837 to its Indian homeland. This pandemic has been described in detail, as it was the first modern experience with the disease for much of the world and because subsequent epidemics or pandemics were to follow much the same route. In addition, a great deal of popular and governmental response to subsequent appearances was based on experience gained during this pandemic.

The Third Pandemic. During the following decade, cholera continued to plague India, and it entered Afghanistan with British troops in 1839, and China in 1840 – again with troops from India – where it remained into 1841 and 1842. In 1844–5, it extended into Persia and Central Asia, reaching the Arabian coast as well as the Caspian and Black seas in 1846–7. Constantinople was attacked on October 24, 1847. In the spring of 1848, it broke out with renewed vigor, advancing as far as a line drawn through Arabia, Poland, and Sweden, reaching Berlin in July and Hamburg and Holland by September, and then London and Edinburgh in short order. After a short period of comparative rest, it renewed its activity in the spring, reaching Paris in March and by now was covering much the same ground of the earlier epidemic. Meanwhile, in December 1848 cholera had crossed the Atlantic to invade New York and New Orleans, and spread rapidly across the continent from these centers. In 1850, it reached California with the wagon trains as well as by ships from Panama. In that year it was reported in North Africa, Europe, and both North and South Americas. In many of these regions, it continued through 1851 and 1852.

There is some debate over the dates of the second and third pandemics. Most accept the worldwide spread of cholera during the decades of the 1840s and 1850s as constituting the Third Pandemic. However, Pollitzer (1959) and a few others date the Third Pandemic at 1852 or 1853, and place the Second Pandemic within the mid-1840s to 1851, in spite of the obvious lull from the mid-1830s to the mid-1840s, at least outside the Indian subcontinent. It is true that cholera was present in eastern Europe in 1852, either because of persistent infection in these areas (i.e., continuation of the earlier pandemic) or because of a fresh wave of infection starting in India in 1849 (Pollitzer 1959). But in either case, it seems fairly unlikely that what for all appearances seems to have been a pandemic would break at mid-point.

The year 1854 found cholera widely spread in Europe, England, Greece, Turkey, and North and South America. It was one of the worst cholera years on record. It was during this pandemic that John Snow made his observations in London that in 1855 led to the publication of his critical, if not immediately appreciated, study on cholera transmission by contaminated water. In 1855 and after, the disease died down in much of the West, but it continued in a few spots there as well as in much of the East.

The Fourth Pandemic Pollitzer dates the Fourth Pandemic from 1863; it was to last about 10 to 12 years. In 1865, Macnamara estimated that a third of 90,000 pilgrims at Mecca succumbed. As before, it reached Constantinople and spread around the Mediterranean, reaching northern Europe in 1866 and 1867, and the United States and the Latin Americas in 1866. It raged over its old grounds until 1874.

The Fifth Pandemic. According to Pollitzer, the Fifth Pandemic began in 1881, and lasted until 1896. It was during this epidemic that the studies of Koch in Alexandria and Calcutta in 1883–4 led to the isolation and identification of the causative microbe. In addition to Egypt, the epidemic was at first largely limited to the Mediterranean shores of Africa and Europe, although it later became widespread in Russia, and in Germany where it was marked by the explosive outbreak in Hamburg in 1892. Importation into New York in 1887 was arrested, but outbreaks did occur in Latin America. The disease was also widely prevalent in the Far East – in China and Japan.

The Sixth Pandemic. The Sixth Pandemic ran from 1899 through 1923. It followed much the pattern of the fifth – largely affecting India, the Near and Far East, Egypt, western Russia, and the Balkan Peninsula. Sporadic outbreaks occurred in southern Europe and Hungary in the West and China, Japan, Korea, and the Philippines in the East. But this time cholera did not reach the Western Hemisphere.

The Seventh Pandemic. The Seventh Pandemic dates from about 1961 to the mid-1970s and followed

much the pattern of the previous epidemic. It is particularly important in providing an opportunity for the significant advances in studies of cholera pathogenicity and therapy extensively described by W. E. Van Heyningen and John Seal (1983), studies carried out in Egypt, India, Bangladesh, and the Philippines by several U.S. teams.

This brief sketch can provide only the barest outline of the nineteenth-century history of this significant disease. Pollitzer's numbering of the pandemics is utilized here for the later ones, although, as has been mentioned, historians of the disease have not always agreed on this numbering. In fact, it is sometimes not entirely clear *why* or *when* one pandemic is said to have terminated and another to have begun.

Historical Considerations of Etiology, Control and Prevention, and Treatment

In addition to the history of the pandemics themselves, the history of several other aspects of the disease seems significant to the overall history of medicine. Among these are the discovery of the etiology of the disease, concepts of contagion, developments in sanitation and public health institutions, and developments in therapy.

Earlier thoughts on the causes of cholera were embedded in notions of disease causation going back to Hippocrates: weather, seasons, geographic environment, bad air and miasmas, and dietary indiscretions. If an infecting agent was referred to at all, it was likely to indicate an "infection" by a poison or miasma.

By the middle of the nineteenth century, however, ideas of a microbial etiology were gaining ground with the writings of such individuals as F. G. Jakob Henle. In 1849, William Budd and two associates described microscopic bodies in cholera excreta and published their findings with illustrations. The French botanist Charles Robin reproduced these illustrations in 1853, denying their "vegetal nature." These were seen by the German botanist Ernst Hallier, who rejected Robin's rejection and set out to grow microbes from cholera excreta using bacteriological techniques that could not have produced success. He published his findings in *Die Cholera-Contagium* in 1867.

T. R. Lewis tried to confirm Hallier's work in Calcutta in 1870, and in failing, became somewhat of an anticontagionist. In the meantime, as already described, Pacini made his correct but at the time largely ignored observations of the actual *V. cholerae* in 1854. Thus it was left to the genius, persistence,

and technical elegance of Koch in 1883 to isolate and identify the microbe and to introduce the modern phase of the understanding of the disease. It was not, however, until 1959 that the toxin produced by the microbe was discovered along with its role in disease causation.

The question of the "contagiousness" of cholera was a matter of heated debate throughout most of the nineteenth century. It can be generally observed that the contagionists were viewed by contemporaries as archaic, conservative, and even antisocial, whereas the anticontagionists were seen as modern, bourgeois, mercantile, and socially responsible. Most of the debate focused on the question of quarantine which, of course, was anathema to mercantile interests, and the anticontagionists gained ground as the nineteenth century progressed. The demonstration of Snow of the waterborne nature of cholera was slow to gain acceptance, but this development, coupled with the discovery by Koch of the infective nature of the disease, finally proved the "contagion" of the disease, providing, of course, that one allows for the intermediary role of infected excreta and water or food, and that some individuals can act as carriers but do not develop the disease.

Sanitation has always played a major role in the thinking and in the efforts of those aiming to understand and control the propagation of cholera. As a consequence, a large body of literature has been generated on the role and influences of cholera epidemics on the development of public health policies, public health organizations, and the development of sanitation procedures and techniques.

The earlier history of the treatment of cholera has been thoroughly treated by Norman Howard-Jones (1972) and Michael Durey (1979). Most of the therapeutics employed were representative of the practice of medicine generally in and before the nineteenth century. Emetics, purgatives, and bleeding seem in retrospect to have been worse than ineffective. Calomel and opium were the standard drugs administered, beginning with British physicians in India. Castor and croton oils, antimony, mustard, bismuth, arsenic, camphor, and quinine were among other drugs administered. A red-hot iron to the heel was widely employed in India, to the spine in Paris. Water hot or cold orally, per rectum, or as baths was sometimes recommended.

The definitive treatment – intravenous fluid and salt replacement – was a long time in developing. As early as 1830, the German chemist R. Hermann demonstrated in Moscow that the change in the blood's fluid balance was reflected in the contents of the

cholera excreta. A German colleague on one occasion injected 6 ounces of water into the terminally ill patients, a treatment that produced a quick, temporary return of the pulse, although death nonetheless occurred 2 hours later. In October 1831, the Berlin surgeon J. F. Dieffenback took the premature step of injecting several ounces of whole blood into three patients. They died 6 minutes, 2 hours, and 6 hours later, respectively, the first during violent convulsions. In Great Britain in late 1831 and early 1832, W. B. O'Shaughnessy published papers suggesting the intravenous replacement of salt and water. These suggestions led Thomas Latta of Leith, Scotland, and two associates to try the treatment on patients. They reported that 5 of 15 patients survived. Other sporadic attempts followed, with some but not convincing success during the 1830s. Sporadic trials continued through the century in Britain and France, and in Calcutta in the 1890s, but the treatment was not successful until Leonard Rogers perfected it in Calcutta in the early 1900s. There were a number of technical problems to be solved first, not the least being sterility. But with these difficulties resolved, the definitive treatment of cholera was established.

VIII.28
Cirrhosis

Cirrhosis is a chronic hepatic disorder, anatomically characterized by diffuse liver fibrosis and nodule formation. These pathological changes produce the clinical features of portal hypertension and hepatocellular failure. Cirrhosis is the end product of progressive liver injury resulting from many diverse causes including toxins, drugs, viruses, and parasites. The clinical manifestations of cirrhosis vary according to the severity and duration of the underlying disease. In the West, cirrhosis is a major cause of disability and death among middle-aged alcoholic males. In the East and Africa, cirrhosis is predominantly an intermediate lesion in the evolution from chronic hepatitis B infection to primary hepatocellular carcinoma.

Classification

Cirrhosis is classified on the basis of morphology and etiology. The morphological classification recognizes three types based on the size of the nodules:

1. *Macronodular cirrhosis.* The liver is firm, large or small in size, with bulging irregular nodules greater than 3 millimeters in diameter.
2. *Micronodular cirrhosis.* The liver is usually enlarged, and very firm or hard in consistency. The nodules on cut sections appear small and uniform, less than 3 millimeters wide.
3. *Mixed micro/macronodular cirrhosis.* The liver

shows groups of small nodules interspersed with fields of large nodules.

The terms "micronodular" and "macronodular" cirrhosis replace the older terminology, *Laennec's* and *postnecrotic cirrhosis.*

Neither the gross nor the microscopic appearance of the liver can alone differentiate among the many causes (see Table VIII.28.1). In individual cases, the etiology is often unknown. Alcohol injury is most frequently associated with the pattern of micronodu-

Table VIII.28.1. *Etiology and incidence of cirrhosis*

Etiology	Incidence
Toxins and drugs Alcohol	5–15% of chronic alcoholics
Methotrexate, methyldopa, and isoniazid	
Infections	1–2% of acute infection
Hepatitis (non-A, non-B virus)	5–15% of chronic disease
Hepatitis (delta virus) Schistosomiasis japonicum	20–60% of chronic disease
Disturbed immunity	
Chronic active hepatitis	30–50% of chronic type B viral hepatitis
Primary biliary cirrhosis	6–15 per 1 million population (incidence)
	4–14 per 100,000 (prevalence)
Chronic cholestasis	
Gallstone, biliary tumor, stricture, biliary atresia	1 per 8,000–15,000 live births
Mucoviscidosis	2–20% of patients (1 per 2,000 live births)
Metabolic disorders	
Primary hemochromatosis	2–3 per 1,000 (prevalence)
Wilson's disease	30 per 1 million population (prevalence)
Alpha-1-antitrypsin deficiency	1 per 15,000 Scandinavian adults
Vascular diseases Veno-occlusive disease Budd–Chiari syndrome Chronic right heart failure	
Others Indian childhood cirrhosis Intestinal bypass	
Cryptogenic causes	

lar cirrhosis, and other causes in this category include primary biliary cirrhosis, primary hemochromatosis, and chronic right heart failure. The macronodular deformation is seen in the cirrhosis due to viral, drug, and cryptogenic origins, and in the end-stage cirrhosis of any etiology.

Distribution and Incidence

Cirrhosis is distributed worldwide, affecting all races, nationalities, ages, and both sexes. Well over 300,000 persons die of the disease annually. This figure, based on World Health Organization statistics of the 1960s, is an underestimate because countries such as mainland China and the former Soviet Union are not included. In the United States in 1983, cirrhosis ranked as the ninth leading cause of mortality, accounting for 27,000 deaths.

The worldwide incidence of cirrhosis is determined chiefly by the per capita consumption of alcohol and the prevalence of the hepatitis viruses. The rise in the number of cases of cirrhosis is attributable to an increase in one or both of these factors. Based on mortality statistics (WHO data, 1983 or 1984), the incidence of cirrhosis in various countries can be grouped as follows:

1. Low incidence (less than 10 cirrhotic deaths per 100,000 population): Canada, Venezuela, England, Scotland, Sweden, Netherlands, Australia, Hong Kong, and the United Arab Republic.
2. Intermediate incidence (11–23 per 100,000): Mexico, United States, Denmark, and Japan.
3. High incidence (greater than 24 per 100,000): Chile, Austria, Italy, France, West Germany, and Portugal.

Occurrence rates for the different types of cirrhosis are presented in Table VIII.28.1.

Epidemiology

The statistics on cirrhosis suffer from the uncertainty of diagnosis, which can be confirmed only on autopsy or by liver biopsy. Nevertheless, the figures generated from many sources are sufficiently consistent to establish that geography, race, age, sex, economic and social class and occupation; the amount, duration, and pattern of alcohol consumption; and prevalence of hepatitis viruses all modify the occurrence of cirrhosis. The prevalence rate of cirrhosis in autopsies averages 3 to 4 percent for most countries in Europe, 5 to 8 percent for North and South Americas, and 1 to 2 percent for Japan. Among selected populations of patients, the prevalence rate of cirrhosis ranges from 0.7 percent in Copenhagen, to 1.3

percent in Wurzburg (Germany), 1.5 percent in Athens, and 3.8 percent in Abidjan (Ivory Coast).

The older epidemiological studies, discussed by John Galambos (1979), disclosed a rising incidence of cirrhosis, especially among women. Recent investigations have confirmed this trend. In the United States, deaths from cirrhosis rose 71.7 percent from 1950 to 1974, while those due to cardiovascular disease fell 2 percent. The age-adjusted death rates from cirrhosis in the United States in the period 1960–74 by race and sex showed that the increase was marked for nonwhite males, moderate for nonwhite females, and only slight for white males and females. For blacks in the United States, mortality rates for cirrhosis were similar to or slightly lower than those of the white population before 1955. The pattern changed rapidly after that, with American blacks experiencing an epidemic of cirrhosis compared to the increase in whites. The rise in cirrhosis deaths followed a geographic pattern. Rates among the blacks quadrupled in urbanized coastal and northern regions and remained low in the southern rural areas of the United States. Among whites the pattern was reversed, with the death rates increasing more in the southern than in the northern industrial areas. For urban America, both male and female mortality rates for cirrhosis in the nonwhite population are at least double those of the white population. The overall cirrhosis mortality in the United States dropped in the late 1970s and, with the exception of 1979, declined further in the early 1980s.

Elsewhere, in Birmingham, England, the annual incidence of cirrhosis rose from 5.6 per 100,000 population in 1959 to reach a peak of 15.3 in 1974, and then fell slightly. The annual death rate for cirrhosis in Denmark climbed from 7.5 per 100,000 population in 1963 to 9.7 in 1978. When analyzed according to sex and age, the increase in mortality rate was 3-fold among young and middle-aged men, but fell by 50 percent among older women. In western Australia cirrhosis mortality for males over age 30 increased from 14.1 per 100,000 in 1971 to 21.0 in 1982. Deaths from alcoholic cirrhosis increased in Finland and Denmark 10-and 5-fold, respectively, from 1961 to 1974. During the same period, males in Sweden and Norway had, respectively, a 3-fold and 2-fold increase in mortality due to alcoholic cirrhosis.

The steady rise in cirrhosis death rates in industrialized nations is linked to the increased per capita consumption of alcohol. Mortality figures from the United States, England, and France have dropped whenever the sale of alcohol has been prohibited or restricted during the twentieth century. A doubling of alcohol intake in a country is followed by a 4-fold increase in alcohol-induced disease. The association between alcohol and cirrhosis has been further strengthened by the confirmation of a dose–response relation. The relative risk (RR) for cirrhosis among the French has been defined as follows:

	20–39 g alcohol/day	40–59	60–79	80–99
Men	3.6 (RR)	4.56	13.47	21.60
Women	4.13	21.60	32.17	–

The risk of cirrhosis increases with the daily intake of alcohol much faster in females than in males. Similar trends in cirrhotic risks also occur in Canadian men and women for comparable levels of alcohol consumption. Although progression to severe liver injury is accelerated in women, the male/female ratio remains at least 2:1 for most groups. There are some notable exceptions, such as American Indian women – who account for 50 percent of the cirrhosis deaths of this ethnic group.

In the West, alcoholic cirrhosis comprises the major share of all cirrhosis. An estimated 75 percent of cirrhosis in the United States is alcoholic in origin; 15 percent is viral, and 10 percent is cryptogenic. A different distribution pertains in Great Britain, where 50 percent is alcoholic, 25 percent is cryptogenic, and 25 percent is viral. In Asia and Africa, where the prevalence of hepatitis B virus is high and the per capita consumption of alcohol is low, the proportion of virus-related cirrhosis to the alcoholic type is the reverse of that seen in the West. Past literature written on the disease from data gathered from east European countries suggests no association between cirrhosis and viral hepatitis. The studies were done, however, before the introduction of serologic markers for hepatitis, and thus, the type of viral heptatitis was not identified. The occurrence rate of hepatitis B virus cirrhosis is uncertain (see Table VIII.28.1). Epidemiological studies strongly support the association between chronic hepatitis B infection and the development of primary hepatocellular carcinoma. Infection at birth results in chronic hepatitis, cirrhosis, and carcinoma 2 to 3 decades later. How the virus causes the carcinoma is not understood, but the process involves cirrhosis, especially among males. Cirrhosis, like its sequela, hepatocellular carcinoma, is common in countries where hepatitis B virus is endemic.

Clinical Manifestations and Diagnosis

Clinically cirrhosis may be latent (5 to 10 percent of cases), well compensated, or active and decompensated. The clinical features depend on the underlying etiology and the appearance of the two cardinal manifestations, portal hypertension and hepatocellular failure. As cirrhosis usually evolves over a period of several years, the course may be intermittent with therapeutic intervention such as with corticosteroids or with temporary cessation of injury. During the early phase of disease, patients often present with nonspecific symptoms and signs including malaise, lethargy, *anorexia,* loss of libido, and weight gain. Incidental laboratory findings of abnormal liver function tests, positive hepatitis B serology and hypergammaglobulinemia, and incidental physical findings such as icterus, hepatomegaly, gynecomastia, and spider nevi may point to the presence of cirrhosis. With the progression of disease, portal hypertension and hepatocellular failure invariably supervene. These two complications are interrelated in their pathogenesis, and often represent the initial presentation of many cirrhotics. Esophageal varices, ascites, splenomegaly, and gastrointestinal hemorrhage indicate elevated pressure in the portal venous system. Jaundice and abnormal liver function tests may occur in early and mild hepatocellular failure, which in its severe state is manifested as hepatic encephalopathy and hepatorenal syndrome.

Prognosis need not be poor, as cirrhosis can be checked, for example, in the alcoholic who abstains from alcohol abuse. Treatment can reverse the hepatic fibrosis and improve the outlook of patients with chronic active hepatitis, primary hemochromatosis, or Wilson's disease. On the other hand, after ascites has developed, the 5-year survival rate falls to below 50 percent.

History and Geography

The ancient Greeks recognized the clinical features of cirrhosis. In about 300 B.C., Erasistratus associated ascites with liver disease. Galen, in the third century A.D., commented on the physical diagnosis, and noted that heavy wine consumption "will increase the damage to the liver when inflammation and scirrhus already existed." His contemporary, Aretaeus the Cappadocian, suggested that cirrhosis may evolve from hepatitis, and carcinoma, from cirrhosis. The clinical descriptions left by the Greeks remained unexcelled until recent times.

In the sixteenth century, Vesalius described rupture of the portal vein in a lawyer with an indurated nodular liver. When pathological anatomy became a discipline in the seventeenth century, sporadic reports of the cirrhotic liver appeared. Among the earliest illustrations of cirrhosis was that by Frederik Ruysch in his atlas of normal and abnormal anatomy (1701–16). In his massive tome on pathology, Giovanni B. Morgagni (1716) introduced the term "tubercle" to denote any nodule of the liver. This covered a variety of lesions, and sowed the confusion between carcinoma and cirrhosis of the liver for decades afterward. Among the English, William Harvey in 1616 reported on two cases of cirrhosis. He antedated John Browne, whose description in 1685 has been regarded by historians as the first in English. Matthew Baillie's accurate description in 1793 established cirrhosis as a nosological entity in pathology. He also noted the strong association between the disease and alcohol intake. During the eighteenth century, a surplus of corn led Parliament to promote distilling and consumption of spirits as a way of stabilizing the price. The excessive consumption of cheap spirits gave rise to an epidemic of cirrhosis, which became popularly known as "gin liver" in England and "brandy liver" in other countries.

Twenty-five years after Baillie, René Laennec, who invented the stethoscope, introduced the name cirrhosis in a brief footnote appended to a case discussion. Subsequently, clinicians on the Continent began to speculate on the morphogenesis of the lesion. In 1829, Gabriel Andral formulated the idea that hypertrophy of the yellow substance of the liver that normally secretes bile accounted for the nodules, whereas atrophy of the red substance containing the vessels represented the depressed areas of cirrhosis. This concept, relating cirrhogenesis to the dual substance of the liver, influenced thinking on this subject for the next two decades. In 1838, Robert Carswell in England conjectured that cirrhosis depended on the growth of interlobular connective tissue. The speculations acquired a more solid foundation when microscopes with good resolving power became available. Also in the early nineteenth century, Gottlieb Gluge and Dominique Lereboullet saw hepatic fat and argued that this was the basic lesion of cirrhosis, whereas Karl von Rokitansky attributed the "granulations" of cirrhosis to the result of chronic inflammation.

During the mid-nineteenth century, interest in vascular studies gathered momentum after improvements were made in cast corrosion techniques. The vascular alterations in cirrhosis also came under scrutiny during the latter half of that century and the first decades of this century, as researchers from Lionel S. Beale writing in 1857–9, through the work

of A. H. McIndoe in 1928, revealed the vascular damage that occurs with cirrhosis. Some, such as Karl von Liebermeister in 1864 and J. M. Legg in 1872, continued to focus on the interlobular connective tissue as the seat of the cirrhotic process. Others emphasized the regenerative aspects of cirrhosis which represented the end product of many injurious episodes. In 1911, Frank B. Mallory summarized the clinicopathological features in an important paper that introduced the entity of alcoholic hepatitis. He regarded it as a precursor lesion of cirrhosis. Mallory's concept was recently revived after a dormancy of 50 years.

While pathologists debated the issue of morphogenesis, speculations on etiology also abounded. Earlier it had been suggested that alcoholic fatty liver was the precursor of cirrhosis. By the second half of the nineteenth century, most physicians accepted this thesis, believing that alcohol intake increased hepatic fat, which in turn was converted into cirrhosis. However, experiments by P. Ruge in 1870 and G. de Rechter in 1892, among others, failed to demonstrate the cirrhogenic effect of alcohol in animals. This result led to the notion that it was not alcohol but some contaminant in the alcohol, such as copper, which damaged the liver, whereas another set of theories stressed that gastric malfunction was the underlying cause in that disturbed gastric function produced or allowed the absorption of hepatotoxins. The hypothesis of nutritional deficiency came to the foreground when experimenters such as J. M. Hershey and Samuel Soskin in 1931 and D. L. McLean and Charles H. Best in 1934 showed that the fatty liver condition caused by insulin deficiency could be prevented by choline and other lipotropic agents. Other dietary models of cirrhosis soon followed, including lipotroph deficiency, a low-fat diet, and vitamin E deficiency. It remained for Harold P. Himsworth and L. E. Glynn in 1944 to correlate the two pathways of cirrhogenesis: (1) a diffuse fatty liver developing into a finely nodular cirrhosis seen in the animal model with lipotroph deficiency; and (2) massive hepatic necrosis proceeding to the coarsely nodular liver created experimentally by cystine deficiency. The nutritional theory declined in popularity when careful experiments by Charles S. Lieber and colleagues, among others, showed in 1968 that alcohol was directly hepatotoxic in humans, and cirrhogenic in baboons.

Another technical innovation has advanced our understanding of cirrhosis. Introduced by Paul Ehrlich in 1884, and popularized by P. Iversen and K. Roholm in 1939, the liver biopsy achieved wide use as a routine method of diagnosis. The accumulated histologic studies clarified the relationship of hepatitis to cirrhosis, and cirrhosis to hepatocellular carcinoma. They also helped to consolidate the various classifications of cirrhosis proposed in the past. The recent standardization of nomenclature (see Table VIII.28.1) was proposed by the Fogarty International Center in 1976 and the World Health Organization in 1977.

Clonorchiasis

VIII.30
Croup

The Chinese liver fluke is a small worm that parasitizes the bile ducts and livers of humans, dogs, cats, pigs, and several wild animals in China, Japan, Korea, and Indochina. It was discovered in 1875, and recently, it was estimated that 20 million individuals in China alone are infected. Eggs are laid in the bile ducts, pass in the feces, and if they reach the proper freshwater snail, undergo a series of stages in this intermediate host. Eventually, free-swimming larvae are formed, which penetrate and encyst the skin or muscles of fish, expecially those of the carp family. Human beings and other definitive hosts become infected by eating the cysts (metacercaria) in raw or poorly cooked fish. Raw fish are a delicacy in many Asian countries, and fish are sometimes raised in ponds fertilized with human feces. Encysted metacercaria larvae are resistant to smoking, pickling, salting, and drying. Imported fish have caused human cases in Hawaii, and the popularity of Asian cuisine poses a potential danger to gourmets far beyond Asia.

Light infections are often asymptomatic. Heavy infections may produce diarrhea, fever, jaundice, and abdominal pain. Bile duct blockage and liver abscesses occur in chronic cases, and Clonorchis sinensis has been tentatively linked to liver cancer. Diagnosis is made by microscopic examination of the feces to discover the characteristic eggs. Drug therapy is sometimes successful. Preventive measures include rural sanitation, regulation of fish-farming methods, and cooking fish thoroughly. It is unlikely, however, that long-established culinary practices can be changed.

The term *croup* is used in an inclusive way to identify several different respiratory illnesses of children manifested by varying degrees of inspiratory stridor, cough, and hoarseness due to upper-airway obstruction. Classically croup was a manifestation of diphtheria. In the twentieth century, many other infectious causes of croup syndromes are recognized, and in addition, similar illnesses can be caused by noninfectious processes.

A classification of crouplike illnesses is presented in Table VIII.30.1. Although long-term obstruction in the glottic and subglottic regions can lead to chronic illnesses, croup syndromes are described here as acute self-limited or fatal illnesses. Most cases of croup today are either laryngotracheitis or spasmodic croup.

Etiology

Acute epiglottitis (inflammation of the epiglottis) is virtually always caused by *Haemophilus influenzae* type B; rare cases have been due to *Streptococcus pneumoniae* and *Staphylococcus aureus*. Laryngitis is usually due to the common respiratory viral agents, the most important of which are adenoviruses and influenza viruses.

Laryngotracheitis and spasmodic croup are common illnesses in children and are due to viruses or *Mycoplasma pneumoniae*. The most important agent is parainfluenza virus type 1. This virus, as well as parainfluenza type 2 and influenza A and B viruses, results in outbreaks of disease. In areas of the world

Table VIII.30.1. *Classification of crouplike illnesses*

Infectious
Epiglottitis
Laryngitis
Laryngotracheitis and spasmodic croup
Laryngotracheobronchitis
Laryngotracheobronchiopneumonitis
Mechanical
Foreign body
Postintubation trauma
Allergic
Acute angioneurotic edema

where diphtheria toxoid immunization is not carried out, laryngotracheitis is also caused by *Corynebacterium diphtheria*.

Laryngotracheobronchitis and laryngotracheobronchiopneumonitis are frequently caused by the same viruses that cause laryngotracheitis. These two illnesses are caused also by *S. aureus, Streptococcus pyogenes, S. pneumoniae,* and *H. influenzae.*

Epidemiology

Croup syndromes occur worldwide. Most illnesses are due to the common croup viruses: parainfluenza types 1 and 2 and influenza viruses. Outbreaks occur every year during the cold-weather months; in the tropics croup is more common during the rainy season. The highest attack rate occurs in children 7 to 36 months of age; few cases occur in children after the sixth birthday. During the second year of life, about 5 percent of children experience an episode of croup. Croup is more common in boys than in girls and also tends to be more severe in boys.

The viruses that cause croup are present in the nasal secretions of adults and children with colds and other upper and lower respiratory tract illnesses. Virus is transmitted from infected persons by sneezing, nose blowing, and the general contamination of external surfaces (including the hands) with nasal secretions. A susceptible child can become infected either by inhaling virus in droplet nuclei (small particles) or by a direct nasal hit of virus-containing large droplets from a sneeze or nose blowing. Infection can also occur indirectly as a result of contamination of the fingers of the recipient. It is important to emphasize that parainfluenza virus infections in adults are manifested by colds; older persons with relatively trivial illnesses may be the source of severe croup in young children.

Clinical Manifestations

Acute Epiglottitis

Acute epiglottitis is a disease of relatively abrupt onset and rapid progression which, if untreated, results in death due to airway obstruction. Illness is characterized by fever, severe sore throat, dysphasia, and drooling. Airway obstruction is rapidly progressive and is associated with inspiratory distress, a choking sensation, irritability, restlessness, and anxiety. In contrast to viral croup, the patient is not hoarse and does not have the typical "croupy cough," but the speech is muffled or thick-sounding. The child with epiglottitis insists on sitting up and

will become worse and exhibit great anxiety if forced to lie down.

Patients with epiglottitis will have leukocytosis with neutrophilia and positive blood cultures for *H. influenzae* type B. The epiglottis is swollen and cherry red. Therapy depends upon rapid diagnosis, the establishment of an airway, and the administration of antibiotics appropriate for the treatment of *H. influenzae* type B.

Acute Laryngotracheitis

In this section, only viral causes of croup are discussed. Initial symptoms in laryngotracheitis are usually not alarming and include nasal dryness, irritation, and coryza (profuse nasal discharge). Cough, sore throat, and fever occur. After 12 to 48 hours, signs and symptoms of upper-airway obstruction develop. The cough becomes "croupy" (sounding like a sea lion), and there is increasing respiratory stridor (difficulty associated with inspiration). The degree of airway obstruction is variable. Most severe disease is manifested by marked respiratory distress with supra- and infraclavicular and sternal retractions, cyanosis, and apprehension. Hypoxia can occur, and if there is no intervention, asphyxial death will occur in some children.

In laryngotracheitis the walls of the trachea just below the vocal cords are red and swollen. As the disease progresses, the tracheal lumen will contain fibrinous exudate, and its surface will be covered by pseudomembranes made up of exudative material. Because the subglottic trachea is surrounded by a firm cartilaginous ring, the inflammatory swelling results in encroachment on the size of the airway; it is often reduced to a slit 1 to 2 millimeters in diameter.

The treatment of laryngotracheitis includes the following: oxygen for hypoxia, fluids (locally via aerosol and systemically) to liquefy secretions, racemic epinephrine by aerosol to decrease inflammatory edema, and rarely the establishment of the mechanical airway. Corticosteroids are also frequently administered to decrease inflammation, but their use is controversial.

Spasmodic Croup

This croup is a distinct clinical syndrome, which in some instances is difficult to distinguish from mild laryngotracheitis. In contrast to laryngotracheitis in which the obstruction is due to inflammatory exudate and cellular damage, the obstruction in spasmodic croup is due to noninflammatory edema. Illness always has its onset at night, and it occurs in children thought to be well or to have a mild cold

with coryza. The child awakens from sleep with sudden dyspnea, croupy cough, and inspiratory stridor. There is no fever.

Spasmodic croup tends to run in families, and affected children often have repeated attacks. Treatment relies upon the administration of moist air and reassurance by the parents.

Acute Laryngotracheobronchitis and Laryngotracheobronchiopneumonitis

These illnesses are less common than laryngotracheitis and spasmodic croup but are more serious. Initial symptoms and signs are similar to those of laryngotracheitis. Usually the signs of lower respiratory involvement develop 2 to 7 days into the illness; occasionally both upper- and lower-airway obstructions occur simultaneously. In addition to the usual findings in croup, patients with laryngotracheobronchiopneumonitis will have rales, air trapping, wheezing, and an increased respiratory rate.

The illness is due to a more generalized infection with parainfluenza or influenza viruses or to secondary bacterial infection of the trachea, bronchi, and lungs. Exudate, pseudomembrane, and respiratory epithelial damage occur. Care involves appropriate antibiotics in addition to conventional treatment for laryngotracheitis.

History

The word *croup* is derived from the Anglo-Saxon word *kropan,* meaning "to cry aloud." Croup was first used in medical writing in 1765 by Francis Home, a Scottish physician. Until this century virtually all croup-like illnesses were confused with diphtheria.

Daniel Slade in 1864 traced the clinical history of diphtheria to the time of Homer, and A. Sanné in 1887 believed that the writings of Hippocrates demonstrate knowledge of diphtheria. Aretaeus of Cappadocia, in the second century A.D., noted extension of the disease to the lower respiratory tract, which resulted in death by suffocation. Galen noted the expectoration of the pseudomembrane. At this time, the disease was common in Syria and Egypt and was called *ulcus Syriacum* or *Egyptiacum* by Aretaeus. Aetius of Amidu, in the fifth century, added his experiences to the previous descriptions of Aretaeus. Although both Aretaeus and Aetius were describing diphtheritic croup, it is clear that there was confusion with other illnesses such as Ludwig's angina and streptococcal tonsillitis.

The historical trail of diphtheria disappeared in the fifth century and did not reappear until the sixteenth century: First, in 1557, Peter Forest described

an epidemic in Alkuaer, Holland. Then in 1576, Guillaume de Baillou described an epidemic in Paris and specifically commented on false membrane. In 1771 Samuel Bard published the first U.S. report on the nature, causes, and treatment of suffocative angina. Pierre Bretonneau named diphtheria in 1826 and recognized its infectious nature. T. A. Edwin Klebs in 1883 noted the diphtheria bacillus in smears from pseudomembranes, and a year later Friedrich Löffler established the organism as the etiologic agent.

From 1920 to 1940 the incidence of diphtheria in the United States fell from approximately 200 cases to 20 cases per 100,000 population as a result of the use, first, of toxin-antitoxin and then of toxoid. In association with this decline in diphtheria, and also predating it, there was a general realization of other cases of croup in this century. Prior to 1900, only occasional notations of illnesses suggesting nondiphtheritic croup appeared. For example, E. Bouchut in 1852 described false croup, *Stridalous laryngitis,* which seems to have been spasmodic croup. In his treatise (1887), Sanné referred to an epidemic of simple croup in Germany, and Home (1765) noted two forms of croup. Bretonneau differentiated diphtheria from spasmodic croup in 1826.

In the United States during the first half of the twentieth century, severe croup was called laryngotracheal-bronchitis. It was recognized that it was caused by *C. diphtheria* bacteria and by other bacteria as well. In 1948, Edward Rabe described three types of croup infections: diphtheritic croup, *H. influenzae* type B croup (epiglottitis), and "virus" croup. Shortly thereafter, with the widespread use of tissue culture techniques, the viral etiology of croup was confirmed. During a period of approximately 30 years (1950–79), croup due to bacteria other than *C. diphtheria* was overlooked in medical papers and textbooks. In 1976, nondiphtheria/bacterial croup was rediscovered, and since then it has received considerable attention in the literature.

The history of spasmodic croup is not clear because the clinical and pathological aspects of the entity are poorly defined. In the 1940s spasmodic croup was separated from other more severe forms of croup by Francis Davison; however, since then the pathogenesis of this entity has received little attention.

VIII.31
Cystic Fibrosis

Cystic fibrosis, also called fibrocystic disease of the pancreas, and mucoviscidosis, is a genetically determined disease of infants, children, and young adults. Most of its many manifestations result from the abnormally viscous mucus, which interferes with pulmonary function, and the insufficient production of pancreatic digestive enzymes, which causes nutritional deficiencies and developmental retardation.

Etiology

Among Caucasians, cystic fibrosis (CF) is the most common fatal disease having an autosomal recessive inheritance. Despite the primary involvement of several organs, the disease is caused by a single defective gene that is located on chromosome 7 and is carried by about 4 percent of the Caucasian population. Its expression is similar in both sexes.

Clinical Manifestations

CF manifests itself at birth in about 8 percent of cases through mechanical obstruction of the small intestine by the secretion of abnormally viscous mucus (meconium ileus). Symptoms of insufficient secretion of exocrine (noninsulin) digestive enzymes by the pancreas appear during the first year of life in 90 percent of cases. The development of such symptoms indicates that pancreatic function is less than 10 percent of normal; and the more severe the deficiency of pancreatic enzymes, the more severe the fecal excretion of undigested fat, usually as diarrhea. As much as 80 percent of dietary fat may be lost, thus partially explaining malnutrition. Loss of undigested nutrients can be corrected only partially by treatment with pancreatic enzyme tablets. Pulmonary disease is responsible for most of the debility and mortality. Onset occurs in the first 2 years of life in at least 75 percent of cases, and by the age of 6 years in most of the remaining cases. The initial pulmonary abnormality is obstruction of the small bronchi by abnormally thick mucus. Structural deterioration of the lungs results in part from this and is exacerbated by an increased susceptibility to infections. A small number of patients retain sufficient pancreatic function to maintain nearly normal digestion; such patients also tend to have fewer respiratory difficulties. The variability in severity is ex-

plained by the occurrence of several different mutations on the pathogenetic gene.

The sweat of a child with CF contains a concentration of sodium and chloride that is about five times greater than normal, although salt is not lost excessively by other routes. Determining the salt content of perspiration has become a basic diagnostic test. The propensity to become salt-depleted makes persons with CF particularly intolerant to heat. As a result of pulmonary and metabolic therapy, many CF patients are now living into reproductive age, and thus it has been found that CF men, but not CF women, are sterile. In spite of all efforts, few patients survive to age 40.

History and Geography

According to a medieval German saying, "The infant who when kissed leaves a taste of salt will not reach the first year of life." Hence, CF was probably recognized many centuries ago. However, it was first identified in 1936 by the Swiss pediatrician Guido Fanconi and associates, and further delineated by Dorothy H. Andersen of New York in 1938. The diagnostic perspirational salt loss was quantified by Paul di Sant'Agnese and associates (New York) in 1953.

CF is most prevalent among people of central European ancestry (1 in 2,000 to 3,000 births) and is somewhat less common in Scandinavia. Inbreeding explains incidences of greater than 1 per 1,000 in small areas. For example, the prevalence of CF among nearly 11,000 Amish in one Ohio county was more than 1 per 600, with all cases within six families, whereas there were no cases in another Amish community in a nearby county. Similar results of inbreeding have been reported from Brittany and from Afrikaners in Namibia. CF has been reported in about 1 in 17,000 black Americans, and in 1 in 90,000 Orientals (mainly Japanese) in Hawaii. The prevalence of CF has not been investigated adequately in Asia or Africa. It is possible that its true prevalence is masked by high infant mortality in large portions of these continents.

The CF gene was identified in 1989. With the rapid advances in gene transfer therapy, it may soon become possible to correct the defect from which the multiple pathological processes of this disease result. Then, instead of merely prolonging life by treating the symptoms, physicians may give CF infants a normal future.

VIII.32
Cytomegalovirus Infection

Cytomegalic inclusion disease (CID) usually occurs as a subclinical infection followed by periodic reactivation revealed by shedding of the virus. It may be serious in the neonate when infection is transmitted to the fetus in utero.

Clinical Manifestations and Pathology
Cytomegalic infection is characterized histologically by the presence of large cells containing inclusion bodies in the midst of an infiltration of mononuclear cells that may be present in any of the body organs.

In prenatal infections most infants are born without clinical evidence of disease, although some 10 to 15 percent may show microcephaly, retardation of growth or mental development, hepatosplenomegaly, jaundice, and calcifications in the brain. There may be abnormalities in liver function tests and in hematopoiesis. Some 10 to 30 percent of infants with symptomatic disease die in early life. Evidence of involvement of the central nervous system can develop in the early years of life, even though the child may appear normal. The evidence is manifested as impaired intellect, neuromuscular abnormalities, chorioretinitis, optic atrophy, or hearing loss.

Neonatal infection acquired at birth from an infected cervix or later from the mother's milk usually goes unnoticed but can be identified by the development of antibodies. In addition, respiratory symptoms including pneumonia, as well as petechial rash and enlargement of the liver and the spleen, may occur. In these cases, however, acute involvement of the central nervous system is rare.

Infection in children is generally asymptomatic and is evidenced only by the development of antibodies and the shedding of virus. Occasionally hepatosplenomegaly and abnormal liver function are found. There is no proof that pharyngitis occurs at the presumed portal of entry.

When infection occurs in adults the clinical picture is similar to infectious mononucleosis, with pharyngitis; lymphadenopathy; systemic symptoms of fever, chills, and headaches, and occasionally a maculopapular rash being the primary symptoms. Atypical lymphocytosis is usual, and there may be abnormal liver function.

In instances where the disease is transmitted by transfusion of blood or its products, the infectious mononucleosis syndrome usually appears as a posttransfusion episode at 2 to 4 weeks. Immunocompromised patients are at special risk of exogenous infection by transplanted organs or by transfusions, or of activation of the latent state. Death may occur from interstitial pneumonia, often complicated by superinfection with gram-negative organisms, fungi, or other unusual invaders.

Distribution and Incidence
Serologic studies show that cytomegalic inclusion disease has a worldwide distribution. It remains asymptomatic despite prolonged shedding of the virus at periodic reactivation but is not highly communicable. Presumably the virus is spread mainly by contact with oral secretions because it is shed from the salivary glands, and cultures from pharyngeal lymphoid structures commonly are positive. The virus has been isolated from urine, breast milk, semen, and cervix uteri, and consequently the infection may be a sexually transmitted disease.

The most serious aspect of CID is its role as a prenatal disease. Even though the mother is asymptomatic and immune, transmission of the virus to the fetus does occur. Recurrence of infection is the most probable explanation for prenatal infection although, of course, primary infection may occur during pregnancy, and there is evidence suggesting that infection in the offspring is more serious under such circumstances than when infection takes place because of recurrence in a mother protected by antibodies. A recent study has shown that children infected in a day-care center may be the source of infection for pregnant mothers.

With a disease spread mainly by oral secretions, a higher incidence is to be anticipated in those living in crowded and unhygienic surroundings. For example, 100 percent of the women in Tanzania have antibodies by the time they reach childbearing age. Other studies show seropositivity in 50 to 80 percent of children in boarding schools and orphanages in England as compared to 10 percent to 20 percent in children of the same age attending day schools. In Puerto Rico, between 70 and 80 percent of adults have the antibodies, whereas in London the figure is only 50 to 60 percent. J. A. Hanshaw has pointed out that studies in the United States and the United Kingdom show that from 0.2 to 7.5 percent of newborns are virus positive, making this disease the most common fetal infection. In the United States, the complement-fixing antibody is present in 5 to 25 percent of infants 8 to 24 months of age. In a study of

the prevalence of cytomegalovirus excretion in 244 children aged from less than 1 year to 4 years in five day-care centers of a southern city of the United States, each child was tested for viral isolation by mouth swab and urine sample. It was found that 49 percent, 40 percent, 32 percent, 13 percent, or 9 percent of children, depending on the center, were excreting virus. Of the workers at the centers, 50 to 100 percent had antibodies to the virus, as did 56 to 88 percent of the parents.

Immunology

Antibodies develop upon infection to last for life. Nevertheless, as in other diseases caused by the herpesviridae, the presence of circulating antibodies even in high titer does not forestall recrudescences of infection.

History and Geography

Early in this century, pathologists noted the enlarged cells with inclusion bodies in organs of children dying of presumed congenital syphilis. The inclusions were thought to be amebae. In 1921 E. W. Goodpasture and F. B. Talbot noted their similarity to changes found in varicella and guessed they represented viral infection and described the cellular enlargement as "cytomegaly." The virus was isolated in 1956 by investigators working independently in St. Louis, Boston, and Bethesda. Epidemiological studies became feasible with the recognition of antibodies to the virus in 1968. A rapid expansion of knowledge concerning epidemiology, incidence, and clinical manifestations continues from the late 1960s.

VIII.33
Dengue

Dengue is an acute febrile disease caused by infection with a group B arbovirus of four serotypes, transmitted by the bite of infected *Aedes aegypti* and *Aedes albopictus* mosquitoes. Endemic throughout the tropics and subtropics, uncomplicated dengue is rarely fatal, although return to normal health after an attack may take several weeks. It does not always have a benign course, however, and can be complicated by hemorrhagic manifestations (hemorrhagic dengue) and circulatory collapse (dengue shock syndrome) with a potentially fatal outcome unless facilities are available for the urgent medical treatment of those affected.

Typical uncomplicated dengue has an incubation period of 3 to 15 days and is characterized by abrupt onset of chills, headache, lumbar backache, and severe prostration. Body temperature rises rapidly, perhaps reaching as high as 40°C; bradycardia (slow heart rate) and hypotension (low blood pressure) accompany the high fever. Conjunctival injection, lymph node enlargement, and a pale, pink rash, especially noticeable on the face, are usually present during this first phase of the disease. In classical dengue, the fever lasts for 48 to 96 hours initially, subsides for 24 hours or so, and then returns (*saddleback fever*), although the peak of temperature is usually lower in the second phase than in the first. A characteristic red rash appears in the second phase, usually covering the trunk and extremities, but sparing the face. The fever, rash, and headache, together

with the other pains, are known as the *dengue triad*. The acute illness ends in 8 to 10 days, and one attack confers immunity to the particular dengue subtype.

Hemorrhagic dengue usually strikes children under the age of 10 and has its highest mortality rate in infants under the age of 1 year. It is more likely to occur when type 2 dengue virus infection follows an earlier type 1 infection in the same individual or when subgroup-specific antibodies have been acquired transplacentally from an immune mother, a phenomenon known as *enhancement*. Signs of this ominous complication usually occur between the second and the sixth day of the illness and include sudden collapse with a rapid pulse of low volume; cyanosis (blue discoloration) of lips, ears, and nail beds; and cold, clammy extremities while the trunk remains warm. Nosebleeds, the appearance of spontaneous bruising, prolonged bleeding from injection sites, and bleeding from both the upper and lower gastrointestinal tract signal the gross disturbances of blood coagulation mechanisms that occur in this form of the disease.

The world *dengue* comes from the Spanish, a homonym for the Swahili *Ki denga pepo* (a sudden cramplike seizure caused by an evil spirit); it was introduced into English medical usage during the Spanish West Indies epidemic of 1827 and 1828. The synonym *breakbone fever* dates from Philadelphia in 1780, and the term *knokkel-koorts* comes from Batavia about the same year. All of these terms refer to some characteristic of the disease, either its sudden onset or the severity of its musculoskeletal pain, or both.

Etiology and Epidemiology

Dengue viruses belong to the family of flaviviridae, the prefix of the family name being derived from *flavus* (Latin: "yellow") and referring to the yellow fever virus. The family consists of the genus *Flavivirus*, which has 65 related species and two possible members – cell fusing agent (CFA) virus and simian hemorrhagic fever virus.

Most flaviviruses are arboviruses, and all are serologically interrelated. They infect a wide range of vertebrate hosts, causing asymptomatic infections and diseases such as yellow fever, dengue, and numerous encephalitides. *A. aegypti* and *A. albopictus* are responsible for dengue transmission in Asia. *A. albopictus* has recently been discovered in the United States and in Brazil, but it has not yet been implicated in the transmission of disease. It is an aggressive, human-biting mosquito with both urban and rural habitats and transmits dengue viruses

transovarially (from female mosquitoes to their offspring through infection of the eggs) and from person to person. Populations of *A. albopictus* found in the United States are capable of overwinter survival in northern latitudes because they are capable of diapause, and thus the spread of this particular mosquito represents a major public health concern. Although recent outbreaks of dengue in Brazil have been atrributed to *A. aegypti,* the presence of *A. albopictus* gives rise to serious concern that it may become an important vector for the introduction of flaviviruses into areas previously free of them.

A. albopictus is primarily a sylvan species that has become adapted to the urban environment, although it is not as strongly dependent on humans as is *A. aegypti*. It breeds in tree holes, bamboo stumps, coconut husks, and other naturally occurring containers in Asia, as well as in tires and discarded water containers. It has apparently been established in Hawaii for many years, although Hawaii seems to be free from dengue.

Dengue outbreaks are particularly likely in endemic areas when there has been a heavy rainfall. Monthly rainfall exceeding 300 mm is associated with a 120 percent increase in the number of cases of dengue, and the lag time between the onset of heavy rain and the outbreak of dengue is between 2 and 3 months. Any condition that increases the number of mosquito breeding sites, or the number of susceptible persons, in dengue endemic areas automatically facilitates the transmission of dengue.

Immunology

Infection with one dengue serotype confers long-lasting type-specific protection, a benefit that may be more apparent than real because the type-specific protection also brings a greatly increased susceptibility to severe dengue disease in the event of infection with dengue virus of another serotype. Epidemiological studies clearly link the severe forms of dengue disease to previous dengue infection and to transplacental acquisition of maternal dengue antibody.

Dengue virus infects mononuclear phagocytes, and there is both in vitro and in vivo evidence that the interaction is facilitated and severe infection more likely when antibody to another dengue serotype is present. This phenomenon alone has important implications for the development of dengue vaccines. Administration of monovalent or polyvalent vaccines, even if they were now available for human use, carries with it serious risk of predisposing partially immune populations to further and more serious dengue virus disease.

Secondary dengue infections that carry no risk of dengue hemorrhagic fever or dengue shock syndrome can occur when sequential dengue infections occur at intervals of 5 or more years, when sequential infections do not end with dengue type 2, and when two or more dengue viruses, including type 2, are endemic in the same area. Malnourished children and alpha-thalassemia patients have a greatly reduced risk of dengue hemorrhagic fever and dengue shock syndrome.

Clinical Manifestations and Pathology

Dengue is characterized by sudden onset of high fever, headache, prostration, joint and muscle pain, lymphadenopathy, and a rash that appears simultaneously with a second temperature rise following an afebrile period (saddle-back fever). However, classical saddle-back fever occurs in only 50 percent of cases; lymphadenopathy is not an invariable finding; and the rash may either never develop at all or else not develop until the fourth or fifth day, or during the second phase if the fever is saddle-backed.

An outbreak of dengue fever occurred at Clark Air Force Base, a large U.S. military installation located about 70 kilometers north of Manila on Luzon Island, Republic of the Philippines, between June and September 1984. Of 119 persons suspected of having dengue, 42 cases were confirmed by hemagglutination-inhibition (HI) antibody seroconversion or by virus isolation. Seroconversion implies that HI antibody was lacking in the serum of patients at an early stage of their illness, but could be detected subsequently, usually during convalescence, providing indirect evidence of the cause of the illness. Virus isolation from the blood of dengue-infected persons is the most accurate diagnostic test for dengue, but it is impracticable for widespread use because the vast majority of cases of dengue infection occur in parts of the world where sophisticated medical facilities are simply not available. A further nine cases were considered to be probable dengue, as HI antibody was detectable in serum obtained from patients during the acute phase of their illness.

The most frequent clinical findings were fever (97 percent), headache (80 percent), and muscle and joint pain (80 percent). Other signs and symptoms frequently reported were malaise, chills, anorexia, nausea, vomiting, diarrhea, and maculopapular skin eruption (blotchy, raised, red rash). Dizziness, unusual taste sensation, and itching/scaling of the palms were less frequently reported. Hemorrhagic signs occurred in 18 patients and consisted of petechiae (pinpoint hemorrhages into skin and mucous membranes) in 13 patients, gastrointestinal bleeding in 4 patients, and gum bleeding in 1 patient.

Common laboratory findings in 29 patients admitted to hospitals were low white blood cell count, relative lymphocytosis (71 percent), and a reduced platelet count. All four dengue serotypes were isolated (12 cases of dengue 1, 4 cases of dengue 2, 5 of dengue 3, and 1 of dengue 4). All patients survived their illness and returned to normal health. This outbreak of mixed classical benign dengue fever and dengue hemorrhagic fever of multiple serotype is typical of current dengue epidemics.

Severe dengue disease – dengue hemorrhagic fever and dengue shock syndrome – proceeds through two stages. The first is similar to that of benign dengue; however, patients deteriorate during or shortly after the fall in temperature. If hypovolemic shock supervenes (because of a greatly reduced volume of plasma), untreated patients may expire within 6 hours. The clinical evidence of disturbances of blood coagulation is accompanied by abnormal laboratory tests. Hemoconcentration and reduced platelet count are invariable findings. Reduced levels of serum albumin, elevations of serum transaminases and blood urea nitrogen, prolonged prothrombin time, and reduced serum levels of factors II, V, VI, IX, and XII are common. Hypofibrinogenemia is a frequent finding, and the condition is best described as an acute vascular permeability syndrome accompanied by activation of the blood clotting and complement systems.

The World Health Organization has developed diagnostic criteria for dengue hemorrhagic fever and dengue shock syndrome:

Clinical

a. Fever – acute onset, high, continuous, and lasting for 2 to 7 days
b. Hemorrhagic manifestations including at least a positive tourniquet test and any of:
   petechiae, purpura, ecchymosis (skin eruptions)
   nose or gum bleeding
   hematemesis and/or melena (passing of black stools)
c. Enlargement of liver
d. Shock – manifested by rapid and weak pulse with narrowing of the range of pulse pressure (20 mmHg/2.7 kPa or less) or hypotension, with cold, clammy skin, and restlessness

Laboratory

a. Thrombocytopenia (0.10×10^{12}/L or less)
b. Hemoconcentration – hematocrit increased by 20 percent or more

Distribution and Incidence

Dengue literally girdles the globe, with a distribution approximately equal to that of its principal vector, *A. aegypti*. Areas of dengue endemicity include tropical and subtropical regions of the Americas, Africa, Asia, and Australia. There are areas of *A. aegypti* infestation in Europe and in the southern United States, where dengue has caused epidemics in the fairly distant past, but which have no current dengue activity although they remain susceptible to its reintroduction. The example of the 1927–8 outbreak of dengue in Athens and adjacent areas of Greece illustrates such a situation, for, although type 1 dengue virus caused an epidemic with a high incidence of hemorrhagic manifestations and a high death rate in the region, that region today is not considered to be one of significant dengue prevalence.

Types 1, 2, 3, and 4 dengue viruses are endemic in Asia. Types 1, 2, and 3 are prevalent in Africa, where type 3 is the most recent arrival, first identified in Mozambique during the 1984–5 epidemic. Types 1, 2, 3, and 4 are now present in the Americas, where type 1 made its first appearance in 1977; in the Caribbean, type 4 appeared in the same region in 1981. Type 1 dengue virus was found to be responsible for the 1981–2 Australia epidemic in northern Queensland.

Dengue fever epidemics typically involve large numbers of people and have a high attack rate. As many as 75 percent of the susceptible persons exposed to dengue virus will acquire the disease. Mosquitoes take between 8 and 11 days to become infectious after ingesting infected blood, and remain infectious for life; therefore, a single mosquito can infect a number of members of a household. The 1977 Puerto Rican dengue epidemic resulted in the infection of an estimated 355,000 persons with types 1, 2, and 3 virus; the 1986 Rio de Janeiro type 1 epidemic affected 100,00 persons between March and May alone.

Recurrent outbreaks of dengue in the same geographic region indicate either that new dengue virus types have been introduced or that endemic types are now affecting groups of the population lacking immunity – generally those born since the last epidemic.

Dengue hemorrhagic fever is especially frequent in Southeast Asia, where it is among the leading causes of hospital admissions in children and the commonest cause of death from communicable disease at any age. Dengue hemorrhagic fever's first reported appearance in epidemic form in the Western Hemisphere came during the 1981 Cuban epidemic. Several cases of dengue hemorrhagic fever with shock and death were reported during the 1984–5 Mozambique epidemic. Review of data from the 1897 epidemic of dengue in north Queensland suggests that the deaths of 30 children were the result of dengue shock syndrome.

A. aegypti is primarily a domestic mosquito, breeding around areas of human habitation in discarded tires, cans, and other containers that can act as receptacles for the water necessary for the mosquitoes' breeding places. Worldwide increase in dengue activity appears to be directly related to a failure to control mosquito populations effectively, to overpopulation, to progressive urbanization, and to the social and political disruptions caused by wars. Although a jungle cycle involving forest mosquitoes and wild monkeys, in a fashion similar to that of yellow fever, has been demonstrated, zoonotic acquisition of dengue does not appear to be a factor in the general pattern of increasing dengue prevalence.

The current pattern of dengue epidemiology in the Americas resembles that of Southeast Asia in the 1950s, before it changed from a benign flulike illness to the leading cause of morbidity and mortality in children.

History and Geography

Dengue has been known as a distinct disease entity for at least several centuries. Benjamin Rush is traditionally given credit for historical priority with his account of breakbone fever, the epidemic that afflicted Philadelphia in 1780. Although his 1789 *Account of the Bilious, Remitting Fever* is generally accepted as the first modern medical account of dengue, claims have also been made on behalf of David Bylon, a Dutch physician who described an epidemic of knokkel-koorts (knuckle-fever), which appeared in the Dutch East Indies in 1779.

The disease discussed by Bylon (1780) superficially resembles dengue (sudden onset of high fever, severe musculoskeletal pain, facial rash, and swelling, benign outcome), but appears atypical in that the severe joint pain suggested by the name is more characteristic of Chikungunya (CHIK) fever, a group A arbovirus infection with a mosquito vector. Bylon, state surgeon to the city of Batavia, treated 89 patients for knokkel-koorts and then caught it himself. His illness began with pain in the joints of his right hand and arm, and rapidly progressed to include a high fever within a few hours. He concluded his account of the epidemic by remarking that the disease was well known in Batavia, but had never before reached epidemic proportions. That alone would serve to distinguish knokkel-koorts

from dengue, given what we know of the epidemiology of the latter disease.

Patrick Macdowall was a Scot who participated in the Darien Scheme, which was an attempt to found a Scottish colony in 1699 on the Isthmus of Panama, then known as Darien. The plan was the brainchild of William Paterson, the founder of the Bank of England, and was intended to gain for Scotland a share of the riches of the New World from Darien's advantageous position astride the Atlantic and Pacific trade routes. The colonists were ravaged by disease, and Macdowall, who kept a journal still preserved in the National Library of Scotland, gave an excellent description of his own illness, which could well have been dengue. Macdowall survived an acute febrile illness lasting 4 or 5 days that was characterized by nausea, vomiting, prostration, severe retro-orbital headache, disordered sensation of taste, bone and joint pain, generalized rash, and faintness. His convalescence was prolonged and marked by general weakness and a continual tendency to faintness.

Was Macdowall's illness dengue? Classical saddle-back fever occurs in only 50 percent of cases of dengue, and even lymphadenopathy is not an invariable finding. Macdowall's personal case history may well be the earliest recorded description of dengue.

The importance of the mosquito in the transmission of dengue was recognized early this century when T. L. Bancroft, using human volunteers, proved that dengue could be transmitted via the bite of infected *Stegomyia fasciata* (*A. aegypti*) mosquitoes and that the infecting agent was neither an intracorpuscular parasite nor a bacterium, but an ultramicroscopic organism. His observations also incriminated *A. aegypti,* of all the possible culprits, as the actual disease vector. However, he erroneously concluded that the dengue organism lives only for a few days in infected mosquitoes, because his attempts to transmit the disease were unsuccessful when he used mosquitoes that had been infected 15 or more days previously. The most likely reason for this error is the inadvertent inclusion of immune subjects in the study population. This, however, should not detract from the credit due him as the person who recognized the viral etiology and mosquito transmission of dengue long before Albert Sabin was able to cultivate the virus in the laboratory in the late 1940s.

Proof that *A. albopictus* is a vector of dengue came in 1931 when James S. Simmons and co-workers published an account of their experimental studies on dengue in the Philippines.

The general pattern of dengue activity since World War II has been one of increasing prevalence and severity within the context of unrestrained proliferation of its vectors. Today those vectors that spread yellow fever as well as dengue pose a very real threat to humanity.

Diabetes

Diabetes mellitus (DM) is an endocrine disorder characterized by the lack or insufficient production of insulin by the pancreas. DM has been recognized as a disease for at least two millennia, but only since the mid-1970s has there been a consensus on its classification and diagnosis.

The primary diagnostic criterion for DM is elevation of blood glucose levels during fasting or at 2 hours following a meal. Normal plasma glucose values for adults in the fasting state are 80 to 120 milligrams per deciliter (mg/dL) or 4.4 to 6.7 millimoles per liter (mmol/L). Definition of unequivocal DM requires a 2-hour postingestion plasma glucose level equal to or greater than 200 mg/dL (11.1 mmol/L) for the appearance of classical symptoms of diabetes. These symptoms, which include excessive urination, urine containing sugar, hunger, thirst, fatigue, and weight loss, are common to all types of DM.

Classification

Today the designation *type I DM,* or *insulin-dependent diabetes,* has replaced terms such as ketosis-prone, juvenile-onset, brittle, and so forth, whereas *type II DM,* or *non–insulin-dependent diabetes,* has replaced the terms ketosis-resistant, maturity-onset, and mild diabetes. Many terms were also used for impaired glucose tolerance, a condition that may be a precursor to overt diabetes. Some of these earlier terms include latent, subclinical, and chemical diabetes, or prediabetes. Other variants of DM include maturity-onset diabetes of youth (MODY), tropical or J-type diabetes, which shows characteristics of both insulin dependence and non–insulin dependence, and gestational diabetes, which occurs during the latter part of pregnancy.

Approximately 90 to 95 percent of all individuals with DM may be classified as non–insulin-dependent, and about 5 percent as classically insulin-dependent. Diabetes may also be secondary to certain conditions or syndromes that result in the permanent or temporary destruction of the insulin-producing pancreatic islet cells. Some 2 percent of diabetes have DM secondary to disease, genetic syndromes, drugs, chemicals, or traumatic injury.

History of the Classification

As early as the sixth century, Hindu physicians recognized the clinical symptoms of diabetes and attributed them to dietary indiscretion. Early descriptions were based on the classic symptoms of diabetes, including its most salient sign of excessive urination. The term *diabetes,* meaning "to run through," was first used in the second century by Aretaeus.

In 1679 Thomas Willis noted the sweet taste of urine from diabetics, and in 1776 Matthew Dobson of Manchester was able to demonstrate that one could assay the amount of sugar in the urine by evaporating it and weighing the dried residue. Dobson stated that this residue looked and tasted like "ground sugar." It was by the absence of this sweet taste that DM was distinguished from *diabetes insipidus.* The thirst and excessive urination of the latter uncommon unrelated disease is caused either by a lack of the antidiuretic hormone from the posterior pituitary gland or by the unresponsiveness of the renal tubules to this hormone. Therefore, glycosuria (sugar in the urine) became diagnostically important and later was used to measure the effectiveness of treatment of DM. In 1815 M. D. Eugène Chevreul published his discovery that glucose is present also in the blood of diabetics.

From the mid-1700s until the 1970s, many types of diabetes were described. Observations by Apollinaire Bouchardat, culminating in his 1875 book on glycosuria, clearly distinguished two types of diabetes: In type I, the patients were relatively young; the onset was acute, weight loss was striking, and death ensued rapidly from *ketoacidosis* – the buildup of poisonous ketones from excessive fat metabolism. In type II, the patients were older and tended to be overweight, and the onset was slower. Some of these individuals could control their glycosuria with a low carbohydrate diet.

Much of the early work focused on elucidating the causes of polyuria. John Rollo, in the late 1790s, did an extended metabolic study of an obese diabetic patient at the Greenwich Naval Hospital. He noted that the amount of urine excreted depended upon the type of food that was eaten. Urinary production increased after ingestion of vegetables and decreased when the diet was high in animal fat and protein. These findings shifted the focus from the kidneys to the gastrointestinal tract and provided a scientific basis for therapeutic diets high in fat and protein and low in carbohydrates.

The gross autopsies that were performed in the 1850s and 1860s revealed no abnormalities of the pancreas of diabetics. In 1855 the French physiolo-

gist Claude Bernard discovered that the liver secretes glucose from the "animal starch" stored in it. Bernard and Moritz Schiff, furthermore, found that the apparent destruction of the pancreas in experimental animals did not result in the onset of diabetes. These findings led some to believe that a liver disease was the source of diabetes. Attention was redirected to the pancreas in 1889 when Josef von Mering and Oscar Minkowski demonstrated that complete removal of the pancreas did cause diabetes in dogs.

Specialized "heaps of cells" had been identified in the pancreas by Paul Langerhans in 1869. Continued research by Minkowski and others in the 1890s demonstrated that these "islets of Langerhans" were the source of an "internal secretion" that regulated glycosuria. This work suggested convincingly that DM is caused by a disorder of the endocrine portion of the pancreas. In 1921 Charles Best and Frederick Banting (Toronto) were able to isolate the internal secretion and named it *insulin*. They realized that insulin is responsible for the control of blood glucose levels and the appearance of clinical symptoms associated with diabetes. During the 1920s, other hormonal secretions of the pituitary and adrenals were discovered, which indicated that glucose control is more complex. However, insulin alone constituted the antidiabetes hormone used in therapy.

Although insulin was first used in 1922, it was not until the 1950s that appropriate bioassays of human insulin were developed. These definitive measurements clearly showed that individuals with juvenile-onset, or type I, diabetes produced no insulin at all, whereas individuals with maturity-onset, or type II, diabetes had varying amounts of insulin produced by the pancreas. This discovery provided a clear rationale for insulin therapy in those individuals with type I DM, and for diet, exercise, and, after 1955, oral hypoglycemic agents in those with type II diabetes.

The first major epidemiological study of DM, by Haven Emerson and Louise D. Larimore (1924), attempted to explain the increases in diabetes mortality in New York City from 1866 to 1923. A number of factors were considered influential, including race, affluence, lack of physical activity, and changes in dietary habits, which emphasized the increasing abundance of all foods. These authors also noted an increasing prevalence of DM among females over the age of 45. It is, however, the famous American diabetologist Elliott P. Joslin whose studies in the 1930s concerning the "epidemic" of diabetes (Joslin, Dublin, and Marks 1933; Joslin 1935) demonstrated the utility of the epidemiological approach.

Etiology and Epidemiology

Insulin-Dependent Diabetes Mellitus (Type I)

Insulin-dependent DM is characterized by clinically acute onset, usually at an early age, lymphoid infiltration of the islets of Langerhans, reduction in the functioning and production of their betacells, reduction in the production and excretion of insulin, increases in islet cell antibodies, weight loss, thirst, frequent urination, and high levels of blood sugar. After the acute onset of type I diabetes, a clinical remission may occur in 25 to 100 percent of the reported cases for periods ranging from 1.8 to 15 months. After this initial period, all patients require insulin therapy to prevent severe symptoms and profound biochemical aberrations that can lead to ketosis, coma, and death.

Typical type I diabetes is uncommon. The prevalence of insulin-dependent diabetes mellitus is less than 0.5 percent of the world's population. The reported prevalence of type I diabetes ranges from 0.1 to nearly 4.0 per 1,000 children under 20 years of age. There are 18 registries evaluating geographic patterns of type I diabetes, many in northern Europe and North America, and as much as a 35-fold difference in prevalence has been reported among populations around the world.

Genetic Markers. The etiology of type I diabetes is multifactorial. There is strong evidence for a genetic susceptibility associated with the antigens of the major histocompatibility complex, the human leukocyte antigens (HLA). Among individuals in whom DM occurs before the age of 16 years, 90 to 96 percent carry either HLA DR3 or HLA DR4. These are present in about 22 percent and 25 percent of the white population, respectively. The presence of one of these antigens increases the risk of the occurrence of DM 3- to 4-fold. Since only 30 to 50 percent of even these individuals develop DM, environmental factors also appear to have an etiologic role.

Infectious Diseases and Immune Responses. The role of infectious diseases, particularly viruses, coupled with the appropriate HLA type, has been investigated in a number of populations. Although there is ample experimental and clinical evidence to implicate the role of Coxsackie B4, mumps, rubella, and other viruses in the destruction of the betacells of the pancreas, the epidemiological data are not definitive. There were early reports of mumps-induced pancreatitis. In 1927 E. Gunderson observed that mortality rates from diabetes increased 2 to 4 years

after epidemics of mumps. More recently, other viruses have been under investigation. For example, investigators in Poland discovered increases in antibodies against enteroviral meningitis and Coxsackie A and B viruses in newly diagnosed diabetics. The meningitis epidemics regularly preceded periods of increased incidence of diabetes by 4 to 6 months.

Many studies have attempted to link infectious diseases to seasonal patterns in the onset of diabetes. The results have not demonstrated a consistent picture. Furthermore, seasonal variation may be linked to factors other than infectious diseases. Worldwide, there is apparently no "peak season" for the appearance of type I diabetes.

Recent work indicates that there is an autoimmune factor in the destruction of the beta cells of the pancreas. Circulating immune complexes have been found in 30 to 90 percent of all newly diagnosed type I diabetics. Antibodies against islet cells are the most common, but antibodies against gastric parietal cells, thyroid, and adrenal tissue have also been detected in some diabetics. A strong association exists between the presence of autoimmune antibodies and HLA DR3.

Other Population Genetic Factors. Genetic factors at the population level may play a role in the etiology of type I diabetes. The relative risk of HLA DR3 is lowest for African blacks and is approximately the same for Caucasians, African-Americans, and Japanese (relative risk: 3.3–3.5). On the other hand HLA DR4 shows a 3-fold higher risk (9.6) for American blacks than for the other three groups.

Low rates of type I DM are found among New World Asian-derived native populations (Eskimos, Aleuts, and Amerindians), as well as Old World Asian populations, including the Japanese and Chinese. Prevalence rates vary considerably on the Indian subcontinent. Rates are lower in the southern part of India (i.e., Bombay) than in northern India (i.e., New Delhi). K. M. West (1978) cites a number of studies indicating an increased prevalence of type I diabetes among populations that previously showed low rates. Increases are particularly marked among Japanese, black Africans, and black Americans. In general, these increases are associated with a "Westernization" in life-style since World War II.

Biological Factors. Sex and age also play roles in the onset of type I diabetes. In most populations, the number of boys and girls afflicted with the disease is nearly equal. However, in children under 5 years of age, the incidence is slightly higher for boys. Age of onset of type I diabetes peaks at the beginning of puberty and during the adolescent growth spurt for both girls and boys.

Nutritional Factors. Some nutritional factors have been suspected of being involved in the etiology of type I diabetes, although again there is no consistent epidemiological picture. Excess caloric intake does not seem to be the important etiologic factor it is in type II diabetes. A Danish study has reported a negative correlation between breast-feeding and type I DM, and finally T. Helgason and M. R. Jonasson (1981) suspect that *N*-nitroso compounds from smoked mutton may be responsible for the seasonal incidence of type I diabetes found in Iceland, where this meat is traditionally consumed at Christmas time. The range of nutritional factors implicated in type II diabetes is much greater and is discussed below.

Other Factors. A further risk factor in type I DM is urbanization with accompanying changes in life-style and a greater risk of infection due to increased population density. Thus there is generally a higher prevalence of type I diabetes among urban as opposed to rural populations within a given country.

Non–Insulin-Dependent Diabetes (Type II)

Between 90 and 95 percent of all individuals with diabetes have type II diabetes and are over the age of 35 years. In contrast to type I diabetes cases, there are many cases (up to 50 percent) that remain undiagnosed. Type II diabetics produce insulin but may require more of it in order to manage their glucose levels. The majority of all patients are treated with dietary modifications, often with caloric reductions for weight loss, and with oral hypoglycemic tablets. Type II diabetics are ketosis resistant but may suffer from the macrovascular and microvascular complications of ketosis (see Table VIII.34.1).

Many factors have been implicated in the etiology and pathogenesis of type II diabetes. Not only are they numerous but also their interactions are complex.

Genetic Factors. The numerous problems in discovering a genetic mechanism responsible for diabetes have been outlined in works by W. Creutzfeldt, J. Kobberling, and J. V. Neel (e.g., 1976), and K. M. West (1978). Unlike type I DM, type II DM (the more common non–insulin-dependent DM) has no associated genetic markers. However, genetic mechanisms

Table VIII.34.1. *Causes and suspected causes of, and risk factors for, diabetes*

Generally accepted
Obesity
  Caloric excess, indolence
Heredity
Destruction or damage of beta cells
  Cancer
  Pancreatectomy
  Pancreatitis from many causes
  Viral infections
  Coxsackie viruses, measles
  Beta cytotoxic drugs
Diabetogenic hormones (exogenous or endogenous)
  Growth hormone
  Epinephrine
  ACTH or glucocorticoids
Hemochromatosis
Disorders of insulin receptors
Factors of immunity and autoimmunity
Human leukocyte antigens (HLA)

Widely suspected of causing or precipitating diabetes
Pregnancy
Excessive serum iron
Cassava (manioc or tapioca) consumption
Some drugs
Cirrhosis
Potassium deficiency
Certain brain lesions
Affluence in some circumstances and poverty in others
Myotonic dystrophy

Suspected by some scientists but doubted by others
Dietary fat
Dietary sugars
Refined carbohydrates
Insufficient dietary fiber
Contraceptive steroids
Deficiency states
  Chromium, iron, zinc, pyroxidine
Severe protein malnutrition
Psychological stress
Stress of prolonged or severe illness
Temperate climate
Hypertriglyceridemia
Specific racial susceptibility
  (e.g., Jews, Indians, American Indians, Polynesians)

Source: Adapted from K. M. West (1978: 34).

interacting in complex ways with environmental factors are involved in the risk for type II diabetes.

Type II DM occurs more frequently in families in which one or more members have DM than in the general population. Yet family studies have not sup-ported a simple mode of inheritance. A 40-fold risk of DM occurs for children of fathers who had an age of onset of diabetes under 20 years. Risks are somewhat less for children of type I mothers, and are increased only one to three times for offspring of parents who had an age of diagnosis of diabetes over the age of 40.

Biological Factors. Both age and sex are risk factors for type II diabetes. In most affluent societies, the rate of diagnosed type II diabetes increases steadily from 30 to 60 years of age. The decline in the rate in old age may be the result of the smaller number of individuals at risk. The extent to which physiological aging is a risk factor is unknown. However, H. Silwer (1978) showed that for Swedish populations the proportion of cases that were "severe" declined sharply in old age, from 28 percent in the sixth decade to 4 percent in the ninth decade.

Many observations have been made on sex differences in the frequency of type II diabetes. Before 1900, diabetes was observed to be more frequent in men in both Europe and the United States. Indeed R. Lepine cited seven different studies from Europe in which women constituted 17 to 43 percent of the cases, whereas Emerson and Larimore found that in England and Wales the male/female ratios were typically 2:1 before 1910. Since 1930, however, clinicians in both America and Europe have repeatedly observed a greater frequency in female diabetics.

Nonetheless, many developing nations show a male predominance. Populations with a high male/female ratio include rural Africans, Hong Kong Chinese, and populations in Iraq, Jordan, Japan, Korea, India, and Pakistan. Populations with a predominance of females include the United States, the Caribbean countries, Sweden, Belgium, the former Soviet Union, Thailand, and South Pacific countries.

Parity has also been considered a risk factor. In 1924, Emerson and Larimore reported that married women in New York City had a rate of mortality from diabetes about four times higher than that of single women. Joslin and his associates, however, found that married diabetic women weighed on the average about 20 pounds more than single diabetic women, and in well-controlled studies no relationship was found between parity and diabetes in Pima Indians. On the other hand, it is true that pregnancy can have a physiological effect that is diabetogenic, and women who suffer from gestational diabetes are at greater risk for type II diabetes in their nonpregnant state. In summary, it appears that parity is not

a major risk factor for diabetes, and that the association is confounded by both obesity and age.

Exercise. Exercise would seem to be a potent protective factor in diabetes. It enhances both carbohydrate metabolism and the efficient use of insulin. As early as 1893, B.C. Sen noted that active men in India had a lower rate of diabetes than their more sedentary counterparts. Overall, a decrease in energy expenditure has been related to changes in lifestyle, a relationship that has been particularly well-documented in the South Pacific. Unfortunately, quantitative data on exercise are limited, and the short- and long-term effects of exercise on carbohydrate metabolism are incompletely understood.

Obesity. There is abundant worldwide evidence associating obesity with type II diabetes, and the 1980 World Health Organization Expert Committee on Diabetes has concluded that it is the most powerful risk factor for non–insulin-dependent DM. Many studies have shown that between two-thirds and nine-tenths of individuals may be classified as obese at the time of diagnosis of DM.

This association between obesity and diabetes is an old one, first noted by Indian physicians. Modern concern with obesity began with Joslin's landmark paper in 1921, in which he assembled overwhelming data showing obesity as the major risk factor for type II diabetes. Diabetes rates were 6 to 12 times greater in obese than in lean individuals. More recently, West (1978) documented high frequencies of both obesity and diabetes among a number of Amerindian tribes in Oklahoma. Later works on native American groups have corroborated these findings. The positive relationship of diabetes with obesity is also found in Latin American populations. Yet it does not hold true for all peoples; in some populations with high levels of both conditions – for example, the Pima Indians and Mexican-Americans – for specific age and sex groups diabetics are not more obese than nondiabetics.

The distribution of body fat presents an additional risk factor. A centripetal distribution of fat around the chest, waist, and abdomen presents a greater risk than an increase in fat in the lower portion of the torso, hips, and thighs. This central or android distribution of fat has been correlated with risk for diabetes in a number of ethnic and racial groups. The duration of the diabetes and other hormonal factors may be additional risks related to the amount of fat tissue or degree of obesity.

Dietary Factors. Calories are units of energy derived from food, and high caloric intake and low caloric expenditure are both related to obesity. Diabetes rates appear to have increased markedly in a number of countries wher caloric consumption per capita has also increased. These countries include Japan, Taiwan, Haiti (among the wealthy), New Guinea, and many parts of Africa. A number of authors have noted that during World War I and II in Europe and during World War II in Japan, when caloric intake was markedly decreased, the rate of obesity and diabetes both declined. On the other hand, recent work in 1975 by J. H. Medalie and his colleagues indicate no significant differences in caloric intake among diabetic and nondiabetic Israeli men.

Many dietary components have been investigated as potential risk factors for type II diabetes. Most researchers agree that there is no convincing evidence that a single dietary component increases the risk of diabetes. For example, West reported 21 studies indicating that table sugar or sucrose consumption was a risk factor for diabetes and another 22 studies suggesting that it was not. Furthermore, the distinction between simple and complex carbohydrates has been called into question in recent years. A number of researchers focusing on previously designated complex carbohydrates (starches such as potato and wheat bread) have shown that these starches can lead to the production of high levels of insulin and glucose in nondiabetics and type II diabetics. In fact, the glucose response to white potatoes and dextrose sugar was approximately the same.

H. C. Trowell, D. P. Burkitt, and colleagues suggest that dietary fiber favorably alters absorption patterns to decrease the risk for diabetes, and currently many different forms of dietary fiber are being investigated in this connection. In most of the epidemiological work, however, it is difficult to disentangle the effects of decreased fiber consumption from increased sugar and refined carbohydrate intake, increased total calories, total fat, decreased caloric expenditure, and stresses associated with rapid dietary change and modernization. Thus, there remain many unanswered questions concerning the role of refined and unprocessed carbohydrates and dietary fiber in the risk and treatment of DM.

Dietary fats have also been viewed as dietary risk factors, although studies investigating fat intake are often confounded because of the higher caloric density of fat compared to carbohydrates and proteins (ratio = 9:4:4). Furthermore, high fat intake is

generally associated with low fiber intake. Historically, one of the more important works on the matter is that of Harold P. Himsworth (1935–6), in which he presented evidence positively linking fat and negatively linking carbohydrate consumption to diabetes. Yet other epidemiological observations have not supported the relationship between high fat consumption and high diabetes rates when diet is controlled for caloric intake. Furthermore, evidence that challenges any such relationship is found among Eskimos living a traditional life-style with diets high in fat and protein yet suffering little from DM. Alternatively, protein deficiency in the tropics has been implicated in certain types of diabetes, particularly those secondary to pancreatic disease.

Finally, deficiencies in micronutrients – in particular, chromium – have been postulated as potential factors for diabetes. However, there are few epidemiological data and the clinical data are conflicting.

Other Factors.   Other life-style factors such as urbanization and psychosocial stress have been implicated in the etiology of type II diabetes. As populations become more "developed," there is an increase in diabetes. The populations of the South Pacific, for example, provide a natural laboratory in which the degree of modernization has been correlated with increases in chronic diseases including diabetes. Many other factors associated with diabetes are listed in Table VIII.34.1.

Tropical Diabetes.   A third type of diabetes found primarily in developing countries in tropical areas has clinical characteristics of both type I and type II diabetes. Tropical diabetes has been described in many areas of the world including the South Pacific, the West Indies, Africa, Southeast Asia, and India. Thus, the disease has been referred to variously as phasic insulin-dependent diabetes, J-type diabetes for Jamaica, K-type diabetes for Kenya, malnutrition diabetes, and tropical pancreatic diabetes. The clinical profile involves the following: (1) a different genetic pattern of diabetes than in temperate regions; (2) a low prevalence rate of type I DM; (3) a younger age on onset of type II; (4) a sex ratio with male predominance in India and Africa, but female predominance in the West Indies; (5) an association of low calorie and protein intake during childhood and adulthood with the presentation of lean or underweight diabetic individuals in Old World tropical areas, but overweight diabetic individuals in the Western Hemisphere; (6) the predominance of diabetes in urban areas in most countries, with the excep-

tion of rural sugar-cane farming populations in the West Indies; (7) ketosis resistance; and (8) intermittent need for insulin therapy.

Information is relatively sparse on the genetics of diabetes in tropical countries. Recent studies on the human leukocyte antigens (HLA) and properdin (factor B, BF) system have shown that there is great population variability in the association of particular HLA haplotypes and increased susceptibility to diabetes. Genetic studies of Indian populations suggest a stronger familial or genetic factor among Indian diabetics compared to diabetics in other populations.

Environmental risk factors for tropical diabetes involve unique dietary items. In 1979, D. E. McMillan and P. J. Geevarghese suggested that the cyanide-containing glycosides of some types of cassava (manioc) may be toxic to the beta cells of the pancreas and thus produce pancreatic damage. Abnormal changes in pancreatic tissue give support to the cassava-cyanide hypothesis in the pathogenesis of diabetes. However, many tropical areas show high rates of diabetes in populations that do not consume cassava, and conversely, some populations have high cassava consumption and low rates of diabetes. In Kenyan (K type) diabetes, a local alcohol called *changaa* is implicated in causing the disease. Finally, in most tropical areas carbohydrates constitute 70 to 80 percent of the total calories of the diet, which is considerably higher than the percentage of carbohydrates in diets of many developing countries. Indeed, such a diet is implicated in classic "malnutrition diabetes" because of the relatively low nutrient density and high fiber content.

Gestational Diabetes.   In 1882, J. M. Duncan noted a type of diabetes present only during pregnancy. However, it was not until the 1940s that the term "gestational diabetes" appeared in the English language medical literature. D. R. Haddon found that from 1975 to 1984, 165 studies on gestational diabetes were published, representing investigations in 25 countries. The majority (69 percent) were from the United States and Europe, although 16 were reported from Australia. One important difficulty in evaluating the incidence of gestational diabetes is that the frequency of type II diabetes among women of childbearing age is unknown for many countries. Therefore, a woman could have diabetes prior to pregnancy, but not have it diagnosed until pregnancy. Babies born to diabetic mothers usually are large (over 9 pounds), but may have organ systems that are not mature, in which case they may not survive.

The prevalence of gestational diabetes varied from 0.15 percent in Newcastle, United Kingdom, to 12.2 percent in Los Angeles, California. In general, cities in the United States report a higher prevalence of gestational diabetes then do European cities. The one African report from Nairobi, Kenya, indicates a prevalence of 1.8 percent. The highest reported rate of gestational diabetes occurs among the Pima Indians of Arizona, who also have the highest prevalence of type II diabetes of any known population.

Distribution and Incidence

Many methods have been used to ascertain the prevalence of DM. Methods have ranged from telephone and household surveys, reviews of hospital records, to screenings using urine and blood determinations of glucose concentrations. Because of its acute onset and obvious symptoms, type I diabetes is readily identified and, therefore, permits a more accurate picture of worldwide prevalence. Data from the 1960s through the 1980s indicated that populations with prevalence rates of insulin-dependent DM of at least 1.0 per 1,000 include Finland, Sweden, the United States, England, France, and Australia. Intermediate prevalence rates of 0.5 to 0.9 per 1,000 are found in Scotland, Switzerland, East Germany, and Denmark. Rates below 0.5 per 1,000 occur in Italy, Japan, India, Taiwan, Vietnam, Libya, China, the South Pacific, Ethiopia, and the West Indies. Type II DM is a chronic disease with generalized symptoms; therefore, many cases are not diagnosed. The American Diabetes Association estimates that 40 to 50 percent of Americans with type II DM have not been diagnosed. On the whole, however, rates of type II do appear to be increasing in developing nations. Table VIII.34.2 lists the prevalence rates of diabetes in 1960–85 for 28 countries.

Most surveys on the annual incidence of insulin-dependent DM include individuals in the age range 0 to 14 or 0 to 16 years. High rates of 15 to 30 per 100,000 are reported for Finland, Sweden, Scotland, Norway, and Yugoslavia; intermediate rates of 10 to 14.9 per 100,000 for Denmark, the United States, the Netherlands, and New Zealand; and low rates of 0 to 9.9 per 100,000 for Israel, Japan, Great Britain, France, Canada, India, Italy, Ghana, and Nigeria. The incidence data from Sweden also indicate an increase in the number of cases of type I diabetes from 19.6 per 100,000 (1970–5) to 24.9 per 100,000 (1980–2) for children age 0 to 14 years. Generally, investigators have been cautious in interpreting the rates as an actual increase in the incidence of insulin-dependent DM. Prevalence rates continue to

rise because of increased longevity of individuals with type I diabetes.

The incidence rates for type II diabetes vary extensively by age and sex for different populations. In general, the incidence increases with age for both males and females until the sixth or seventh decade of life. The incidence of diabetes in the United States, or the number of newly diagnosed cases per 10,000 population per year, has risen 7-fold since the

first large-scale survey in 1935–6, when the rate was 3.8 per 10,000. The highest incidence was reported in 1973 (29.7 per 10,000) and the information from 1979 to 1981 reveals a rate of 22.7 per 10,000. Approximately 95 percent of these cases are type II diabetes.

Incidence rates of greater than 200 per 100,000 population of adults or total population are found in the United States, Israel, Finland, England, Denmark, Saudi Arabia, the South Pacific islands, and Australia. Intermediate rates between 100 and 200 per 100,000 population per year have been found in Scotland, Germany, Spain, Yugoslavia, Czechoslovakia, and Romania, and lower rates have been found in Canada, India, Southeast Asia, and some African countries.

Clinical Manifestations

There are five stages in the natural history of DM:

First stage: susceptibility based on a combination of (1) genetic risk factors; (2) physiological states such as obesity for type II diabetes; (3) and environmental factors including diet, climate, activity, and other life-style patterns.

Second stage: glucose intolerance, which is recognized as a phase preceding both insulin-dependent and non–insulin-dependent diabetes. Not all individuals having impaired glucose tolerance progress to symptomatic diabetes.

Third stage: chronic hyperglycemia without complications.

Fourth stage: frank diabetes with complications but without disability.

Fifth stage: disability due to functional impairment from the complications of diabetes, which involve primarily the vascular system. Common complications include renal disease, blindness due to retinopathy, neuropathy, cerebral vascular disease, cardiac disease, and peripheral vascular disease often leading to lower limb amputation.

Mortality

Diabetes represents an underlying and contributing cause of death that places it among the top 10 causes of death in developed countries. In Western countries, DM ranks seventh as a cause of death. In the United States from 1976 to 1983, diabetes was listed as the cause of death in 14.8 per 100,000 population. This rate was considerably higher in Mexico and in the Caribbean, with rates as high as 45 deaths per 100,000 for Trinidad and Tobago. In Africa the mortality rates are generally below 10 per 100,000. In

Table VIII.34.3. *Diabetes mortality trends by country and geographic area, 1970–2 and 1976–83 (rates per 100,000 population)*

Area and country	1970–2	1976–83	Increase/Decrease
Africa			
Egypt	6.0	7.1	↑
Mauritius	12.9	17.1	↑

Asia rates range from 5.1 per 100,000 for Hong Kong to 15.1 per 100,000 for Singapore. In Europe, the rate ranges from a high of 21.7 per 100,000 for Malta to a low of 9.4 per 100,000 for England and Wales.

The best early data on mortality are reported by Joslin and his associates in the 11 editions of Joslin's book, *Treatment of Diabetes Mellitus,* the first of which was published in 1916. These volumes document a trend toward a decrease in early mortality from diabetes, due to increasing sophistication in therapeutic approaches, particularly with the advent and wide-scale use of insulin. Table VIII.34.3 reports comparative statistics for changes in diabetes mortality rates by geographic region for both developed and developing nations.

History and Geography

One of the best accounts on the geography of DM, published in the *British Medical Journal* in 1907, was a symposium on diabetes in the tropics, which was chaired by Richard Havelock-Charles. The authors reviewed within- and between-country differences in the prevalence of diabetes. It was noted, for example, that diabetes was more common in Bengal than in upper India, and was less common in Sudan and the Cameroons than in Europe. Papers also indicated the rarity of diabetes in Japan and China. In 1908 Robert Saundby reviewed differences in the

prevalence of diabetes in Europe. Richard T. Williamson in 1909 reported high rates of DM in Malta, which were substantiated in later works. He also noted that there were low rates in Cyprus, Hong Kong, Malaya, Aden, Sierra Leone, British Honduras, Cuba, Labrador (Eskimos), Fiji, and certain populations of Asian Indians and Chinese. In addition, he summarized available evidence on rates by time and place in many European populations. In 1922 Fredrick L. Hoffman published data on mortality rates due to DM for 15 countries or regions for persons over the age of 20. These rates ranged from 67.8 per 100,000 in Malta to 8.6 in Italy. The extensive data on the epidemiology of diabetes of Emerson and Larimore published in 1924 included mortality statistics by geographic region. Comparative mortality data were also published in the many editions of Joslin's *Treatment of Diabetes Mellitus*. In the 1930s, there were many reports showing very low rates of diabetes among Eskimos and American Indians. Other pioneering studies on the prevalence in other European populations between 1916 and 1952 have been summarized by Silwer (1958).

Modern observations of geographic differences began with the publication of S. M. Cohen's (1954) paper showing marked differences in diabetes rates among Amerindian tribes. This was followed shortly by J. G. Cosnett's (1957) work describing very high rates of diabetes in Asian Indian immigrants to South Africa. These rates were 30 to 40 times higher than among black South Africans. *Diabetes Mellitus in the Tropics* (1962), by J. A. Tulloch, summarized much of the evidence on the prevalence of diabetes in developing and developed countries.

Attempts to standardize definitions and criteria began when the International Diabetes Federation held its first conference in 1952. The National Diabetes Data Group published the presently used classification of diabetes in 1979, and in 1980 the World Health Organization Expert Committee on Diabetes Mellitus published a second report standardizing definitions and criteria for DM and imparied glucose tolerance. One good example of these international efforts is the work edited by J. I. Mann, K. Pyorala, and A. Teuschner in 1983 covering epidemiology, etiology, clinical practice, and health services throughout the world. In 1985, the National Diabetes Data Group published *Diabetes in America*.

Data in Tables VIII.34.2 and VIII.34.3 show contemporary prevalence figures for different countries and, in some cases, distinguish between urban and rural populations. Virtually all of these figures were derived from actual determination of the concentra-

tion of blood glucose, either fasting or after an oral glucose challenge.

Many migrant populations have been especially prone to high rates of diabetes. For example, Jews have shown an increased susceptibility to diabetes in native European enclaves as well as in various migrant groups. It was noted that Jews in New York City had rates 10 times higher than other U.S. ethnic groups. A number of studies from the early 1900s show high rates of diabetes among Jews in Budapest, Bengal, Boston, and Cairo. More recently, studies have shown that Sephardic Jews in Zimbabwe and Turkey have high rates of diabetes. Migration of Jewish people to and from Israel has produced many different ethnic subgroups. Newly immigrant Yemenites and Kurds to Israel show lower rates than long-time residents of the same ethnic groups. A. M. Cohen and colleagues, publishing in 1979, found that in a 20-year period there was an increase from 0.06 percent to 11.8 percent in the prevalence of diabetes found among Israeli Yemenites. Medalie and co-workers, studying various ethnic groups in 1975 in Israel, found that European-born Jews had a lower incidence of diabetes than those born in Africa, Asia, or Israel. They found that obesity was a significant predictor of the prevalence of diabetes among these Israeli ethnic groups.

Early reports for Chinese populations indicate a very low prevalence of diabetes, and in fact, Saundby in 1908 observed that none of his colleagues had ever seen a case of diabetes in a Chinese patient. In modern China, the rates remain very low, ranging from 0.2 percent to 1.2 percent. Most authors conclude that the Chinese have a reduced susceptibility to diabetes, although rates are somewhat higher in immigrant Chinese populations in Hawaii (1.8 percent), Singapore (1.6 percent), and Malaya (7.4 percent). The Japanese, like the Chinese, also show a very low prevalence of diabetes in their native countries. However, with migration, the Japanese in Hawaii and California have also showed increased rates of DM.

Amerindians, in particular, have very high rates of diabetes. The highest rates occur among the southwestern Indian groups, with the Pima Indians exhibiting the highest rate (35 percent) of DM. Yet the high rates among Amerindians appear to be recent. Early reports (using different testing methods, of course) indicated very low prevalence of diabetes among North American Indian groups at the turn of this century. Moreover, rates among South American Indian groups still tend to be low.

Other aboriginal groups also seem to be particu-

larly prone to diabetes, among them Polynesians and Micronesians. Rates are somewhat lower among Melanesians. Hawaiians have a diabetes rate seven times higher than Caucasians in Hawaii. Among New World black populations in the West Indies and in the United States, there is a high prevalence of type II diabetes, particularly among women. Michael Stern and other researchers have documented high rates of diabetes among Mexican Americans.

One explanation of the high frequency of type II DM among certain of these populations is that they developed a highly efficient carbohydrate metabolism under traditional life-styles of a feast and famine cycle. The thrifty mechanisms of carbohydrate metabolism, however, became detrimental with rapidly changing life-styles associated with a decrease in physical activity, an increase in energy in the diet, a reduction of dietary fiber, an increase of refined carbohydrates, and an increase in psychosocial stress.

Among Asian Indians, diabetes rates are low. The overall prevalence of diabetes in India is approximately 2 percent. Diabetes is more prevalent among urban populations, the rich, and the professional classes. In Indian men there also is a north-to-south gradient of diabetes prevalence, with thrice the prevalence in the south.

Yet like other migrant groups, Asian Indian migrants to other countries show high prevalence rates compared to those of indigenous populations. For example, in South Africa only 1 to 4 percent of blacks had DM compared to 17 to 32 percent of Asian Indians. High rates have also been reported from East Indian populations in Fiji, Trinidad, and Singapore. The Indians in South Africa, in particular, were brought over as indentured servants and had a life-style not dissimilar to those of New World black populations. A diabetes-thrifty genotype may have been selected for in these populations as well.

Among black Africans DM is still comparatively rare. Nevertheless, increased prevalence has been noted by Tulloch for urban Africans in a number of nations. Apparently, for susceptible genotypes, the life-style changes associated with rural-to-urban migration result in higher relative risks for type II diabetes.

It is important to note that there is a great deal of genetic heterogeneity among socially designated racial and ethnic groups. This heterogeneity should not be ignored when looking at the environmental or geographic factors that lead to increases in the relative risks for type II diabetes.

The foregoing historical and geographic data in-dicate that we may anticipate an increase in the worldwide prevalence of DM. The focus has been and remains on treatment of hyperglycemia and the vascular complications of long-term diabetes. Using the epidemiological data and historical perspectives, we are now beginning to develop better programs aimed at early intervention and prevention.

Diarrheal Diseases (Acute)

Acute diarrheal illness can be defined as the sudden onset of the passage of a greater number of stools than usual that show a decrease in form. It is generally accompanied by other clinical symptoms such as fecal urgency, tenesmus, abdominal cramps, pain, nausea, and vomiting. In most cases the symptom complex is a result of intestinal infection by a viral, bacterial, or parasitic enteropathogen; occasionally it is secondary to ingestion of a microbial exotoxin.

Distribution and Incidence

Acute diarrhea is often hyperendemic in certain populations: infants and young children in developing tropical countries of Latin America, Africa, and southern Asia; persons traveling from industrialized to developing regions; military populations stationed in or deployed to tropical areas; and toddlers who are not toilet trained and are attending day-care centers. Diarrhea rates in children less than 5 years of age in developing countries range from between three and seven episodes per child each year. The rate of diarrhea for non-toilet-trained infants in day-care centers in urban areas of the United States is comparable to the rate of illness seen in Third World countries. Travelers' diarrhea occurs in 20 to 40 percent of persons visiting high-

risk areas from regions showing low disease endemicity. The rate of diarrhea occurrence in infants and young children under 5 years of age in the United States is approximately 0.8 to 1.0 episode per child each year. In all populations, acute diarrhea occurs less commonly in older children and adults than in infants.

Etiology and Epidemiology

The ultimate source of most of the enteric pathogens is infected humans, although for selected pathogenic organisms (i.e., *Salmonella, Giardia*), animals may serve as a reservoir. Environmental factors play an important role in disease endemicity. Both water quality and water quantity are important. Although the degree of microbial contamination of water may be responsible for exposure to diarrhea-producing organisms, the availability of adequate amounts of water for personal and environmental cleansing, even if it is contaminated, may be beneficial. Sewage removal is a prerequisite for clean water and a healthful environment.

Personal and food hygiene standards in a population are important to enteric infectious disease occurrence. Effective handwashing as a routine practice is practically unheard of in many areas of the developing world. Food all too often is improperly handled. Vegetables and fruits rarely are washed properly when reaching the house prior to preparation, despite the fact that they may have been exposed to human excreta used as fertilizer. Foods may be contaminated by unclean kitchen surfaces or hands. One of the most important errors in food hygiene is the storage of foods containing moisture at ambient temperatures between meals, which encourages microbial replication. This problem is especially severe during the warmer months. Medical care is often inadequate so that intestinal carriage of microbial pathogens and continued dissemination of the agents continue. Finally, underlying medical conditions can contribute both to the occurrence of diarrhea and to the severity of the resultant disease; measles and malnutrition are two important examples.

In most countries where acute diarrhea is a serious medical problem, it tends to be most prevalent during the warmer months. The reason is probably that bacteria grow rapidly in warm, moist conditions. Flies also can play a role in the transmission of enteric infections.

In day-care centers, when a non–toilet-trained child develops diarrhea, a variety of fecal organisms may spread to the hands of teachers and children, and to the toys shared by the children. Because of the efficient interchange of organisms during outbreaks, several pathogenic organisms are often identified during the same time period.

By employing optimal enteric microbiological techniques, an etiologic agent can be detected in approximately 50 percent of cases of acute diarrhea. The specific agent responsible for acute diarrhea will generally depend upon the age of the host, the geographic location, and the season. Table VIII.35.1 summarizes the most important etiologic agents in diarrhea, and Table VIII.35.2 indicates the microorganisms most frequently associated with diarrhea in certain settings.

Immunology

When an enteric infectious microorganism is highly endemic and there is a high degree of antigenic homogeneity among the implicated strains, immunity tends to develop with age. The infectious enteric organisms that fit this description and to which immunity is known to increase with age in endemic areas are the following: *Vibrio cholerae, Salmonella typhi,* enterotoxigenic *Escherichia coli, Shigella,* Norwalk virus, and *Rotavirus.* There is great hope that effective immunizing agents against these organisms will be developed for use in high-risk populations.

Clinical Manifestations

For most of the enteric infections, a characteristic clinical illness is not produced by a given etiologic agent. When patients acquire enteric infection, a variety of symptoms other than diarrhea may result, including abdominal cramps and pain, nausea, vomiting, and fecal urgency and incontinence or the urge but inability to defecate. When patients experience fever as a predominant finding, invasive bacterial pathogens should be suspected (*Salmonella, Shigella,* and *Campylobacter*). Vomiting is the primary complaint in viral gastroenteritis (often due to rotavirus in an infant or Norwalk-like viruses in older children or adults), staphylococcal food poisoning, or foodborne illness due to *Bacillus cereus.* When dysentery (the passage of small-volume stools that contain gross blood and mucus) occurs, amebic *Shigella* or *Campylobacter enteritis* should be suspected. In salmonellosis, gatroenteritis stools are grossly bloody in just under 10 percent of cases. Other less common causes of dysentery are inflammatory bowel disease, *Aeromonas, Vibrio parahemolyticus, Yersinia enterocolitica, Clostridium difficile,* and *Entamoeba histolytica.*

Table VIII.35.1. *Commonly identified etiologic agents in diarrheal disease*

Agent	Comment
Bacterial	
Escherichia coli	
Enteropathogenic *E. coli* (EPEC)	Causes infantile diarrhea; may cause chronic diarrhea
Enterotoxigenic *E. coli* (ETEC)	Major cause of infant and childhood diarrhea in developing tropical countries, and travelers' diarrhea
Enteroinvasive *E. coli* (EIEC)	Occasionally causes foodborne febrile diarrhea
Enterohemorrhagic colitis (EHEC)	Causes colitis, low-grade fever associated with hamburger consumption; may result in hemolytic uremic syndrome
Shigella, Salmonella, Campylobacter jejuni	Common in all areas, especially during the summertime
Aeromonas	Of uncertain importance
Plesiomonas shigelloides	Causes diarrhea in travelers and those exposed to seafood
Vibrio parahemolyticus, other nonagglutinable vibrios	Causes diarrhea in those exposed to seafood
Staphylococcus aureus, Bacillus cereus	Associated with foodborne outbreaks of vomiting (± diarrhea)
Viral	
Rotavirus	Found in infants <2 years age; shows wintertime propensity in temperate climates; occurs in all seasons in tropical areas
Norwalk viruses	Major cause of waterborne and shellfish-associated gastroenteritis
Caliciviruses and enteric adenoviruses	Of uncertain importance
Parasitologic	
Giardia lamblia	Causes protracted diarrhea commonly in those exposed to mountainous areas or day-care centers
Entamoeba histolytica	Commonly causes recurrent diarrhea in persons living in tropical countries
Cryptosporidium	Causes diarrhea in patients with AIDS, those in day-care centers, and in travelers to Leningrad

Table VIII.35.2. *Etiologic agents of diarrhea, characteristically identified in special settings*

Setting	Commonly identified agents
Day-care centers	Rotavirus, *Giardia, Shigella,* Cryptosporidium
Person traveling from industrial to developing countries	Enterotoxigenic *Escherichia coli, Shigella, Salmonella, Campylobacter, Plesiomonas, Giardia*
Male homosexuals	*Herpes simplex, Chlamydia trachomatis, Treponema pallidum, Neisseria gonorrhoeae, Shigella, Salmonella, Campylobacter, Clostridium difficile, Giardia*
Acquired immune deficiency syndrome	Cryptosporidium, *Isospora belli, Herpes simplex,* cytomegalovirus, *Salmonella, Mycobacterium avium–intracellulare*

Pathology

A basic prerequisite for infection by enteric pathogens is attachment to the intestinal lining by the pathogenic microorganism. The mechanism of the attachment varies from a highly specific receptor–ligand interaction, as seen for enterotoxigenic *E. coli,* to a nonspecific type of attachment, as is seen for the protozoan *Giardia,* which possess sucking disks for intestinal adherence. Variable degrees of intestinal damage can be seen in enteric infection. No anatomic or structural alterations are found in infection by enterotoxigenic *E. coli* or *V. cholerae,* where intestinal secretion and watery diarrhea occur secondary to cyclic nucleotide stimulation.

In shigellosis and campylobacteriosis, extensive inflammation with microabscess formation is seen. Small bowel pathogens (rotavirus, Norwalk viruses, and *Giardia*) may lead to depletions of intestinal disaccharidases and lactose (milk) intolerance. Malnutrition, which is common in areas where diarrhea is highly endemic, leads to a more prolonged disease of greater severity, although malnutrition does not predispose to the occurrence of diarrhea.

The synergy between the effects of malnutrition and diarrhea is an important reason why death from diarrhea is so common in Third World countries. Diarrheal illnesses have adverse effects on growth and contribute to malnutrition. There is a 20 to 60 percent decrease in body caloric intake during a bout of diarrhea. Ways in which malnutrition contributes to more severe or prolonged diarrhea may include decreased gastric acidity, impaired intestinal immunity, greater exposure to a contaminated environ-

ment, delayed recovery of intestinal mucosa, and persistent lactase deficiency. The agents producing the greatest frequency of dehydration are *V. cholerae*, enterotoxigenic *E. coli*, and rotavirus. Rotavirus is the major cause of death in infants with diarrhea.

History

Diarrheal diseases have been important to all societies since the beginning of recorded history. Hippocrates used the term "dysentery" to denote a condition wherein the affected person, experiencing straining and painful defecation, passed many stools containing blood and mucus. Through the First World War, outbreaks of diarrhea and dysentery were as important to deciding the outcome of many military campaigns as were war-related injuries.

The modern era of diarrheal diseases began, as was the case with other infectious disorders, with the identification of the causative agents involved. During the mid-1800s, *Giardia lamblia* and *Entamoeba histolytica* were first identified. Then during the latter part of the nineteenth century, *Shigella* and *Salmonella* organisms were characterized, and the two forms of dysentery – bacillary and amebic – were distinguished.

During the 1960s, a series of landmark studies helped to elucidate the mechanisms of disease production when cholera toxin was purified. As an extension of research with *V. cholerae* during the 1970s, enterotoxigenic *E. coli* were identified as important causes of diarrhea. Soon thereafter, other enterotoxin- or cytotoxin-producing bacteria were discovered: *Salmonella, Aeromonas, Yersinia, Clostridium perfrigens, C. difficile,* enterohemorrhagic *E. coli,* noncholera vibrios, and *Staphylococcus aureus*.

Also during the early 1970s, viruses were clearly implicated as causes of diarrhea in humans. Initially, Norwalk virus was shown to produce gastroenteritis in volunteers fed bacteria-free stool filtrates derived from an elementary school outbreak in Norwalk, Ohio, and the 27-millimeter viral particle was visualized by electron microscopy. Soon thereafter, larger viral particles were observed in the duodenal mucosa of infants with diarrhea, and within a few years rotaviruses were established as a major cause of infantile gastroenteritis. Additional pathogens are being identified in cases of diarrheal disease as the research laboratory discovers novel mechanisms of pathogenesis or as new microbiological techniques for isolation and identification are developed. The future will bring studies of organism-specific epidemiology, therapy, and disease prevention.

Prevention and Treatment

The factors contributing to the problem of acute diarrhea are well known. However, their modification will not be easy because of cost and required changes in behavior. The important variables that will require attention include the following: availability of plentiful potable water; adequate systems of sewage removal; improved personal and food hygiene; improved nutrition through food supplementation programs; discontinuance of the practice of using night soil as fertilizer; promotion of breast feeding; effective measles vaccine programs; availability of adequate health care to administer oral rehydration therapy and selected antimicrobial therapy; family planning; insect control; vaccine development and implementation for certain enteric infections such as cholera, enterotoxigenic *E. coli* diarrhea, rotavirus gastroenteritis, shigellosis, and typhoid fever. Because achieving all of these activities will initially be too costly in developing areas, research in developed countries will be essential to devising cost-effective prevention and treatment methods.

Currently there are three forms of therapy for acute diarrhea. The first and most fundamental form of treatment is fluid and electrolyte replacement. Nearly all forms of acute diarrhea can be successfully managed by administering oral rehydration solution. For dehydrating choleralike illnesses, the solution should have optimal electrolyte–glucose concentrations to facilitate intestinal absorption. The major problems with this solution are that it does not provide the caloric requirements of infants with diarrhea, and it may actually increase stool fluid losses. Newer "super solutions" are being evaluated that are better absorbed and furnish more calories at no osmotic expense. For nondehydrating forms of diarrhea, solutions with lower sodium concentrations are useful. The second form of therapy involves drugs that reduce the symptoms of diarrhea by inhibiting secretion or by binding to luminal water. The final form is antimicrobial therapy directed against a bacterial or parasitic agent, which is of value in the treatment of enterotoxigenic *E. coli* diarrhea, shigellosis, and travelers' diarrhea.

VIII.36
Diphtheria

Diphtheria is a human disease caused by *Corynebacterium diphtheriae,* so named for its clubbed shape (Greek: *koryne,* or "club") and for the hidelike pseudomembrane (Greek: *diphtheria,* for "shield" or "membrane") that forms on the tonsils, palate, or pharynx in severe cases of infection. Although this bacillus may cause no more than an innocent, subclinical infection and can be transmitted via well carriers, during diphtheria epidemics more virulent strains are responsible for case fatality rates ranging from 30 to 50 percent of affected young children. In such circumstances the bacterium itself is infected by a phage virus responsible for the elaboration of a potent exotoxin. Even though the exotoxin can cause rapid fatty degeneration of the heart muscle and peripheral nervous system damage resulting in paralysis, young children often die because the airway is occluded. Both the suddenness of suffocation in children and the capricious emergence of virulent epidemics of diphtheria are important features of historical interest in the disease.

Also called the Klebs–Löffler bacillus in early twentieth-century medical literature, this gram-positive organism is usually spread by respiratory secretions and droplet infection. After a brief incubation period of 2 to 4 days, the bacillus multiplies in the upper respiratory tract, creating a membranous exudate on pharyngeal tissues. The bacillus invades the local tissues and kills cells, causing necrosis and, often, discoloration of the membrane. The foul breath associated with necrosis and the greenish or blackened membrane are hallmarks of the disease to most clinical observers differentiating diphtheria from streptococcal sore throat and from croup. The

organism rarely causes a systemic infection, however, although skin infections are common in tropical regions. Most damage to the infected individual is produced by the powerful toxin disseminated through the bloodstream.

Distribution, Incidence, and Immunity

Corynebacteria are distributed throughout the world, but *C. diphtheriae* occurs naturally only in humans. Farm animals can be infected through human cases, and many laboratory animals are susceptible to deliberate infection. Indeed, diphtheria's wide host range accounts for part of the success in studying this organism during the early bacteriologic revolution.

In historical accounts, it is often described as a malignant sore throat, and one of the most puzzling features is the sudden appearance of an epidemic. In the "throat distemper" epidemic of colonial New England, Boston was spared the high childhood mortality and morbidity experience elsewhere in Massachusetts and New Hampshire, illustrating the patchy geographic distribution of severe cases that one could observe even during an epidemic. Peter English (1985) describes how a phage virus is associated with the virulence of the diphtheria bacilli in that the "tox" gene can either elaborate toxin (tox$^+$) or not (tox$^-$). But in both cases the presence of this gene incorporated into the bacterial DNA stimulates immunity to virulent diphtheria. Because a low-iron environment or medium tends to stimulate or facilitate the production of toxin, English further speculates that the nutritional poverty of many premodern populations helped to discourage the frequent recurrence of epidemic diphtheria. Many other researchers, including Ernest Caulfield (1939), point to a mixture of organisms during epidemics of sore throat, diphtheritic and pseudodiphtheritic. In the Boston epidemic of sore throat in 1735, for example, a rash accompanied clinical cases, suggesting coinfection with streptococcal organisms. Suprainfection with streptococcus is common even for true diphtheria, but it is not known what influence, if any, the presence of a copathogen has in the elaboration of toxin.

The phage carrying the tox$^+$ genome does enhance iron binding, permitting the microorganism to acquire this essential metabolite for its reproduction. Normally the human immune system is able to withhold iron and "starve" a pathogen (Weinberg 1978). Thus the production of toxin and the emergence of virulent strains should not depend upon an individual host's nutritional status. Epidemiologically the appearance of virulent diphtheria epidem-

ics should reflect increased opportunities for transmitting the bacillus to susceptible hosts, as through crowding or urbanization. Historically diphtheria epidemics were recorded only after medical theories supported recognition of the clinical specificity of this disease.

Epidemiology

The ultimate sources of diphtheritic contagion are humans. In addition to respiratory transmission of the bacillus through cutaneous diphtheritic lesions, the disease can be spread by touch and by fomites – such as schoolchildren's pencils. Thus, an infection can be transmitted to a cow's udders from an infected milker's fingers. Milk, if unpasteurized, can also transmit the infection. Even dust around the bed of a diphtheria patient can remain infective for weeks (Christie 1974).

The experience with diphtheria in England and Wales, from 1915 to 1942, is probably typical of industrialized countries in the twentieth century. Early in this period, over 50,000 cases were reported each year, and it was the leading cause of death for children aged 4 to 10 years. Over this time period, however, case fatality rates declined by 40 percent as a result of more rapid diagnosis and therapeutic interventions in the form of antitoxin and tracheostomy (surgically providing a way to breathe when the upper pharynx is occluded).

After World War II, mass immunization efforts effected a rapid decline in the overall number of cases, and the age of incidence rose. In virulent cases of diphtheria, mortality remains today around 5 percent, a fact that leads A. B. Christie (1974) to assert that we do not possess convincing proof that antitoxin alone reverses the clinical course of diphtheria. The organism itself is sensitive to penicillin.

Unlike measles, the common early springtime viral disease of childhood, diphtheria in temperate climates usually peaks in incidence in autumn and early winter. Most cases during the last 200 years have occurred among individuals under 15 years of age. Crowded conditions to which the poor are subjected facilitate passage of the organism, and so accounts of diphtheria before the germ theory of disease was widely accepted often described it as a filth disease naturally favoring the poor (Ziporyn 1988). In tropical regions cutaneous diphtheria is much more common, resulting in "punched," weeping ulcers sometimes called "desert sores." Contact with these lesions, usually on the extremities, is probably an important means of spreading the disease in such regions.

Clinical Manifestations and Pathology

Even virulent diphtheria begins quietly, after a brief incubation period. Its victims rarely suffer the high fever, vomiting, or myalgias common in acute viral illnesses, and the sore throat is much less pronounced than it is in streptococcal pharyngitis. As the organism multiplies and invades pharyngeal tissues, however, the area around the neck can swell dramatically, and internally the passage of air becomes difficult. The "bullneck" appearance of a diphtheria sufferer differs from the streptococcus victim because there is little enlargement of the regional lymphatic nodes. If the victim can open his or her mouth, an observer usually will see a membrane 1 to 3 millimeters thick, its rough edge curling away from the tonsils, palate, uvula, or pharynx. Depending upon the amount of destruction of local blood vessels, this "shield" can range in color from a more benign-appearing yellowish white, to green or even black. An exudate that remains white, whether or not it looks like a membrane, is usually not due to diphtheria.

The German pathologist Edwin Klebs first identified the *C. diphtheriae* in 1883 by peeling off this membrane and culturing the bleeding surface underneath. The following year Friedrich Löffler developed an enriched medium on which to grow the delicate bacillus, which could be rapidly overgrown by other organisms cultured from the mouth and pharynx. Both noted the absence of other affected organs at autopsy of diphtheria victims. The bacillus is not distributed through the body, but the toxin alone seems to have the lethal effects described above. Most perplexing is the peripheral nervous system involvement, contributing to a characteristic progression of paralysis in diphtheria victims: first the palate, then the eyes, then the heart, pharynx, and larynx (with respiratory muscles), and finally the limbs. In virulent diphtheria, patients appear quite toxic, and, although the fever is not usually high, the pulse is elevated.

Diagnosis and Treatment

The "Schick test" can help to identify diphtheria sufferers in that it depends upon a patient's failure to react to a small amount of purified toxin injected subcutaneously, thus signaling the absence of antitoxin in the body, in turn indicating an absence of previous diphtheria infection. Because many factors can influence the accurate reading and interpretation of such a test, most laboratory diagnosis depends upon culture of the organism itself on enriched "blood agar" or the "Löffler slant" tellurite

medium developed over a century ago. Penicillin, antitoxin, and maintenance of an open airway are the usual means of clinical intervention.

History

It is impossible to determine whether diphtheria was at any point a "new" disease in recorded human history, though it is so described during the early modern period. Diseases resembling diphtheria are also described in Greek medical literature of antiquity (English 1985) and during the sixteenth through eighteenth century. Historical interest in this particular disease has nevertheless been confined largely to the role diphtheria played in the emergence and confirmation of the germ theory of disease. As Terra Ziporyn (1988) points out, diphtheria was to a considerable extent "the darling of the bacteriological revolution."

A clinician of Tours trained during the French Revolution, Pierre Bretonneau was the first to describe the specific clinical features of diphtheria and to give the disease its name. Witnessing relatively severe epidemics in the mid-1820s, Bretonneau carefully noted the appearance of a pseudomembrane as a hallmark of the disease and used this particular infection to elaborate his concepts of disease specificity, based on uniform clinical and postmortem findings. Nevertheless, diphtheria was usually viewed as a disease of poverty, rather than as an exceptionally severe threat to human survival, as were epidemics of cholera and yellow fever. Periodic peaks in diphtheria mortality received no attention among clinicians.

Immediately after Robert Koch articulated a germ theory of disease based on his 1882 work with tuberculosis, Klebs and Löffler clearly demonstrated the precise causal connection between diphtheritic organisms and membranous sore throat. Löffler especially provided an elegant summary of the isolation and culture of *C. diphtheriae* together with a description of Koch's principles as "postulates" proving the germ theory (Lechevalier and Solotorovsky 1974). Löffler's classic paper in 1884 also introduced some of the most basic and innovative research problems for germ theorists. Speculating upon the reasons why diphtheria bacilli, unlike *Mycobacterium tuberculosis,* failed to invade areas of the body other than the nasopharynx, Löffler ventured that an "extraordinarily deleterious" poison was disseminated through the bloodstream. Moreover, his careful work illustrated that the organism could not always be cultured from the throats of clinically "typical" cases and that healthy individuals could carry diphtheria bacilli. The latter

phenomenon led Löffler in 1887 to a description of nonvirulent strains of diphtheria.

Filtering cultures of bacilli in Louis Pasteur's laboratory, P. P. Emile Roux and Alexandre Yersin demonstrated the probability of Löffler's hypothesis that a toxin was involved in lethal cases of diphtheria. In 1888 they showed that bacteria-free filtrates reproduced all features of the disease in experimental animals except the formation of a membrane, and they tried unsuccessfully to apply Pasteur's rabies method in habituating animals to the toxin. Soon afterward, in 1890, Emil Behring and Shibasaburo Kitasato, working in Koch's laboratory, explored the use of serum from convalescing individuals to treat diphtheria patients (and experimental animals). Thus before the beginning of the twentieth century, diphtheria had provided the best single model for proving the germ theory of disease, and suggested the concept of the healthy carrier, the possibility of filterable (nonbacterial) disease agents, and the general usefulness of serology in diagnosis and treatment of infectious disease.

After a legendary, dramatic, Christmas eve rescue of a diphtheritic child with the Kitasato–Behring serum, Behring personally escalated his study and production of "antitoxin," standardizing and popularizing his procedures for harvesting immune serum from horses inoculated with filtered toxin. Diphtheria rapidly became a largely curable disease, and Behring was honored as the "children's savior" and elevated to the hereditary nobility of Germany. Simultaneously, however, diphtheria was depicted as a classic, feared contagious disease and, unlike so many diseases in this category, as a widespread, merciless killer of innocent children. Indiana physician Thurman Rice, for example, vividly recalled that his father "drove two miles out of his way to avoid passing in front of a house where there was a case of diphtheria, and yet this house stood at least one hundred yards back from the road; he had children and was taking no chances" (Rice 1927). Diphtheria also frames the plot for one of the most famous physician stories in the English language, William Carlos Williams's "The Use of Force" (1933).

Finally, the study of diphtheria was involved in two further stages of twentieth-century research on the germ theory and its applications. First, the Schick test helped to identify individuals who had no immune response to small doses of toxin injected just under the skin. In the testing of immunity and the anaphylactic responses of individuals with "serum sickness" in response to foreign sera (a considerable problem with Behring's method), clinicians used

Table VIII.36.1. *Diphtheria mortality rate per 100,000 population*

	New York	Chicago	Boston	Pitts-burgh	Washing-ton
1890–4	134.4	117.3	112.2	86.4	77.9
1895–9	85.8	69.7	83.9	32.9	50.9

diphtheria throughout the early part of the century to delineate the research problems in human immunity (Levy 1975). (See Table VIII.36.1 for trends in large U.S. cities.) Second, in the early 1950s, identification and isolation of the phage virus that infected diphtheria bacilli greatly aided early research establishing phage–bacterial chromosome relationships and, in the process, the fields of bacterial genetics and molecular biology (Berksdale 1971).

VIII.37
Down Syndrome

Down syndrome, previously called "mongolism," is a relatively common condition resulting from the presence of an extra chromosome, number 21, in all the cells of the body. In each human cell, there are 23 chromosome pairs containing basic genetic material that organizes the body's development and physiological functioning. Each pair has a distinctive size and conformation and can be readily identified on microscopic examination. Chromosome pair number 21 is one of the smaller chromosomes. In Down syndrome there are usually three (*trisomy*) rather than two number 21 chromosomes (*trisomy 21:* found in 95 to 98 percent of all cases). In a small number of children with Down syndrome, the extra number 21 chromosome is attached to a chromosome of a larger pair (numbers 13 to 15; *translocation Down syndrome* – about 2 percent of all cases). In some children with the features of Down syndrome, the extra chromosome is present in less than 90 percent of the cells (*mosaic Down syndrome* – about 2 to 4 percent of all cases). Down syndrome is the most frequently occurring chromosome abnormality in live-born humans, and is also among the most frequently identified chromosomal abnormalities, representing about 4 percent of all aborted fetuses (Lilienfeld 1969). Down syndrome is usually recognizable at birth as a cluster of physical and neurological abnormalities (see Clinical Manifestations), which develop in a characteristic fashion during the life cycle.

Distribution and Incidence

Recent estimates of overall worldwide incidence of Down syndrome are around 0.8 per 1,000 live births (Janerich and Bracken 1986). In the United States, the 1983 Birth Defects Monitoring Program indicated an incidence of 0.82 per 1,000 live births. These figures evidence a decline from those reported 20 years ago in Western countries, where incidence was about 1.7 per 1,000. This change is thought to be the result of the use of prenatal diagnosis.

Down syndrome occurs in all races and ethnic groups, though good documentation of specific incidence in many groups and geographic areas is lacking (Lilienfeld 1969). There is some evidence for spatial aggregation, such as in northern Finland and British Columbia (Janerich and Bracken 1986), but these instances appear to be sporadic, and are probably related to environmental sources.

Epidemiology and Etiology

The presence of the additional number 21 chromosome in all cells of the individual with Down syndrome is usually the result of an error in cell division called *nondisjunction*. In normal cell division, the two members of each of the 23 chromosome pairs separate and move into one of the two resulting cells, whereas in nondisjunction, both members of the chromosome pair end up in a single cell. In Down syndrome, the nondisjunction has usually occurred during meiosis (sex cell division) usually of the female sex cell (the ovum). Thus, when an ovum with two number 21 chromosomes is fertilized, three number 21 chromosomes (two from the mother and one from the father) will be passed on to all the cells in the developing fetus. The occurrence of Down syndrome is most consistently associated with advanced maternal age, with incidence rising from 0.45 per 1,000 live births in women 20 to 24 years of age (8 studies) to 9.4 per 1,000 live births for women 40 to 44 years (7 studies). The largest risk increase occurs between the age groups 30 to 34 and 34 to 39 years (Lilienfeld 1969).

Four potential reasons for the maternal age association have been suggested:

1. Whereas the prenatal incidence of Down syndrome is constant across all ages, the older uterus is less selective in rejecting the Down syndrome conceptus.
2. Longer delays between intercourse result in a relatively "aged ovum," more likely to experience nondisjunction.
3. In older women, the ova themselves have aged longer and have an increased rate of nondisjunction.
4. Long-term exposure to environmental agents has resulted in damage to the spindle mechanism that in turn produces meiotic nondisjunction.

Because the additional chromosome can be traced to the father in 20 percent of the cases of Down syndrome, studies have also evaluated a paternal age effect on incidence. However, such an effect cannot be conclusively demonstrated (Janerich and Bracken 1986).

About 30 to 60 percent of all Down syndrome births, however, are not age dependent, meaning that they occur in mothers of ages under 30 years. Indeed, a high incidence of infants with Down syndrome has recently been reported in women less than 15 years of age. In both younger and older sibs of index patients, the risk of having offspring with Down syndrome is increased 2- to 10-fold. Younger mothers are more likely to have a second offspring with Down syndrome than are older mothers. The recurrence risk is 1 in 3 for mothers who are translocation carriers.

A number of environmental and metabolic mechanisms for Down syndrome have been evaluated, among them maternal drug, tobacco, alcohol, and caffeine use; use of hormonal and nonhormonal contraceptives; fluoridated water; and radiation exposure. However, findings from these studies have been inconsistent. Some investigators have suggested that a possible recessive gene producing nondisjunction might explain up to 10 percent of the cases. However, studies in consanguineous marriages do not support this suggestion. Dwight Janerich and Michael Bracken (1986) indicate that the association with elevated maternal age is undoubtedly a surrogate variable for other underlying associated factors, the most important of which are probably endocrine changes associated with aging.

Clinical Manifestations

The most easily recognizable features of Down syndrome derive from abnormalities in growth of the cranium and face. These include a short, relatively broad head (brachycephaly), hypoplastic maxilla, upslanting palpebral fissures, epicanthal folds, increased neck skin, small ears, and flattened nasal bridge. Common postcranial anomalies include a wide space between the first and second toe, abnormal finger and palm dermatoglyphs (in particular, the occurrence of single palmar creases), and shortened distal long bones. About 80 percent of children

with Down syndrome are hypotonic and 90 percent are hyperflexible. There are also variably associated major organ anomalies, the most important being congenital heart disease (CHD), which occurs in 30 to 50 percent of all children with Down syndrome. In addition, metabolic and hormonal systems are variably affected and include, among others, carbohydrate metabolism, deficient absorption of vitamin A, elevated serum uric acid, and abnormal serotonin metabolism.

In an extensive recent survey of 1,341 children with Down syndrome born between 1952 and 1981 in British Columbia, Patricia Baird and Adel Sadovnick (1987) reported survival rates up to 30 years of age in 50 percent for those with CHD, but nearly 80 percent for those without CHD. The survival rate for the latter group, however, was less than that for a comparison group of mentally retarded individuals without Down syndrome.

Children with Down syndrome experience abnormal physical and cognitive development. Birth weight and length are near normal, but the growth rate in the first 3 years of life is significantly slower than normal, and most children are less than the fifth percentile in height by the time they are 3 years of age. Growth rate during childhood is near normal, but the adolescent growth spurt is often absent (Cronk et al. 1988). Deficient growth differentially affects distal segments of the long bones. Whereas some early developmental milestones are normal, more marked delays in walking, talking, and other motor and cognitive skills usually become apparent by the end of the first year of life. Mild to moderate mental retardation (IQ: 30 to 67) is commonly present by childhood. Recent innovations in early intervention and new special education programing allow individuals with Down syndrome to hold jobs as adults in sheltered work situations.

History and Geography

Probably the earliest record of Down syndrome was a Saxon skull excavated in the seventh century showing osteological changes consistent with the condition. There are also accounts of sixteenth-century paintings of children having the features of the syndrome. The first accounts of Down syndrome, however, did not appear until the nineteenth century. In 1846 E. Sequin wrote of a specific type of mental retardation case, which he described as a "furfuraceous cretin with its white, rosy, and peeling skin, with its shortcomings of all the integuments, which give an unfinished aspect to the truncated fingers and nose; with its cracked lips and tongue; with its

red ectropic conjunctiva, coming to supply the curtailed skin at the margin of the lids" (quoted in Brousseau and Brainerd 1928). The first formal description was given in a report by J. Langdon Down in 1866. He described a type of congenital defect bearing resemblance to the Tartar race which he called Kalmuc or Mongolian. Down, who had been influenced by the racial hypothesis and the writings of Charles Darwin, suggested that the entity represented a reversion to an earlier phylogenetic type. This hypothesis never gained wide acceptance, and in fact, Down's own son, also a doctor, disagreed with it, suggesting that the features of the syndrome were accidental and superficial (Brain 1967).

The next important reports were presented by John Fraser and Arthur Mitchell in 1875 at the Royal College of Physicians in Edinburgh. Mitchell pointed out the similarities between the syndrome and "cretinism" (congenital hypothyroidism). Reports by W. W. Ireland and G. E. Shuttleworth followed during the 1870s and 1880s. Shuttleworth suggested that children with the condition were actually "unfinished," representing the persistence of anatomy characteristic of a particular phase in fetal development. He specifically cited the already recognized association between the syndrome and advanced maternal age, pointing out the large number of children with Down syndrome who were the last-born in large families. During the end of the nineteenth and beginning of the twentieth centuries, many reports appeared, expanding the description of the syndrome's phenotypic manifestations. Important among these were the extensive neuropathological descriptions by A. W. Wilmarth presented in reports from 1885 to 1890.

From the initial description in the mid-nineteenth century to 1959, a large number of etiologic hypotheses were advanced for the syndrome, including maternal syphilis, familial tuberculosis, familial incidence of epilepsy, insanity, instability, and mental retardation. Once the increased incidence of congenital heart disease in the syndrome was recognized by John Thomson and A. E. Garrod in 1898, a cause in early fetal existence was sought. Among theories advanced were maternal alcoholism, fetal hyperthyroidism, maternal dysthyroidism, hypoplasia of the adrenals, dysfunction of the pituitary, abnormality of the thymus, chemical contraceptives, curettage, faulty implantation, degeneration of the ovum, and emotional shock in early pregnancy.

As early as 1932, a chromosomal anomaly was suggested as a possible cause of the disorder (Bleyer 1934). In 1959, shortly after the correct diploid

number of chromosomes in the human cell was established, a small sample of children with Down syndrome were demonstrated to have an extra acrocentric chromosome and a total chromosome number of 47 in cultures of fibroblasts. This finding was verified by subsequent studies. Later in the same year, J. A. Book and co-workers (Book, Fraccaro, and Lindsten 1959) concluded that the extra chromosome was most similar to number 21 in the Denver classification. In 1960, other investigators reported the case of a girl with Down syndrome having only 46 chromosomes, and postulated a reciprocal translocation occurring between two chromosome groups (Polani et al. 1960).

Initially, Down syndrome was thought to occur only in the Caucasian race. Subsequently, however, reports have shown that it occurs in every racial group and country although thorough, well-designed studies have not allowed an accurate picture of its true distribution across racial and ethnic groups. Early reports indicated a low incidence in African and black American groups. However, recent investigations in Ibadan, Nigeria, and in Memphis, Tennessee, found black incidence rates much the same as those of white populations (Janerich and Bracken 1986). Similarly, although detection in Oriental populations is thought to be inhibited by sameness of features, recent studies in Japan reveal rates much like those in the United States. An extensive study from the World Health Organization in 1966 indicated that a low incidence of Down syndrome is reported in India, Malaysia, and Egypt (Lilienfeld 1969), whereas by contrast a high incidence was reported in Yugoslavia, Czechoslovakia, and at least one location in Melbourne, Australia.

A. M. Lilienfeld (1969) summarized 11 studies that attempted to indicate the spatial and temporal clustering of the syndrome. However, even the most sophisticated of these, carried out in Melbourne, Australia (Collman and Stoller 1962), failed to give satisfactory statistical proof for clustering. A 1983 report by P. M. Sheehan and I. B. Hillary describes a cluster of children with Down syndrome born to women who attended the same boarding school in their youth. This suggests that in some instances, an environmental agent may influence the incidence of Down syndrome.

This disease is a pathological condition resulting from infection with the parasite *Dracunculus medinensis*. In most instances, the adult worms, which are about 1 meter long, are quite evident as they emerge slowly through the skin of their victims.

Distribution and Incidence

In the 1980s and 1990s, Dracunculiasis is found mainly in India, in Pakistan, and in a band of 19 African countries between the Sahara Desert and the equator, from Senegal in the west to Ethiopia in the east (see Map VIII.38.1). Formerly this disease was much more widespread in the Middle East and Africa, and it occurred for some years in the Americas after it was introduced there by infected Africans during the slave trade.

In general, the incidence of dracunculiasis is significantly higher in endemic rural Africa communities than in endemic Asian villages. In West Africa especially, for example, rates of infection in affected areas often reach 20 to 40 percent, and sometimes exceed 50 percent, whereas in Asia, the rates usually are below 20 percent. In rural areas, the disease occurs sporadically, with adjacent villages sometimes differing greatly in the percentage of those infected. Susan Watts (1987), a medical geographer, has estimated that the number of persons at risk of this infection in Africa is about 120 million, with

Map VIII.38.1. Areas in which dracunculiasis is reported or probably exists.

another 20 million at risk in India and Pakistan, based on the assumption that everyone is at risk who is living in a rural district where a minimum of one case of dracunculiasis has occurred.

The number of persons affected annually by this infection is not known. Although diseases are often underreported in the countries affected, the reporting of dracunculiasis is especially poor because the infection generally is found only in impoverished rural communities where medical facilities are rare, and where many victims cannot walk and have little incentive to seek treatment because there is no drug that can cure the infection. The best estimate is that probably between 5 and 15 million persons contract dracunculiasis each year.

Epidemiology and Etiology

Dracunculiasis is a seasonal infection, usually occurring at the precise time of year when rural villagers must plant or harvest their crops. People are infected when they drink water containing a tiny crustacean of the genus *Cyclops,* called a copepod, which harbors the infective larvae of the parasite. About a year later, the adult worms emerge through the skin to discharge larvae into freshwater, to be ingested by an appropriate copepod, thus continuing the cycle. In drier ecological areas, such as the Sahelian zone in Africa, the infection appears during the brief rainy season (summer), when surface water is available. In areas that receive more rainfall, such as the coastal regions along the Bight of Benin, the infection appears, and is transmitted, during the dry season (winter), when stagnant surface water sources are scarcest and most polluted.

The most commonly affected age groups are generally persons 15 to 45 years of age – that is, working adults. Younger children are affected, but not infants under 1 year, and generally not many children under 5 years. Often farmers are particularly liable to infection, apparently because they drink large volumes of contaminated water while laboring on their farms. School children also suffer high rates of infection in some areas. Male or female victims may predominate in any given area, depending on their relative exposures.

There is no drug suitable for effective mass treatment of dracunculiasis, and from time immemorial, the disease has been treated by slowly winding the emerging worm around a stick. The disease can, however, be prevented by teaching villagers to boil their drinking water or filter it through a cloth, by treating contaminated sources of water with a chemical (temephos), or by providing protected sources of

drinking water, such as tube wells or draw wells (rather than ponds or open "step wells").

Clinical Manifestations and Pathology

Usually the first clinical sign of infection is a blister, which the adult worm produces, accompanied by severe burning of the skin, at the site where the worm is about to start emerging. This begins about 1 year after the contaminated water has been drunk. The blister ruptures when the affected part of the body is immersed in water, leaving a small ulcer, at the center of which is the worm. Most worms emerge on the foot, ankle, or lower leg, but they can emerge through the skin on any part of the body. Sometimes the worm first appears as a curvy line beneath the skin, or at the center of a painful abscess or nodule.

Worms that do not emerge from the body die and are then absorbed, or calcify, in which case they appear as characteristic curled lines on X-ray. The worms may invade a major joint, the brain or spinal cord, or other vital area, producing more serious manifestations, although this is rare. Much more common are secondary infections of the local wound that give rise to abscesses, local arthritis, and sometimes tetanus. In most patients, only one worm emerges at a time, though as many as two dozen or more may present themselves simultaneously in one person.

Affected persons may be crippled for several weeks or even months, by the pain associated with the worm's slow emergence and secondary infections. Because the infection appears at such a critical time of year for food production and cripples large numbers of persons simultaneously, it has an enormous economic impact. Moreover, people who are infected develop no immunity, so they may be and often are infected year after year.

History and Geography

This is a very old infection, which many believe to have been the "fiery serpent" said by Moses to have attacked the Israelites when they were on the shores of the Red Sea. At least one calcified *Dracunculus* worm has been discovered in the mummy of a 13-year-old Egyptian girl who died around 1000 B.C., and a treatment for this condition may be described in the *Ebers Papyrus*.

Some Greek and Roman writers described the infection, and it was Galen who named it "dracontiasis." The ancient medical practice of treating infections by winding the worm slowly around a stick is thought by some historians to have been the origin of the Staff of Aesculapius. Several medieval Ara-

bian physicians described dracunculiasis. Of these, Avicenna gave the first detailed clinical description of what he called "medina sickness," because the infection was then so common in Medina. Shortly before, Rhazes showed that the swelling caused by the infection was due to a parasite.

Sixteenth-century European travelers mentioned having encountered cases of the disease in Persia and the Congo. It is said to have been called "Guinea worm" for the first time by another European who saw persons suffering from the infection on the Guinea Coast (West Africa) early in the seventeenth century. The disease is also mentioned in the traditional legend by which the Dahomeyans explained the founding of their ancestral cult. Although G. H. Velschius described the parasite clearly in his monograph, published in 1674, it was left for Linnaeus (Carl von Linné) to give the worm its modern scientific name of *Dracunculus medinensis* in 1758.

British army medical officers reported seeing cases of dracunculiasis among British military personnel serving in India in the nineteenth century, and a large punitive English expedition sent to invade Ethiopia in 1868 also suffered greatly from the same disease. The role of the copepod intermediate host in the life cycle of the parasite was discovered only in the 1870s, by a Russian, Aleksei Fedchenko.

The geographic extent of dracunculiasis shrank considerably during the first half of the twentieth century, largely, it appears, because of gradually improving standards of living, and especially standards that have produced better water supplies. The disease was eliminated from the southern area of the Soviet Union in the 1930s by means of a deliberate campaign, and from Iran in the 1970s. With the advent of the United Nations-sponsored International Drinking Water Supply and Sanitation Decade in the 1980s, India and several other endemic countries began national campaigns to eradicate dracunculiasis. In 1986, the World Health Assembly adopted a resolution calling for the elimination of this disease country by country. It appears likely that this ancient disease will not plague humankind much longer.

VIII.39
Dropsy

The historical diagnosis of dropsy – which is now obsolete – indicated simply an abnormal accumulation of fluid; the word derives from the Greek *hydrops* (water). Alternative or supplementary terms included *hydrothorax* (fluid in the chest cavity), *ascites* (which still indicates excess free fluid in the abdominal cavity), *anasarca* (still used to describe generalized edema throughout the body), *hydrocephalus* (used until the nineteenth century to indicate excess fluid within the skull), and *ovarian dropsy* (large ovarian cysts filled with fluid). Edema was often a synonym for dropsy, but it now has additional connotations, and pulmonary edema has been differentiated from hydrothorax. Since the mid-nineteenth century, dropsy has been recognized as a sign of underlying disease of the heart, liver, or kidneys, or of malnutrition. Untreated dropsy was, eventually, always fatal.

Etiology and Epidemiology

The major underlying causes of dropsy are congestive heart failure, liver failure, kidney failure, and malnutrition. Because they were not clearly differentiated before the nineteenth century, a historical diagnosis of dropsy cannot be taken to indicate any one of these alone in the absence of unequivocal supporting evidence, as from an autopsy. However, heart failure was probably the most frequent of the four.

The etiologies of dropsy can be explained most conveniently in terms of fluid balance. One principal force in the maintenance of normal fluid balance is the hydrostatic (or hydraulic) pressure within capillaries. The other major force is oncotic pressure, the normal tendency for sodium or large particles (e.g., proteins) in capillary blood to draw water out of tissues, much as salt draws water to the cut surface of a raw potato. Thus, fluid accumulates in tissues when either intracapillary pressure increases or the blood's ability to remove water from tissues decreases. In both cases, fluid that has moved out of the capillaries is poorly reabsorbed. Most hydrostatic defects are primary heart diseases, whereas most oncotic defects result from renal and hepatic disease.

Congestive heart failure produces dropsy, or edema, when the heart becomes too weak to maintain the normal pressure head behind blood flow in the capillaries, so that even the normal resistance to flow through them facilitates the leakage of water from capillary blood into surrounding tissues. The adjective "congestive" refers to the accumulation and stagnation – congestion – of blood in organs, especially the lungs, when they are not adequately emptied because of backward pressure from obstructions distal to them.

The other major causes of dropsy, which appear chiefly as edema of the foot (pedal edema) and ankle, ascites, and occasionally anasarca, are listed below for the sake of completeness, but will be discussed further only in relation to heart failure:

1. *Liver failure* capable of producing ascites most often occurs in advanced cirrhosis because the diseased liver cannot manufacture sufficient protein (albumin) to maintain the oncotic pressure of the blood. Right ventricular failure (see below) can also produce hepatic congestion and failure.
2. *Renal failure* causes dropsy when the glomerular filtering units become so diseased (e.g., in glomerulonephritis, first known as Bright's disease) that albumin and other large molecules are lost from the blood into the urine, resulting in decreased oncotic pressure.
3. *Malnutrition* results in ascites when protein intake is so low that the liver is unable to manufacture adequate amounts of albumin. Beriberi, the result of insufficient dietary thiamine, can also weaken the heart.

The epidemiology of dropsy is that of its underlying causes. For instance, elevated serum cholesterol levels and smoking both predispose to hypertension and myocardial infarction ("heart attack"), which are major causes of heart failure. Beriberi heart disease is associated with diets consisting chiefly of highly polished rice, and with alcoholism. Similarly, the epidemiology of streptococcal infections governs the appearance of the inflammatory reactions that can eventuate in glomerulonephritis or in cardiac valve distortions.

However, the epidemiology of some forms of dropsy has changed in recent years. The introduction of penicillin for the treatment of streptococcal infections after World War II, for example, has reduced the occurrence of their cardiac and renal sequelae. On the other hand, the increasing life expectancy of Americans in the twentieth century for many years meant an increased incidence of heart disease. Now, however, recent data suggest that the incidence of coronary artery disease and myocardial infarction has been falling, perhaps as a result of factors such as changes in diet and exercise level.

Heart failure occurs more often in men than women, inasmuch as men are at greater risk for most forms of cardiovascular disease. The risk is greater for older than younger patients: Three quarters of heart failure patients are over 50 years of age. Risk factors for hepatic cirrhosis include chronic alcoholism and hepatitis, just as renal causes of dropsy may be associated with rheumatic fever or the nephrotic syndrome.

Distribution and Incidence

The distribution of dropsy within or among populations parallels the distributions of its underlying causes, such as hypertension, myocardial and coronary artery insufficiency, hypercholesterolemia, valvular disease, streptococcal infection, cirrhosis, and renal glomerular disease. Risk factors for these conditions are still being identified and their clinical implications evaluated. Only for malnutrition are geographic distinctions clear-cut (e.g., in drought-stricken areas of Africa, or countries where diet centers too closely on polished rice).

Historically, a diagnosis of dropsy was based simply on abnormal accumulations of fluid in the legs, abdomen, or chest. The diagnosis was so easy that artists such as Thomas Rowlandson (in his 1810 print "Dropsy Courting Consumption") could portray it in popular prints with the expectation that their customers would recognize it immediately. Consequently, it is not surprising that the reported incidence of dropsy has not changed substantially over the 400 years for which comparable records are available. That is, dropsy has been diagnosed in about 3 to 5 percent of deaths, hospital admissions, or adult patients in London in 1583–1849, and in American villages and cities in 1735–1839. Typical modern incidences of congestive heart failure include 7 percent of patients discharged from a Baltimore hospital medical service in 1969–70, 2.31 percent of outpatients who had prescriptions filled in a San Francisco hospital in 1971, and 3.05 percent of persons over 30 years of age in the

Framingham (Mass.) Heart Study in 1971. In 1985, 3 of every 1,000 Americans were reported to develop heart failure annually, producing an overall incidence of about 1 percent of the population, regardless of age; 34 to 58 percent of heart failure patients die each year.

Clinical Manifestations and Pathology

This discussion focuses only on congestive heart failure because it was probably the major underlying cause of dropsy. The heart is able to compensate, up to a point, for diminished strength of contraction, for increased resistance to arterial outflow (resulting in "pressure overload"), and for accumulations of blood that cannot be completely removed from the ventricles at each contraction (resulting in "volume overload"). The usual responses to these stresses include the following: (1) reflexly increased heart rate (tachycardia), to speed blood flow (actually, oxygen delivery) into the arteries; (2) hypertrophy (increased mass) of ventricular muscle, in response to pressure overloads; and (3) dilation and thinning of ventricular walls, in response to volume overloads, although hypertrophy can be expected to follow as a further adjustment.

Symptoms of heart failure begin to occur when no further compensations can be made. "Forward failure" symptoms occur when the heart can no longer empty the left ventricle completely because of reasons such as myocardial weakness or obstruction to aortic outflow. Normally the ventricles eject 60 to 66 percent of the blood in them at each beat. But when only 40 percent of the blood in the left ventricle can be expelled, symptoms begin to appear, and they become severe when only 20 percent can be expelled. Symptoms of "backward failure" occur when the heart chambers become incapable of complete filling, due to incomplete relaxation of the heart between beats, or to obstructions to venous inflow into the right atrium.

Heart failure can be produced by several underlying pathological causes, although seldom does any one of them occur alone:

1. *Myocardial insufficiency,* in which the heart is too weak to maintain normal blood flow, occurs acutely when a substantial portion of the muscle is incapacitated by infarction, or in association with gradual left ventricular failure. Both dilation and hypertrophy are likely adaptations.
2. *Left ventricular failure* may occur suddenly, after a myocardial infarction, or slowly, owing to pressure overload, most often imposed by increasing

resistance (hypertension) to blood expelled into the aorta. Other causes include stenosis (narrowing) of the aortic valve, which increases the pressure against which the heart must pump, and aortic insufficiency, also called regurgitation, which occurs when an incompetent valve that cannot close permits a volume overload to build up as blood flows back into the left ventricle instead of forward into the aorta.

3. *Right ventricular failure* usually follows when the pressure head built up as a result of left ventricular failure is transmitted backward through the pulmonary vessels to the right ventricle. Other causes of right heart failure include stenosis of the mitral valve, cor pulmonale (see below), and insufficiency of the tricuspid valve.

4. *Failure of both ventricles* simultaneously usually accompanies a strain common to both sides of the heart, as in constrictive pericarditis, beriberi, hypothyroidism, or anemia so severe that the heart rate increases markedly to compensate for the reduced number of red blood cells delivering oxygen to the tissue.

5. *Chronic cor pulmonale* (pulmonary heart disease) occurs when chronic obstructive pulmonary disease (e.g., emphysema) increases resistance to outflow from the right ventricle, resulting in right ventricular failure.

6. *Acute cor pulmonale* is caused by sudden massive obstruction of the pulmonary circulation, almost always by a clot that has formed as a result of thrombophlebitis in a leg vein, and has dislodged (embolized) so that it follows the venous pathway to the right heart and thence into the lungs, where it becomes wedged so as to obstruct blood flow distal to it. The results include infarction of the affected lung, impaired venous return, and dilation of the right ventricle.

7. Less frequent causes of congestive heart failure include, among others, diminished arterial blood flow to both kidneys, resulting in decreased sodium excretion.

Whatever the underlying cause, the major manifestation of heart failure is reduced cardiac output, measured as the liters of blood ejected from the left ventricle per unit time. The associated symptoms and signs are usually clearly recognizable.

For instance, the first symptoms of *left heart failure* are those of being quick to tire and having shortness of breath (*dyspnea*), due to insufficient delivery of oxygen to the body's tissues, followed by rapid breathing (*tachypnea*) as the respiratory system attempts to compensate for the lack of oxygen. Both dyspnea and tachypnea increase as fluid from the pulmonary capillaries begins to flood the lungs. When the lungs become sufficiently congested (*pulmonary edema*), the patient coughs up copious sputum, which is characteristically rust-colored (with small amounts of blood) if mitral stenosis is present. *Stertor* (noisy inspirations) often accompanies the dyspnea. A more serious form of dyspnea is *orthopnea*. This term is applied to shortness of breath that prevents the patient from sleeping horizontally because venous blood, which remains in the lower part of the body as a result of gravity during waking hours, further congests the lungs, causing dyspnea. An exaggerated form of orthopnea called *paroxysmal nocturnal dyspnea* may waken the patient suddenly at night; it is sometimes called "cardiac asthma" because it produces wheezing and labored breathing.

Physical examination and X-rays reveal cardiac enlargement and fluid in the lungs and chest; other tests can confirm that cardiac output is low. Further symptoms of left heart failure as it worsens include pale dusky skin, sweating, cold hands and feet, and tachycardia, all reflex responses to diminished cardiac output, and decreased urine output (oliguria) secondary to diminished blood flow through the kidneys.

Although *right heart failure* is far more likely to occur as a sequela of left heart failure than by itself, it does produce distinctive symptoms in addition to the usual dyspnea and tachypnea, both of which may be more pronounced in right than left heart failure. Pedal edema occurs, accompanied by hydrothorax. Ascites is a late sign of right heart failure, and may be followed by anasarca and oliguria. The skin becomes bluish (cyanosis), because the sluggishly moving red cells are not adequately oxygenated in the lungs. The jugular veins in the neck distend because the increased pressure in the right heart prevents them from emptying completely into the superior vena cava. Other evidence of increased venous pressure includes congestive enlargement of the liver (hepatomegaly) and sometimes the spleen (splenomegaly).

History and Geography

Dropsy is not much different from one geographic area to the next, except when it accompanies localized famines or beriberi induced by local dietary habits, and the symptoms of dropsy have not changed over the centuries. Its history is the story of evolving interpretations of its clinical features over 2,000 years as the relationships of dyspnea, "suffocative

catarrh," pulmonary edema, hydrothorax, ascites, syncope, and "fever" to heart failure were elucidated.

Antiquity Through the Fifteenth Century

The first known mention of dropsy is in an Egyptian medical text of about 1550 B.C., the *Ebers Papyrus*. It associates dropsy with increased abdominal girth, and hints that it is accompanied by a weak pulse. The Hippocratic *Aphorism* VII, 47, correctly prognosticates that "[t]here is no hope when a patient suffering from dropsy develops a cough." And Jesus defied the lawyers and Pharisees by healing a man with dropsy on the Sabbath (Luke 14), although no symptoms are recounted. Soon after, Aulus Cornelius Celsus described two forms of dropsy: (1) generalized edema (*aqua inter cutem*), which could be drained through small skin incisions above the ankle; and (2) ascites, in which the excess fluid detectable by observing fluid waves in the abdominal wall could be removed by *paracentesis,* or *tapping* (i.e., drainage through a metal tube inserted through an incision in the abdominal wall).

Galen of Pergamum listed several causes of dropsy in the first century A.D., including a hardened liver, as well as inadequate blood formation (which he thought occurred in the liver), hemorrhoids, and both amenorrhea and uterine hemorrhage. Virtually all writers on dropsy until the mid-seventeenth century cited the teachings of Hippocrates, Celsus, and Galen. Their ideas were also relayed in the eleventh century by Avicenna of Baghdad, who thought that the tachycardia, palpitations, pulmonary edema, dyspnea, and syncope (fainting or shock, which he postulated was a sign of a weak heart) that accompanied dropsy were related to one another.

Sixteenth and Seventeenth Century

Five centuries later, the French surgeon Ambroise Paré described dropsy in identical terms. His countryman Jean Fernel relied on the same theories when he associated heart disease, but not dropsy specifically, with palpitations, syncope, and the pallor, cold sweat, and weak pulse often observed in cardiogenic shock. Also in the sixteenth century, Paracelsus theorized that dropsy (*wassersucht*) occurred when the body's tissues dissolved. He associated it with dyspnea, cough, and oliguria. Following his usual mystical chemical reasoning, he recommended that dropsy be treated with mercuric oxide to remove superfluous water, with other metallic oxides to dry the patient's body, and with sulfur,

because its drying action was analogous to that of the sun in dispelling rain.

Like his contemporaries, Girolamo Capivaccio of Italy agreed with Galen that dropsy was due to liver disease and impaired blood formation, so that fluid was released into the abdominal cavity to form ascites, which he detected by percussion, as Celsus had. Capivaccio also attributed dropsy to disease in other organs, such as obstruction of the pathways to the kidneys, but he did not mention the heart or even hydrothorax; he surmised that dyspnea was caused by upward pressure from a pathologically enlarged liver on the diaphragm.

The sixteenth-century physician Ludovicus Mercatus of Valladolid defined dyspnea as rapid, difficult breathing, sometimes accompanied by stertor, caused by constricted airways or by excess heat in the heart and lungs; he thought the chief function of respiration was to cool the heart. He followed Galen's classification of dyspnea into three stages of increasing severity: tachypnea, asthma (by which he meant convulsive gasping for breath), and orthopnea. Mercatus thought that hydrothorax fluid descended from the brain to produce the "suffocative catarrh" described by Galen as suffocation in the absence of inflammation, and that its associated dyspnea was caused by fluid in the lungs, or even by heart disease. He theorized that hydrothorax fluid was overflow from ascites or from obstructed urinary passages.

Throughout the seventeenth century, it became increasingly clear that dropsy was associated with altered fluid dynamics as postmortem dissections and experimentation were exploited more frequently. For instance, Carolus Piso (Charles le Pois) of Lorraine detected hydrothorax as "bubbling" when he applied his ear to the chest. Coupling clinical observations with autopsy findings, he attributed paroxysmal nocturnal dyspnea to fluid in the chest cavity. Fabrizio Bartoletti of Italy disagreed with Mercatus and Capivaccio in some of their interpretations, but he used observations like Piso's to hypothesize that hydrothorax fluid came from the lungs. He noted that the first clue to its presence was dyspnea on exertion, followed by "fever" (which he probably detected as modest tachycardia), tachypnea, orthopnea, dry cough, thirst, syncope, leg and scrotal edema, and, finally, ascites. Bartoletti thought that although hydrothorax was not rare, it was always fatal because it suffocated its victims.

In 1616 William Harvey found that edema accumulated behind ligated veins. Later he postulated that if the entire venous system were maximally distended, the heart would stop and suffocation

would follow. In *De Motu Cordis* (1628), he described the heart and lungs as "storehouses" for the blood, the metaphor that Saul Jarcho, the leading student of dropsy, thinks led to the concepts of pulmonary engorgement and passive congestion – concepts that would prove to be critical to further understanding of dropsy in the chest.

In his *Tractatus de Corde* (1669), Richard Lower of Oxford and London described how he had produced edema and ascites in dogs by ligating the jugular veins and the superior vena cava. He also found that excess fluid in the pericardial sac could restrict cardiac expansion sufficiently to diminish venous return, resulting in bradycardia, syncope, and death. Lower went on to postulate that the right and left sides of the heart should be of equal strength in order to maintain the circulation, while noting that the left side alone may be weakened, an early expression of the notion of forward failure. He also perceived that excessive amount, pressure, or flow rate of blood might adversely affect health. Finally, he recognized Galen's "suffocative catarrh" as pulmonary edema, although they were considered to be separate clinical entities for many years afterward.

In 1681 Marcello Malpighi of Bologna carried Harvey's quantitative approach to experimental physiology an important step further when he noted the increased weight of dyspneic lungs (attributable to the stagnant blood within them). Because he had discovered capillaries 20 years earlier, he could hypothesize that blood escaped from them into the lungs. Malpighi thought that stagnant blood in the pulmonary vessels produced palpitations and irregular pulses because it precluded an orderly blood supply to the heart. He reasoned that an imbalance between arterial outflow and venous resorption of water from the blood caused dropsy, but he attributed the imbalance to chemicals that constricted blood vessels or irritated and thus stimulated the nerves that controlled the heart and the respiratory muscles. One of Malpighi's students, Giorgio Baglivi, described the symptoms of suffocative catarrh so that it finally became clearly recognizable as acute pulmonary edema (not the result of fluid falling from the head): dyspnea, cough, stertor, sensitivity to cold, chest pain, thirst, anxiety, and, one of his major original observations, foaming at the mouth.

Eighteenth Century to Modern Times

Physicians were slow to understand that the heart *could* be diseased, probably because it was thought to be absolutely essential to life, but in the early eighteenth century two students of dropsy provided the first clues that cardiac disease might not be incompatible with life. One of them, Raymond Vieussens of Montpellier, correlated the work of Harvey, Lower, and Malpighi with his own postmortem dissections of dropsy patients. By 1705, he had concluded that structural disease of the heart could result in dropsy, after showing how mitral or pulmonary stenosis, or aortic insufficiency, could produce the clinical signs of what is now called backward failure. At almost the same time, Giovanni Maria Lancisi was dissecting victims of sudden death in Rome. Although among the last to cite Fernel, his own observations permitted him to recognize that edema, hydrothorax, and ascites could be related to failure of the heart's propulsive force (i.e., forward failure), to aortic regurgitation, and to obstructions in the right heart. Explicitly recognizing the importance of hydrostatic principles in cardiovascular physiology, Lancisi went on to explain how stagnation of blood within the pulmonary vasculature could result in dyspnea, and he learned how to diagnose hydrothorax ante mortem. He cited Lower's experiments to support his conclusion that right heart failure could produce engorgement and pulsation of the jugular vein. Thus together Lancisi and Vieussens uncovered the cardiac basis of dropsies of the lungs and thorax.

Their work was expanded a few years later by another of Malpighi's pupils, Ippolito Francesco Albertini, also of Bologna. He echoed his mentor's conclusion that sluggish circulation through the lungs leads to dyspnea. A frequent dissector, Albertini emphasized the time course of dyspnea when he pointed out that it comes on rapidly when obstructions occur in the pulmonary vein of the left heart, resulting in delayed removal of blood from the lungs, erosion of the pulmonary vessels, hemoptysis, and hydrothorax.

Another interpretation of dropsy arose from Harvey's demonstration that the blood circulates within a closed system. In this case, dropsy came to be seen as a febrile disease, because it was usually accompanied by a fast pulse, regarded as a cardinal clinical sign of fever over the centuries before clinical thermometers became widely available in the 1870s. Thus Thomas Willis, Lower's mentor and colleague, defined fever as an "intestine motion or commotion of the blood" arising in chemical disturbances like those described over a century earlier by Paracelsus.

Hermann Boerhaave of Leyden was a major proponent of the idea that dropsy was a fever, which should be treated accordingly. He based much of his teaching on the work of Friedrich Hoffmann of Prus-

sia, who saw the body as a machine, subject to the effects of mechanical forces. This led Boerhaave to argue that in dropsy, fever is the result of increased cardiac work and increased vascular resistance to blood flow – in short, of friction. Therefore, by his reasoning, dropsy was a fever because it was associated with a fast pulse. At the same time, he postulated that dropsical fluid accumulated because defective veins released more fluid into body tissues than those weakened vessels could reabsorb. In Italy, Luca Tozzi, who adopted the newer ideas of Paracelsus, Lower, Malpighi, and Hoffmann, was among the first to differentiate hydrothorax, pulmonary edema, and pneumonia at autopsy, which permitted him (and, later, Albertini) to differentiate pulmonary and thoracic dropsies ante mortem by palpating the chest and apical impulse of the heart.

A new method for detecting hydrothorax appeared in 1761, when Leopold Auenbrugger of Vienna described how to strike the chest with the fingers to estimate, by the resonance they produced, the amount and nature of fluid in the pleural cavity and lungs. However, his discovery of percussion added no new information about the pathology of dropsy, and was neglected until it was reintroduced in France in 1808.

The first book devoted to dropsy alone was published in 1706 by the Leopoldine Academy of Sciences in Breslau; its principal author was probably Christianus Helwich. The Academicians described the clinical features of dropsy much as previous authors (especially Piso) had done, but they attributed the escape of fluid from the vessels to diminished blood viscosity and to defective vessel walls, as Boerhaave, too, was suggesting.

In 1733, Stephen Hales, a rural English clergyman, concluded from his experiments in animals that dropsy could be caused by decreased numbers of red blood cells. However, he did not reason that the paucity of red cells would decrease blood viscosity, much less oncotic pressure. Rather, he thought that the body would compensate for the lack of "red Globules" by heating the blood into a feverish state that resulted in dropsy. He was perhaps the first to recognize that inadequate venous return to the heart in dropsy could lead to compensatory (reflex) tachycardia.

Donald Monro of Edinburgh published the second book devoted to dropsy in 1755. He followed Boerhaave in ascribing it to "a weakness and laxity of the fibers . . . when the vessels do not act with sufficient force," and listed several factors that would tend to weaken blood vessels: a watery diet, "any great evacuation," kidney disease, obstruction

of small or large vessels, or any debilitating disease. Neither Monro nor later writers mentioned the blood viscosity hypothesis.

In 1763 Samuel Clossey of Dublin and New York applied the principles governing the relationship between pressure and flow velocity, outlined 35 years earlier by Daniel Bernoulli of Basel, to his own studies of the hydrostatic properties of the cardiovascular system. Clossey realized that the development of hydrothorax is a long process, when he computed that it would take about 2 years for 3 pints of hydrothorax fluid to accumulate. He followed Lancisi in associating dropsy with weakness of the heart, but postulated that cardiac strength derived from that of the blood vessels.

Thus, regardless of how they were interpreted, the major clinical manifestations of dropsy had been identified by the mid-eighteenth century. Some physicians followed Boerhaave's dictum that dropsy was caused by weak blood vessel fibers, whereas others attributed the omnipresent dyspnea to weakened cardiac contraction, as did the medical encyclopedist Robert James of London in his *Medicinal Dictionary* of 1745. But by the turn of the century, unproven – and unprovable – theories of dropsy based on fever, chemical disturbances, blood viscosity, and fiber tone began to fade, and the role of the diseased heart came into sharper focus.

In 1806, Jean-Nicholas Corvisart, who would soon popularize Auenbrugger's discovery of percussion in French translation, showed how heart disease could produce dropsy, dyspnea, and orthopnea when venous return was slowed. Three years later Allan Burns of Glasgow demonstrated that ossification of the mitral and pulmonary valves leads to right heart dilation and dropsy, although it is not clear whether he was aware of Vieussens's pioneering observations along the same lines. And in 1835 James Hope of Cheshire showed how myocardial failure results in dyspnea.

In 1813 John Blackall of London was among the first to suggest that dropsy can result from noncardiac conditions such as liver and kidney disease, when he demonstrated that the albumin content of urine can help differentiate among the underlying causes of dropsy. Blackall's thesis about renal causes of dropsy was confirmed by Richard Bright, whose careful autopsies at Guy's Hospital in London led him to report, in 1827, that albumin could be found in the urine of patients with glomerulonephritis who died of dropsy. A few years later, Bright showed that renal disease could also be associated with left ventricular hypertrophy, presumably because hyperten-

sion is often associated with renal disease. In 1909 C. J. Rothberger and H. Winterberg in Austria, and Thomas Lewis in London, independently showed that a nonanatomic cardiac condition, atrial fibrillation, could produce heart failure, and in 1935 Paul Dudley White and Sylvester McGinn of Boston described acute cor pulmonale.

Although many details of the pathophysiology of congestive heart failure are still being ascertained, all investigators continue to exploit the relationships discovered by Ernest Henry Starling at University College, London. He noted in 1897 that the strength of heart muscle fiber contraction is proportional to fiber length – up to a point. But it was not until 1920 that he adduced experimental evidence to demonstrate the relevance of the rate of blood flow from the veins into the heart, and of the arteries' resistance to outflow, to his basic "Law of the Heart." In 1936 Tinsley R. Harrison of Vanderbilt University consolidated Starling's and other surviving concepts of heart failure to explain the phenomenon more or less as we understand it today, although heart failure remains the subject of many increasingly detailed investigations.

Historical Treatments

The earliest measures for treating dropsy were chiefly attempts to correct humoral imbalances. Celsus, for example, recommended drugs he regarded as diuretics, as well as a wide variety of other medicines with different physiological effects. (One of his diuretics, squill, was finally abandoned only after White demonstrated its lack of dependability in 1920.) During the Renaissance, Capivaccio, Mercatus, and Piso were still recommending Galenic drugs to carry away dropsical fluid, especially cathartics, emetics, diaphoretics, expectorants, and diuretics like squill. In addition, Capivaccio pointed out that blistering with cantharides ("Spanish flies") and paracentesis would remove dropsical fluid, but he recommended bleeding only if the patient's blood had been diseased because of disturbed liver function.

The number of drugs recommended for dropsy diminished during the course of the seventeenth century. The Leopoldine Academicians described some they thought would increase blood viscosity by removing excess fluid from the body, such as diuretics, cathartics, and diaphoretics. Baglivi and Lancisi favored diuretics almost exclusively. Malpighi and his student, Albertini, on the other hand, who based their treatments on the teachings of Hoffmann, recommended tonic drugs to strengthen the tone of the weakened resorbing veins, so that fluid that had

leaked into the tissues could be removed more readily. So did Clossey and Monro, who said that dropsy should be treated with tonic drugs, "which by their stimulus force the sensible [i.e., excitable] organs into contractions."

In 1785, there appeared the single most influential – and perhaps most widely read and immediately accepted – book in the history of dropsy, *An Account of the Foxglove,* by William Withering of Birmingham, England. His was the first prospective study of the clinical efficacy and safety of any drug, for the treatment of any disease. Using historical controls as negative controls, Withering clearly demonstrated the therapeutic benefit of digitalis in patients with dropsies that were not related to primary disease in other organs, such as the ovaries. Because increased urine production usually followed the administration of digitalis, he thought it was a diuretic. Although he noted that the pulse rate fell in patients whose symptoms were ameliorated by the new drug, he did not recognize the drug's tonic effect on the heart.

Because dropsy had been seen since the mideighteenth century as a "weakness and laxity of the fibers," some physicians who followed Withering concluded that digitalis stimulated the "system," whereas others concluded that it was a depressant because it reduced fast heart rates. In 1813 Blackall (not John Ferriar, as some have supposed) first suggested that digitalis actually strengthens the heart. This concept resurfaced in papers published in 1905–11 by James Mackenzie of London and Karel Frederik Wenckebach of Holland and Vienna, but it was only verified in 1938–44, by H. J. Stewart and John McMichael. Wenckebach also demonstrated the efficacy of digitalis in atrial fibrillation.

The two major clinical goals of treatment in congestive heart failure today are improved oxygenation of the tissues by increasing cardiac output, and reduction of hydrostatic pressures in the veins. Digitalis glycosides (chiefly digoxin and digitoxin, both of which must still be extracted from the purple foxglove, *Digitalis purpurea,* or the white species, *Digitalis lanata*) increase cardiac output by strengthening the force with which the heart contracts; diuresis occurs secondarily, because the resulting increase in the amount of blood that can then be circulated to the kidneys permits increased removal of water into the urine. True diuretics, which act on the kidneys alone, relieve pressure in the venous system by removing excess fluid from the body via the urine.

Other drugs now used in the treatment of heart

failure include dopamine, dobutamine, hydrala-zine, nitroprusside, and enalapril; although all of these agents reduce hydrostatic pressures by dilating blood vessels, they act on the vessels in different ways. Enalapril is unusual in that it can also facilitate reversal of left ventricular hypertrophy. In addition, amrinone and milrinone both dilate vessels and increase the force of cardiac contraction. Oxygen and rest, which may have to be induced with sedatives, are important adjuncts to drug therapy. Paracentesis and thoracentesis may occasionally still be required, but the subcutaneous leg drainage tubes described by R. Southey of London in 1871 were abandoned with the advent of true diuretics. Patients with acute pulmonary edema (as in acute cor pulmonale) are often treated with morphine, which reduces not only their anxiety and their tachycardia but also their hydrostatic pressures against blood flow (via an effect in the central nervous system).

Dysentery

Dysentery is an inflammation of the large intestine characterized by loose stools containing blood and mucus, and by tenesmus – painful and unproductive attempts to defecate. Diarrhea, marked by the frequent production of watery stools, may be confused with dysentery in historical accounts, but references to "bloody flux" refer to true dysentery. The condition may be caused by an ameba, *Entamoeba histolytica*, or by several species of bacteria, especially in the genus *Shigella*. See Amebic Dysentery, Bacillary Dysentery, and Diarrheal Diseases (Acute), Chapters VIII.5, VIII.14, and VIII.35, this volume.

VIII.41
Dyspepsia

Derived from Greek roots meaning "difficult digestion," dyspepsia has long served as a synonym for indigestion, one of the most common – and etiologically varied – of human miseries. It has thus been as regularly employed to label the symptoms of diverse organic disorders as to identify a distinct disease, with the result that some gastroenterologists find the word uselessly elastic: "This is really a meaningless term because it has so many meanings." The majority of practitioners, however, have reached a consensus to use dyspepsia to denote either the ailment of functional indigestion or the symptoms of peptic ulcer.

Distribution and Incidence

Peptic ulcer dyspepsia is rare in people under the age of 20, but by age 30, 2 percent of the males and 0.5 percent of the females in a population have developed the condition. For men, the incidence increases steadily with age, reaching a peak of around 20 percent in the sixth decade of life. The incidence for women remains low, about 1 percent, until menopause, after which it climbs as rapidly as in men. A morbidity rate of nearly 14 percent has been re-

ported in women in the age group 70 to 79. Death from peptic ulcer occurs three times as often in men as women.

The prevalence of functional dyspepsia, by contrast, is uncertain. Having no distinct pathology, being neither communicable nor reportable, and only occasionally motivating its victims to seek medical help, it does not generate statistics. The widely shared clinical impression is that women are affected more than men, and people under the age of 40 more than those over age 40. Functional dyspepsia is also believed to be more prevalent in developed countries.

Epidemiology and Etiology

Although the most common, peptic ulcer is hardly the only organic source of dyspepsia. Esophagitis; hiatus hernia; gastritis; carcinoma of the stomach, colon, or pancreas; Crohn's disease; disease of the biliary tract; chronic nephritis; or any of several other conditions, including pregnancy, can produce indigestion. In approximately half of the cases of dyspepsia, however, no lesion can be found, and symptoms arise from derangements of motor, secretory, or absorptive functions, especially delayed gastric motility, esophageal reflux, and hyperacidity. This functional indigestion has been related to physical stress (aerophagia, fatigue, dietary indiscretion) and, more commonly, to nervous stress. Anxiety, anger, frustration, and other indications of emotional turmoil can significantly impair digestive function in sensitive or tense individuals (a similar psychic component – chronic tension and repression of emotion – has been implicated in peptic ulcer). Because the symptoms of functional dyspepsia are virtually identical to those of peptic ulceration, the condition has also been termed *X-ray negative* dyspepsia and *nonulcerative* dyspepsia; the term *endoscopy-negative* dyspepsia has been proposed as well in recent years.

Clinical Manifestations

That most eminent of Victorian dyspeptics, Thomas Carlyle, likened his torment to "a rat gnawing at the pit of the stomach." Dyspepsia's victims still complain of gastric pain, along with fullness or heaviness in the stomach, nausea and vomiting, belching, flatulence, and/or acid eructations. Finally, dyspeptics may suffer heartburn, a caustic pain behind the sternum that sometimes climbs into the throat, resulting from esophageal reflux. Heartburn is the special affliction of those with sliding hiatus hernia when they bend or lie down.

History and Geography

Great suppers do the stomach much offend,
Sup light if quiet you to sleep intend.

So advised the author of the medieval *Regimen Sanitatis Salernitanum,* and no doubt his words were already age-old wisdom. Yet if indigestion has plagued the human race for as long as it has eaten, and no less hoary an expert than Hippocrates described its tortures, it was not until the nineteenth century that dyspepsia attained a prominent standing in pathology. Previously it was regarded as a too common but predictable and temporary discomfort brought on by immoderacy in diet. Alexander Pope's scolding couplets characterized pre-Victorian views (Davis 1966):

[T]he stomach cramm'd from every dish,
A tomb of roast and boil'd, of flesh and fish,
Where *bile* and *wind,* and *phlegm* and *acid* jar.
And all the man is one intestine war.

The sources of intestinal turbulence came to appear more numerous during the early nineteenth century. The distrust of sensuality that marked the Victorian ethos more than once expressed itself in the blaming of physical decline on moral perversion. And because dyspepsia was so often found in patients guilty of some excess and just as often lacked any apparent organic basis, physicians found it easy to explain the condition on the basis of any aberrant behavior that might plausibly have upset the patient's system. Gluttony, of course, was still a sin, and doctors had no quarrel with Ambrose Bierce's (1911) definition of a glutton as "a person who escapes the evils of moderation by committing dyspepsia." They generally added to gluttony the bolting of inadequately chewed food, a practice that many charged was epidemic in the dining rooms of ever-in-a-hurry America. Nevertheless, a nineteenth-century attack of dyspepsia was just as likely to be blamed on the abuse of spirits or tobacco, to the reading of French novels, or to masturbation or "excessive venery."

The nineteenth century's list of dyspepsia's causes was also lengthened by examples of fast living of a second type, that of the mental and emotional excitation accompanying the bustling anxiety-filled life of the industrial city. A. P. W. Philip's *Treatise on Indigestion* (1825), which recommended against excessive venery, also warned, in the same breath, of the dangers of "too long application to business [and] severe study." Such caveats would appear with increasing regularity in medical texts and home health guides alike until finally becoming manda-

tory with the ascension of neurasthenia, or nervous exhaustion, to the position of *the* disease of modern society during the last quarter of the century. George Beard, neurasthenia's prophet, declared "delicacy of digestion" to be "one of the best known and first observed effects of civilization upon the nervous system," and his message that dyspepsia was on the rise as the special complaint of the modern brainworker and risk-taker met with universal acceptance. The 1873 proclamation of *The Household Physician* by Ira Warren and A. E. Small was not hyperbole for the time:

Dyspepsia is a disease of civilization. Savages know nothing of it. It is the costly price we pay for luxuries. All civilized nations suffer from it, more or less, but none so much as the people of the United States. It is here, in the new world, that the disease has become domesticated, and we, as a people, who have threatened to monopolize its miseries.

The neurasthenia era, furthermore, defined "modern dyspepsia" as a nervous complaint that gave as good as it got, one that having originated in anxiety, then generated more anxiety, as well as irritability, depression, and other neurotic suffering in addition to mundane heartburn. This virtual equation of dyspepsia with nervousness led to its being defined almost exclusively as a functional condition produced by stress.

During the first half of the twentieth century, that same stress of coping with civilization seems to have brought about an abrupt increase in dyspepsia of organic origin as well. Between the two world wars, peptic (particularly duodenal) ulcer grew from a rarely encountered condition to a significant cause of disability, reaching a high point in the 1950s, then declining sharply to the present. This pattern has suggested that ulcer dyspepsia is less a disease of civilization than a condition of adjustment to civilization; the first generations to confront the pressures of urban-industrial life are buffeted more heavily than those born after the turbulent transition period. Functional dyspepsia, of course, might be expected to decrease for the same reason, yet its domain has been diminished still more rapidly by the X-ray and the endoscope, improved diagnostic techniques having transferred many cases of "nervous indigestion" to peptic ulcer's column. Advances in understanding of the neurohumoral mechanisms that regulate the digestive tract and the biochemical basis of emotion, furthermore, promise to provide organic interpretations for the dyspepsias now identified as functional. As a consequence, the very term

"dyspepsia," historically associated with nervous, nonorganic illness, is becoming antiquated. In the last decades, medical writers have taken to encapsulating the word in quotation marks to call attention to its quaintness, and inserting it into the index only to be followed with "see indigestion."

Ebola Virus Disease

Textbooks on tropical diseases in Africa are well out of date. With the recognition of new and deadly viral infections – Lassa, Marburg, Ebola, Congo–Crimean Hemorrhagic Fever, Rift Valley Fever, and AIDS – the classical descriptions of major diseases such as malaria and yellow fever must be thoroughly revised, and to the roster of more minor ailments can be added dengue, Chikungunya, O'Nyong Nyong, West Nile fever, and others. One must be ready to challenge earlier descriptions of African fevers in general. Malaria in particular has been an "umbrella" diagnosis, which obscured and still obscures the diagnosis of other, sometimes dangerous concomitant illnesses in regions where malaria itself is endemic to hyperendemic. The absolute need for laboratory confirmation to support the clinical impression is slowly being recognized. This must extend beyond the simple demonstration of presence of malaria parasites in the blood. Malaria parasites in the blood certainly prove that the individual in question harbors the parasite. But it is not necessarily proof that the actual immediate infection from which the individual is suffering is related to the existing chronic malarial position. Treatment of the malarial infection is indicated, and is followed almost universally in tropical Africa, with or without confirmation of the presence of malaria parasites. The first diagnosis entertained for all of the viral infections listed above is almost always "malaria."

It is when the patient does not respond to the antimalarial therapy exhibited that other possible diagnoses are considered. In addition to the viral possibilities, the list should also include influenza, typhoid fever, various rickettsioses, leptospiral infections, bacterial and viral enteropathogenic agents – indeed the range of infections capable of inducing a febrile response.

After the appearance of the Marburg virus in 1967 and the Lassa virus in 1969 had given a jolt to complacency, the Ebola virus in 1976 provoked a convulsive shudder. The Ebola story began with almost simultaneous outbreaks of a deadly infection in the Maridi region of southern Sudan and in the Bumba Zone of the equator region of north central Zaire, neighboring on the Sudan, and in towns along the course of the Ebola River. The Sudan and Zaire foci are about 150 kilometers distant from each other, and people are continually passing back and forth between these regions.

Epidemiology, Distribution, and Incidence

The epidemic of a highly fatal disease (later named Ebola virus disease) began in June 1976, with an index case in Nzara, southern Sudan, among workers in a cotton factory. This patient went to a large hospital in Maridi, where the disease spread rapidly among hospital patients and staff. The epidemic ran its course by November 1976. There were 148 deaths in 284 detected cases (52 percent mortality). In 1979 a further outbreak occurred in southern Sudan, with fewer cases and a small number of deaths.

The epidemic in Zaire was traced to an index case seen on September 1, 1976. The individual in question had received an intravenous injection of chloroquine for presumptive malaria with fever at the outpatient clinic of Yambuku Mission Hospital, Bumba District. He recovered, but within a week a large epidemic of fever began in hospital patients and staff. A total of 318 cases occurred, with 288 deaths (90.5 percent mortality). A number of inpatients and members of the hospital staff, physicians, and attendants also died. The epidemic had terminated by November 5, 1976. The diagnosis of the first epidemiological team sent to the area was "a fulminating epidemic of typhoid fever in a nonvaccinated population." Fatalities, however, occurred in a hospital in Kinshasa in the cases of three nurses who had been transferred from the infected area, and it became clear, as investigations continued, that passage of the virus from human to human had occurred through the medium of contaminated needles and syringes. Whereas formerly rigidly enforced isolation and barrier procedures had been somewhat relaxed, strict syringe and needle discipline and isolation of patients were reestablished and maintained as a permanent part of hospital operations protocol.

The epidemics in the Sudan and Zaire terminated as abruptly as they had started. However, in 1979 another hospital-centered outbreak occurred in Tandala, Zaire, 300 kilometers distant from the original Bumba outbreak. In total, 33 patients were diagnosed, of whom 22 died (66 percent mortality). Through the 1980s no further outbreaks have been reported in Sudan or Zaire or elsewhere in Africa, with the exception of a probable case from Kenya reported in 1983.

Complacency was shattered in the United States and internationally in early November 1989 when an epidemic, confirmed to be caused by Ebola virus,

erupted in a shipment of 100 *Macaca cynomolgus* monkeys originating in the Philippines and shipped to a laboratory in Virginia, in the United States, via Amsterdam and J. F. Kennedy airports. Sixty of the 100 monkeys died. A second shipment received 2 to 3 weeks later in Virginia had two infected monkeys therein.

Extensive epidemiological explorations internationally have focused on this frightening episode. No human cases have been reported. At the time of writing (February 14, 1990), no satisfactory explanations have been advanced. All exposed individuals are being monitored.

This demonstration of the danger of transmission of virus by use and reuse of inadequately sterilized needles and syringes has important implications for medical practice, not just in underdeveloped countries but also in developed cultures because of AIDS. Excessive parenteral administration of many drugs, which could be equally efficacious given by mouth, constitutes bad medical practice. Parenteral administration of drugs in medical emergencies is understandable and desirable. But such a practice for the "typical" patients seen at the clinic for undiagnosed fevers that are not immediately life-threatening is indefensible.

Unsophisticated patients unfortunately cherish an intuitive feeling that drugs, from vitamin preparations up the scale to specific therapeutic agents, are much more effective when given intradermally, subcutaneously, intramuscularly, or intravenously. Indeed, patients often demand parenteral administration of drugs and think poorly of a physician who does not oblige them. This view unfortunately is not discouraged by some practitioners of the medical arts, both licensed and unlicensed, and the practice also greatly increases the bill for pharmaceuticals benefiting drug companies and pharmacists. The poorer countries can ill afford the increased cost.

Epidemiologists have been active in trying to trace the origins of the Ebola virus and the distribution of the infection throughout Africa, locate host vertebrates other than humans, as well as learn methods of transmission to humans and the ways the virus is maintained and propagated in nature. Table VIII.42.1 summarizes these data. Although it may appear that much has been done, actually efforts have been limited to a handful of dedicated investigators, and to a scattered, spotty sampling of the vast expanse of Africa south of the Sahara.

Primates have been sampled (see Table VIII.42.1) and have revealed no involvement, or at best mini-

mal involvement. In connection with the 1979 Tandala, Zaire, outbreak is the unexpected finding of guinea pig immunes. Guinea pigs are South American rodents, inquilines in human habitations in the high Andes. The inhabitants raise them for pets and for food. They were introduced to Africa decades ago and in some regions have established themselves as inquilines in houses. In this respect, their behavior resembles that of the abundant multimammate rat (*Mastomys natalensis*), already known to be involved in Lassa virus maintenance and spread to human beings. Guinea pig immune rates as high as 26.1 percent were found in these animals in some houses in Tandala. Study of the background of those who were positive, however, failed to indicate guinea pig-to-guinea pig transmission, guinea pig-to-human spread, or human-to-guinea pig spread.

Etiology

The Ebola agent was demonstrated by electron microscopy to consist of long filamentous rods, sometimes branched, often intertwined. The virion contains one molecule of single-stranded RNA and is not of itself infectious.

The infectious virus particle is inactivated by ultraviolet (UV)-irradiation, gamma-ray irradiation, 1 percent formalin, beta-propiolactone, and lipid solvents. The particles closely resemble those of the Marburg agent, but there are some distinguishing characteristics. The Ebola agent, for example, has more branching than the Marburg agent. Oligonucleotide patterns are distinctive. Seven nucleoproteins have been described. Serologically no relationship has been demonstrated, either to Marburg or to Lassa or to any other of a long list of arbo and nonarbo viruses. Another distinguishing characteristic of Ebola–Sudan and Ebola–Zaire is pathogenicity. Both cause excessive mortality, but mortality is lower for the Sudan strain than for the Zaire strain. *Cercopithecus* monkeys infected with and recovered from Ebola–Sudan virus, and therefore resistant to superinfection by the homologous virus, nonetheless succumbed when inoculated with Ebola–Zaire virus. A new family, Filoviridae, has been created for the agents Marburg and Ebola. As of 1988, no further agents have been proposed.

Clinical Manifestations

Onset of illness was usually sudden, with progressively more severe frontal headache of a type frequently seen with *P. falciparum* malaria infection, spreading occipitally. Fever and weakness were al-

ways present. Myalgia appeared early. Arthralgia of the large joints was very common from the onset. Severe generalized disease followed in a matter of a day or two. Patients were lethargic, their faces expressionless with deep set eyes. Loss of appetite, sometimes accompanied by vomiting and rapid weight loss, was a nearly constant feature. In 2 to 3 days, gastrointestinal symptoms developed, frequently accompanied by cramping.

In later stages, particularly in patients with hemorrhagic manifestations, red blood was seen in the stools. Vomiting was common, being seen in nearly half of the patients with hemorrhagic signs; vomitus was often of red blood or changed blood (cf. the *vomitusniger* of yellow fever). Other common manifestations included sore throat and dysphagia, fissures and open sores on the lips, conjunctivitis sometimes accompanied by subconjunctival bleeding, and coughing. Jaundice occurred in some. Pancreatitis (clinical diagnosis) was also seen frequently, and abortion occurred in 23 percent of 82 infected pregnant women. Hemorrhagic manifestations, seen in many patients and in over half of those who died, probably resulted from disseminated intravascular coagulation. Death occurred as early as the fourth day, but more usually on the fifth or sixth day and in occasional cases as late as the twentieth day.

Pathology and Diagnosis

Very few specimens were obtained for histological study. In three adequately preserved liver specimens available, fatty changes and necrosis of hepatocytes and Kupffer cells were noted, necrosis being of the focal type, distributed throughout the liver lobules. Intact cells with hyalinized cytoplasm and ghostlike nuclei (Councilman bodies of yellow fever fame) were seen, as were large amounts of karyorrhectic debris. Inflammatory changes were minimal in the liver and other organs.

Comparisons were made with Marburg disease, for which there was a large amount of pathological material available, both from human beings and from experimental animals. Here, in addition to the focal necrotic centers in the liver, was evidence of hemorrhagic diathesis in many organs and of panencephalitis in the brain, with glial nodule formation, perivascular lymphocyte cuffing, and interstitial edema.

Several pathologists deemed the differential diagnosis of Ebola infection to be extremely difficult in settings where there might be malaria, Lassa fever, Marburg disease, yellow fever, Congo–Crimean hemorrhagic fever, typhoid fever, infectious hepatitis,

leptospirosis, brucellosis, and other fevers. Some other pathologists felt the lesions observed to be adequately specific to permit an Ebola diagnosis.

Clinical pathological data are extremely limited. A few white blood cell counts were normal to slightly elevated. No differential counts were made. Proteinuria occurred frequently.

Treatment and Prevention

Plasmapheresis with plasma from recovered patients has been tried as treatment. Interpretation of limited trials (at the tail end of the epidemics) indicates little hope of an effective therapy. No drugs have been effective. A hospital staff member attending an Ebola patient (from Africa) in a hospital in England became ill and soon was gravely ill. Interferon and immune plasma were both given and the patient recovered. A possible vaccine remains a dream.

Interestingly, 11 of 11 blood donors for plasmapheresis had microfilariae, although no protozoa, in their blood. It should be emphasized that most of the Ebola patients who came to a clinic or a hospital had had several days of treatment with an antimalarial drug, often followed by typhoid treatment or antibiotics of whatever kind available. Malarial parasites could hardly be expected to be found under such circumstances.

VIII.43
Echinococcosis (Hydatidosis)

The larval stages of three tapeworms of the genus *Echinococcus* can cause severe disease in humans. All three normally become adults in the intestines of dogs or other canids. Eggs are passed in the feces and, if ingested by a herbivore, develop in the liver or other organs into a saclike container of larvae, the hydatid cyst. Carnivores become infected by eating cysts with the flesh of the herbivore. *Echinococcus granulosus*, which commonly has a sheep–dog cycle, but which may also infect goats, cattle, swine, and camels, is the most likely to infect human beings. Human echinococcosis occurs primarily in sheep-rearing areas. Dogs ingest cysts in the offal of dead sheep and pass eggs in their feces. Humans acquire the eggs from a dog's fur or from contaminated food or water. Cysts holding 2 or more liters of fluid and larvae can grow for years in the liver, lungs, brain, or other organs and exert enough mechanical pressure to cause grave or fatal consequences. Rupture of a cyst by trauma or surgery releases daughter cysts, which may grow elsewhere in the victim; the hydatid fluid can cause fatal anaphylactic shock.

Hydatid cysts in humans and animals have been known since Roman times, but, as was true for the other tapeworms, the relationship between the larval cyst and the adult worm was not suspected until the eighteenth century. *E. granulosus* was described as a separate species in 1850, and its life cycle was worked out with feeding experiments in 1863.

The parasite first became a serious danger to humans when animals were domesticated. The expansion of European settlement spread infection to the Americas and Australasia. Echinococcosis is also found in North Africa, Cyprus, the Middle East, northern and central Asia, and most of sub-Saharan Africa. Iceland was a major focus in the mid-nineteenth century, but education, dog control, and sanitary slaughtering have eliminated the disease. Similar methods, including the mass treatment of dogs, have greatly reduced its incidence in Australia and New Zealand. The highest known prevalence of echinococcosis is among the Turkana, a stock-raising people in northwestern Kenya. Colonial medical authorities in Kenya did not recognize the disease until the 1950s, and an incidence rate of 96 per 100,000 was estimated in 1976, more than seven times the previous record rate in Cyprus. The Turkana problem is linked to a very close association between children and dogs.

Echinococcosis is often difficult to diagnose. Cysts can be detected by X-rays or surgery; several serologic tests are also used. Surgery was the only effective therapy until the early 1980s, when the drug mebendazole was employed with at least some success.

VIII.44
Eclampsia

Eclampsia is a puzzling hypertensive disorder affecting only women. Associated solely with pregnancy and childbirth, it is an epileptic form of convulsions that develops during the second half of pregnancy and disappears after conception. The severity depends upon the degree and timing of the illness as well as the characteristics of the patient. Eclampsia is associated with hypertension, edema, and toxemia, and all three can cause the symptoms of the disease to vary widely. *Preeclampsia* refers to hypertension, abnormal edema, or proteinuria during pregnancy, whereas eclampsia is the disease's most extreme form, manifested by severe convulsions, coma, and even death. Eclampsia is a leading cause of maternal and fetal mortality and can cause stillbirths or premature labor. Medical experts remain confused about the cause of this disorder and have no effective way to cure the disease other than to terminate pregnancy by delivering the baby. Through careful prenatal care, however, physicians can usually control the problem, and it is now relatively rare in the United States and Europe.

Not only is the disease difficult to define, but also accurate records of its existence are rare, especially in Third World countries where prenatal care by a medical attendant is uncommon. Although eclampsia is one of the diseases most troubling to obstetricians, research on the illness is difficult because it is found only in human beings. Its etiology remains unknown but may be multifactorial.

Distribution and Incidence
For reasons not understood, eclampsia seems to be more common among the economically underprivileged. The typical patient is a young woman in her first pregnancy, who is of low socioeconomic status and has had little or no prenatal care. It is more common among women who (1) are diabetic; (2) have high blood pressure or suffer from renal or vascular diseases; (3) suffer from poor nutrition or hydatiform moles; (4) are on the age extremes of their childbearing years; and (5) bear twins. It occurs more frequently in the spring and summer and in certain locations. It also evinces a familial tendency, suggesting some kind of genetic disorder.

Eclampsia is less likely to occur in women who have experienced a previous case. There are few conclusive studies indicating that race is a factor, though it has been suggested that black women in the United States are more likely to suffer from eclampsia than their white counterparts because of greater tendency to develop chronic hypertension on the one hand, and less opportunity for proper maternal care on the other. The disorder occurs in 6 to 8 percent of all pregnancies. Statistics show that it is more common in urban areas, though this association may reflect only the fact that urban women who experience eclampsia or preeclampsia receive more medical assistance in giving birth than rural women, and thus the condition is more frequently noted and reported. Indeed, it is difficult to determine the frequency of eclampsia in rural areas or Third World nations because women there seldom seek, have access to, or can afford regular prenatal care and a hospital delivery. In the United States it has been estimated that the incidence of toxemia is between 5 and 7 percent of all deliveries, and that of eclampsia between 0.12 and 0.26 percent of all deliveries. On the other hand, the incidence figures from several Navajo studies soar to as high as 15.2 and .41, respectively, yet hypertension does not seem to be a predisposing factor (Slocomb and Kunitz 1977). Afro-Americans also have a much higher incidence of toxemia and eclampsia than the general U.S. population, but in this case hypertension does seem to predispose to the disease (Williams, ed. 1975).

Clinical Manifestations
Symptoms of eclampsia and preeclampsia include excessive and sudden weight gain, edema, hypertension, and proteinuria. Patients may also suffer from headache, dizziness, visual disturbances, anorexia, nausea, vomiting, upper abdominal pain, and swelling of the face and extremities. In severe cases, women experience visual and neurological disturbances, oliguria (a deficiency of urine excretion), and, of course, convulsions. In addition, cardiac output increases and the kidneys (which seem to be the target organ for the disease) are affected. Eclampsia can lead to lethal complications affecting the liver, kidney, uterus, and brain, such as *abruptio placentae,* acute renal failure, cerebral hemorrhage, disseminated intravascular coagulation, and circulatory collapse. Preeclampsia does not occur before the twentieth week of pregnancy, and eclampsia rarely before the thirty-second week. Doctors carefully monitor blood pressure and weight gain to prevent its occurrence, although the disease's progress can be rapid and sudden.

History and Geography

It is difficult to determine how common or serious eclampsia was in ancient times. The writings of Egyptian, Chinese, Indian, and Greek scholars do not convincingly note cases, other than an occasional remark describing a pregnant woman's convulsion, fit, or headache. For centuries eclampsia was commonly mistaken for epilepsy. If discussed at all, writers generally attributed the disease to uterine suffocation, believing that the uterus had wandered into the abdominal region. Therapy focused on encouraging a retrograde motion of the uterus to relieve pressure on the upper body and brain. Medieval writings only hint at the disease, but perhaps the reason for this paucity of information was that midwives had a monopoly on assisting births and did not provide written descriptions of problems they encountered. In the second century, Galen noted that epilepsy could be fatal to pregnant women, and Eucharius Rösslin in the sixteenth century stated that convulsions and unconsciousness were ominous signs in pregnant women. Jacques Guillimeau in 1612 concluded that convulsions occurred because the fetus was striving to come forth or that improper positioning extended the womb, thus fostering convulsions. François Mauriceau in 1688 was the first physician systematically to describe eclampsia, thereby indicating a new concern with the disorder as men began entering the field of obstetrics. He also was the first to note that primogravids were at greater risk that multigravids. Mauriceau suggested several causes, including excessive hot blood flowing from the uterus and malignant vapors from a dead fetus. In 1694, he recommended that two or three phlebotomies be performed routinely during pregnancy should a woman exhibit eclamptic tendencies. All early medical experts agreed that it was a dangerous disease.

During the nineteenth century, speculation about the disease was widespread, and physicians considered it to be the most dreaded disorder associated with pregnancy. Doctors speculated on numerous possible causes of eclampsia, including a woman's rapidly changing emotions, a sanguine or plethoric state, excessive hemorrhaging, blood to the brain, nutritional deficiency, excessive protein in the system, albuminuria, renal deficiency, retention of urinary constituents, nerve irritation, high blood pressure, seasonal changes, lethargy, melancholia, wealth, improper positioning of the womb, corrupt menstrual flow, a bad seed, an unstable personality, passions of the mind, and interrupted circulation.

Therapy was generally "heroic." Solutions included warm baths, doses of opium, extensive bleeding from the jugular vein or a temporal artery, depletion to rid the body of toxins, removal of meat or milk from the diet, mustard poultices, ice or cold water on the head, snuff, clysters, emollients to dilate the cervix, and plasters to the lower body to draw the uterus downward. Doctors disagreed on whether it was wise to deliver the baby immediately. Heroic cures, especially those emphasizing depletion, doubtlessly contributed to maternal deaths.

In 1768 Thomas Denman wrote one of the earliest monographs on the disease in English. John Lever and James Young Simpson in 1843 simultaneously discovered the consistent occurrence of proteinuria in preeclamptic patients by finding albumin in their urine. This was a major breakthrough, for the disease could now be considered a toxemia rather than one caused by mechanical pressure. Until the twentieth century, eclampsia was associated with wealthy women, probably because they used male doctors who wrote about the disorder. Not until the 1930s were poor women viewed as susceptible. Unwed mothers were also seen as vulnerable, perhaps because their infants were more likely to be primogravids. Early in the twentieth century, eclampsia was usually associated with hypertension and elevated blood pressure, though speculation as to its origin was still common.

Today physicians depend upon careful monitoring of blood pressure and proteinuria during pregnancy, while watching for edema and excessive weight gain. Early detection is essential. If a woman should suffer preeclampsia, physicians recommend rest and constant monitoring. If a patient suffers from convulsions, attendants take immediate measures to prevent physical injury by suctioning her air passage, providing oxygen, and employing magnesium sulfate to control the seizures. Should the convulsions persist, in rare cases sodium amorbarbital, a barbituate, is administered. Seizures can cause fetal death because the convulsive woman is not breathing and thus the baby is cut off from its oxygen supply. If the baby is near term, doctors make every effort to deliver it once the convulsions have subsided and the patient is conscious. Eclampsia remains one of the greatest puzzles in the list of human diseases and fosters much debate and concern. Doctors have developed better means to manage the disease but still lack an understanding of its etiology.

VIII.45
Emphysema

Pulmonary emphysema is defined in morphological rather than clinical terms. The 1958 Ciba Symposium defined emphysema as an "increase beyond the normal of air spaces, distal to the terminal bronchiole, either from dilation or from destruction of their walls." The subsequent American Thoracic Society statement in 1962 made anatomic destruction a part of the definition: "Emphysema is an anatomic alteration of the lung characterized by an abnormal enlargement of the air spaces distal to the terminal, nonrespiratory bronchiole, accompanied by destructive changes of the alveolar walls."

The definition was refined in 1985 in a workshop report of the National Heart, Lung, and Blood Institute: "Emphysema is defined as a condition of the lung characterized by abnormal, permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by the destruction of their walls, and without obvious fibrosis."

Emphysema can also be subclassified in anatomic terms. The *acinus* is the gas-exchanging unit of the lung served by a single terminal bronchiole. Within the acinus, the terminal bronchiole is succeeded by three orders of branching respiratory bronchioles that are subsequently succeeded by alveolar ducts and terminal alveolar sacs, all of which bear alveoli. If emphysematous changes predominate in the region of respiratory bronchioles, the condition is termed *centriacinar* or *centrilobular* emphysema. More uniform involvement constitutes *panacinar* or *panlobular* emphysema. Emphysema located predominantly in the periphery of the acinus along lobular septa is *paraseptal* emphysema. Occasionally, emphysema may occur adjacent to a scar or fibrotic process and is called *paracicatricial* emphysema.

Distribution and Incidence

Because emphysema is, by definition, a morphological diagnosis, its presence and prevalence depend on the interpretation of an examination of the lungs during an autopsy. Obvious emphysema is likely to be found in at least 50 percent of an average autopsy population, with a frequency of about 65 percent in men and 15 percent in women. Incidence increases with age, reaching 30 percent by the fourth decade and 60 percent by the seventh decade of life. It has been suggested that at least some emphysema may

be a universal finding in elderly adults if properly prepared lungs are carefully examined.

Epidemiology

Whereas most epidemiological studies are based on information elicited by questionnaires or physiological tests, emphysema is a morphological diagnosis and epidemiological studies must be confined to autopsy data. Furthermore, the lungs must be properly fixed on inflation and examined using comparable techniques and emphysema grading methods. Perhaps because of a younger average age of the population examined and a lower prevalence of cigarette smoking, studies from Africa reveal a lower frequency of emphysema than elsewhere. Yet even when populations are of the same age, and the lungs are examined by the same investigators, there appear to be some national and even regional differences. For example, the frequency of emphysema is greater in parts of the United Kingdom than in Sweden or some parts of North America, and lower in some North American cities than in others. The frequency differences may reflect different patterns of cigarette smoking or levels of air pollution, or the selection of people autopsied. The various studies do agree that the amount and severity of emphysema increase with advancing age, and cigarette smoking is a primary cause of the disease. In the various studies, emphysema is found, and in more severe form, at least twice as often in men as in women. The greater incidence of emphysema in males may reflect the greater prevalence of smoking in men; if that is the case, then as more women take up cigarette smoking, this sex preference may change. Although emphysema is remarkably common, it is a cause of, or contributes to, death in only a small percentage of cases.

Etiology

The disruption of alveolar architecture characteristic of emphysema appears to be the result of tissue destruction caused by elastolytic proteases derived from polymorphonuclear leukocytes and alveolar macrophages. Uninhibited digestion of tissue is observed in patients with alpha-1-antitrypsin deficiency. This genetically determined *protease inhibitor phenotype Z* (PiZ) occurs in no more than 1 in 1,000 individuals in a general population, however, and thus can account for only a small proportion of emphysema cases. Evidence suggests that cigarette smoke can enhance accumulation of leukocytes and macrophages in the lung with release of elastolytic enzymes, and can also inhibit antiprotease activity

by mechanisms still under study. Although some forms of mild emphysema are quite common and can occur in nonsmokers, there is nonetheless a strong association between cigarette smoking and emphysema. Thus, although the precise mechanisms remain to be elucidated, cigarette smoking is the most important cause of the moderate to severe forms of emphysema, causing clinical symptoms, respiratory impairment, disability, and death.

Clinical Manifestations

The patient with clinically significant emphysema is typically an older male smoker who gives a history of breathing difficulties that increase in severity over time. On physical examination, he is usually thin, with a thoracic configuration (barrel chested) suggesting hyperinflation, and has markedly diminished breath sounds when listened to on ausculation. Airflow obstruction can be demonstrated by slowing of forced expiration. The chest radiograph confirms hyperinflation with a relatively small heart and decreased peripheral lung markings. However, this "typical" clinical picture is more often the exception than the rule. In several reported series of autopsies, moderate to severe forms of emphysema were found in a significant proportion of individuals who did not exhibit clinical evidence of the disease. In addition, chest radiographs are not reliable in either diagnosing or ruling out emphysema. Most often, emphysema occurs in conjunction with chronic bronchitis and is accompanied by a chronic productive cough.

The presumptive diagnosis of emphysema cannot be made without pulmonary function tests. Chronic airflow obstruction manifested by slowing of forced expiration is characteristic of moderate to severe emphysema, although even this finding may not be universal. When emphysema increases in severity, hyperinflation is reflected by an increase in total lung capacity and residual volume, and the carbon monoxide diffusing capacity is reduced. Loss of lung elastic recoil is commonly associated with emphysema. Such physiological data provide more sensitive indicators of the presence of emphysema than do clinical signs and symptoms or radiological findings.

History

In a postscript to his 1698 *Treatise of the Asthma,* John Floyer described bullous emphysema, together with hyperinflation and loss of lung elastic recoil, from his dissection of a broken winded mare. In his 1793 book on *Morbid Anatomy,* Matthew Baillie described the morphology of human emphysema with

tissue destruction leading to airspace enlargement. There is good evidence that the lung used as an illustration in Baillie's book was that of Samuel Johnson, whose lungs, at autopsy, were found to be permanently distended and failed to collapse on opening the chest. René Laennec's classic *Treatise on the Diseases of the Chest* first appeared in 1819 and was expanded in a subsequent edition in 1826, the year of his death. In it, Laennec provided the first description of pulmonary emphysema, the destructive nature of the disease, and its association with chronic bronchitis. James Jackson, Jr., accumulated a series of cases of emphysema and noted that the disease exhibited a familial predisposition. Though he died in 1834, his work was published in a paper by his mentor Pierre Louis in 1837. It was not until 1963 that the genetically determined alpha-1-antitrypsin deficiency associated with emphysema was described. The physiological changes associated with emphysema have attracted the attention of many investigators over the years. The loss of lung recoil associated with emphysema was inferred from early observations. It was noted by Fritz Rohrer in 1916 and studied by K. von Neergaard and K. Wirz in 1927 and Ronald Christie in 1934 among others. Recent advances in the pathological anatomy of emphysema stem from the work of J. Gough in 1952 using techniques developed by him and by J. E. Wentworth. The precise mechanisms leading to the lung destruction characteristic of emphysema are under current investigation.

VIII.46
Encephalitis Lethargica

Foremost among recorded encephalitis epidemics was the global pandemic of encephalitis lethargica that emerged in and from Europe during the last years of the Great War and occurred in successive waves throughout the world during the following decade. Although the diagnosis of encephalitis lethargica is sometimes applied to sporadically occurring cases of inflammation of the brain having a strong lethargic or stuporous aspect, this discussion focuses upon the encephalitis pandemic that accompanied and followed the 1918 influenza pandemic.

Clinical Manifestations and Pathology

Clinically, encephalitis lethargica was characterized by diffuse involvement of the brain and spinal cord, producing practically the entire range of the signs and symptoms of neurological disease. Sometimes occurring in close conjunction with respiratory-spread influenza, but more often after a long interval, encephalitis patients developed an illness usually characterized by the triad signs of fever, lethargy, and disturbances of eye movement, along with a broad range of other signs and symptoms. These included headache, tremor, weakness, depression, delirium, convulsions, the inability to articulate ideas, coordinate movements, or recognize the importance of sensory stimuli, as well as psychosis and stupor. Oculogyric crisis (eyeballs fixed in one position for a period of time) and other disorders of eye movement, the most frequent sign of localized damage to the nervous system, were present in three-fourths of the cases. Lethargy, another common symptom, in some patients lasted only a few days, but in others it persisted for weeks and months or until death from comatose respiratory failure. Not infrequently, spasmodic twitching and severe psychic and behavior changes persisted long after the acute illness. Approximately a third of encephalitis lethargica patients died of their acute illness, and a large proportion (80 percent) of survivors developed parkinsonism during ensuing decades.

The main pathological findings during the acute encephalitic illness were a diffuse inflammatory reaction in the meninges and around the blood vessels of the brain and the spinal cord; degenerative changes were found in the neurones, especially in the brainstem, basal ganglia, and cerebellum, but
Figure VIII.46.1. Encephalitis lethargica, influenza-pneumonia, other pneumonia/bronchitis deaths in Seattle–King County, Washington, 1918–26. (From Ravenholt and Foege. 1981. 1918 influenza, encephalitis lethargica, parkinsonism. *Lancet* 2: 860-4, by permission of *The Lancet.*)

also including the cortex and the subcortical white matter. In the spinal cord, both the white and gray matter were involved in the inflammatory, degenerative disease process.

Epidemiology

The dominant epidemiological feature of encephalitis lethargica was its unique time distribution. Although epidemics of encephalitic disease had occurred in conjunction with many previous influenza epidemics – 1580, 1658, 1673–5, 1711–2, 1729, 1767, 1780–2, 1830–3, 1847–8, and especially 1889–92 – the global pandemic of encephalitis accompanying and following the 1918 influenza pandemic was in a

class by itself with respect to virulence and sequelae. Along with its unique time distribution, 1917–26, the encephalitis lethargica epidemic, as Figure VIII.46.1 indicates, also had a pronounced seasonal predilection for the winter months. Encephalitis cases often occurred in such close conjunction with individual and community attacks of influenza that many professional and laypersons initially believed the disease to be caused by the devastatingly virulent influenza. But the fact that many cases and epidemics of encephalitis subsequently occurred at times when, and in places where, there was no discernible influenza activity generated confusion and skepticism that influenza could be the principal cause. Long

latent intervals and slow viruses were not well recognized in 1918; hence encephalitis epidemics occurring a year and more after attacks of influenza were perceived as evidence against rather than supportive of influenza as the cause. Likewise, the fact that influenza was highly contagious and encephalitis was not was misinterpreted as indicating that these were unrelated diseases rather than being different manifestations of the same viral agent.

Earliest reports of epidemic encephalitis in 1917 by Constantin Economo in Vienna and by French observers differed little in substance; but Economo's provocative title, encephalitis lethargica – giving unique emphasis to one sign in the broad spectrum of clinical manifestations – gained him lasting recognition while generating ongoing diagnostic confusion.

Although these reports of encephalitis preceded the explosive general global dissemination of influenza in 1918, influenza was active in war-torn Europe during the winter of 1916–17. In 1918, in close association with the initial massive waves of influenza, encephalitis was reported in Britain, Scandinavia, Germany, the United States, and many other countries; but the greatest epidemic peaks of encephalitis occurred in 1919–20 and during subsequent winters – as shown for Seattle in Figure VIII.46.1.

Typically, encephalitis lethargica was generally distributed by age, sex, race, occupation, education, economic status, and geographic location. Ages of cases ranged from infancy to old age, with the highest attack rates among young adults; and the sexes were equally represented. Rarely was there discernible clustering of encephalitic cases within families and neighborhoods; and where such was reported, it is retrospectively apparent that the clustering arose as a result of diagnostic confusion with other causes of central nervous system disease – for example, botulism.

Attack rates for encephalitis lethargica during the pandemic years 1918–26 approached 1 case per 1,000 general population in the United States and in European countries where fairly complete records were maintained. Of those afflicted, roughly one third died during their acute illness. Extensive but less precise reports from throughout the world indicate that attack rates for encephalitis lethargica may have been similar worldwide, except in those few small populations, most notably American Samoa, where neither influenza nor encephalitis occurred during the pandemic years. Hence, the world total of encephalitis lethargica cases was probably more than 1.5 million – of whom about 500,000 died of acute illness and more died from parkinsonism and other complications following the acute illness stage.

Etiology

Despite the assertions of F. G. Crookshank (1919), Rudolf von Jaksch (1923), and others that 1918 influenza was the principal cause of encephalitis lethargica, leading researchers of the 1920s, such as E. O. Jordan (1927) and A. J. Hall (1924), judged the relationship between influenza and encephalitis to be so inconsistent and confusing that they stated the etiology of encephalitis lethargica to be "unknown." But now, 60 and more years after the pandemic, from research done in Seattle and Samoa by R. T. Ravenholt and W. H. Foege (1982), the etiology of encephalitis lethargica seems clear. Death records in Seattle show a characteristic modal lag of approximately a year from influenza-pneumonia death peaks to onset of encephalitis lethargica clusters terminating in death (Figure VIII.46.1), providing strong evidence that encephalitis cases previously thought to have occurred independently of influenza were actually late sequelae.

The Samoan Islands were chosen as another site for study because the sharply contrasting experience of Western and American Samoa with respect to the 1918 influenza epidemic provided a unique basis for study of its pathological effects. As stated by Jordan:

In no part of the world did influenza exact a more crushing toll than in the islands of the South Sea. In Western Samoa the steamer Talune from Auckland introduced the disease on November 7, 1918, into the islands of Upolu and Savaii. As a result there were nearly 8,000 deaths, the population during the two months ended December 31, 1918, being reduced from 38,178 to 30,636.

Meanwhile, American Samoa, just 70 kilometers away, and inhabited by the same racial stock, managed to exclude the infection with strict quarantine measures and good fortune.

During May 1982, American Samoa records stored in the National Archives and Records, in San Bruno, California, along with death records for American Samoa maintained by the Lyndon B. Johnson Tropical Medicine Center on Tutuila, and death records for Western Samoa available in the Registrar's Office at Apia were analyzed. Although the rudimentary nature of the death records in Western Samoa limited the comparative studies that could be made of mortality patterns in American and Western Samoa during the 1920s, it was clear that whereas Western Samoa

suffered heavily from both influenza-pneumonia and encephalitis lethargica during the years 1918–22, American Samoa was remarkably free of both these diseases during those years. The evidence, then, is compelling that the pandemic of influenza beginning in 1918 and the pandemic of encephalitis lethargica generally beginning the following year had a common etiology. Both pandemics were globally distributed and were closely related in time, and only one etiologic agent (swine influenza virus) has been reliably identified.

Local, regional, and national influenza-pneumonia epidemics ordinarily (perhaps invariably) preceded local, regional, and national epidemics of encephalitis lethargica. A large proportion of individual encephalitis lethargica cases during the early years of the pandemic had had clinical influenza. Later, as influenza and encephalitis occurrence patterns shifted from massive epidemic to sporadic endemic, the relationship between these two diseases became progressively obscured.

Seasonal and global occurrence patterns of encephalitis lethargica rule out the possibility that this pandemic was caused by an arbovirus or any known nonrespiratorily spread infection. Moreover, although influenza-pneumonia was highly communicable from person to person, encephalitis lethargica was remarkably noncommunicable from person to person by any known route.

Analogous pandemics of encephalitis have been recorded in close association with other influenza epidemics, although none as severe as that in association with the 1918 influenza pandemic. Guillain–Barré's disease following inoculation with swine influenza antigen suggests a neurotoxic effect of this organism, even in the killed state. Likewise occurrence of parkinsonism during convalescence from influenza and/or encephalitis and during many years and decades thereafter demonstrates the extraordinary neuropathogenic qualities of the causative agent – now identified as the 1918 (swine) influenza virus.

Immunology

The immunologic findings of E. T. Gamboa and colleagues in 1974 support the contention that the 1918 influenza (swine, type A) and encephalitis lethargica epidemics had a common etiology: They found deceased patients with well-documented postencephalitic parkinsonism to have intranuclear fluorescent antibody to neurotropic influenza A strain antigen in hypothalamic and midbrain sections, whereas no such fluorescence was observed in similar sections

Table VIII.46.1. *Time interval from encephalitis to parkinsonism to death in six patients*

Patient	Year of encephalitic illness	Years from encephalitic illness to parkinsonism	Years from encephalitic illness to death
1	1925	1	47
2	1927	13	45
3	1924	2	48
4	1926	17	46
5	1921	12	51
6	1918	30	54

from brains of persons with idiopathic (not postencephalitic) parkinsonism. The long intervals between the several manifestations of 1918 (swine) influenza virus – pneumonia, encephalitis lethargica, parkinsonism – must be kept in mind when seeking to understand the interrelated epidemiology of these diseases (see Table VIII.46.1).

History

From among all causes of encephalitis – structural, chemical, and microbiological – it was a difficult task sorting out the many infectious causes of encephalitis by specific causative organism and route of transmission. But with the explosion of scientific knowledge in the late nineteenth and twentieth centuries, many important agents and vectors of encephalitis were identified, among them, the spirochete of syphilis, and the trypanosome of African sleeping sickness, transmitted by sexual contact and tsetse flies, repectively; the bacterial toxin of botulism, from ingested food; the viruses of yellow fever, Japanese B encephalitis, equine encephalitis, transmitted by mosquitoes; the virus of rabies, transmitted by the bite of rabid animals; the viruses of influenza, mumps, and measles, transmitted by the respiratory route; the enteroviruses, transmitted by the fecal–oral route; and, most recently, the human immunodeficiency virus, transmitted by sexual contact and blood.

Adding to the diagnostic confusion generated by these numerous encephalitic microorganisms were the many cases and deaths from stuporous encephalitic reactions to various toxins and drugs, especially Reye's syndrome following the use of aspirin (introduced in 1899) to control the fever and discomfort of influenza, varicella, and other childhood diseases. The role of aspirin in the production of Reye's syndrome has become known only in the last decade.

But the main causative agent of epidemic encephalitis during the pandemic years 1917–26 was the respiratorily spread influenza virus. Successive peaks of encephalitis occurred in European, Asian, African, and American countries from 1918 to about 1926. In the United States, encephalitis lethargica progressed across the country from the east to the west in 1919, just as influenza had the previous year, reaching peak occurrence in New York during January 1919, in Virginia during February, and in Illinois, Louisiana, and Texas during March; whereas in California more cases were reported in April than in any other month, and in Seattle the first encephalitis lethargica cases were reported in October 1919. Although Britain reported its peak number of cases in 1924, this was apparently a reporting artifact – as judged from the mortality pattern during the 1920s.

For too long, medical science has tended to relegate the 1918 influenza–encephalitis lethargica–parkinsonism puzzle to an intellectual ash heap, apparently on the assumption that these epidemics are past history and of little or at least dwindling importance to current and future health. But failure to identify influenza virus as the cause of encephalitis lethargica and parkinsonism has crippled progress toward the understanding of influenza pathology and epidemiology needed to fuel and guide prevention of these elusive but exceedingly important diseases.

According to William Osler, Karl Menninger, and August Wimmer, almost every disease of the central nervous system (CNS) may follow influenza. Thus we should look to the diminutions of CNS structures caused by influenza attacks during earlier life when seeking the keys to prevention of much serious CNS disease, especially senile dementia (Alzheimer's disease).

VIII.47
Enterobiasis

The pinworm *Enterobius vermicularis* (formerly *Oxyuris*) is a common parasite around the world and is the most prevalent parasitic helminth in developed countries today. Enterobiasis has afflicted and annoyed humans from ancient times; it was known to ancient Chinese, classical, and Islamic writers and was present in pre-Columbian America. Humans are the only hosts. Mature worms, ranging from 2 to 13 millimeters in length, inhabit the cecum and adjacent regions of the large and small intestines. Gravid females migrate out the host's anus and deposit thousands of eggs on the skin of the perianal region. The eggs mature quickly and are infectious in several hours. Infection by ingestion of eggs from the hands is common, as the worms induce itching and scratching. Eggs are frequently eaten with contaminated food, and, because they are light, they are easily inhaled in household dust. Eggs hatch in the small intestine and develop into mature adults in as short a time as 4 weeks. Retroinfection,

when the eggs hatch on the perianal skin and the larvae crawl back into the rectum, is possible but rare. Pinworms are especially prevalent among small children and often become a family affair.

Enterobiasis is rarely a serious disease. Intestinal disturbances, if any, are minor, but pinworms can cause great discomfort, and scratching can lead to secondary infections. Migrating worms occasionally reach the vagina or appendix, but rarely cause serious harm. Rectal itching and consequently insomnia, especially in children, are suggestive of pinworm infection.

Diagnosis is made by microscopic examination of perianal swabs to detect eggs. The condition normally is self-limiting in the absence of continuing reinfection. Drug treatment is safe and effective, but often the whole family or institutional living group must be treated simultaneously, and bedding and clothing must be thoroughly cleaned. Even the most fastidious housekeepers may find it very difficult to rid a home of airborne eggs. Personal hygiene is the best preventive measure.

| Epilepsy |

Epilepsy is characterized by the repeated occurrence of seizures that result from recurrent, abnormal, excessive, synchronous discharges of populations of cerebral neurons (Epilepsy Foundation of America 1981). It has a worldwide distribution and probably has been in existence since the dawn of human history. The condition is chronic but rarely fatal, and most types of epilepsy do not disturb the affected individual's desire or ability to lead a normal life. Modern antiepileptic medications most often control seizures, and the limitations imposed by the disorder may be negligible. Unfortunately, epileptics are all too frequently stigmatized and excluded from many activities of daily life. Outdated beliefs and misconceptions about epilepsy have only recently shown signs of lessening in the United States and other industrialized societies.

It is misleading to think of epilepsy as one disease. There are many causes of this symptom cluster, just as there are for the symptom cluster of nausea and vomiting. A better term would be "the epilepsies." The epilepsies do, however, share certain physiological characteristics. Clusters of neurons in some parts of the brain begin to discharge impulses in a disorganized fashion. The parts of the body controlled by the affected neurons respond with disorganized activity such as convulsions or tremors, or by loss of normal function such as loss of consciousness, paralysis of a limb, or localized numbness. The condition is also chronic, marked by the recurrence of seizures. By monitoring the brain with electrodes, an electroencephalographer can often detect abnormal brain waves, either localized in one part of the brain or coming from all parts at once.

Etiology

Although epilepsy can begin at any age, the majority of patients have their first seizure before the age of 20. In fact, the age of onset is often related to the cause. Perinatal injuries, severe hypoxia, developmental brain defects, and genetic metabolic defects are common causes of epilepsy among infants and the newborn. Brain infections such as meningitis and encephalitis often result in damage to some brain cells with subsequent development of epilepsy. Many children experience seizures during periods of high fever caused by infection in parts of the body

other than the brain. Only a very small percentage of these febrile seizures persist after the age of 4, however. Head trauma is one of the most common causes of seizures among adults, although brain tumor must also be suspected, as about 40 percent of all patients with brain tumors have seizures. Later in life, seizures may be caused by cerebrovascular attacks.

Despite medicine's increased ability to determine the various causes of epilepsy, no known cause can be found or reasonably presumed for a large proportion of seizures. Until a very few years ago, genetic predisposition was thought to be the cause of what was called "idiopathic" epilepsy. Today, most experts do not believe that heritability plays as large a role as the proportion of patients whose seizures have been diagnosed as idiopathic might suggest. That genetic factors are involved, however, is indicated by the fact that people with a family history of epilepsy have a higher incidence of seizures than the population in general. In addition, the electroencephalogram (EEG) tracings of asymptomatic relatives of patients with some forms of epilepsy show a higher incidence of abnormal discharge than is found among the rest of the population.

Epilepsy is characterized by *recurrent* seizures; therefore, an individual's first seizure does not, of itself, indicate its presence. Nervous system infections, metabolic imbalance, and transient reactions to head injury may all result in a seizure episode without putting the individual at risk for further seizures. Among epileptics an almost infinite number of stimuli may trigger seizure activity. Fatigue, alcohol abuse, and infection, for example, commonly precipitate attacks in people whose epilepsy is otherwise well controlled. Despite the great variability in thresholds and types of seizures and in the unpredictability of its course during the patient's lifetime, some features appear with striking frequency, and some attacks are remarkably similar for many people.

Epileptics as well as nonepileptics may experience seizures that are not associated with abnormal brain wave activity and that have no known physiological cause. These *pseudoseizures* are often called *hysterical seizures* or *conversion reactions*. Like epileptic seizures, pseudoseizures have characteristics that appear repeatedly. Epileptics with pseudoseizures tend to exhibit the same signs and symptoms in the same sequence with each episode. Nonepileptics' symptoms may vary in site and nature if there are many episodes. Despite the fact that pseudoseizures are responsive to the social environment and appear to vary among cultures, they are often very difficult to distinguish from epileptic seizures. Between 8 and 20 percent of epileptics are thought to experience pseudoseizures in addition to their epileptic seizures, and it has been estimated that even experienced neurologists can identify pseudoseizures only 75 percent of the time (Lechtenberg 1984).

Epidemiology

Because epilepsy is a nonreportable disease, it is difficult to arrive at reasonable estimates of its incidence. Perhaps half the cases in the United States are preventable in the sense that they are the sequelae of trauma, infections, birth injury, and so forth, with clear damage to the brain, the seizures appearing as a secondary symptom of the underlying brain damage. In cases of cerebral palsy or mental deficiency, epileptic seizures are often the least dramatic of the symptoms. These secondary cases are more frequent when there is poor prenatal and perinatal care and in populations suffering from poverty with its attendant overcrowding, malnutrition, neglect, and violence. From a world health point of view, epilepsy is a very common and disabling condition, particularly in regions where there is a high incidence of low virulence central nervous system infections causing secondary cases, and where traumas, particularly the subdural hematomas of infancy and early childhood, are neglected.

Distribution and Incidence

In the United States the incidence of epilepsy is about 0.3 to 0.4 percent per year, or roughly one tenth the incidence of mental deficiency and perhaps one half the incidence of schizophrenia. The rate for males is slightly higher than that for females for all types of seizures combined, and is highest for ages 0 to 4 years, reaches a low level after adolescence, and peaks again after 70 years as the result of late cerebral disease (Kurland 1949).

Since the early 1970s, several good epidemiological surveys of epilepsy have been made in Iceland, England, and the United States, which report crude prevalence rates between 3.6 and 5.5 per 1,000 population (Kurland, Kurtzke, and Goldberg 1973). Epidemiological studies of epilepsy, however, are plagued by a variety of problems. Of prime importance in this regard is the lack of agreement on the definition of epilepsy itself as well as what constitutes an active or an inactive case. In addition, there are difficulties involved in estimating the size of the population universe and the number of cases not identified by the case finding procedures. The most

rigorous survey conducted in a community in the United States was done in Rochester, Minnesota (Hauser and Kurland 1975). The crude rate for all types of epilepsy was 5.7 per 1,000 population. Seventy-five percent of the patients' seizures were of undetermined cause, and approximately 70 percent had generalized seizures. A prevalence rate of 2.8 per 1,000 population has been reported for Tokyo (Tsuboi 1988) and of 2.47 for rural Kashmir, India (Koul, Razdan, and Motta 1988).

Crude prevalence rates between 7.6 and 8.4 per 1,000 population have been reported for four North American Indian tribes (Levy, Neutra, and Parker 1987). Environmental factors account for the difference between Indians and the non-Indians of Rochester. The former have significantly more epilepsy attributed to trauma, postencephalopathy, and inflammatory disease. Even higher rates are found in urban ghettos, where lead poisoning and drug addiction are among the leading causes of epilepsy (Hauser, personal communication).

Classification, Clinical Manifestations, and Pathology

The growing emphasis on physiological mechanisms and electroclinical correlations has led to a classification of the epilepsies by the localization of the electrical abnormality in the brain. The major division is between *generalized (centrencephalic) seizures,* where the brain activity is spread over the entire cerebral cortex; and *partial (focal) seizures,* which occur when only one part of the brain is involved. Generalized seizures demonstrate bilateral motor activity and involve a loss of consciousness, which may or may not occur in partial seizures depending upon the part of the brain initially affected and the subsequent involvement of other structures. There is an approximate correspondence between the sites of the brain where electrical abnormality occurs and the clinical manifestation of the seizure.

Generalized Seizures

The term "epilepsy" was first used to denote the symptoms of *major,* or *grand mal seizure,* currently referred to as a *tonic-clonic seizure.* To this day, over 60 percent of all individuals diagnosed as epileptic have tonic-clonic seizures. A sudden burst of discharges involving the whole brain occurs without warning. The patient falls to the ground unconscious. Then, in the tonic phase, the patient goes rigid and often gives a short cry, due to the contrac-

tion of the diaphragm and chest muscles. The eyes may roll up or turn to one side, and the tongue may be bitten. After this, a period of jerky, clonic, spasms alternately flex and extend the muscles of the head, face, and extremities. During this phase, the patient may injure him- or herself as well as be incontinent. Cyanosis is generally marked. Breathing is deep, and there is sweating and salivation. Subsequent to the seizure, the patient may wake in a confused state (*postictal twilight state*) and even display some bizarre behavior. Sometimes patients are hard to arouse, sleep for hours, and awaken with headache or sore muscles. Although most tonic-clonic seizures last for only a few minutes, some patients develop a series of seizures with no letup, or a continuous prolonged seizure. This is a serious condition known as *status epilepticus,* which may lead to death if immediate care is not provided.

A variety of other generalized seizures have also been recognized. Sometimes patients exhibit only the tonic or clonic aspects of the seizure. Between the ages of 4 and 12 years, *absence seizures* often occur. These have been known as *petit mal* because they are of such brief duration, no more than a few seconds, that they often go unrecognized and untreated. During the brief lapse of consciousness, the child stares vacantly and neither speaks nor hears. Subsequently, activity is resumed with no period of stupor. Equally brief are *atonic seizures,* during which the child simply falls to the ground; *myoclonic seizures,* which are sudden, brief, and massive, involving either the entire body or confined to the extremities, face, or trunk; and *infantile spasms,* during which the child is jerked into a fetal position with the knees drawn up. Many children with infantile spasms are also mentally retarded.

Partial Seizures

All partial seizures begin in one part of the brain, and, because different parts of the brain control different parts of the body as well as mental and sensory functions, their signs and symptoms are varied and, often, quite complex. Many patients exhibit behaviors easily mistaken as psychiatric problems which can make accurate diagnosis difficult. It is also among victims of partial seizures that one is most likely to observe displays of bizarre, learned, culturally conditioned behavior.

Simple partial seizures have been variously called *focal, focal motor,* or *focal sensory seizures.* Although the symptoms may be motor, autonomic, psychic, sensory, or a combination, they are all linked to the affected area of the brain. The patient does not lose

consciousness as a general rule, and the attacks last no more than 30 seconds. One type of simple partial seizure has been called the *Jacksonian*. It characteristically begins with the twitching of one foot or hand, and the patient retains consciousness. Until very recently, seizures were classed as Jacksonian even if the activity subsequently spread to both sides of the body and involved loss of consciousness. Today, however, such seizures are classed as partial but secondarily generalized.

Complex partial seizures are characterized by complex symptoms and, unlike simple partial seizures, by impairment of consciousness. Often the patient appears to be conscious but later has no recollection of the episode. These seizures are usually associated with the temporal or frontal lobe and often begin with an aura that warns of the impending attack. Auras may include any of a large variety of sensations. Some of those most commonly reported are nausea; faintness; dizziness; numbness of the hands, lips, and tongue; choking sensations; and chest pain. Less often, patients have reported visions, palpitation, or disturbances of smell or hearing. Some patients have sensations that may begin hours or even days before the seizure. These symptoms are called the *prodrome* and most often involve irritability or feelings of uneasiness. When psychomotor symptoms appear during a seizure, they are generally semipurposeful and inappropriate actions such as clumsy attempts to disrobe. Patients often stagger about uttering guttural sounds. Such behavior is often confused with psychiatric disorder and is often alarming to those present.

Secondarily generalized partial seizures occur when seizures with a focal onset spread throughout the brain and produce generalized tonic-clonic seizures. Because the generalized phase is so dramatic, patients and their families often overlook the focal onset. The presence of an aura indicates the presence of the focal onset and the need to observe the initial phase more closely.

The diagnosis of epilepsy and the classification of the type of seizure depend primarily on information obtained from the medical history. The first task is to determine whether the patient has epilepsy or has experienced another kind of brief, reversible alteration of consciousness or behavior. Subsequently, specifying the type of epileptic seizure is important for confirming the diagnosis and as a major guide in choosing the initial antiepileptic medication. Because the physician is most often unable to observe the patient or obtain an EEG reading during a seizure, an accurate medical history is of crucial impor-

tance. EEGs administered between seizures may or may not reveal patterns suggestive of epilepsy. Nevertheless, because they often do reveal abnormal discharges, routine administration of EEGs is of significant value in the evaluation of any patient with a history suggestive of epilepsy.

By conservative estimates, some 50 percent of patients can have their recurrent seizures controlled without side effects when optimal medical treatment is available. Another 30 percent can achieve seizure control but experience some side effects of the medication. For some patients whose seizures cannot be controlled by medication, surgery may be an option if a distinct piece of brain tissue that is causing the seizures can be identified, and if its removal will not cause unacceptable neurological deficits such as speech difficulty or memory loss.

History

Antiquity

The antiquity of epilepsy is attested to by an ancient Akkadian text that speaks of a person whose neck turns left, whose hands and feet are tense and eyes wide open, from whose mouth froth flowed, and who lost consciousness. The Greeks referred to it as "the sacred disease" as well as "epilepsy," which means seizure and which may derive from the idea that all diseases represented attacks by supernatural beings. The term "sacred disease" is found first in the writings of Heraclitus and Herodotus, but its identification with epilepsy is made explicit in the book *On the Sacred Disease*, part of the Hippocratic collection of medical writings from about the year 400 B.C. and the first monograph on epilepsy we possess.

Underlying the great variety of explanations offered by the ancients lies the basic belief that epilepsy is an affliction or possession by a higher power and that its cure must be supernatural. The Romans called epilepsy *morbus comitalis* because the attack spoiled the day of the comitia, the assembly of the people. There was also the idea that the disease was contagious: The epileptic was unclean and whoever touched him or her might become prey to the demon. The idea that epilepsy was contagious was one of the factors that made the epileptic's life miserable and gave him or her a social stigma. To the ancients the epileptic was an object of horror and disgust and not a saint or prophet as has sometimes been contended. Wherever the physicians of antiquity wrote of the sacred disease, they meant epilepsy and differentiated it from hysterical attacks as well as from madness.

In the struggle between supernatural and scientific explanations of disease, science has gradually emerged victorious in the Western world. The fight, however, has been long and eventful, and in it epilepsy held one of the key positions. Showing both physical and psychic symptoms, epilepsy more than any other disease was open to interpretation both as a physiological process and as the effect of supernatural influences. The first record we have of the battle is in *On the Sacred Disease,* an attack on popular superstition that called epilepsy the "sacred" disease. It maintained that epilepsy was hereditary, that its cause lay in the brain, and its treatment was to be by diet and drugs as long as it had not yet become chronic. It is here we first find the fundamental statement that the seat of the disease is in the brain and that the brain is the organ of all psychic processes both normal and pathological. Moreover, according to the author of this work, not only epilepsy but all mental diseases were to be explained by disturbances in the brain.

Middle Ages Through the Eighteenth Century

During the Middle Ages, the literature on epilepsy propounded two contrasting views. On the one hand, the "falling evil" was bound to demoniac beliefs and theological speculations; on the other, physicians clung to the idea of a definite natural disease. Little effort was made to force the issue, however; physicians rarely discussed the theological aspects and seem, moreover, to have been unable to rid themselves of traditional definitions and explanations. By the end of the sixteenth century, this appears to have changed, the debate became open, involving the role of the devil, witchcraft, and various types of magical treatment. Despite many efforts to define epilepsy and classify types of seizures, little progress was made medically, although, gradually, the idea that epilepsy was a natural disease did gain more credence, especially after the Age of Enlightenment.

Nineteenth Century

By the beginning of the nineteenth century, epileptics were hospitalized, but unlike the insane, were allowed to go to mass on Sundays. Confined epileptics, however, became the object of systematic medical attention only in the early nineteenth century. The care of epileptics, especially children, progressed slowly. Only in 1838 were epileptic children in Paris transferred from the Hospital of the Incurably Ill to the Bicêtre, where some kind of education was provided for them. The separation of hospitalized epileptics from the insane was motivated less from solicitude for the epileptics who might suffer from contact with the insane than from the belief that epilepsy was an infectious disease that would affect the insane even more than it did the healthy. The confinement of epileptics in separate wards of lunatic asylums became established procedure in Europe around 1850 and was soon followed by requests for special institutions for epileptics.

During the early part of the nineteenth century, the most valuable contributions to the medical history of epilepsy were made by physicians associated with hospitals and lunatic asylums, and it was then that new terminology, increased use of statistics, and interest in the psychiatric side of epilepsy developed. The terms grand and petit mal, absence, status epilepticus, and aura, for example, were in common usage and survive to this day. The growing use of statistics fostered investigations into the inheritability of epilepsy and determination of the various causes of the illness, prominent among which were fright, sorrow, and masturbation. Despite the increased attention paid to epilepsy, however, modern medicine's understanding is usually said to have begun around 1880, when the impact of John Hughlings Jackson's work in England and that of Jean Charcot in France began to be felt. Jackson outlined a neurological theory of epilepsy, while Charcot separated epilepsy from hysteria more emphatically than any of his predecessors. Jackson's principles were publicly demonstrated in 1888, by William Macewan, who was "probably the first surgeon to localize the cerebral focus by inference from the motor or sensory signs of the epileptic seizure" (Temkin 1971).

Ergotism

Ergotism is a disease condition acquired by eating cereal grains infected with ergot fungus. Known since the time of Galen, it was prevalent in medieval Europe, particularly among the poor who, during famine, consumed bread made from spoiled rye. Ergot (*secale cornutum,* spur of the corn, horned rye, womb grain), the dried sclerotium of *Claviceps purpurea,* develops on the ovary of common rye, or on corn, where it was previously known as corn smut. The actual cause of ergot in grasses was hotly debated by early naturalists, some of whom thought it occurred in rainy weather and was attributable to fog or impure atmosphere. Others believed it to be the work of worms or butterflies, whereas still others regarded it as the product of improper fecundation or perhaps the cooking of the sexual parts of the plants.

Classification

Ergotism has two forms: (1) *convulsive,* or *spasmodic,* also known as *creeping,* which affects the central nervous system; and (2) *gangrenous,* which affects the blood vessels and blood supply to the extremities. Common names for the gangrenous form are *St. Anthony's fire* (after the patron saint of the disease), hidden fire, saint's fire, evil fire, devil's fire, and holy fire. As a result of early imprecision in disease specificity and diagnosis, physicians confused ergotism with the plague and a variety of other diseases including leprosy, anthrax, typhus, smallpox, and scurvy.

Clinical Manifestations and Pathology

Convulsive or spasmodic ergotism affects the central nervous system, causing areas of degeneration in the spinal cord. Early German accounts mentioned tingling and mortification in the fingers and toes, with occasional extension to the rest of the body, and vomiting, diarrhea, intense hunger, anxiety, unrest, headache, vertigo, noises in the ear, stupor, and insomnia as symptoms. Often the limbs became stiff, accompanied by convulsive contractions of the muscles which led to staggering and awkward movements, often aggravated by being touched. Although many victims recovered, symptoms sometimes remained for long periods, resulting in permanent stiffness of the joints, muscular weakness, optic disorders, and occasional imbecility. In the 1930s, Ralph Stockman demonstrated that convulsive ergotism was "caused by poisons (phytates) normally present in rye and other grains" which, unless broken down in the bowel, were absorbed, creating lesions in the nervous system.

Midwives and empirics discovered that spasmodic ergotism caused abortion or miscarriage in pregnant women, the drying up of milk in lactating mothers, and amenhorrea in young girls. This abortifacient or oxytocic effect was later noted by orthodox medicine and led to the widespread use of ergot to accelerate uterine action. Before long, doctors began distinguishing ergot with such sobriquets as *poudre obstetrical, forcing powders,* or more commonly, *forcing drops.* Not surprisingly, it also played a major role among quacks, charlatans, and "private specialists" who promised a quick and painless cure for women desiring to "regulate" their menstrual cycles. The term "regulation" was euphemistically used to mean the termination of a pregnancy. For some, ergot substituted for the more common borax, cinnamon, and turpentine as an abortifacient.

Gangrenous ergotism often began with itching and formications in the feet, or sensations of extreme coldness, followed by burning pain, or a crop of blisters. A dark spot usually appeared on the nose or affected extremity, leading to loss of sensibility in the part. Early nineteenth-century accounts mentioned headache, dizziness, nausea, vomiting, diarrhea, and spreading erysipelatous redness. The epidermis was raised by serous exudation, and the surface assumed the appearance of gangrene with the extremities becoming withered and blackened. Usually the gangrene was dry, but the moist variety was not unknown. The patient suffered from a continual low fever and phthisical symptoms, and faced eventual

death from exhaustion or septicemia. Often, however, recovery followed loss of the affected limb. When gangrene attacked the viscera, however, death occurred quickly. Matthias Grunewald's Isenheim Altarpiece, commissioned between 1508 and 1516 at the Antonite monastery, and currently displayed in the Musée d'Unterlinden in Colmar, testifies to the outbreak of St. Anthony's fire in France and its gruesome impact on those afflicted.

History and Geography

First allusions to ergotism are concurrent with the French monastic hospices, which cared for the common people and which took special note of the disease. Along with these observations came the designation of patron saints for ergotism, including St. Benedict of Umbria, St. Martial of Limoges, St. Geneviève of Paris, St. Martin of Tours, and St. Anthony of Egypt whose remains were carried to France in the eleventh century. From this last saint the name St. Anthony's fire was derived.

In his *Handbook of Geographical and Historical Pathology* (1883–6), August Hirsch recorded 132 epidemics of ergotism between 591 and 1789. Accounts of ergotism are also found in the *Annals* of the Convent at Xanten, near the Rhine, detailing an outbreak in 857, and are described by François Eudes de Mézeray in the seventeenth century as St. Anthony's fire. Later French epidemics of the gangrenous type reportedly killed 40,000 in 922 and 14,000 in Paris alone during 1128–9. The spasmodic form occurred in Spain in 1581 and 1590 and in Germany in 1595; epidemics in the Sologne district of France, in Germany, and in Switzerland recurred throughout the seventeenth century. The French districts of Sologne and Dauphiné, frequently subject to flooding, suffered continuously from outbreaks of ergotism, as did Artois, Lorraine, and the Limousin. The disease also affected the Netherlands, Sweden, Majorca, Italy, Poland, and central Russia, where outbreaks were reported as late as 1926. Hirsch noted three epidemics in the British Isles, and during the American Revolutionary War soldiers stationed in upper New York State reportedly sickened on ergotted flour shipped from Ohio. A later American outbreak reportedly occurred at a New York prison in 1825.

More recent research has suggested that ergotism can explain the convulsions and hallucinations that attended religious revivals, including the Salem witchcraft affair, as well as the time of "The Great Fear" (between July 20 and August 6, 1789), which swept through the rural countryside prior to the French Revolution, and even the seasonability of mortality and conception patterns in Europe.

Epidemiology and Etiology

Research in the 1930s suggested that the distribution of convulsive and gangrenous ergotism was a function of the presence or absence of vitamin A in the diet. An analysis of the 1770 epidemic of gangrenous ergotism in Sologne and of convulsive ergotism in Hanover indicated that Sologne, on the left bank of the Rhine, was a dairy district that provided a diet rich in vitamin A, whereas Hanover, on the right bank, was unable to sustain a dairy economy. The striking difference in the effects of ergot on the two communities in close proximity caused researchers to study their differing experiences in a laboratory by feeding ergot to dogs along with different levels of vitamin A. The results confirmed the efficacy of vitamin A in mitigating the effects of ergotism.

Similarly, while some researchers believed that England's relative freedom from ergotism was due to the abundant ingestion of meat and potatoes, others demonstrated that the English diet, which was rich in milk and butter products, had enabled its inhabitants to remain relatively free from the convulsive effects of ergotized grain. In areas rich in dairy products, the phytase and the bowel bacteria broke down the poisonous phytates of the grain into the comparatively innocuous inorganic phosphates. Thus, the convulsive ergotism which had been common to nondairy areas was virtually absent in England and certain sections of France.

Erysipelas

The term erysipelas (*erythros* = red, *pella* = skin) was used in Hippocratic times (often but not always) to describe classic cellulitis. For the past century or so, however, erysipelas has commonly referred to infection of the derma with a streptococcal organism, usually *Streptococcus pyogenes*. Infection with a group A, beta-hemolytic streptococcus can produce a painful, red, edematous indurated skin lesion called *peau d'orange* for its resemblance to the texture of an orange skin. Sharp borders of the infection extend rapidly, dissecting the underlying dermis from the epidermis. Erysipelas usually appears on the face, producing a butterfly rash over the cheeks and nose. The same streptococci that cause erysipelas can also cause scarlet fever, giving both diseases a fairly distinctive age pattern: Erysipelas is much more common among adults who generally escape scarlet fever, which normally attacks the young. The prognosis for untreated erysipelas is especially serious when this infection is secondary to some other insult such as laryngeal infection, or puerperal sepsis. Indeed distinctions are still made among gangrenous erysipelas, erysipelas grave internum (a form of puerperal fever), surgical erysipelas (which occurs after a surgical procedure), and traumatic erysipelas (which begins in a wound).

History

Antiquity Through the Eighteenth Century

Early accounts of erysipelas are often confusing because they lumped purulent and gangrenous afflictions under this rubric. Thus Hippocrates distinguished between "traumatic" erysipelas, which accompanied wounds, and a myriad of other skin lesions that had no known external cause. Galen in turn distinguished between "phlegmon," including suppurative ulcers and gangrene, and nonnecrotic cellulitis – but viewed both as forms of erysipelas. Celsus, in the first century A.D., considered septic ulcers, "canker," erythematous wound infections, and *Ignes Sacer* to all be types of erysipelas.

Such confusion has continued into the modern period, with some historians interpreting epidemics of *Ignes Sacer* (sacred fire) or Saint Anthony's fire as ergotism, whereas others have viewed these scourges as recurrent erysipelas. Before the modern period, however, physicians tended to embrace the distinc-

tions made by Galen, and consequently included a wide variety of ailments including diseases of the uterus and lungs among the varieties of erysipelas.

Nineteenth Century

During the nineteenth century, physicians began giving greater attention to the causes and prevalence of erysipelas because, on the one hand, the disease seemed connected to wound infection, and, on the other hand, because epidemics of erysipelas were occurring simultaneously with peak years of puerperal sepsis, or "childbed fever." Their investigations eventually led to the discovery of streptococci and the distinctions that have provided us with our current definitions of erysipelas.

In 1795 Alexander Gordon of Aberdeen became the first clinician formally to associate erysipelas with puerperal fever (Loudon 1987). Then around the middle of the nineteenth century, two seminal studies appeared. In 1842, Oliver Wendell Holmes published an essay on the contagiousness of puerperal fever, and in 1861 Philip Ignaz Semmelweis published his classic study of *The Etiology, Concept, and Prophylaxis of Childbed Fever*. Both men blamed physicians for carrying infective particles to the bedsides of parturient women. Holmes stated specifically that puerperal sepsis could be caused "by an infection originating in the matter or effluvia of erysipelas" (Carter ed. 1983). The great French clinician Armand Trousseau, writing during this same period, regarded even trivial skin injuries as precursors to erysipelas.

In 1882 following the discovery of streptococci, Friedrich Fehleisen published a study of the etiology of erysipelas, which he associated with *S. pyogenes*. In addition, he reported using his cultures on human subjects, justifying the production of iatrogenic infection as a means of combatting some forms of cancer – a procedure in vogue in Germany at the time. In follow-up studies, another German surgeon, Friedrich Julius Rosenbach, described the ability of the erysipelas-causing streptococci to spread through host tissues without causing suppuration. This research was of paramount interest to surgeons concerned with controlling the omnipresent infections – occasionally called "hospitalism" – that killed survivors of otherwise "successful" operations.

Twentieth Century

Although the use of aseptic and antiseptic techniques led to dramatic reductions in postsurgical mortality rates, maternal mortality still remained high. During the 1920s and 1930s, the research of Leonard and

Dora Cook and others permitted the identification and typing of strains of streptococci. This, in turn, led to irrefutable evidence that puerperal fever was an exogenous infection, usually transmitted from a physician, midwife, or nurse attending a parturient woman (Loudon 1987). Yet even family and friends could communicate the streptococci that caused puerperal sepsis in women in labor, for these were the same streptococci that caused erysipelas. Consequently, maternal mortality from puerperal fever declined only some time after effective antibiotics became available. Indeed, Irvine Loudon (1987) has shown that despite well-known changes in the virulence of streptococcal organisms historically, no sudden and spontaneous decline in the virulence of the organism can account for the abrupt decline in mortality from erysipelas, scarlet fever, and puerperal fever. Instead, credit for moderating these ancient scourges belongs to the beginning of the antibiotic era and, in particular, to the use of sulfonamides.

The liver fluke *Fasciola hepatica* is usually a parasite of sheep and cattle. "Liver rot" in sheep was described in a French work in 1379, and the first human case was described in 1760. The fluke's life cycle was discovered in 1881. Fascioliasis is a significant veterinary problem, but human infection is also fairly common. The fluke's life cycle is much like that of *Fasciolopsis buski* (see Fasciolopsiasis), with people or herbivores infected by eating raw watercress or other plants contaminated by the cysts of the fluke. Adult worms settle down in the bile ducts after a period of wandering in the liver. Mild infestations may cause little damage, but fever, jaundice, and right upper quadrant abdominal pain radiating to the shoulder blade are common symptoms. Bile ducts may become partially or totally obstructed, and liver destruction can be severe.

F. hepatica is cosmopolitan in distribution, with important foci of human infection in southern France, in Algeria, and in South America. Diagnosis is made by examining the feces of symptomatic patients with a microscope to find the eggs. Treatment is generally effective. Prevention is by treating sheep to keep them from perpetuating the cycle, controlling snail intermediate hosts, and keeping domestic animals away from ponds where watercress is grown.

Fasciolopsiasis

Fasciolopsiasis is caused by the giant intestinal fluke, *Fasciolopsis buski*. Discovered in 1843, the organism occurs in China, Korea, Southeast Asia, and parts of India and Indonesia. The adult worm, which has a life-span of only 6 months, attaches itself to the wall of the small intestine of humans. Pigs and dogs can also be infected, and sometimes are important reservoir hosts. Eggs produced by the hermaphroditic adults pass out in the feces and, if they reach fresh water, produce motile larvae that penetrate into the tissues of certain planorbid snails. After two generations of reproduction, another motile form leaves the snail, finds a plant like the water chestnut, water caltrop, or water bamboo, and encysts on it. Humans become infected with cysts by peeling raw fruits of plants with their teeth or eating them uncooked. The disease can become very prevalent in areas where these plants are cultivated with human feces as fertilizer.

Mild infections are often asymptomatic, but flukes can irritate and even ulcerate the intestinal mucosa. Abdominal pain, diarrhea, anemia, and fluid accumulation in the abdomen are common symptoms. Extreme cases can be fatal. Diagnosis is made by discovery of the eggs in the feces. Drug therapy is usually effective. Prevention includes better rural sanitation and control of swine reservoir hosts. Cooking vegetables would also be very beneficial, but drastic changes in long-established culinary habits are unlikely.

Favism

Favism is an acute hemolytic reaction triggered by exposure either to fava beans (*Vicia faba*) or to certain drugs (e.g., sulfa-based antibiotics and the antimalarial primaquine) in people with an inherited deficiency of the enzyme *glucose-6-phosphate dehydrogenase* (G6PD). In favism, the patient can suffer from destruction of red blood cells, severe anemia, and possibly death. There are two necessary conditions for the disease: (1) genetic inheritance of the "Mediterranean" variant of the abnormal gene trait for G6PD deficiency; and (2) ingestion of fava beans, usually fresh, or exposure to some drugs. The bean is a dietary staple in areas where favism is reported. Only an estimated 20 percent of those with the genetic trait for G6PD are likely to experience episodes of favism. Under modern medical conditions the hemolytic anemia caused by favism is only rarely fatal. Strong evidence suggests that both the gene for G6PD deficiency and the cultural practice of fava bean consumption are evolutionarily adaptive traits that protect against death from all types of malaria. Favism, then, could be described as a negative outcome of the interaction of the positive adaptive qualities of both the gene and the bean.

Distribution and Incidence
Favism is found primarily in the Mediterranean and Middle East regions where fava beans are a staple food and the Mediterranean variant of G6PD deficiency gene is relatively common. Mark Belsey (1973) reports that it is frequently encountered in Greece, Sardinia, Italy, Cyprus, Egypt, Lebanon, Israel, Iran, Iraq, Algeria, and Bulgaria, and is particularly common among Sephardic Jews. Favism has also been sporadically reported in China, Germany, France, Poland, Romania, Yugoslavia, Great Britain, and the United States. The disease is considered a serious public health problem in contemporary Greece (Trakas 1981).

The incidence of favism has been estimated for few areas. The most complete study in two Iranian provinces on the Caspian coast found an annual incidence that ranged between 0.65 and 6.39 cases per 10,000 population, with some areas reporting incidences as high as 9.27 cases per 10,000 (Lapeyssonnie and Keyhan 1966). William Crosby (1956), on the other hand, estimated 50 cases per 10,000 for Sardinia. Mortality is generally rare, with rates

ranging between 1 and 4 percent of the reported cases.

Epidemiology and Etiology

Favism is generally a pediatric illness in which the majority of victims are between 2 and 5 years of age, although cases as young as 6 months and as old as 65 years have been reliably reported. The disease has a marked seasonal cycle corresponding to the harvest of fresh fava beans, a 4- to 5-week period between April and July, although in areas where the bean is dried for later consumption, cases can occur all year. There is evidence that the toxic factor that induces the favism crisis has four characteristics:

1. It is located in the skin of the bean.
2. It is heat stable.
3. It is able to enter the breast milk of lactating women.
4. Its toxicity decreases when the beans are dried and the skin changes color.

Active biochemical agents in the skin of the bean – the pyrimidine oxidant compounds vicine, isouramil, divicine, and L-dopa – are probably responsible. These same biochemical agents are believed to provide some protection against malaria for people with normal genotypes when they eat fresh fava beans. Although it is widely believed that inhalation of pollen of the *V. faba* can trigger cases of favism, recent studies indicate that this is not true.

Boys are much more likely to suffer favism attacks than girls, with male/female case ratios varying from 2.1:1 to 2.7:1. The reason for the increased risk for males is that G6PD deficiency is a sex-linked trait; the gene is located on the X chromosome. Only carrier males (hemizygotes) and homozygous females can suffer from favism. Heterozygote females appear to be at an evolutionary advantage because they have no risk of favism and also enjoy a degree of protection against the malaria protozoa *Plasmodium.*

The G6PD enzyme, found in all tissues, plays important housekeeping functions in red blood cell metabolism. The cells of enzyme-deficient individuals tend to become oxidant-sensitive, and any exogenous sources of increased oxidants (malaria parasites, antimalaria drugs, or fava beans) can result in the lysis (explosion) of the cell (Katz and Schall 1979). In enzyme-deficient individuals, this process can result in either favism or protection from a severe malaria infection, depending on the context.

The geographic distribution of the many varieties of G6PD-deficient genes has been exceptionally well studied by population biologists. Over 200 varieties

of the gene have been identified. Both population genetic data and in vitro studies indicate that the distribution of these genes is correlated with the historical distribution of malaria. Favism occurs in only a small proportion of individuals with the Mediterranean variant of G6PD deficiency, and within that population it follows familial lines. It has been recently recognized that there is substantial genetic variation within the Mediterranean variant (Luzzatto and Battistuzzi 1985).

Clinical Manifestations

Favism is characterized by five general symptoms: weakness, fatigue, pallor, jaundice, and hemoglobinuria (blood in the urine). The anemia caused by hemolysis is severe. In a clinical study in Greece, one-third of favism cases had hemocrit levels below 4 grams of hemoglobin per 100 milliliters of blood (Kattamis, Kyriazakov, and Chidas 1969). In populations at risk, this set of symptoms is recognized as a distinct illness, often referred to as "fava bean poisoning."

History and Geography

The historical puzzle of favism is that peoples of Mediterranean and Middle Eastern societies would continue to eat a food that regularly causes illness and even death. From an evolutionary perspective, both fava bean consumption and G6PD deficiency appear to be retained in populations because they provide some protection from malaria. The correlation between the geographic distribution of these traits and malaria is one line of evidence for this relationship. Fava bean cultivation dates back to the Neolithic period in areas that have favism. Ancient Indo-European culture, and particularly Greek culture, placed remarkable emphasis on the symbolic rather than nutritional qualities of the fava bean. Alfred Andrews (1949) argues that "no plant or animal known to the Indo-Europeans has produced a more luxuriant growth of benefits than fava beans."

Fava beans have had three primary symbolic associations: the life principle, the souls of the dead, and the generative powers of male sexuality, and they are ritualistically eaten at certain times of the year, a practice that continues in European folk cultures. On the other hand, taboos against the consumption of fava beans for certain groups, particularly priests, have been reported in ancient Greece, Egypt, India, and Africa. The most famous case of such a taboo was among the Pythagoreans, who had the maxim, "It is an equal crime to eat beans and the heads of one's parents." Although many historical analyses for this taboo have been suggested, a medically informed hy-

pothesis based on the risk of favism appears most reasonable (Brumbaugh and Schwartz 1979).

In the history of medicine, the early clinical descriptions by the Italian physician Antonio Gasbarrini were a landmark for the diagnosis and treatment of favism attacks of varying severity. Within the tradition of Galenic medicine, treatment, although not always for favism attacks, emphasized the reinforcement of the blood with red wine among other things. Understanding the evolutionary history of favism has been a recent development that paralleled the discovery of the malaria connection with other genetic polymorphisms like thalassemia and sickle-cell anemia. The analytical connection with G6PD deficiency was first suggested in 1956, by Crosby, and the development of a genetic screening technique for the trait created a wealth of population genetic data during the 1960s. Such data on genetic markers in populations – for example, the variants of G6PD deficiency – have a potential for historical reconstruction of population movements and culture contact (Brown 1981).

Filariasis

The term "filariasis" refers to several diseases of both humans and animals caused by infection with a specific group of parasitic nematodes called *filarial worms* (named for the hairlike appearance of the adult form). Those worms that affect humans belong to the Order Filarioidea, Family Dipetalonematidae. They include (1) *Wuchereria bancrofti* and *Brugia malayi*, which are common causes of *elephantiasis* (extreme swelling and skin thickening of the legs, scrotum, labia, or arms) and *chyluria* (lymph and emulsified fat globules in the urine); (2) *Loa loa*, the "eye worm"; and (3) *Onchocerca volvulus*, the cause of *onchocerciasis*. Depending upon their species, adult filarial worms of both sexes reside in the lymphatic system, subcutaneous tissues, or peritoneal and pleural cavities. Sexual reproduction results in embryos (microfilariae) that enter blood or skin, where they are ingested by a particular intermediate host (certain species of mosquitoes, horse fly, black fly, or other arthropods). The microfilariae develop into larvae in their intermediate hosts and then reenter vertebrate hosts (humans or animals) through bites in the skin made by the intermediate host arthropods. Loa Loa is endemic in West and central Africa, whereas onchocerciasis is found in Mexico, Central America, and West Africa. Discussion of human lymphatic filariasis in the remainder of this entry will be limited to the most prevalent form (90 percent of infections), that caused by *W. bancrofti* (Sasa 1976; Beaver, Jung, and Cupp 1984; Mak 1987; Manson-Bahr and Bell 1987).

Distribution and Incidence

Bancroftian filariasis is widely distributed throughout the tropics. Though it no longer exists in areas such as North America (most notably the Charleston, S.C. area), southern Europe, Australia, and some Caribbean islands, and is decreasing in prevalence in other Caribbean islands, Central America, and South America, *W. bancrofti* is becoming more prevalent in parts of Asia. At some time nearly every nonarid region of the tropics or subtropics as well as temperate parts of China and Japan has experienced *W. bancrofti* infection (Sasa 1976; Beaver et al. 1984; Mak 1987; Manson-Bahr and Bell 1987).

Although no precise count of the number of people infected with *W. bancrofti* exists, in 1984 the World Health Organization estimated that number at more

than 81 million. Prevalence is highest in Asia (especially China, India, and Indonesia) and Africa. The disease affects primarily the rural and urban poor of working age living in areas of poor sanitation where mosquitoes abound (Mak 1987; Partono 1987).

Etiology and Epidemiology

The threadlike, white, adult *W. bancrofti* (males: 40 mm long × 0.1 mm in diameter; females: 65–100 mm × 0.2–0.3 mm) lie coiled together in human lymphatic vessels and lymph glands, where they can live for 10 to 18 years. Within 6 months to 1 year of infection, tiny larvae called *microfilariae* leave the adult female and enter the host's peripheral blood and lymph channels. Microfilariae move freely through the lymph or blood and, depending on the strain, show nocturnal or diurnal periodicity in the blood. Nocturnal microfilariae (the most common infective form) reside in the arterioles of the lungs during the day, whereas the diurnal (also called subperiodic) strain appears in the peripheral blood continuously, although in reduced numbers at night. Geographically, nocturnally periodic microfilariae are generally found west of 140° east longitude, and diurnal microfilariae are present east of 180° east longitude. Both types may be found between these two meridians. The largest concentrations of diurnal microfilariae exist in the Polynesian and New Caledonian regions of the Pacific Ocean (Sasa 1976; Beaver et al. 1984; Manson-Bahr and Bell 1987).

Bancroftian filariasis is transmitted only by mosquito. There is no known animal reservoir of *W. bancrofti*. Microfilariae may be transmitted to another human through blood transfusion, and from the maternal to the fetal circulation, but in both situations the microfilariae never develop into adults (Beaver et al. 1984; Manson-Bahr and Bell 1987).

Microfilariae have adapted their daily cycles to either day- or night-feeding mosquitoes, depending on the species and activity of these insects in a particular geographic area. The mosquito becomes an intermediate host of microfilariae after taking a blood meal. Microfilariae develop into infective larvae within the insect host in less than 2 weeks, and escape from its proboscis onto the skin of the mosquito's next human host during feeding. The larvae burrow into the human's skin through the tiny puncture wound and find their way to lymph vessels where they mature within a year and mate, producing more microfilariae (Beaver et al. 1984; Manson-Bahr and Bell 1987).

In a given geographic area, the *microfilaria rate* (percentage of a given population carrying mi-

crofilariae in the peripheral blood), the density of the intermediate host mosquito population, and the presence of a susceptible human population available for repeated bites by infected mosquitoes are key factors in the epidemiology of bancroftian filariasis. The significance of filariasis in an area may be measured by either the microfilaria rate or the *actual disease rate* (percentage of the population displaying symptoms of filarial infection) (Beaver et al. 1984; Manson-Bahr and Bell 1987).

Clinical Manifestations and Pathology

In nature, only humans develop elephantiasis from filarial infection of the lymphatics, so scientists could not easily study the pathogenesis of bancroftian filariasis until the recent development of a cat model. As a result of this and other work, researchers have described the pathogenesis and pathology of bancroftian filariasis more accurately. Filarial disease may not manifest itself for many years despite the presence of microfilaremia. If reexposure to larvae does not occur, infection usually disappears within 8 years. Repeated exposure over many years generally results in clinical disease during adulthood. Newly exposed adults display a different disease pattern and a stronger reaction than do persons who are exposed from childhood. In both cases clinical symptoms occur throughout the body because of widespread disruption of the lymphatics (Beaver et al. 1984).

Once the filarial larva settles in a human lymph channel and begins to mature, it provokes a localized response consisting of lymph vessel dilation and a slowing of lymph flow through that worm-occupied channel. With time the host body responds immunologically, sending eosinophils, plasma cells, and macrophages to the sites of infection. Lymphangitis (inflammation of lymph channels) usually results in swelling, redness, and pain, and, when the lymph vessels become hypertrophied, in varices. Fibrosis of the vessel occurs, trapping and killing the adult worm, which is absorbed or calcified. Obliteration of the lymph vessel forces extravasation of lymph into the tissue space, where it accumulates and causes the typical lymphedema of filarial elephantiasis. The swelling can become quite large, consisting of lymph, fat, and fibrotic tissue under tightly stretched and thickened skin (Beaver et al. 1984; Manson-Bahr and Bell 1987).

The clinical course of bancroftian filariasis can follow one of two paths: In highly endemic areas, people are exposed to repeated filarial infections from a very young age. The microfilariae provoke

only a weak local tissue response, and the children show little effect of infection. When the larvae move to and then reside in lymph vessels, their hosts in these highly endemic areas do not react with a strong immunologic response (or display severe symptoms), thus allowing new microfilariae to be discharged through the now dilated lymph channels into the blood. The living worms survive for years, producing microfilariae that circulate in their hosts' blood. These microfilariae soon become part of mosquitoes' meals and are passed on in their larval stage to other human hosts. As the adult worms eventually die in their tolerant human hosts' lymphatics, fibrosis and calcification of these channels disrupt the lymph system. In this chronic phase of filarial infection, as lymph channels become obstructed, typical elephantoid manifestations develop, especially in the groin and lower extremity. People in highly endemic areas are repeatedly infected over the years and so will manifest various stages of filariasis simultaneously.

Uninfected adults newly arrived in an endemic region generally show an inflammatory response to filarial infection. American troops in the Pacific during World War II experienced this problem. Their immune systems reacted quite strongly to the presence of microfilariae in lymphatics, sending a variety of cellular defenders to the affected areas. They surrounded the worms, ultimately causing stenosis of the lymphatics. Many soldiers developed very painful swelling of the scrotum, spermatic cord, and arms or legs, as well as orchitis, lymphangitis, and *filarial fever* (acute fever with headache and symptoms resembling malaria, recurring sometimes for years). Such a powerful response generally kills the worm, making it impossible for microfilariae to develop and circulate in the blood, but also causing disruption of the lymphatic system and the early development of elephantiasis. Some researchers believe that extreme elephantiasis occurs as a result of secondary infection with streptococcus or other bacteria.

Chronic obstructive filariasis can result in lymph gland enlargement, chyluria (due to obstructed lymph flow to the thoracic duct above the lymphatic branches of the kidney), lymph scrotum (scrotal thickening with lymphatic varicosities), hydrocele, and elephantiasis of the legs, scrotum, labia, arms, or (rarely) breasts (Beaver et al. 1984; Manson-Bahr and Bell 1987; Partono 1987).

Treatment and Control

Several microfilaricidal drugs exist; the most effective is diethylcarbamazine citrate (DEC), first used in 1947. This drug also kills adult worms. When DEC is used in conjunction with a comprehensive mosquito control plan, the rate of *W. bancrofti* infection in an area declines dramatically. Mosquito control alone is not highly effective because of the long reproductive life of the adult worms in human lymphatics. Behavioral measures, such as wearing clothes that leave little of the body exposed to mosquitoes, avoiding outdoor gatherings at night, and avoiding outdoor work at peak mosquito biting times, also help to reduce transmission of the disease, but these measures are difficult to implement (Beaver et al. 1984; Mak 1987; Manson-Bahr and Bell 1987).

Surgical treatment of elephantiasis does not permanently cure the problem, though removal of thickened skin and extra tissue from the affected area generally relieves the patient's burden. Pressure bandaging of affected lower limbs helps reduce swelling.

Once a person is infected with *W. bancrofti*, prognosis depends on the extent and nature of the infection, reexposures to the parasite, and the body's reaction to the infection. Chronic cases have a poor prognosis.

History and Geography

Antiquity Through the Eighteenth Century

The preponderance of evidence indicates that bancroftian filariasis existed in the ancient tropical world. One can find discussions of something called elephantiasis in the works of many ancient Greek and Roman authors, including Celsus, Galen, Aretaeus, Caelius, Aurelianus, Pliny, and Plutarch. The disease many of them were describing, however, was probably leprosy, which came to be known as *elephantiasis graecorum*, to distinguish it from another form of elephantiasis with a different appearance, *elephantiasis arabum*, probably bancroftian filariasis. Leprosy can cause affected parts of the skin to resemble that of an elephant, but does not cause the scrotal or leg swelling so characteristic of filarial infection.

Bancroftian filariasis was probably not endemic in ancient Italy, Greece, or the Mediterranean region in general, except for certain parts of the Nile Delta. Traders and travelers brought knowledge of the condition to residents of the region, and an occasional newcomer undoubtedly carried the disease from his or her home country and suffered from its various manifestations in the Mediterranean region. Ancient descriptions of a medical condition resembling bancroftian filariasis exist not only from Greco-Roman writers but also from people in the Nile

Delta, Polynesian islands such as Fiji and the Society Islands, and India. Late Roman and medieval Arab writers also discussed elephantiasis, the former primarily describing leprosy, and the latter, including Rhazes, Avicenna, and Albucasis, filariasis (Adams 1844, 1846, 1847; Bhishagratna, ed. 1911; Castellani 1919; Hoeppli 1959; Foster 1965; Laurence 1967; Sasa 1976).

The historian B. R. Laurence argues that bancroftian filariasis actually originated in Southeast Asia and spread with the migration of people from that region to the South Pacific islands (especially Polynesia) and to Africa. To survive, the filarial worm adapted its life cycle to the mosquito vectors available in these new areas, thus explaining why *W. bancrofti* shows both diurnal (i.e., microfilariae present in peripheral blood during the daytime) and nocturnal periodic strains. The elephantiasis described by early Indian writers, Laurence argues, was actually caused by *B. malayi* (another filarial worm, much more limited in its distribution) rather than by *W. bancrofti*. The continued migration of tropical peoples and the opening of the tropical world to trade over the past 300 to 400 years, plus the adaptability of *W. bancrofti* to a variety of mosquito vectors, resulted in the spread of the parasite throughout the tropics, including China and India (Laurence 1968, 1977). Filariasis came to the New World, most likely as a result of the African slave trade. That trade, conducted by white Europeans, brought concentrations of infected black Africans to slave depots on West Indian islands like Barbados, where they were sold and redistributed to other West Indian islands, or to the North and South American mainlands. A legacy of this black African slave trade in the United States was the establishment of a focus of bancroftian filariasis at Charleston, South Carolina, and the surrounding "Low Country," which survived until the early twentieth century (Savitt 1977; Chernin 1987; Reynolds and Sy 1989).

Seventeenth Through Nineteenth Century

Seventeenth-, eighteenth-, and nineteenth-century European observers in tropical lands described numerous cases of leg and scrotal elephantiasis, and some of endemic hydrocele and of lymph scrotum. A few even recognized and traced the development of elephantiasis from fever through lymphangitis and lymphadenitis, to gradual swelling of a limb or scrotum. Though these writers located the seat of the disease in the lymphatics, none could identify the cause (Castellani 1919; Laurence 1970). That discovery had to await refinements to, and physicians'

acceptance of, the microscope in the latter half of the nineteenth century. Between 1863 and 1900, researchers uncovered the basic etiology and epidemiology of bancroftian filariasis (Manson-Bahr 1959; Foster 1965; Sasa 1976; Chernin 1983).

The first breakthrough in understanding the cause of elephantiasis occurred in 1863 when a French physician, Jean-Nicolas Demarquay, described microfilariae (Demarquay 1863). Demarquay withdrew a milky fluid from the swollen scrotal sac of an 18-year-old Cuban in 1862 and then again a year later. This latter time, viewing the substance under a microscope, he reported: "Attention was drawn above all to a little elongated and cylindrical creature" that "had extremely rapid movements of coiling and uncoiling" (Demarquay 1863). Demarquay and his colleagues found these worms and their eggs in five successive preparations but found none once the scrotal fluid had cooled down. He could not explain the worms' presence in the microscopic preparation, but hoped that there would be some scientific value for others in publishing the case.

Exactly 4 years after Demarquay's discovery, Otto Eduard Heinrich Wucherer, a Portuguese-born physician of German parentage who practiced in Bahia, Brazil, found "some threadlike worms" in a urinary blood clot of a woman suffering from hematuria (Wucherer 1868). Theodor Bilharz had discovered a worm in Egypt in 1852 that caused hematuria (*Schistosoma haematobium*); Wucherer was investigating the urine of Brazilian hematuria patients to learn whether the cause of the disease was the same in the New World. What he saw under the microscope differed greatly from the schistosomes Bilharz had described. Two years later, after seeing these worms in two more hematuric patients and finding that he could not identify their species from the books on human parasites that he possessed, Wucherer published his story "as an incentive for some of my colleagues, better qualified and more fortunate than I, to attempt to shed light on a disease, the etiology of which is still enigmatic today" (Wucherer 1868).

In March of 1870, in a different part of the tropical world, India, Timothy Richards Lewis found worms like those Wucherer had described. An 1867 medical graduate of the University of Aberdeen, Scotland, Lewis was treating a 25-year-old East Indian male suffering with chyluria. That patient left the hospital before Lewis could study his condition further, but a second patient, a woman with hematuria and chylous urine, entered the hospital a few days later. Lewis now took a step beyond Demarquay and Wucherer

and removed blood from the patient's finger and studied it microscopically. He found what he called filariae in this blood, just as he found them in the urine. Lewis's report of these and other patients, published in 1872, documented for the first time both the presence of microfilariae and the presence of any microorganism in human peripheral blood. He also described, but could not explain, the disappearance of microfilariae from the blood. Lewis (1872) named the organism *Filaria hominis sanguinis*.

All three of these filarial researchers knew they had identified an immature form of the filarial worm. Nor were they the only ones who saw the microfilariae in chylous urine. Both T. Spencer Cobbold of London and M. Robin of Reunion Island reported similar findings in the early 1870s.

The man who brought together the various bits of knowledge published about human filarial infection and produced a useful theory was Patrick Manson. Born in Aberdeenshire and an 1866 medical graduate of Aberdeen University, Scotland, Manson spent much of his early professional life, beginning in 1866, as a medical officer in the Chinese Imperial Maritime Customs Service. He treated many Chinese elephantiasis patients, recognized and named the condition called "lymph scrotum," and devised an operation to remove scrotal tumors. During a 1-year leave in England in 1875, he read the available literature on the conditions he had been treating, including descriptions of lymph scrotum in India, the relation of lymph scrotum to elephantiasis, and Lewis's papers on filarial worms in the blood and lymph of patients with tropical chyluria (Foster 1965). In articles published in 1876 and 1877 in the *China Imperial Maritime Customs Medical Reports*, Manson presented case studies to show that lymph scrotum, elephantiasis, and tropical chyluria were etiologically related, all caused by the filarial worm described by Lewis, seated in lymphatics (Manson 1876–7). He apparently knew nothing of Demarquay's or Wucherer's articles, published in journals as poorly circulated as the one in which he himself published.

Manson tried in vain to obtain an adult filarial worm from newly deceased patients. Thwarted by the Chinese people's reluctance to allow autopsies of humans, Manson suggested in print that physicians in India, where the prejudice against dissection was much less, seek out adult worms in patients who had died with these conditions (Foster 1965). The first person to demonstrate the presence of adult filariae in humans practiced, not in India, but in Australia. Joseph Bancroft, an 1859 medical graduate of St.

Andrews University in Scotland, moved to Queensland in 1864 and found a number of patients with lymphatic conditions, though none with elephantiasis. His first adult worm came from a patient with a lymphatic abscess of the arm. He obtained another four from a hydrocele of the spermatic cord. He forwarded these specimens in 1877 to Cobbold in London, the leading British helminthologist of the time. The latter published Bancroft's cover letter with his own commentary in the *Lancet* (Cobbold 1877). Cobbold had previously encouraged Bancroft to look for the adults after Bancroft sent him, through a former teacher, immature filariae obtained from these patients. It was Cobbold who suggested naming the filarial worm for Bancroft. A co-worker of Wucherer wrote to the *Lancet* shortly after Cobbold's article appeared, suggesting that Wucherer deserved credit for discovering the parasite. Both physicians were so honored, and the filaria is known as *Wuchereria bancrofti* (Foster 1965).

How did the worm find its way into humans? Manson continued his work in China and made a key suggestion in an 1877 essay (not published until 1878), the same year Cobbold announced the discovery of the adult worm in human lymphatics (Manson 1877). The *Filaria sanguinis hominis* embryos, Manson argued, could not develop, mature, and enter the bloodstream without overwhelming their human host by their sheer number. Using his knowledge of the known life cycles of animal parasites and of certain human parasites, Manson suggested and then demonstrated that the mosquito was the "nurse" of the filarial embryo. The insect ingested filariae in its blood meal and the young worm developed in the body of this second host. When the mosquito died, usually on stagnant water a few days after feeding, Manson continued, the filariae escaped into the water and were ingested by humans drinking the now contaminated liquid. The need for a certain mosquito host, in addition to the human host, Manson concluded, explained "the limitation of the distribution of elephantoid diseases to certain districts and zones of the earth's surface . . . where the mosquito flourishes" (Manson 1877).

Another filarial mystery remained to be solved: the unpredictable disappearance and reappearance of worm embryos from the blood of patients known to harbor the parasite. Manson employed two assistants to take blood around the clock from a filariasis patient. He discovered that the number of microfilariae grew and shrunk in a regular diurnal pattern, the embryos reaching their peak presence in blood in the hours just before and after midnight. He

concluded, in his 1879 article (published in 1880), that "[t]he nocturnal habits of the *Filaria sanguinis-hominis* are adapted to the nocturnal habits of the mosquito, its intermediary host, and is only another of the many wonderful instances of adaptation so constantly met with in nature" (Manson 1879).

What happened to the filariae during the rest of the day? Manson asked that question in his 1879 article but could not answer it for almost another 20 years. In February 1897, Manson, now in London, had the opportunity to study the organs of a patient with filariasis who had committed suicide at 8:30 in the morning, presumably just after the worms would have left the peripheral blood for the day. Postmortem examination revealed huge numbers of the embryo parasites in the small blood vessels of the lungs and others in the large pulmonary blood vessels (Manson 1899).

Over the next few years, Manson helped revise the answer to a question he had asked in 1877: How did the filariae pass from mosquitoes to humans? Manson's earlier answer, that humans ingested them with contaminated drinking water, was challenged shortly after it was suggested. The work of Thomas Bancroft, Joseph Bancroft's son in Australia, and of Manson's protégé, George C. Low, who used the mosquito specimens Bancroft sent to Manson, published in 1900, suggested that filarial embryos exited from the mosquito's proboscis and entered human skin when the insect was in the act of biting (Low 1900). That idea was confirmed by B. Grassi and G. Noe (1900) later that year.

British physicians working in various tropical colonies of the empire had made almost every breakthrough in uncovering the mystery of filarial infection during the previous 40 years. By 1900 the medical world had a basic understanding of a disease that had plagued and puzzled people since ancient times.

VIII.55
Fungus Infections (Mycoses)

Although today, some 200 fungi are established as pathogenic for humans, causing a wide range of diverse mycoses (with an incidence measured in millions and a worldwide distribution), through the mid-nineteenth century, only two human diseases (or rather disease complexes) caused by fungi were generally recognized. These were ringworm and thrush, known since Roman times. Two important additions came at the end of the century: mycetoma of the foot (Carter 1874) and aspergillosis (Lucet 1897; Rénon 1897).

Fungi were the first pathogenic microorganisms to be recognized. Toward the end of the eighteenth century and the opening years of the nineteenth, they had been shown experimentally to cause disease in plants and insects, and during the 1840s both ringworm and thrush were shown to be mycotic in origin. For a short period, fungi were blamed for causing many diseases. Cholera, for example, was attributed to fungi. But with the recognition of the major role played by bacteria (and later, viruses) in the etiology of human disease, fungi were neglected and medical mycology became very confused. It has been only since the 1930s, with the deployment of trained mycologists to work in conjunction with clinicians, that the identity of the pathogenic fungi has been clarified, and studies on their ecology have done much to elucidate epidemiological problems. In general, the geographic distribution of mycoses (which at first tended to coincide with that of medical mycologists) has been established, and the relation of mycoses to other human diseases has been brought into perspective.

Some of the fungi causing human disease show clear adaptations for the pathogenic state, whereas others do not, and it is probable that none is dependent on a human or animal host for survival. Most are also pathogenic for animals, both domesticated and wild, which are also subject to mycoses caused by related species able to induce human infections. Many fungi pathogenic for humans are apparently members of the normal fungus flora of the environment, and their pathogenicity is regarded as "opportunistic" or "iatrogenic" when infection is rendered possible by the side effects of therapy.

Classification

Mycoses (which exhibit a wide range of symptoms) have often been named according to the part of the body affected (e.g., bronchomycosis, dermatomycosis, tinea capitis, ringworm of the scalp, athlete's foot) or the name of the pathogen (e.g., aspergillosis, cryptococcosis, dermatophytosis, rhinosporidiosis), and they have been categorized as cutaneous, subcutaneous, systemic, opportunistic, and iatrogenic, although these divisions are not mutually exclusive. In this study, for convenience, mycoses are considered under ringworm, candidiasis (including thrush, which is oral candidiasis), systemic mycoses, and opportunistic and iatrogenic mycoses.

Ringworm (Tinea, Dermatophytosis)

History

Favus (Latin for "honeycomb"), a distinctive type of ringworm because of the characteristic scutula, was described by Celsus in the first century, A.D., in his *De Medicina*. He called it *porrigo,* a term also used by Pliny in his *Historia Naturalis* of the same century and by dermatologists up to the nineteenth century. It is now, however, obsolete, having been replaced by tinea (derived from *Tineola,* the generic name of the clothes moth). Celsus also described the inflammatory lesion of some forms of ringworm, which has been known ever since as the "kerion of Celsus."

Not until the mid-1840s was the mycotic nature of favus recognized by three independent workers: J. L. Schoenlein and Robert Remak in Berlin, and David Gruby in Paris. The latter also differentiated microsporosis and the ectothrix and endothrix trichophytosis, which he showed to be caused by distinct fungi.

A period of mycologic confusion followed, complicated by the difficulty of determining the life histories of the pathogens (largely due to deficiencies in culture technique) and settling the question as to whether there was one ringworm fungus or many. Gruby's findings had been forgotten and had to be rediscovered during the 1890s by Raymond Sabouraud, a famous Parisian dermatologist, who consolidated his researches in an impressive monograph published in 1910. Many ringworm fungi were described and classified variously according to the degree of emphasis placed by different workers on mycologic and clinical features. Some thousand different names had been proposed up to 1934 when C. W. Emmons, a mycologist by training, in the United States showed that, mycologically, the many species

could be accommodated in the three genera: *Microsporum, Trichophyton,* and *Epidermophyton.* Today the number of ringworm fungi accepted is of the order of 30. At first, only asexual spore states of these pathogens were known, but later sexual states were obtained, and evidence provided that dermatophytes are closely related to a group of predominantly soil fungi.

Two historical landmarks in the treatment of ringworm were the introduction of X-ray epilation for the therapy of head ringworm in the opening years of this century and the introduction of the antibiotic griseofulvin in 1958 as an orally administered antimycotic drug.

Distribution and Incidence

The geographic distribution of the ringworm fungi is interesting. In Sabouraud's time the distribution corresponded to that of interested dermatologists. Now the ringworm fungi of most countries have been surveyed, or at least sampled, so that a more accurate knowledge of their geographic distribution is available. Some, such as *Trichophyton mentagrophytes* (causing tinea pedis and so forth) and *Epidermophyton floccosum* (tinea cruris), occur worldwide.

Microsporum audouinii (tinea capitis; the classical cause of ringworm in children), which appears to have originated in Europe, is now endemic in North America. Although frequently introduced by European children to the tropics, it has never established itself there in the indigenous population. Likewise *Trichophyton concentricum* (tinea imbricata) is endemic in Southwest Asia and the South Sea islands, where it was first recorded by William Dampier in 1686 when circumnavigating the globe. It has other minor endemic centers in South America, and, although frequently seen in Europe on returning travelers, it has never become endemic there. By contrast, *Trichophyton rubrum,* believed to have been introduced into the United Kingdom by troops returning from the Boer War, is now widespread in north temperate regions.

In similar fashion, *Trichophyton ferrugineum* established itself in western parts of the Soviet Union, after being introduced by soldiers returning from the Far East. Classical favus in western Europe is caused by *Trichophyton schoenleinii,* but typically by *Trichophyton violaceum* in North Africa and the Mediterranean basin. *Microsporum canis* (tinea canis [cat and dog ringworm], tinea capitis, and tinea corporis), coextensive with cats and dogs as pets, has become endemic in New Zealand in feral

cats. Human infections are also contracted by contact with ringworm in cattle (*Trichophyton verrucosum*), horses, and other farm animals. *Microsporum gypseum* (which could be considered as an opportunistic dermatophyte) has a worldwide distribution, the outbreaks in humans usually being sporadic, short-lived, and sometimes traceable to a group of people having access to the same soil in which the pathogen is an inhabitant.

Candidiasis (including "Thrush")

Reports and studies of the many and diverse manifestations of candidiasis caused by *Candida albicans* and other species of *Candida* (e.g., *Candida guilliermondii, Candida krusei, Candida stellatoidea, Candida tropicalis*) have made a major contribution to the literature of medical mycology, as they still do. As for ringworm, a stable taxonomic base was necessary to underpin both clinical and microbiological observations and research on this mycotic complex because *C. albicans* was described as new on a number of occasions and acquired some 90 specific names distributed among a dozen genera. Much confusion resulted. One taxonomic error that the reader must still remember when consulting the earlier literature is the assignment back in 1890 of the thrush fungus to the genus *Monilia* because "moniliasis" became the generally accepted, worldwide name for candidiasis. It was mainly a group of yeast specialists working in the Netherlands who clarified the taxonomy; the genus *Candida* was proposed in 1923.

Thrush (Oral Candidiasis)

This disease (infection of the mucous membrane, especially of the mouth) in infants was referred to in the Hippocratic corpus (400 B.C.) and later by Galen and other classical writers under the heading "aphthae." Over the centuries, references to thrush in the young, as a feature of terminal illness and as a vaginal infection in women, continued, with the clinical descriptions being given increasing precision (see Higgs 1972). Candidiasis, like ringworm, was demonstrated to be mycotic by three independent workers in the 1840s: B. Langenbeck in Berlin, F. T. Berg in Stockholm, and Gruby in Paris. Berg, who had studied under Gruby, subsequently published on thrush in infants and in 1844, J. H. Bennett described in Edinburgh what was probably *C. albicans* from the human lung.

A wide range of pathological conditions attributed to *Candida* were subsequently recorded; virtually all parts of the body, with the notable exception of the hair, were susceptible to such infection under favorable conditions. Numerous surveys have shown that many apparently normal individuals carry *C. albicans:* 10 percent, in the mouth; about the same proportion of women, in the vagina (with higher values in pregnant women); and 25 percent, in the feces and gut. Although *C. albicans* has occasionally been isolated from soil, from hospital bedding (the incidence of *Candida* in hospital patients is often high), and from a wide range of animals (especially domestic animals and birds), it is clear that most human infections have an endogenous origin. Infection (clinical candidiasis) seems always to be determined by predisposing factors that may be environmental: For example, having the hands frequently wet favors paronychia (candidiasis of the nail fold). Age, debility, dentures, and drug therapy also can predispose one to infection.

The patenting of the orally administered antibiotic nystatin in 1956 was a notable contribution to the therapy of candidiasis, which has been the subject of several monographs.

Systemic Mycoses

The pathogens of the five systemic mycoses to be considered all show specialization for parasitism. All are *dimorphic* – that is, the saprobic state is mycelial (filamentous) and the pathogenic phase is unicellular and yeastlike. It is possible to effect the mycelial-to-yeast conversion in vitro. For *Blastomyces dermatitidis* (blastomycosis), the transformation is temperature dependent; for the others, nutritional adjustments are also necessary. On first description there was a tendency to assign these pathogens to the Protozoa.

Coccidioidomycosis

The first case of this disease was described from Argentina by Alejandro Posadas in 1892. About the same time a case was also studied in California by E. Rixford and T. C. Gilchrist, who attributed the cause to a protozoan, which, in 1896, they named *Coccidioides immitis*. In 1905, however, a fellow American, W. Opuls, established its mycotic nature. It was known only as a rather rare, acute, or chronic disseminating and often fatal disease. In 1938, Myrnie A. Grifford and E. Dickson, independently, and then in collaboration, established that "valley fever," prevalent in the San Joaquin Valley of California, was a mild form of coccidioidomycosis. Further investigations showed mild, often subclinical, respiratory *Coccidioides* infection to be widespread in arid parts of California and neighboring states and to induce lifelong immunity to subsequent at-

tack. This immunity is demonstrable by a positive skin test with an antigen (*coccidioidin*) prepared from cultures of the pathogen.

C. immitis was isolated from soil, and when Emmons showed desert rodents to be infected, they were at first thought perhaps to constitute an animal reservoir of infection. But it soon became clear that these rodents, like humans, were subject to infection by this soil-inhabiting fungus. It also became clear that the dry, airborne (or dustborne) spores of the pathogen were extremely infectious (there have been many accidental laboratory infections) and that coccidioidomycosis could be contracted, for example, by servicing automobiles that had been driven through areas where the mycosis was endemic. In addition, dust storms were found to increase the rate of conversion from negative to positive skin tests with coccidioidin in local inhabitants and their domestic animals. It may be noted, that although light- and dark-skinned peoples appear to be equally susceptible to *C. immitis* infection, the disease is more likely to be systemic in those with pigmented skin. Filipinos and blacks, along with the Portuguese, are those chiefly employed in agriculture in the districts where coccidioidomycosis is endemic.

Coccidioidomycosis is endemic and of high incidence in warm dry regions (the Lower Sonoran Life Zone) of the United States and Mexico and also in parts of Central and South America where the climatic conditions are similar. Records from other parts of the world are of doubtful validity.

Histoplasmosis

This disease (*Histoplasma capsulatum*) shows many parallels with coccidioidomycosis and may be viewed as the humid region equivalent. At first considered a rare protozoan disease, it has been shown to be mycotic, and to have a mild form affecting millions of the inhabitants of the midwestern United States. The pathogen shows a predilection for bird (chicken, starling) and bat droppings.

Blastomycosis and Paracoccidioidomycosis

The former (North American blastomycosis), caused by *B. dermatitidis,* and the latter (South American blastomycosis), caused by *Paracoccidioides brasiliensis,* are both chronic granulomatous diseases of the skin and internal organs, characterized by budding cells of the pathogen in the infected tissues. The two were at first confused both with each other and with cryptococcosis (called "European blastomycosis" or "torulosis" and caused by *Cryptococcus neoformans*), but these three mycoses are now well differentiated.

Blastomycosis was first described by Gilchrist in the United States in 1894, and paracoccidioidomycosis, by Adolfo Lutz in Brazil during 1908. Neither has a mild form such as that characteristic of coccidioidomycosis and histoplasmosis, and though there have been a few records of both pathogens from soil, the natural habitats of both these fungi have not been established with certainty.

Paracoccidioidomycosis is confined to Central and South America, where it has been the subject of intensive study. Blastomycosis is endemic to the western and southeastern states of the United States, where epidemics occur; there are also records of the disease from a number of tropical African countries.

Sporotrichosis

This disease shows certain parallels with mycetoma but is included here because the causal pathogen is dimorphic. It is a cutaneous and subcutaneous infection characterized by the development of nodular lesions, often in a series affecting successive lymph nodes. Infection is frequently initiated by a lesion, often of the hand. It is caused by *Sporothrix schenckii* and was first described in the United States by B. R. Schenck in 1898. Subsequently many cases were reported from Europe, especially France, where the disease was the subject of a massive monograph, *Les Sporotrichoses,* by C. L. de Beurmann and H. Gougerot in 1912. Sporotrichosis, which is sporadic in north temperate regions, has also been recorded in Central and South America. In Uruguay, J. E. Mackinnon (1949) attempted to correlate incidence of the disease with the weather, and obtained evidence that infection occurred during periods of moist warm weather, which he suggested encouraged growth of the pathogen on plant material from which humans are infected. *S. schenckii* is one of the rare fungus pathogens of humans that has been shown experimentally to cause disease in plants (carnations). The largest outbreak of sporotrichosis ever recorded was in the Witwatersrand gold mines in South Africa during 1941–3, when approximately 3,000 miners were infected. The epidemic was brought under control by potassium iodide therapy for the men affected and fungicidal treatment of the mine timbers from which the infection was contracted.

Opportunistic and Iatrogenic Infections

To categorize some fungal infections as opportunistic is convenient, if artificial. Most fungi pathogenic for humans, even those causing such significant mycoses as coccidioidomycosis and histoplasmosis, seem to

have some natural habitat in the environment and infect humans only incidentally. Candida infections are different in that they are endogenous, and some types of ringworm are also to some extent opportunistic. The mycoses to be considered next include examples of infection resulting from the exposure of a susceptible individual to the *normal* fungus flora of the environment, and attention is drawn to the increased risk shown by compromised patients.

Mycetoma

This disease is a well-defined clinical entity characterized by swelling that affects the subcutaneous tissues, with sinuses discharging grains or granules of the pathogen, which vary in color from white through yellow, red, and brown to black. The foot is most frequently involved ("Madura foot"), but the hand or other part may be infected. Its geographic distribution is mainly tropical.

The condition was first recorded in the Indian Vedic Medical treatises (c. 2000–1000 B.C.) as *padaavalmika* ("foot ant-hill") and first described in modern times from southern India by members of the Indian Medical Service during the mid-nineteenth century. H. Vandyke Carter, who coined the designation "mycetoma," wrote a monograph on the disease in 1874. Carter suspected the disease to be mycotic and submitted material to the Rev. M. J. Berkeley, the leading British mycologist of the time, who described a now unidentifiable fungus he obtained from the material as a new species. From the turn of the century onward, more than 25 diverse fungi (including representatives of the genera *Acremonium, Aspergillus, Curvularia, Leptosphaeria, Madurella,* and *Pseudallescheria*) and actinomycetes (aerobic species of *Actinomadura, Nocardia,* and *Streptomyces*), responsible for the condition, were identified by workers in North Africa and elsewhere, with the color of the grains often providing a clue to the identity of the pathogen.

Carter distinguished "melanoid" and "ochroid" mycetoma, and, as his illustrations show, his black-grained form was caused by the fungus that E. Brumpt in 1905 taxonomized as *Madurella mycetomatis,* which is the most important cause of mycetoma. In 1894, H. Vincent had described and named the actinomycete that he had isolated from yellow-grained mycetoma from Algeria as *Streptothrix madurae* (now designated *Actinomadura madurae*). Later, when differentiating the two classes, researchers A. J. Chalmers and R. G. Archibald at the Wellcome Laboratory for Tropical Medicine at Khartoum in the Sudan introduced the term "madura mycosis" for mycetoma caused by actinomycetes. Today the terms "Eumycetoma" (or "Eumycotic mycetoma") and "Actinomycetoma" (or "Actinomycotic mycetoma") are preferred. Classical actinomycosis caused by the anaerobic *Actinomyces israeli,* which gives rise to yellow grains ("sulfur granules"), is excluded from the complex.

There have been many publications on the incidence and etiology of mycetoma, which occurs most frequently in a band of the tropics north of the equator extending from India, across Africa, to Central and South America. Incidence is particularly high in India, the Sudan, and Senegal (where *M. mycetomatis* predominates) and Mexico (where actinomycetoma predominates). All these regions are hot and arid. *Pseudallescheria boydii* seems to favor more humid conditions, with species of *Nocardia* responsible for mycetoma in temperate Europe and North America. *Madurella grisea* is limited to South America, whereas *Cephalosporium* infections are cosmopolitan.

It was early thought probable that infection was initiated by injury, and a correlation between mycetoma and injury from plant thorns has frequently been made. Sometimes the pathogen may have been growing as a saprobe on the thorns (*Leptosphaeria senegalensis* and *Pyrenochaeta romeroi* have been isolated from such sites, and *M. mycetomatis* will grow on dead wood in sterile water); or the thorn may provide the point of entry for an organism present in the environment (dry granules from mycetoma have a long survival time), especially in soil from which pathogenic species of *Nocardia* and *P. boydii* have been isolated. All this evidence points to mycetoma being a typical opportunistic infection.

Cryptococcosis

This disease is a subacute or chronic infection of the lungs, skin, or other parts, especially the central nervous system, caused by the yeast *Cryptococcus neoformans,* which is widely distributed in nature and is sometimes the dominant organism in the droppings and debris of pigeon roosts. Although the pigeon is not infected and the yeast survives passage through the bird, human cases have frequently been associated with inhalation of the pathogen when clearing out old pigeon roosts. The most frequent infections are subclinical and self-limiting, with fatal and more generalized infection occurring mostly in debilitated patients or in those "compromised" by drug treatment.

First recorded in Europe in 1894, human cryptococ-

cosis has a worldwide distribution. In 1946, L. B. Cox and Jean C. Tolhurst published a monograph, based on 13 Australian cases termed "torulosis" caused by *Torula histolytica;* later a very comprehensive study of the disease was published by M. L. Littman and L. E. Zimmerman (1956).

Rhinosporidiosis

This disease, an infection of mucous tissue, especially of the nose, results in the development of large polyps and is exceptional among mycoses in that the causal agent, *Rhinosporidium seeberi,* has not been cultured and its taxonomic position is uncertain. Outbreaks of the disease, which attacks both humans and animals (especially bullocks set to the plough), have been associated with water and the soil. Rhinosporidiosis was first reported from Argentina in 1900, but it occurs sporadically throughout the tropics, the highest incidence being in southern India and Sri Lanka. A monograph was published by J. H. Ashworth (1923) in Edinburgh from a case involving an Indian student at the university.

Aspergillosis and Mucormycosis

Species of *Aspergillus* and mucoraceous fungi are a conspicuous and ubiquitous component of what has been called "common mold." They are therefore not infrequently found as contaminants of cultures from morbid material and may be mistaken for pathogens. On the other hand, human infections by these and similar molds do occur sporadically and have been reported worldwide.

The pathogenicity of *Aspergillus fumigatus* is well established. It is widespread in the environment; found on decaying vegetation, it has spores that are readily airborne. Because its growth is favored by high temperatures, and it is customary to incubate bacterial cultures at 37° C (a temperature detrimental to many common molds); *A. fumigatus* frequently occurs as a contaminant of cultures from sputum and other pathological material. Thus, its significance, when it is detected, is often uncertain, and clinical and other evidence must be considered in its detection.

A. fumigatus is able to cause fatal infections, particularly in birds in which it was first recorded early in the nineteenth century, lining the airsacs with a profuse sporulating growth. J. B. G. W. Fresenius in 1850 proposed the name *Aspergillus fumigatus* based on an isolate from a bustard (*Otis tarda*). Rudolf Virchow in Germany in 1856 described human pulmonary aspergillosis caused by the same species. The classical cases of human pulmonary aspergil-

losis were those of French pigeon squab feeders in the late 1890s, who chewed in their own mouths the grain used for fattening the birds. Interest in aspergillosis in France was then at its height.

Several other species of *Aspergillus* are pathogenic. *Aspergillus niger* is often associated with infection of the ear, whereas aspergillomas or "fungus balls" sporulating growths of the pathogen in lung tissues or cavities are not uncommonly associated with pulmonary disease.

Diverse mucoraceous fungi are regularly, if sporadically, recorded in north temperate countries as responsible for human infections, especially of the rhino-facial-cerebral region when the outcome is fatal. Debility is a predisposing factor.

Dependent Mycoses

The attribution of disease to the human "constitution" has a long history. Even at the beginning of the nineteenth century, dermatologists, unable to accept the concept of pathogenicity, were attributing ringworm in children to constitutional factors, and nutrition does apparently affect symptom expression. During World War II, for example, ringworm symptoms disappeared in European prisoners held under starvation conditions by the Japanese, only to reappear on the restoration of a full diet. Also, tinea capitis (*M. audouinii*) in children, although a persistent infection, resolves spontaneously at puberty for reasons not yet fully understood. Tinea pedis has been claimed as an occupational disease of coal miners and soldiers who wear heavy boots. It is well established that *Candida* infection is affected by pregnancy, and that metabolic disorders such as diabetes are also frequently associated with the disease.

Recently, iatrogenic mycoses have been aggravated by or have resulted from the use (or abuse) of antibacterials, which can cause a change in oral conditions whereby bacterial competition is eliminated and candidosis is thus induced. In addition, the introduction of heart surgery and organ transplantation following the use of immunosuppressive drugs has resulted in *Candida* endocarditis and mycotic septicemia so that antimycotic therapy is now a routine supplementary practice.

Fungus Poisoning

Two categories of fungus poisoning may be distinguished: (1) *mycetism*, the result of eating poisonous fungi mistaken for the edible variety (which has a long history and a worldwide incidence), and (2) *mycotoxicoses*, the result of inadvertent ingestion of food containing toxins produced by fungi. The latter, although also of worldwide incidence, has (with the exception of ergotism) been generally recognized only during the twentieth century.

Mycetism
Calamities tend to impress, and the first reference to fungi in the Greek classics is an epigram by Euripides writing about 450 B.C. He was commemorating the death of a woman and her two children, in one day, after eating poisonous fungi. During Roman times, edible fungi were a delicacy, and diverse advice regarding them was offered by several authors such as Horace, Celsus, Dioscorides, Galen, and Pliny. The advice consisted of how to avoid poisonous species, how to render poisonous forms harmless, and how to treat fungus poisoning.

Much of this ancient folklore on precautions to ensure edibility was compiled by the authors of the first printed herbals in the fourteenth and fifteenth centuries, and some has even survived to the present day. It is, however, invariably unreliable because the distribution of poisonous and edible species seems to be random. For example, the esteemed esculents *Amanita caesarea* ("Caesar's mushroom," a Roman favorite) and *Amanita rubescens* ("the blusher") are congeneric with *Amanita phalloides* ("death cap") and several related species (*Amanita pantherina, Amanita verna, Amanita virosa*) that have been, and still are, responsible for most fatalities from fungus poisoning in north temperate regions. The only reliable guide is correct identification.

The most frequent effect of fungus poisoning is gastroenteric disturbance of greater or lesser severity. *Amanita phalloides* toxins, symptoms of which occur 4 to 6 hours or more after ingestion, also cause severe damage to the liver and kidneys. Other *Amanita* toxins have a hemolytic effect, whereas hallucinogenic species cause psychosomatic symptoms. Fever is unusual.

The chemistry of toxic fungi has been under investigation since muscarine was isolated in Germany in

1869. That name came from the "fly agaric" (*Amanita muscaria*) which has been equated by R. G. Wasson (1971) with the Indian soma. T. Wieland (1986), together with his father, brother, and other collaborators, has made extensive studies of the *Amanita* toxins (amatoxins, phallotoxins, virotoxins).

As already indicated, mycetism is of worldwide distribution, the species of fungi implicated depending on the locality, but there are variations in its reported incidence. In western Europe, for example, there are more published records of mycetism in France, where edible forms of fungi are widely collected from the wild for sale, than in the United Kingdom, where eating wild forms is still regarded with suspicion. Most poisonous fungi are larger basidiomycetes, but a few ascomycetes with large fruit bodies are poisonous (e.g., *Gynmitra esculenta*, which is, however, edible if dried or if the cooking water is discarded).

A recent development that has led to increased incidence of fungus poisoning originated from the ethnomycological studies of Wasson (1971). These studies drew attention to the hallucinogenic properties of some larger fungi, particularly species of *Psilocybe* containing the compound *psilocin* – which is able to induce psychotropic effects similar to lysergic acid and mescalin. Collection of such forms in the wild for self-administration or illegal sale has resulted in misidentifications or overdoses and the need for medical attention.

Mycotoxicoses

Until the twentieth century, the only mycotoxicosis of human beings generally recognized in the West was ergotism, although serious outbreaks of human mycotoxicoses had occurred in Russia and Japan. *Kaschin–Beck* (or Urov) *disease* of children is characterized by generalized osteoarthritis caused by eating moldy grain. It was prevalent among the Cossacks and endemic in both Asiatic and European Russia and in northern Korea and China in the 1860s. A similar mycotoxicosis (the "drunken [or intoxicating] bread syndrome") was also prevalent in Russia. But the most extensively documented mycotoxicosis in Russia is *alimentary toxic aleukia* (or septic angina); it was known before World War I and became epidemic during World War II in the Russian grain belt, when some 10 percent of the population was affected and suffered high death rates (Mayer 1953). The problem was that in affected districts it was the practice to allow the ripe cereal crop to go through the winter under the snow. When the snow cover was so heavy that the underly-

ing soil did not freeze deeply, and the spring was mild with frequent thawing and freezing, the grain was molded by *Fusarium* species and other fungi that produced toxins (mostly trichothecines).

Known in Japan from the seventeenth century, a form of cardiac beriberi (*Shoshin–Kakke*) was shown in 1891 to be caused by eating moldy rice. In 1940 the toxin involved was identified as citreoviridin, produced by *Penicillium citreo-viride*. After World War II, a severe outbreak of a similar but different mycotoxicosis due to eating rice that had deteriorated in storage ("yellowed rice") was recorded in Japan.

Several major mycotoxicoses of farm animals have been documented in Russia, and a few more have been reported elsewhere. Significant attention was focused on mycotoxicoses after the summer of 1960, when more than 100,000 young turkeys and other poultry died in the United Kingdom after being fed a ration containing ground peanut (*Arachis hypogea*) meal imported from Brazil. Cattle and pigs were also affected, and feeding experiments induced cancer of the liver in the rat. The toxin, found to be produced by strains of *Aspergillus flavus,* was designated *aflatoxin.* At first, testing for aflatoxin was limited to animal tests using 1-day-old ducklings, which are particularlly sensitive to the toxin, but a sensitive chemical test was soon developed.

Aflatoxin was shown to be widespread in foods containing peanuts, and in parts of Africa and Asia the incidence of human liver cancer has been correlated with the intake of aflatoxin. It has not been possible, however, to legislate for aflatoxin-free peanut products because the methods of harvest and storage of peanuts in the primary peanut-producing countries are such that the introduction of the necessary changes could be effected only in the long term. The U.S. Food and Drug Administration, therefore, has set an aflatoxin tolerance of 20 parts per billion (ppb) for finished peanuts products. Interest in *aflatoxicosis,* because of its carcinogenic potential, is still intense. The literature on this subject is very extensive, and includes two major monographs (Goldblatt 1969; Heathcote and Hibbert 1978) and numerous reviews.

VIII.57
Gallstones (Cholelithiasis)

Classification

Gallstones are quite common in modern populations, occurring in nearly 20 percent of autopsies. Though often asymptomatic, they can produce significant morbidity, leading to cholecystitis, cholangitis, biliary cirrhosis, and pancreatitis.

The chief constituents of gallstones are cholesterol, bilirubin, and calcium. Other components may include fatty acids, triglycerides, protein, and polysaccharides. Descriptively, there are four major types of gallstones: (1) pure cholesterol stones; (2) mixed stones composed of cholesterol, bilirubin, and calcium; (3) combined stones having a cholesterol center and laminated exterior of cholesterol, bilirubin, and calcium; and (4) black or brown pigmented stones composed of calcium bilirubinate.

The first three types comprise the vast majority of gallstones and may be grouped together as *cholesterol-based stones,* pathogenetically related to abnormal cholesterol and bile salt metabolism. *Black pigmented stones* are commonly associated with chronic hemolysis, particularly sickle-cell disease. Gall-stones occur in 40 to 60 percent of patients with sickle-cell disease. Brown pigmented stones are associated with infection. These were historically more common in China and Japan, perhaps related to bile stasis and infection caused by *Ascaris lumbricoides* (roundworm) and *Clonorchis sinensis.*

Etiology and Epidemiology

Though incompletely understood, the three major factors in gallstone formation are abnormality in bile composition, biliary stasis, and gallbladder infection. These factors are interrelated, but current thinking ascribes the primary role to abnormal bile composition, related to cholesterol and bile acid metabolism. This in turn is affected by dietary, genetic, and hormonal factors.

A common medical maxim describes a typical patient with gallstones as "fat, fair, female, and forty." Obesity is associated with increased cholesterol secretion, producing a supersaturated or lithogenic bile. Overconsumption of calories, particularly through refined sugar and flour, appears to be the major factor accounting for the high incidence in Western countries (Heaton 1973). It also explains the increasing prevalence of cholesterol and mixed gallstones among Japanese, Eskimo, and certain African populations adopting a more Western diet. A diet high in cholesterol-rich foods may have a secondary role.

Gallstones are two to four times more common in females than in males. Estrogen causes increased secretion of cholesterol as well as decreased production of bile salts required to form soluble micelles with cholesterol. In addition, childbearing results in further elevation of estrogen in the third trimester and also promotes biliary stasis; thus multiparity is a risk factor.

There is a steady increase in gallstone prevalence with advancing age. Clinically, the symptoms of gallbladder disease related to gallstones most commonly present between the ages of 40 and 60 years.

Distribution and Incidence

Conclusions regarding the geographic distribution of gallstones are based on a variety of autopsy, hospital admission, and population survey data. The large Framingham, Massachusetts, study showed a prevalence of documented gallbladder disease among adult males (30 to 62 years old) of 1.3 percent and among adult females of 5.9 percent (Friedman, Kannel, and Dawber 1966). Many studies have shown a higher prevalence among American Indian groups, particularly in the Southwest (Brown and

Christensen 1967; Comess, Bennett, and Burch 1967; Heaton 1973). For example, a study of the Pima Indians using identical criteria and age groups as the Framingham study showed a prevalence of 5.9 percent among adult males and 36 percent among females (Comess et al. 1967).

Gallstones are usually asymptomatic. This feature, in combination with the increased prevalence with age, explains the much higher incidence of gallstones at autopsy. A large autopsy series from Philadelphia spanning the years 1920 to 1949 demonstrated gallstones in 7.8 percent of males and 16.8 percent of females. The incidence among blacks was less than half that for whites (Lieber 1952). An autopsy series of adult whites in New York City found gallstones in 16.0 percent of males and 32.5 percent of females (Newman and Northup 1959).

A similar prevalence of gallstones has been demonstrated in autopsy series from Europe, including England, France, and Germany, as well as Western-style societies such as Israel, South Africa, and Australia (Brett and Barker 1976). Sweden appears to be second only to certain American Indian groups in the frequency of gallstones. An autopsy survey from Malmo found stones in 32 percent of men and 57 percent of women over 20 years old. The prevalence rose to peaks of 70 percent in women by age 70, and 50 percent in men by age 90.

Gallstones are relatively uncommon in oriental countries; prevalence rates as low as 1.8 percent among adult men and 3.9 percent of adult women are found in Thailand. Prevalence remains low in Japan; however, there has been a shift from the infection-related pigmented stones to the Western diet-related cholesterol stones.

Most African populations demonstrate an extremely low prevalence of gallstones. Only 1.3 percent of autopsied adults in Uganda had gallstones. Many of these were black pigmented stones related to chronic hemolysis (Owor 1964). No gallstones were found in a series of 4,395 autopsies in Ghana. The disease is virtually unknown among the Masai of East Africa.

There is a general impression that gallstones are increasing in frequency in industrialized countries as well as in countries undergoing rapid development. A recent review of pre- and post-1940 autopsy series shows increasing prevalence of gallstones in Europe, North America, Japan, Chile, and Australia (Brett and Barker 1976).

A genetic tendency to develop gallstones under certain dietary conditions may account for the high rates of gallstones noted in various American Indian

groups, including Pima, Navajo, and Chippewa as well as in groups with significant Indian admixture from Mexico, Bolivia, Chile, and Peru (Weiss et al. 1984). It has been postulated that a genetic defect in conversion of cholesterol to bile acid results in lithogenic bile (Grundy, Metzger, and Adler 1972).

The geographic epidemiology of gallstones indicates a susceptibility in New World populations that is not shared, however, by their Asian ancestral relatives. The Americas were settled by crossing via the Bering land bridge formed during glacial epochs. Survival under the harsh climatic conditions depended on hunting and gathering strategies with unpredictable periods of near starvation. Individuals who could rapidly store excess calories as fat would have had a pronounced survival advantage over individuals lacking this trait. This is the "thrifty gene" theory postulated to explain the prevalence of diabetes among American Indians (Neel 1962, 1982) and possibly accounting for the association of obesity, parity, and puberty, with the formation of gallstones in American Indian females and to a lesser degree in males now exposed to a perpetual "feast" of calories and sedentary living (Weiss et al. 1984). Indeed, the worldwide distribution of other populations with high risk of gallstones corresponds closely to the area covered by the last glacial epoch (Lowenfels 1988).

History and Paleopathology

Hippocrates and Aristotle were familiar with the clinical findings of jaundice and biliary disease, but their writings do not specifically mention gallstones. Hippocrates differentiated four types of jaundice due to disease of the liver, but he did not describe any cause related to obstruction. Diocles of Carystus referred to possible mechanical obstruction of the flow of bile. Accounts of Alexander the Great's illness prior to his death in 323 B.C. are quite suggestive of gallstones and cholecystitis (Gordon-Taylor 1937).

Galen described various types of jaundice, including obstructive jaundice. He stated that small foreign bodies such as grain or fig and pomegranate seeds could obstruct the common bile duct. Given the close similarity of small gallstones to certain seeds, Galen may in fact be referring to gallstones. Gallstones in lower animals had been recognized for centuries, and crushed gallstones were an important ingredient in yellow pigment. The codified Talmudic law of the fourth century A.D. considered animals with sharp-edged gallstones unfit to eat (*terefah*), but kosher to eat if the gallstones were smooth like a date pit.

Alexander of Tralles of the sixth century was a Byzantine physician with wide clinical experience but scanty knowledge of anatomy and physiology. He described both gallstones and renal calculi. Haly Abbas, a tenth-century Persian physician often quoted in early Renaissance medicine, recorded the presence of calculi in the gallbladder and liver (Wilkie 1934).

Mundinus was professor of anatomy and surgery at the University of Bologna from 1295 to 1326. His manuscript on anatomy was based on the writings of Hippocrates, Galen, and Arabic authors and was widely used for nearly 250 years. He also mentions stones formed within the gallbladder and kidneys. Gentile da Foligno was a graduate of Bologna and professor at Padua, who died of the plague in 1348. In 1341 he carried out one of the earliest autopsies on record, and an account of that autopsy states that a gallstone was found embedded in the cystic duct of the gallbladder.

Antonio Benivieni wrote the first book devoted to pathological anatomy, which was published posthumously by his brother in 1507. This work, *De Adbitis,* contains 111 observations based on 20 autopsies, including two descriptions of gallstones found within the gallbladder and liver. Numerous other Renaissance physicians were familiar with gallstones encountered in clinical practice or more often at autopsy (Steinbock 1990).

Giovanni Battista Morgagni profoundly altered medicine in 1761 with the publication of *On the Sites and Causes of Disease.* He provided a vast array of pathological findings related to the clinical picture for a large number of diseases, including gallstones. Morgagni noted the increased frequency of gallstones with age, the greater preponderance of women suffering from them, the variation by locale, and an association with a very sedentary life. Bile stasis again figured as a prominent factor in gallstone formation. He also considered irritation or inflammation of the glands within the gallbladder wall as a cause of stones.

Gallstones have been recovered in burial excavations, and this evidence greatly extends the known antiquity of the disease. Given their frequency, more such examples should be expected. The earliest case comes from Mycenae, Greece, dating 1600 to 1500 B.C. Several gallstones were found between the right lower costal margin and right iliac crest of the skeleton of a 45- to 55-year-old man (Angel 1973). The stones are reddish brown in color with green patches and have several facets.

The mummy of a priestess of Amen, who died 945

B.C., revealed an intact gallbladder filled with stones. A radiograph of an intact mummy from the late Dynastic period (525 to 343 B.C.) shows a cluster of gallstones in the gallbladder. Subsequent analysis showed these to be the mixed variety (Gray 1967).

An extremely well preserved body of a 50-year-old female from the Hunan province of central China demonstrated multiple gallstones, including one obstructing the common bile duct. This example dates to the Han Dynasty (206 B.C. to A.D. 220) (Wei 1973).

In Europe, gallstones were recovered along with skeletal remains in a wooden coffin dating to Merovingian times or about A.D. 750. The coffin was found in Mainfranken, Germany. In Herault, France, the remains of an older adult buried in the ninth century also yielded gallstones. A single gallstone was recovered from 234 graves in a London cemetery dating from A.D. 1000 to 1200 (Steinbock in press).

In the New World, 16 individuals from the Libben site in Ohio exhibited gallstones (Lovejoy 1979). This Late Woodland site dates from A.D. 1000 to 1200. In northern Chile, at a site dating from A.D. 100 to 300, 2 of 75 mummies had gallstones (Munizaga, Allison, and Paredes 1978). Both individuals had pure cholesterol stones.

The frequency of cholesterol-based gallstones is affected by age, sex, parity, diet, genetics, and other factors. Infection and hemolysis are important in the formation of pigmented stones. A variable frequency in ancient human populations is to be expected, and because of dietary factors they may have been quite rare in many instances.

VIII.58
Gangrene

Gangrene is the term used by the clinician to describe local death of tissue (*necrosis*) occurring in the living body. Gangrene implies a fairly rapid process (developing in days) extending over a large visible area (a few to many centimeters) with an obvious inability of the tissues to repair or replace the gangrenous part. Although gangrene can occur in internal organs (e.g., large intestine), it generally refers to a process occurring on the surface of the body. It may involve only the skin, or it may extend into deeper tissues such as muscle or nerves.

Gangrene may be either dry or moist. Dry gangrene describes necrosis of the tissues of the extremities resulting from vascular occlusion, such as occurs in severe arteriosclerosis of the legs. Wet or moist gangrene occurs when bacteria invades dead tissue, producing putrefaction. When the gas-forming group of bacteria is involved, gas gangrene occurs. A gangrene may be dry at first, and be converted to the moist type by invading bacteria.

Clinical Manifestations

In dry gangrene, the arterial supply is gradually cut off and a drying or mummification of the tissues results. There is frequently an absence of inflammation, but pain of varying degree may precede the color changes. The soft tissue slowly and progressively shrinks and the color gradually deepens until the whole area is coal black. Constitutional symptoms may occur but are less severe than in moist gangrene.

Moist gangrene may be preceded by inflammation or trauma. The part is initially swollen and painful. The color is at first red then blue and finally turns to a green black. There is boggy swelling and putrid odor. If the moist gangrene is extensive, constitutional symptoms, such as fever, may be present.

A vivid description of hospital gangrene illustrates well the clinical aspect of moist gangrene:

A wound attacked by gangrene in its most concentrated and active form presents a horrible aspect after the first forty-eight hours. The whole surface has become of a dark-red color, of a ragged appearance, with blood partly coagulated, and apparently half putrid, adhering at every point. The edges are everted, the cuticle separating from half to three-fourths of an inch around, with a concentric circle of inflammation extending an inch or two beyond it; the limb is usually swollen for some distance, of a white, shining

color, not peculiarly sensible except in spots, the whole of it being oedematous and pasty. The pain is burning and unbearable in the part itself, while the extension of the disease, generally in a circular direction, may be marked from hour to hour; so that in from another twenty-four to forty-eight hours nearly the whole of a calf of a leg, or the muscle of a buttock, or even the wall of the abdomen may disappear, leaving a deep great hollow or hiatus of the most destructive character, exhaling a peculiar stench which can never be mistaken, and spreading with a rapidity quite awful to contemplate. The great nerves and arteries appear to resist its influence longer than the muscular structures, but these at last yield; the largest nerves are destroyed, and the arteries give way, frequently closing the scene, after repeated hemorrhages, by one which proves the last solace of the unfortunate sufferer. . . . The joints offer little resistance; the capsular and synovial membranes are soon invaded, and the ends of the bones laid bare. The extension of this disease is in the first instance through the cellular structures. The skin is undermined and falls in, or a painful red and soon black patch is perceived at some distance from the original mischief, preparatory to the whole becoming one mass of putridity, while the sufferings of the patient are extreme. (Buck 1902)

Etiology

Gangrene can have many causes; Table VIII.58.1 indicates the major ones. Some are now quite rare but at one time were common. Using this table as a guide, we shall discuss the various causes, highlighting those that have been of major consequence throughout recorded history.

Vascular Causes

Historically, *ergotism* resulted from ingesting rye bread contaminated by the fungus *Claviceps purpurea*. It led to a permanent decrease in the caliber of arterioles and, eventually, to dry gangrene of the fingers and toes and, less commonly, of the ears and nose. Ergotism was responsible for many epidemics of gangrene during the Middle Ages in Europe. Along with erysipelas it was known as St. Anthony's fire. Although rare, ergotism may still occur today, as ergot preparations are often used in the treatment of migraine headaches.

Raynaud's Syndrome. This syndrome is characterized by marked episodic vascular spasms of the extremities. During a typical attack, one or more digits initially turn white. After a few minutes, the color changes to a bluish red. Slowly, the normal color returns. These episodes are often triggered by cold or emotional stress. In severe cases, gangrene may ensue, which is characteristically symmetrical and con-

fined to the fingers and toes. It was once known as relapsing gangrene. Raynaud's syndrome may occur alone (*Raynaud's disease*) or in association with another condition usually of the collagen group of diseases (*scleroderma, systemic lupus erythematosus, rheumatoid arthritis*). It has also been seen as an occupational hazard in people who manipulate vibratory instruments such as jackhammers or chainsaws.

Embolism.   Embolism is the sudden occlusion of an artery by blood-borne particles. These may be atheromatous material dislodged from a vascular plaque upstream; vegetations from an infected heart valve; or other unusual particles such as fat (after extensive bony fractures), gas (decompression sickness), abnormal blood proteins (dysproteinemias), or blood clots. The acute vascular compromise can lead to gangrene of the extremities, usually of the dry type.

Arteriosclerosis.   Arteriosclerosis may be an underlying cause of embolism, and can also lead to gradual local vascular occlusion (*thrombosis*) of large and medium-sized arteries. It is common in the elderly and therefore has been called *senile gangrene*. A dry gangrene, it occurs mainly in the foot and was therefore previously called *Pott's disease of the toe*. It is generally preceded by severe pain and discomfort in the lower leg and foot. A special form of arteriosclerosis is *thromboangiitis obliterans* or Buerger's disease. It commonly occurs in young and middle-aged men who are heavy smokers. Finally, *diabetes* can predispose to arteriosclerosis of smaller vessels with eventual gangrene of the feet and toes. Diabetic gangrene is usually of the moist type. There are multiple other factors that may predispose to arteriosclerosis. They include hereditary factors and general life-style habits such as overeating of animal fats, lack of exercise, and smoking. With recent changes in these habits and better control of diabetes, arteriosclerosis and its resultant gangrene are now becoming less common. Surgical techniques are also available for replacing or recanalizing occluded arteries

of the legs, so that blood supply to the feet can be restored.

Physical Agents
Various types of injuries such as frostbite, compound bony fractures of the legs, contusions, gunshot wounds, and burns, if serious enough, may be the initial factor that triggers production of gangrene. However, this complication was more prevalent before effective medical care became widely available.

Chemical Agents
Tissue can also be destroyed by chemicals either of exogenous or endogenous origin. Caustics such as carbolic acid (previously used as an antiseptic solution) have been known to cause gangrene. Venoms of certain snakes (i.e., water moccasin), spiders (i.e., brown recluse spider), and jellyfish (i.e., Portuguese man-of-war) can cause local necrosis at the site of the sting or bite. Many chemotherapeutic agents (such as those used to treat malignancies) may also lead to local tissue destruction when they inadvertently seep into the surrounding area during intravenous administration. Some systemically administered drugs may rarely cause gangrene (i.e., some anticoagulants such as coumadin).

Microbiological Agents
Many organisms produce a toxin that will directly cause cell death. Other toxins have vascular effects such as spasm or vasculitis. Some organisms produce enzymes that can break down tissue locally. Other organisms – in particular, viruses – can directly destroy cells by invasion. Only a few of the most important infections will be discussed here. Many can be found elsewhere in this work.

Various streptococci, including *Streptococcus pyogenes* (group A beta hemolytic strep.), have been found to be the cause of certain varieties of gangrene. Of historical importance is *hospital gangrene,* also known as necrotizing fasciitis and *pourriture des hôpitaux*. This form of gangrene was the scourge of hospitals in the preantiseptic era. Today it is almost never seen. Trauma is usually the initiating factor, whereas predisposing factors are diabetes, alcoholism, and a generally debilitated state. Within 48 to 96 hours, gangrene would set into a wound and characteristically was rapidly progressive and deeply destructive. The patient would become febrile and eventually succumb. Although some authorities feel that this type of gangrene was due solely to *S. pyogenes,* there is now more evidence to suggest that other organisms (alone or in combination) may give a simi-

lar clinical picture. Another streptococcal gangrene, called *Fournier's gangrene,* is an acute gangrene localized to the scrotum. Finally, anaerobic streptococci in combination with other bacteria such as *Staphylococcus aureus* are the cause of postoperative synergistic gangrene. After a few days or weeks, gangrene develops around an abdominal or thoracic surgical wound site. The process is rapidly progressive and may, if left untreated, lead to the death of the patient.

History and Geography

Ergotism has long been an important cause of certain epidemics of gangrene in humankind. Gangrene of the limbs has been recognized since ancient times, and a description of gangrene following trauma appears in Hippocrates. It is probable that gangrene in ancient Greece and Rome was due mainly to infections initiated by trauma of either accidental or military origin.

In temperate and Arctic zones of the world, cold injuries causing frostbite that led to gangrene have always occurred. Explorers of cold regions were often affected, and gangrene produced by cold injury has also been a tremendous problem in troops engaged in wartime activities. Gangrene, for example, was quite prevalent among soldiers during Napoleon Bonaparte's invasion of Russia. Yet frostbite was only one of the causes of gangrene associated with military activity. Trauma from penetrating wounds, contusion of soft tissues, and compound bony fractures were often the initial insult. The introduction of gunpowder in Europe in the sixteenth century produced a tremendous loss of life and limbs from gangrene that developed in these traumatic wounds. Poor hygienic conditions and overcrowding in hospitals led to epidemic wound infections. Because hospital gangrene was rapidly progressive and lethal, many lives were lost, particularly during the Napoleonic Wars, the Crimean War, and the American Civil War. In many cases, there were almost as many soldiers killed from wounds and gangrene as were killed in action.

By the time of World War I, hospital gangrene was much less prevalent. The art of amputation and setting of fractures was advanced by the important contributions of such surgeons as Ambroise Paré in the sixteenth century, Pierre-Joseph Desault in the eighteenth, and John Bell at the turn of the nineteenth, among others. Their work significantly contributed to decreased mortality from gangrene. The concept of antisepsis and asepsis was introduced in the late nineteenth century with the work of Louis Pasteur. This concept, when applied to management of wounds, is known as *Listerism,* in honor of Lord Joseph Lister, who was the first to recognize the value and clinical application of Pasteur's discovery. Finally, the introduction of penicillin in the early 1940s totally eradicated hospital gangrene.

Arteriosclerosis is probably as old as humankind. Leonardo da Vinci, in the fifteenth century, illustrated the arteries of a subject with senile arteriosclerosis in one of his anatomic sketches. Along with prolonged life expectancy has come a greater susceptibility to degenerative diseases such as arteriosclerosis and other vascular disorders. In the early nineteenth century, it gradually became clear that organic occlusion of the arteries could cause dry gangrene. Maurice Raynaud, in his now famous 1862 thesis, *On Local Asphyxia and Symmetrical Gangrene of the Extremities,* attempted to prove that there was a disease of the arterial system that might produce gangrene, but in which arterial obliteration was not present. Only recently have the roles of life-style, diabetes, and hypertension been recognized as contributing factors in the production of arteriosclerosis. Fortunately, widespread public education is now contributing to the decline of severe peripheral vascular disease and its associated gangrene.

In advanced countries of the world today, gangrene is much less common. Infectious gangrenes are easily treated or avoided by the appropriate antiinfective agents. However, there are now a growing number of individuals who are immunosuppressed from chemotherapeutic agents and corticosteroids, which are used to prevent rejection in transplant patients, and to treat various cancers and autoimmune diseases such as rheumatoid arthritis. In such an immunocompromised state, these patients are at increased risk of developing unusual infectious gangrenes whose etiologic agents may not be easily recognized or be readily treatable.

VIII.59
Giardiasis

Infection with the small flagellate *Giardia lamblia* is found around the world. This protozoan inhabits the small intestine of humans and is especially common in children. Other mammals, including beavers and muskrats, also harbor *Giardia* and are important reservoir hosts. The parasite was first seen by Anton van Leeuwenhoek in 1681 and described scientifically in 1859.

Adult parasites, the trophozoites, attach to the intestinal wall with sucking disks. As trophozoites detach and pass down the intestinal tract, they transform themselves into cysts that are able to resist many environmental pressures, including water filtration and chlorination. Humans almost always acquire infection by swallowing fecally contaminated food or water. In developed countries, many cases of giardiasis have been traced to campers who have drunk from what appeared to be pure wilderness streams, but that had been contaminated by animals. Because the cysts are surprisingly resistant to normal water purification methods, public water supplies can become infected by faulty sewer lines, as happened in two fashionable Colorado ski resorts in 1964 and 1978. Giardiasis is a frequent cause of "traveler's diarrhea," and tourist groups in Leningrad have suffered well-publicized outbreaks. In 1983, 22 of New York City's 55 police and fire department scuba divers had *Giardia*, presumably from the heavily polluted waters of the harbor. Four percent of 1 million stool samples submitted to state laboratories in the United States from 1977 to 1981 were positive for *Giardia*. Prevalence rates in developing countries range from 8 to 20 percent and higher. In poor countries like Bangladesh, where water and sanitation standards are often very favorable for transmission, a majority of the children and many adults repeatedly acquire infection.

There has been considerable dispute in the past about the clinical importance of *Giardia* infection. Although many cases are in fact asymptomatic, it is now clear that the flagellates damage the intestinal wall and that heavy infestations can cause nutritionally significant malabsorption of food. Symptoms include diarrhea, flatulence, abdominal discomfort, and light-colored, fatty stools. The classic method for detecting *Giardia* infections is to find the trophozoites in the feces with a microscope, but surveys that depend on this technique will generally underestimate prevalence because trophozoites do not appear consistently in the stools. Repeated examinations and use of serologic techniques developed in the 1980s give more accurate results for either an individual patient or an entire population. Most infections are self-limiting and treatment is effective, but reinfestation must be avoided. There is some evidence that mothers' milk helps protect infants against infection.

Glomerulonephritis (Bright's Disease)

Glomerulonephritis, an immunologic disease of the kidneys, affects the *glomerulus*. This structure, a cluster of capillaries, is the filter in the functioning unit of the kidney, the *nephron*. Inflammation, initiated by immune complexes (defined below), injures the glomerulus. Often the disease is acute, but it may be silent and completely undetected until signs and symptoms of chronic kidney failure prompt a biopsy, leading to diagnosis. Alternatively, this silent disease may prove fatal, and the diagnosis is made at autopsy.

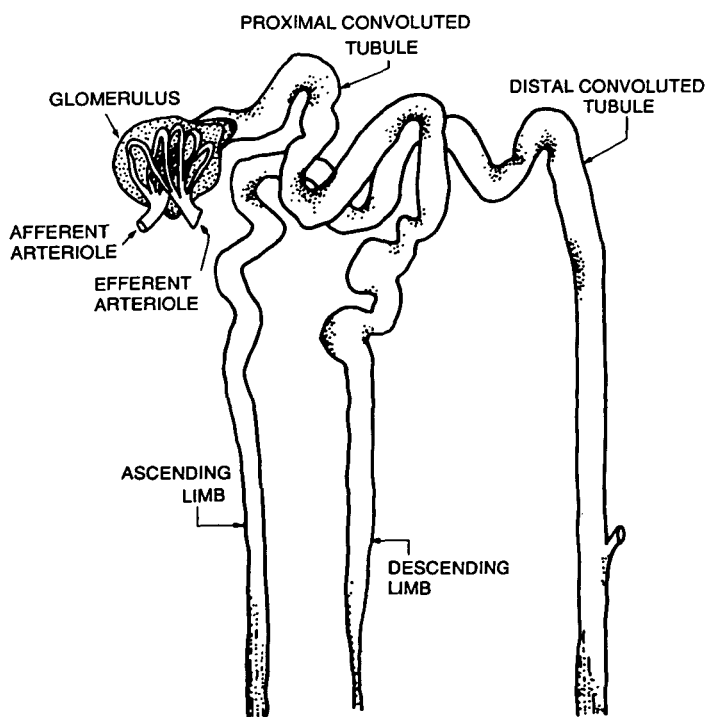
The urine-secreting structure (nephron) (Figure VIII.60.1) consists of the glomerulus and its tubular system. Each glomerulus consists of a tangle of interconnecting capillaries branching between two tiny arteries (arterioles). A glomerular cross section shows these capillary loops (Figure VIII.60.2). The glomerulus is a blood filter that controls passage of molecules through the basement membrane, depend-


Figure VIII.60.2. Normal glomerulus. It consists largely of a tangle of tiny blood vessels (capillaries), many of which have been cut in a cross-sectional plane. They appear as spherical or oval empty spaces surrounded by a thin membrane. Many contain a nucleus (dark-stained spots) of the capillary lining (endothelial) cells.

ing on their size and charge. Normally red blood cells and albumin are not permitted to pass through the membrane. The tubules reabsorb, secrete, synthesize, and excrete solutes and metabolites, thereby maintaining physiological equilibrium.

This article will deal only with poststreptococcal glomerulonephritis. This disease, described by Richard Bright in the early part of the nineteenth century, still bears his name. Other forms of glomerulonephritis, which he also described, and the glomerular diseases termed *glomerulopathies,* seen in diabetes or amyloidosis, are not discussed.

Distribution and Incidence

Glomerulonephritis occurs worldwide. The disease was seen frequently in Europe during the eighteenth and nineteenth centuries as a complication of scarlet fever during epidemics. Today glomerulonephritis occurs sporadically. Several epidemics have occurred since the 1950s in the United States, Trinidad, and Venezuela. The disease would seem to be more prevalent in the Western world, probably only because modern diagnostic aids are available. Children contract it more commonly than adults, but it occurs in all age groups. Because the disease is often silent, the exact incidence of glomerulonephritis remains unknown.

Figure VIII.60.1. Urine-secreting structure (nephron). (Modified from Arthur C. Allen. 1962. *The Kidney: Medical and Surgical Diseases,* 2d edition, 27, plate 13A. New York.)

Epidemiology, Etiology, and Immunology

For more than 200 years, physicians have known that swelling of the face and extremities (dropsy) occurred

in some individuals 10 to 14 days after bouts of scarlet fever (scarlatina). Early physicians believed that toxins, released during the fever, caused the dropsy, and long after Bright discovered the association of post-scarlatina dropsy with changes in the kidney, the role played by scarlet fever still remained a mystery. These earlier beliefs were afforded credibility with the discovery, in the latter part of the nineteenth century, that the scarlatina rash resulted from streptococcal toxins.

It was only in the latter half of the twentieth century that F. G. Germuth (1953) and F. J. Dixon and others (1961) found that rabbits developed glomerulonephritis when given injections of a foreign protein (bovine albumin). About 2 weeks after these injections, the glomerulus sustained injury from immune complexes. An *immune complex* consists of an *antigen* (the protein), an *antibody* (produced by the rabbit), and a *complement* (humoral component). Immune complexes localize in the glomerulus and damage the basement membrane. The damaged membrane leaks protein and red blood cells into the urine; swollen cells lining the capillary block the glomerular capillaries.

In humans, events mimicking this model follow certain streptococcal infections caused by "nephritogenic" strains. Before the advent of antibiotics, glomerulonephritis usually followed an attack of scarlet fever. Today, in the Western world it more often follows streptococcal infections of the throat and skin, since scarlet fever is quite uncommon. Some part (still not identified) of the streptococcus serves as the stimulus for antibody formation.

Clinical Manifestations and Pathology

Signs of kidney disease usually follow infection, but not all patients have such a history. Many have no known or recognized antecedent illness. Generalized edema is often an early symptom. Red-brown or frankly bloody urine, reduced urine volume, hypertension, and headache from fluid accumulation are other common symptoms.

In children, poststreptococcal glomerulonephritis is usually a mild disease, and most children recover without permanent kidney damage. In adults, in contrast, permanent kidney damage occurs more often. The reasons for this difference are unknown.

The main pathological changes in glomerulonephritis are an increase in glomerular cellularity (Figure VIII.60.3) and red blood cells in the tubules. With special studies, one can detect immune complexes in the glomeruli on the basement membranes. In an occasional individual, masses of cells, called *epithe-*
Figure VIII.60.3. Acute glomerulonephritis. As compared with Figure VIII.60.2, the glomerulus is larger and the nuclei (dark-stained spots) are both more numerous and swollen to the point of obliterating the capillary lumens, rendering them indistinguishable.

lial crescents, surround the glomeruli, and strangle blood flow to the capillaries, causing kidney failure and death to the patient unless hemodialysis is undertaken.

History and Geography

Early Accounts Through the Eighteenth Century

Dropsy, a clinical finding, occurs not only in glomerulonephritis, but also in a number of other conditions and diseases including heart failure and end-stage liver disease. There are early accounts of dropsy, and some of these certainly refer to glomerulonephritis. Glomerulonephritis also causes bloody urine, but other common causes of this symptom include urinary tract stones, tumors, and parasitic diseases.

In the writings of Rufus of Ephesus, of about A.D. 100, we read of "hardening of the kidneys." This was noted in patients who had only small amounts of urine, were free of pain, and who sometimes developed dropsy. This description could certainly be chronic glomerulonephritis. Ancient Hindu writings refer to dropsy attributed to heart disease. Avicenna, an Arabian physician and author of the *Canon,* perhaps the most famous medical text ever written, referred to patients with "chronic nephritis" around A.D. 1000.

The treatise on surgery written by Gulielmus de Saliceto of Bologna about the middle of the thirteenth century but not published until 1476, has a reference to dropsy, scanty urine, and hardened kid-

neys. This is chronic kidney disease, and was very likely glomerulonephritis.

In another surgical text, Peter Lowe, a Scottish physician, wrote that "hydropsie" is a "Tumor against nature, engendered of great quantitie of Water, Winde, or Flegme, which sometimes is dispersed through the whole bodie, and is called Universall," and "The cause interne of hydropsie . . . cometh . . . through the vice of the . . . kidneyes."

Scientific urinalysis, representing a major step forward from the "looking and tasting" era of the Pisse Prophets, commenced with Frederick Dekkers, who discovered in 1695 that some urine samples, like serum, would coagulate with the application of heat or the addition of acetic acid. Today we know such a coagulum as *albumin*.

In the next century, Domenico Cotugno, an anatomy professor at Naples University, was attending a young soldier with a febrile illness, who "on the fifth day had a wonderful eruption of intercutaneous water." This fluid and the urine each "contained a coagulable matter . . . over the fire." There is no indication that he knew of Dekkers' observation, and Cotugno may be the first to have noted albumin in the urine, associated with dropsy.

About this same time, Nils Rosén von Rosenstein, a Swedish physician, wrote an account of observations made during the scarlatina epidemic in Upsala in 1741:

But others . . . between the eighteenth and twenty second days, when the disease was to supposed to be quite cured . . . complained of weakness . . . and then the body began to swell, as in a dropsy [anasarca]; and upon this came on a fever, anxiety, uneasiness, oppression and asthma. Very little was discharged, and it is said to have been bloody in some patients, or appeared as water in which fresh meat has been washed.

This is an early, accurate account of post-streptococcal glomerulonephritis.

Nineteenth-Century Writings

The relationship between scarlet fever and dropsy was well recognized over the next 50 years. Thomas Bateman described eight patients with post-scarlatina dropsy seen between 1804 and 1816 in the public dispensary in London. At St. Thomas Hospital, William Charles Wells observed in 1811 that the urine in patients with dropsy after scarlet fever "contains almost always the serous, and sometimes the red matter of blood." Unaware of Cotugno's writings, he credits another with first noting, in 1798, "serum" in the urine of patients with dropsy. He

looked for serum in the urine of 130 persons who had dropsy and found it present in 78 of the samples. He also noted that "urine in dropsy, when it contains serum, is often more abundant than in health." (The increased urine volumes probably compensate for the loss of urine concentration in patients with failing kidneys.) He observed altered kidneys in one dropsical patient at autopsy who had serum in his urine, but with this limited observation did not feel justified in associating the findings with the kidney abnormalities, and wrote that "the morbid appearances in the kidneys might be altogether unconnected with morbid secretion. . . ."

In 1818 John Blackall also observed dropsy, albuminuria, and bloody urine in patients after scarlatina. Sometimes these patients at autopsy had "kidneys firmer than the ordinary, in one of them very strikingly so, approaching the scirrhus; but whether this is merely accidental, or the effect of such a course and what relation it bears to the discharge of serum must be left for future observations."

Those observations were soon to be made by Bright, a giant of medicine, who was conducting his landmark studies as a staff physician at Guy's Hospital in London, on patients with post-scarlatina dropsy and albuminuria. In 1827, he first reported his findings and wrote, "The observations which I have made respecting the condition of the urine in dropsy, are in a great degree in accordance with what had been laid down by Dr. Blackall in his most valuable treatise." Bright's meticulously recorded accounts of the clinical features of the disease, and his colored illustrations of the pathological changes in the kidneys, remain a model for us today. He firmly established that dropsy was accompanied by pathological changes in the kidneys. His studies, however, did not address the question of how albumin enters the urine. This question could not be answered until nephron structure was further defined.

Marcello Malpighi had tried to answer the question in 1666 at Bologna. He knew of the glomeruli, and that they could be filled by injected dye into the blood vessels, but his frustration in being unable to establish their function is indicated in his writing:

I worked a long time in order that I might subject to the eye this evident connection [between "glands" and tubules] *which reason sufficiently attests. For I have never been able* to observe liquids perfused through the arteries penetrating the urinary vessels, even though they fill the glands, and the same is true when the veins are filled. . . . So that, in spite of many attempts (but in vain) I could not demonstrate the connection of the glands and the urinary vessels. (Italics mine)

In the early nineteenth century, the Berlin school, led by Johannes Peter Mueller, dominated anatomy and physiology in Europe. Mueller knew of Malpighi's descriptions of the glomeruli, but he considered them to be simply receptacles of blood. He believed that urine was secreted by the epithelium of the proximal tubules.

But William Bowman in 1842 (then just 26 years old) wondered, as Malpighi had, why the glomerulus would end blindly in a space opening into the tubules. He wrote:

It would indeed be difficult to conceive a disposition of parts more calculated to favour the escape of water from the blood than that of the Malpighian body. . . . Why is so wonderful an apparatus placed at the extremity of each uriniferous tube, if not to furnish water, to aid in the separation and solution of the urinous products from the epithelium of the tube? This abundance of water is apparently intended to serve chiefly as a menstruum for the proximate principles and salts which this secretion contains, and which, in speaking generally, are far less soluble than those of any other animal product.

Bowman suggested that protein and red cells might pass through the glomerulus under abnormal circumstances!

A German physiologist, Carl Ludwig, followed up on Bowman's anatomic observations just a few years later, with the view that the glomerulus was a semipermeable filter. Hydrostatic pressure pushed fluids through the capillaries that held back the proteins. In 1861 Thomas Graham showed that membranes could hold back colloids but permit the passage of crystalloids. The glomerulus was established as the source of urine, but albuminuria was still thought to come from tubular epithelium. For many years the term *nephrosis* was used to express this belief and define proteinuric states.

Through the rest of the nineteenth century, pathologists adhered to this view, even as microscopic studies advanced. The source of urinary albumin in dropsy was not determined for more than a century.

Bright's descriptions of the kidney contained no records of microscopic examination. Rudolph Virchow established the cellular basis for pathology in 1858, and classified Bright's disease into three categories – involving the tubules, the connective tissue, and the blood vessels. In some of his later writings, he referred to glomerular changes, but he continued to believe the main changes were in the tubules. The first pathologist to use the word "glomerulonephritis" was Edwin Klebs in 1879. The term became synonymous with Bright's disease after F. Volhard and T. Fahr (1914, in Heptinstall 1983, Vol. 1) intro-

duced it into their classification. That classification remained in use with little modification for nearly a half century.

The active use of biopsy to evaluate the nature of the kidney disorder in the patient was also an important clinical contribution. As biopsy experiences accumulated in the 1950s, 1960s, and 1970s, clinical and pathological classifications of Bright's disease appeared in large numbers. Basic science investigators gave us an understanding of the important role of the immune system in glomerulonephritis, and they established the glomerular basement membrane as the site of leakage in albuminuric states. The tubule is *not* the source of the urine protein, but altered tubular reabsorption possibly plays a lesser role in albuminuria. The major contributions of pathology in the twentieth century are the use of thin sections, immunofluorescent techniques, and electron microscopy in biopsy interpretation.

Thus, today Bright's disease consists of many different disorders, all of which can be considered glomerulonephritis. The diagnosis and management of these disorders will continue to challenge clinicians, pathologists, and basic science investigators into the twenty-first century.

Goiter

Quis tumidum guttur miratur in Alpibus?
Juvenal, *Satire 13*, c. A.D. 127

Goiter is an ancient disease that has always been more common in some places than in others. Chinese writings show that goiter was known at least by the third century B.C. (Lee 1941) and possibly earlier (Needham et al. 1970). When Juvenal (Decimus Junius Juvenalis), the Roman satirist, wrote, about A.D. 127, "Who is amazed at a swollen neck in the Alps?" he knew that goiter was so much more common there than elsewhere that it should be no surprise.

Terminology

The word "goiter" (or *goitre* in Europe) derives from the Latin *gutter*, but the meaning has shifted from "throat" or "neck" to mean specifically an enlarged thyroid gland. An ancient Greek synonym was *bronchocele*, a term actually used to describe any enlargement in the neck, although it meant literally a swelling or an outpouching of the trachea. Over time this term also came to mean an enlarged thyroid (e.g., the English "bronchocele" of the eighteenth and nineteenth centuries). Modern synonyms are the Spanish *bocio* (from Latin, *botium*), the Italian *gozzo*, and the German *Kropf*. The ancient Latin word *struma* was probably originally used to describe inflamed lymph nodes in the neck, most likely tuberculous, but was later used to denote the normal thyroid gland, and is still so used although it is almost obsolete.

Confusion over names is understandable, as the thyroid gland itself was unknown until the sixteenth century. Leonardo da Vinci may have drawn the thyroid about the year 1500, but the drawing was not published until much later. Andreas Vesalius did note "laryngeal glands" in 1543, but not in humans. Nevertheless, by the end of the sixteenth century, Vesalius's contemporaries and successors had clearly identified the human thyroid gland as a discrete structure: Bartolomeo Eustachi in 1552, Realdo Colombo in 1558, and Giulio Casserio in 1600. In 1619, Hieronymus Fabricius ab Aquapendente realized that goiter arises from an enlargement of this gland, and in 1656 Thomas Wharton named the gland by virtue of its proximity to the thyroid ("shield-shaped") cartilage.

Classification and Diagnosis

Although shown on an occasional autopsy or dissection, the connection between goiter and the thyroid gland was not clear as a concept. Other diseases of the neck confounded the connection in a living patient. The main confounder was *scrofula*, which in medieval Latin meant "swelling of the glands" and today is still used to connote tuberculous lymph glands (or nodes) in the neck.

Because obvious and severe goiter affecting large portions of a population occurred only in certain regions, the disease in these areas was called *endemic*. In these instances the connection to the thyroid gland was fairly clear. But where only a few individuals in a population had a mass in the neck, it might be called *sporadic* goiter – because not endemic – or something else. If the mass was not too large, it might move with swallowing and so was called an *enlarged* thyroid. But if the mass were nodular, firm, and immovable, then it was considered to be probably characterized by tuberculous nodes. This diagnostic confusion persisted until the mid-nineteenth century. Jean Louis Alibert, for example, classified endemic goiter as a type of scrofula ("endemic scrofula") found in rural areas (Alibert 1835). Today endemic goiter is arbitrarily defined; it is present, according to some, if more than 10 percent of a population is goitrous.

Besides the occasional large and disfiguring goiters that were cosmetically distressing and sometimes blocked breathing, endemic goiter areas also produced a much smaller number of people who were retarded from birth, both mentally and physically, whose faces were disfigured, and who were sometimes deaf and mute. Most but not all had goiter, which was also common in their mothers. They were called *cretins*, and their disease, *endemic cretinism*. The word "cretin" probably derives from the French *crétien*, and thence from the Latin *christianus* (or Christian); the term was probably used to make clear that these persons were truly human.

Cretinism is probably as ancient a disease as goiter, but descriptions are not as old. Travelers' observations, again in the Alps, go back to the early thirteenth century, but clinical allusions begin with Paracelsus (Theophrastus Bombastus von Hohenheim), lecturing about 1527, who connected cretinism (or at least "fools") with goiter. Good descriptions begin with Felix Platter, who probably observed it in 1562 and who also made the association of cretinism with goiter (Cranefield 1962).

Thus, by the seventeenth century, the concept of

goiter as an abnormally enlarged thyroid gland was reasonably well established as was its association with cretinism and with the mountainous alpine areas of Europe. Yet, cretinism in particular was rare outside densely goitrous sites in the Alps, and thus most European physicians never saw it. Just as goiter could be confounded with other neck diseases, so could cretinism with any sort of mental retardation. Thus a certain amount of diagnostic "fuzziness" persisted into the nineteenth and twentieth centuries.

Today goiter means only an enlarged thyroid, and any large thyroid is a goiter. The goiter may be uniformly and diffusely enlarged ("simple" or diffuse goiter), have several lumps in it (multinodular goiter), or be only a single nodule, although on closer study many of the latter prove to be multinodular. The standard screening method of the World Health Organization in endemic areas is to assign gradations to the disorder. Grade 0 is no goiter, grade 1 is a goiter that is palpable but not visible, grade 2 is an easily visible goiter, and grade 3 is a very large goiter visible 30 meters away (Stanbury and Hetzel, eds. 1980).

Some goiters are malignant (e.g., thyroid cancer or lymphoma), but the vast majority are benign. Some are associated with specific thyroid diseases such as *hyperthyroidism* (an overactive thyroid); its opposite, *hypothyroidism* (an underactive thyroid; such as in goitrous cretinism); and *thyroiditis* (an inflammation of the thyroid that can be acute or chronic). The taxonomies (geographic, clinical, and etiologic) persist today, derived from different types of data with different historical origins. They overlap considerably and continue to give rise to confusion in diagnosis and treatment.

Cretinism is called *endemic* if it is found in an area of endemic goiter, but is called *sporadic* if not found in an endemic area; the latter is almost always nongoitrous. Again, entirely different causes underlie the two types. Both goiter and cretinism, whether endemic or sporadic, can be associated with hypothyroidism, although the notion that cretinism is synonymous with childhood hypothyroidism is false. Hypothyroidism is common but not universal in cretinism, and it occurs only occasionally with goiter.

Early Treatment

Goiter of itself is not particularly harmful unless it grows to compress the trachea or causes emotional upset. But when therapy for a large goiter was required, the only solution until the twentieth century was to remove it, or at least part of it, surgically. The problem was that surgery commonly killed the patient, and some surgeons said that such an operation should simply not be done. Others persisted, and by the 1880s were able to remove all or most of a goitrous thyroid with death rates under 1 percent.

E. Theodor Kocher in Berne and the cousins Jacques-Louis and Auguste Reverdin in Geneva were pioneers in this surgery. In 1882–3, however, these Swiss surgeons realized that removing the entire thyroid caused symptoms resembling cretinism, but that this did not happen when only part of the thyroid was taken out. Simultaneously in London, Felix Semon proposed that cretins, patients after total thyroid removal, and adults with a mysterious disorder called *myxedema* (described by William Withey Gull in 1873) all suffered because they lacked thyroid glands. He was ridiculed, but 5 years later a committee appointed to investigate this theory found Semon to be correct (Ord 1888). Thyroid deficiency or myxedema, now called *hypothyroidism,* is a synonym for decreased thyroid function or a lack of thyroid hormone secretion.

Etiology

Early Theories

Many theories were generated over the centuries to explain goiter. An ancient idea was that goiter is due to an excess of phlegm descending from the head to the throat. An excessive flexing of the head was seen as the cause by many, including Michelangelo (Michelagniolo Buonarroti), who suggested it in 1509. Geographic peculiarities were frequently blamed as well, such as high altitude or narrow valleys, as were climatic features such as high humidity, too much sun, and polluted air, proposed by physicians such as Horatio-Bénédict de Saussure in 1779 and F. E. Fodéré in 1789. Differences in drinking water were also viewed with suspicion, especially cold water, water made from snow, and water from streams or springs believed to be tainted. Finally, hereditary or constitutional factors were thought important; that idea is attributed to Jacques de Vitry about A.D. 1220.

Nineteenth-Century Theories

During the nineteenth century, the major theories of the etiology of goiter focused at least in part on some peculiarity of the drinking water, a lack of iodine, an infection of some sort, or some combination of these.

Climatic factors had been dismissed when it turned out that goiter can occur in almost any climate, dry or wet, from the Arctic to the equator (Hirsch 1885). High altitude had been rejected as well, for the disease was not limited to mountainous regions; flatlands had endemic goiter as well.

The long process of linking endemic goiter and cretinism to iodine deficiency began in 1811, when Bernard Courtois discovered the element while making saltpeter for gunpowder during the Napoleonic Wars. He noticed it as a violet vapor released from the residue of burnt seaweed by sulfuric acid. It was subsequently named iodine by Joseph Louis Gay-Lussac from the Greek word for "violet." The key was the seaweed. For hundreds of years, dating at least from the twelfth and thirteenth centuries in Europe, and from the third century A.D. in China, seaweed and marine sponge had been placed among the many animal and vegetable remedies for goiter, sometimes burned before use. Within a few years after Courtois' discovery, iodine was detected in various seaweeds by Humphry Davy, Gay-Lussac, and Andrew Fyfe.

In 1818, Jean-François Coindet, a Geneva physician, suggested that because some seaweeds were effective in treating goiter, iodine might be the active principle. He asked Jean-Baptiste Dumas (then aged 18 and later to become one of France's most famous chemists) to look for iodine in marine sponge; Dumas did and found it (Thorpe 1902). Coindet then gave iodine, mostly as potassium iodide, to goitrous patients, with good results that were almost immediately confirmed by other Swiss physicians.

An effective therapy, however, does not necessarily mean that a disease is due to a deficiency of the therapeutic agent. (Few would suggest, for example, that pneumococcal pneumonia results from penicillin deficiency.) Thus although the chemist Jean Baptiste Boussingault suggested as early as 1825 that iodine deficiency might be the cause of goiter and recommended the addition of iodine to table salt to prevent it, little came of this suggestion.

A generation later, Jean-Louis Prévost, another Geneva physician, made the same suggestion as Boussingault. But iodine had fallen into disfavor as therapy for goiter because of toxic side effects when given in excess, including (in retrospect) iodine-induced hyperthyroidism. Coindet himself had seen this (he used a dose of 1 to 2 grains of iodine per day) and had cautioned against too high a dose, but to no avail.

In the 1850s, Adolphe Chatin, a French pharma-cist and botanist, using a somewhat better assay for iodine, found the element in *freshwater* plants and suggested these plants be used to prevent goiter (Chatin 1850a). He went on to measure iodine in water samples from all over France, and in some foods as well, and concluded that a lack of iodine in drinking water in certain areas appeared to be the principal cause of goiter (Chatin 1850b). The following year, the French Academy of Sciences appointed a committee to study Chatin's results; its report (Thénard et al. 1852) congratulated Chatin for his work, but viewed the association between a lack of iodine and goiter as unproven.

There were successful trials of iodine prophylaxis of endemic goiter in the nineteenth century, notably in South America in 1835 (Dumas et al. 1851) and in Savoy in the 1840s. Yet success did not encourage further trials, and the question of iodine as a goiter preventive was not pursued.

The rise of the "new pathology" with Rudolph Virchow as its leader in the mid-nineteenth century also interfered with the idea of iodine deficiency as the cause of endemic goiter. During the 1860s Virchow himself felt that excessive growth of a tissue, in this case goiter, must be due to some irritation that stemmed from a "positive substance" and not a deficiency (Follis 1960). In France the view persisted that goiter and cretinism were serious problems but that the cause was not iodine deficiency. Rather, an *agent toxique spécial* was thought to be responsible (Baillarger 1873).

The reluctance to accept iodine deficiency as a cause of goiter is understandable: There was then no good example of a disease known to be caused by a deficiency. Further, the theory did not explain why only some people in low-iodine areas got goiter while others did not. This problem remains unresolved today.

Later in the nineteenth century, after the discovery of the bacterial cause of many diseases, it was postulated that goiter was caused by either a bacterium or a bacterial toxin, perhaps in the water. Edwin Klebs, a pioneer microbiologist, believed he had found such an agent in 1877, and August Hirsch (1885) stated flatly that "endemic goitre and cretinism have to be reckoned among the infective diseases." Indeed, the notion that goiter has an infectious cause had its twentieth-century adherents at least until mid-century, although the evidence put forth has never been convincing. But while the infectious hypothesis has faded, the parallel notion of a toxin in the water, possibly of bacterial origin, is still alive (Gaitan et al. 1983) and warrants serious con-

sideration, particularly in areas where there is much goiter despite adequate iodine intake.

Iodine as a therapy in medicine, in contrast to its use solely to treat goiter, caught on rapidly in the decade after its discovery. Beginning in the late 1820s, for example, Jean-G. A. Lugol, another Geneva physician whose name is memorialized in the still-used Lugol's solution of iodide–iodine, employed it against any scrofulous disease (Lugol 1829). Its use spread rapidly to include treatment of other conditions, among them rheumatic diseases, almost any pulmonary condition, any disease that involved swelling of a part of the body, and syphilis. Late-nineteenth-century texts on medicine and pharmacology indicate its continued wide use while recognizing the hazards of overdosage (Wood 1881; Pepper 1894; Osler 1892). Iodine as therapy for goiter did persist (Inglis 1838; Wood 1881) but only as one of several possible treatments (Pepper 1894; Osler 1896) and was employed without much enthusiasm.

In sum, up to the 1890s there was no resolution of the problem of the cause of endemic goiter or cretinism. No clear choice could be made among the drinking water, iodine deficiency, or toxic-infective hypotheses. Prophylaxis of goiter with iodine on a mass scale was not popular and hence not done. Fear of inducing serious side effects if everyone took iodine in salt or food was widespread since, after all, iodine was a known poison. Social and political issues frequently arose, similar to those that surround questions of the chlorination or fluoridation of water.

It was in the 1890s, however, that substantial advances began to be made in goiter research. George R. Murray (1891) discovered that a glycerin extract of sheep thyroid cured myxedema (hypothyroidism). After this, investigators began to look for iodine in the thyroid gland itself. Eugen Baumann (1895), for example, in looking for the active compound in the thyroid, made a fairly potent extract. When analyzing that extract, he routinely looked for iodine, not expecting to find it; to his surprise it was there.

Twentieth-Century Theories

From this point research diverged: One path led to the isolation of a specific thyroid hormone, *thyroxine,* by Edward C. Kendall in 1914 (Kendall 1915) at the Mayo Clinic; and another led to studies relating goiter to the iodine content of the thyroid rather than to that of the environment.

David Marine came to Cleveland, Ohio, an area of endemic goiter, in 1905. He was aware of the importance of *hyperplasia* – the process that leads to

goiter – through William Halsted, his teacher at Johns Hopkins Medical School. By 1910, he showed that iodine prevented goiter in brook trout (Marine 1910), and therefore gave it to patients at Cleveland's Lakeside Hospital and to children of friends to prevent goiter. In fact, he tried to give it to all school-children in Cleveland, but the school board, led by a goiter surgeon, said it would poison the children. (At the time there was also a controversy over compulsory smallpox vaccination.) Not until several years later was Marine able to carry out a large-scale study of iodine prophylaxis for goiter. The results were clear-cut: Sixty-five percent of goiters became smaller, whereas this happened in only 14 percent of the control group, and new goiter was largely prevented (0.2 percent got new goiter among those treated versus 21 percent for those untreated) (Marine and Kimball 1920). This study provided the impetus, in the United States, for the use of iodized salt, which now contains 0.01 percent potassium iodide.

Even though Marine showed iodine to be both a treatment and a preventive for endemic goiter, he had not proven that these patients were iodine deficient. It remained for J. F. McClendon, a nutrition officer in the U.S. Army during World War I, to measure accurately iodine in water and food. He showed not only that there was a correlation between lower iodine in food or water and the presence of human goiter, but also that rats on a low-iodine diet got goiter (McClendon and Williams 1923). He later put together worldwide data to support his thesis that low iodine in the water causes goiter (McClendon 1939); although the data in general did support the idea, close reading shows many exceptions.

By 1924, Michigan, a state with endemic goiter, offered iodized salt to the public after an intense public education campaign; within 12 years goiter prevalence fell from 37 percent to 8 percent and, by 1951, to 2 percent. Ohio, Marine's own state, never acted. Still, Marine's statement that "endemic goiter is the easiest known disease to prevent," though a bit hyperbolic, was finally shown to be reasonably correct.

Over the years since Marine's study, the average daily iodine intake in the United States has increased several times not only because of iodized salt (the label now says that iodine is "a necessary nutrient"), but because of the widespread use of purchased foods that contain iodine, such as bread and milk. Thus, in the United States, few can today develop iodine deficiency, and, as in countries with similar food sources, goiter is mostly sporadic and

occurs either spontaneously or as a result of factors other than iodine deficiency, such as exposure to therapeutic X-rays (DeGroot et al. 1983) or radiation from atomic fallout (Hamilton et al. 1987; Morimoto et al. 1987). Sporadic goiter is also called *nontoxic goiter,* meaning that the patient is not hyperthyroid. Sporadic goiter can be any of the clinical types (i.e., diffuse or nodular). Yet, some areas of endemic goiter persist in the United States, especially in parts of Appalachia, and may be caused by a *goitrogen* (a substance that causes goiter). Goitrogens certainly exist, but how much they contribute to human goiter is unclear (Delange and Ermans 1976).

Prevention and Treatment

In many other parts of the world, both rich (Scriba et al. 1985) and poor (Prevention 1986), goiter remains endemic (World Health Organization 1960; Stanbury and Hetzel 1980) with its attendant disfigurement, cretinism, and hypothyroidism. It is worth noting that persons in an endemic area could have any of the diseases that cause sporadic goiter, which is one reason why goiter prevalence never falls to zero even with iodine repletion. For some areas this endemia is a major public health problem, and millions of people remain at risk. The disease, when endemic, is almost always associated with low iodine intake and iodine deficiency, and while there remains no good explanation as to why some do not develop goiter in areas of low dietary iodine, iodine does prevent the disease. The issue then becomes a social and political one of providing iodine to those in deficient areas and then getting them to take it. As Marine wrote, "Endemic goiter will be prevented only when society decides to do it."

If a large goiter already exists, however, iodine will likely not be of help and surgery may be needed. On the other hand, thyroid therapy alone can shrink some goiters, as was shown as early as 1894 (Bruns 1894; Reinhold 1894), and prevent recurrence of others after surgery even if the goiter is cancerous (Mazzaferri and Young 1981). Thus thyroid hormone can be the initial treatment for goiter and should be used after any goiter surgery.

Therapies for endemic and sporadic goiter and cretinism are fairly straightforward, although some disagree on details of testing or timing. In developed countries they are easy to apply in principle; the major problems are societal and relate to detection and prevention. In less developed countries the public health aspects are paramount, especially where budgets are limited; prevention of endemic goiter and cretinism is an effective use of funds.

Conclusions

Overall, changes in how goiter was defined progressed erratically. As theories and techniques employed in anatomy and pathology were developed, the concept of "goiter" shifted from the simplistic idea of a swollen neck, to an enlarged thyroid of several types, to a range of different thyroid diseases. However, early taxonomies did not disappear but persisted along with the new.

Along with these changes in taxonomy came parallel changes in purported causes and the possibilities of prevention. Focusing for the moment only on *iodine,* one can demonstrate a continuous link from the Chinese use of seaweed through the European Middle Ages and folk medicine, to the discovery and use of the element in the nineteenth and twentieth centuries. In actuality, however, although empirical "folk" medicines containing iodine were effective against goiter, they were used along with many others that seem to have had no benefit. Nineteenth-century French physicians may have been "right" in proposing iodine as a treatment for endemic goiter, but they did not convince their colleagues. That iodine deficiency might cause goiter was confounded by iodine's use in goiter treatment and prophylaxis; furthermore, the technical inability to measure consistently and accurately small amounts of iodine led to persistent and valid controversy. Improvements in the iodine assay in the late nineteenth and early twentieth centuries provided a solid basis for resurrecting earlier beliefs in its effectiveness; moreover, because it was thought that iodine *ought* to prevent endemic goiter, the studies were done that proved it. But the pendulum then swung to the other extreme, with many researchers believing that iodine was the answer to all endemic goiter. It was not, however, and we now face the scientific challenge of teasing out several probable factors in addition to iodine deficiency that can produce endemic goiter, as well as the political challenge involved in iodine prophylaxis on a worldwide basis.

In conclusion, *sporadic goiter* is usually not due to iodine deficiency but is mainly the result of an intrinsic thyroid disease, often related to genetic, immunologic, or enzymatic factors; it is apparently influenced by gender, as it is more common in women. *Sporadic cretinism* (or *neonatal hypothyroidism*) is almost never caused by iodine deficiency, but is usually the result of failure of the thyroid gland to develop; thus there is no goiter. For this condition, a public health approach, with testing of all newborns, is mandatory to prevent irreversible brain damage. On the other hand, *endemic goiter* and *cretinism*

are usually related to a low dietary iodine, although goitrogens, genetic, and immunologic factors may be operative in some locales. Taking iodine cures some and prevents almost all; again a public health approach is essential.

VIII.62
Gonorrhea

The name *gonorrhea,* which means "flow of seed," and its vernacular counterparts ("clap," "dose," "strain"), reflect a hazy comprehension of the disease. The only accurate term in common use is "drip," which acknowledges the white-to-yellowish milky discharge from the male penis. But even this more honest description includes only the male urethral portion of a broader syndrome.

Gonorrhea is an infection of mucosal surfaces caused by a small gram-negative bacterium – the gonococcus – whose only reservior in nature is human. Its presence in the lower male or female genital tract defines the condition gonorrhea; otherwise, the adjective "gonococcal" is used to precede a generic infective syndrome (as in "gonococcal endocarditis"). Though gonorrhea is transmitted primarily to genital mucosa through sexual contact, it may cause localized abscesses or generalized dissemination, with infection of the skin, heart valves, joints, and central nervous system. It is rarely the cause of

death, but, if untreated, it produces serious sequelae in both men and women.

The gonococcus, *Neisseria gonorrhoeae,* shares an ecological niche with other sexually transmitted pathogens such as *Chlamydia trachomatis, Ureaplasma ureslyticum,* and *T-mycoplasmas.* It depends for its survival on variable virulence, sufficient numbers of asymptomatic infectees, an ability to produce a rapid genomic response to antibiotic pressure, a symbiotic relationship with new pieces of genetic material (called *plasmids*), and propitious set of social and sexual mores among its hosts. As history demonstrates, this seemingly delicate balance has been universally available.

Etiology and Diagnosis

The causative agent of gonorrhea is the gonococcus (*N. gonorrhoeae*) – a small, diplococcus whose flattened apposing surfaces, tinctorial properties (when stained by Gram's method), and association with polymorphonuclear leukocytes provide a typical microscopic picture. In certain sites (e.g., urethra, joint, cerebrospinal fluid, ocular conjunctiva), demonstration of the typical morphology is virtually diagnostic. From other sites (rectum, pharynx), however, the possible presence of other gonorrhea types renders the Gram-stained smear less sensitive. For all sites, culture of the organism on artificial media is required for diagnostic assurance. Confirmation requires typical morphology, demonstration of indophenol oxidase production, and the ability of the organism to metabolize glucose, but not fructose, maltose, sucrose, or mannitol.

Clinical Manifestations

Genital Site Infections in Men and Women

Pus issuing from the penile opening, often accompanied by discomfort, pain, or burning on urination, is the most frequently recognized clinical manifestation of gonorrhea. The gonococcus adheres to cells that line the distal urethra, establishing – in the symptomatic individual – an inflammatory reaction and the subsequent outpouring of polymorphonuclear leukocytes. (This primary pathological process is basically the same at all mucosal sites of infection.) Though the majority of men will become symptomatic 3 to 5 days after adequate exposure, the clinical spectrum varies. In perhaps one-quarter of patients, pain or discharge will be attenuated or subsymptomatic (i.e., insufficient to cause the patient to seek medical care). In addition, a substantial proportion of men with gonorrhea will be asympto-

matic. Before the advent of antibiotics, the major sequelae of male urethral infection were postinflammatory fibrosis and stricture of the urethra. Such complications are now rare.

Though women have long been known to harbor the organism, only recently have distinct clinical syndromes been identified. Part of the delay is due to the fact that asymptomatic infection probably occurs more frequently in women, and little clinical attention is paid to the "normal" vaginal discharge. Infection of the female urethra occurs in 70 to 90 percent of women with gonorrhea, but rarely in the absence of concomitant infection of the endocervix. The more important lower tract manifestation of gonorrhea in women is infection of the uterine cervix. A syndrome of purulent or mucopurulent endocervical discharge characterizes the infection. Though the clinical diagnosis may be complicated by the coexistence of infection with other pathogenic organisms, cervical mucopus is clearly not "normal" and requires systematic bacteriologic investigation.

Both sexes contract anal and throat infection from direct exposure to infected penile secretions. Both are associated with symptoms in a minority of cases. Asymptomatic rectal infection probably plays a major role in transmission. Throat infection is of minor importance, except as a site for dissemination of the gonococcus into the bloodstream.

Pelvic Inflammatory Disease (PID)

Perhaps the major modern concern about gonorrhea is its potential for destruction of female reproductive organs. The gonococcus may spread upward from the cervix to inflame the uterine lining of the fallopian tubes (salpingitis) and ultimately cause peritonitis. Once established, PID becomes chronic, of long duration, and with serious consequences. Approximately 20 percent of women will have a recurrence after treatment for a primary episode of gonococcal PID. The syndrome of chronic pain, lower abdominal discomfort, and dyspareunia reflects insidious scarring and closure of the fallopian tubes, which may cause ectopic pregnancy and lead ultimately to involuntary infertility. Studies in Sweden indicate that the risk of sterility is 12 to 16 percent after a single episode of salpingitis and rises to 60 percent after three episodes.

Disseminated Gonococcal Infection (DGI)

An uncommon but distinctive picture appears when the gonococcus is spread via the bloodstream. The classic picture includes (often) asymptomatic infection of the pharynx, penis, vagina, or rectum in association with characteristic skin lesions and arthritis. The skin lesions are small, hemorrhagic areas with necrotic centers, and generally number fewer than 20. The infected joint(s) usually exhibit(s) the four classic features of arthritis: swelling, redness, pain, and heat. The knee is most frequently involved, followed by elbows, ankles, wrists, and small joints of the hand. Patients with DGI usually respond well to routine treatment and rarely suffer long-term musculoskeletal complications.

Other Clinical Manifestations

A variety of other rare infections with the gonococcus have been documented. Adults occasionally develop gonococcal conjunctivitis, with a potential for more serious ocular involvement, through direct (i.e., hand-to-eye) contact with infected secretions. Gonococcal endocarditis, myocarditis, hepatitis, and meningitis may occur as part of the disseminated syndrome. *Perihepatitis* (termed the *Fitz–Hugh–Curtis syndrome*) has traditionally been attributed to gonococcal infection in the upper right quadrant, usually in association with classic PID. Recent evidence, however, indicates that the syndrome is more often associated with chlamydial, rather than gonococcal, infection.

Gonococcal Infection in Children

The other major mode of transmission of the gonococcus is from mother to child. A newborn may become infected during passage through an infected birth canal, and the most common clinical manifestation is gonococcal ophthalmia. The typical syndrome includes the development of purulent discharge from one or both eyes with relatively rapid progression, in the untreated child, to more generalized ocular involvement, scarring, and blindness. The use of routine eye prophylaxis with silver nitrate (see discussion under History, below) was a landmark in preventive medicine and greatly reduced the occurrence of this syndrome. Children may develop gonorrhea in sexual sites as well. It has become apparent, in recent years, that the majority of infected children have suffered sexual abuse. In boys, symptomatic or asymptomatic anogenital infection may occur. In girls, the primary manifestation is a vulvitis, because the prepubertal cervix is not an adequate milieu for survival of the gonococcus.

Classification, Immunology, and Pathology

The importance of gonorrhea is measured not only by its considerable burden of acute disease and long-term consequences, but also by some of its extraordi-

nary biological characteristics. The virulence of the gonococcus rests in its ability to adhere to muscosal surfaces, to resist immunological defenses, to cause asymptomatic infection, and to resist antibiotic killing. These qualities have been important in the development of four major classification schemes based upon the following:

1. The presence or absence of *pili* (long, filamentous projections on the surface of the gonococcus), which determine adherence to mucosal cells. Their presence is, in turn, reflected in the size, shape, and opacity of gonococcal bacterial colonies, and forms the basis for the earliest classification scheme used.
2. The nutritional requirements of the gonococci. Typing of organisms based on their need for certain amino acids (*auxotyping*) has determined the presence of special strains that are more or less sensitive to antiobiotics, and that have a greater propensity to cause disseminated infection.
3. The antigenic structure of the gonococcal cell envelope, which provides a mechanism for classification (*serovars*). Serovars have been used, in conjunction with auxotyping, to show patterns of distribution and to link cases epidemiologically.
4. Susceptibility to antibiotics. Four transferable pieces of genetic material (*plasmids*) have been identified, which have helped in geographic localization of cases.

These systems for classification reflect the considerable pathogenetic repertoire available to the gonococcus. In contrast, the immunologic armamentarium of the host seems inadequate. Genital secretions may have some inhibitory effect on gonococci in vitro, but are not protective. Local immunoglobulin production has been demonstrated but may be counteracted by protease produced by the gonococcus. Serum antibody is usually demonstrable in previously infected persons, but resistance to serum killing is a typical feature of freshly isolated gonococci. Indeed the net result of studies to date simply reflects the time-honored observation that people may contract gonorrhea again and again. There is no apparent protective human immunity. The existence of asymptomatic infection, and the apparent immunologic tolerance of the host, may account in part for the ecological success of the gonococcus.

Distribution and Incidence

Gonorrhea is found worldwide, but documentation of its true extent is lacking. Direct comparisons of incidence among nations are difficult to make because of the wide variation in clinical and diagnostic facilities, the extent of disease reporting, and the degree of care given to case finding. The disease is widespread in both the industrialized and the developing world, but it is likely that the burden on developing nations is greater. It is estimated that the incidence in some large African cities may be as high as 3,000 to 10,000 per 100,000 population. Because gonorrhea is, in principle, a disease of high incidence and low prevalence, it is noteworthy that surveys of women attending prenatal and family planning clinics in Africa disclose a prevalence as high as 17 percent. Among prostitutes in Latin America, Asia, and Africa, the prevalence of gonorrhea may be 30 to 50 percent. These are, of course, occasional surveys of selected populations, but, in the absence of systematic information, they provide some sense of the magnitude of the problem.

A number of industrialized nations, on the other hand, do have systematic reporting of gonorrhea. Routinely collected statistics have permitted documentation of the major epidemiological event in the history of gonorrhea: a worldwide pandemic that began in the late 1950s and peaked in the mid-1970s.

A comparison of disease rates in the United States, the United Kingdom, Sweden, and Canada (Figure VIII.62.1), all of which have advanced
Figure VIII.62.1. Gonorrhea incidence in selected countries, 1940–83. (From R. C. Barnes and K. K. Holmes. 1984. Epidemiology of gonorrhea: Current perspectives. *Epidemiological Reviews* 6: 1–30; 3, fig. 1, by courtesy of *Epidemiological Reviews* and the *American Journal of Epidemiology*.)

health care systems, indicates a rise in gonorrhea occurrences after World War II, with a subsequent fall to a nadir in the mid-1950s. Though varying in size and timing, an increase in gonorrhea throughout the 1960s, with termination of the accelerated rise by the mid-1970s, was experienced by each nation. The graph is representative of the situation for most industrialized countries during the interval, and conveys the disparity with which nations were apparently affected. At the peak, in the mid-1970s, rates among industrialized nations differed by as much as 10-fold. (By contrast, rates among developing nations during the interval differed even more wildly, but here the variation in reporting clearly plays an important role.)

The impact and specific features of the pandemic may be demonstrated by examining the history of the disease in the United States during this period. Between 1956 and 1985, rates of gonorrhea increased in all age groups for both men and women (Figure VIII.62.2). Rates for females are higher at younger ages, and peak at ages 15 to 19 years. Rates for males peak at ages 20 to 24, producing a crossover pattern (Figure VIII.62.3). The origin of this increase, and of the pandemic in general, is not fully understood. It is often attributed to changes in sexual mores during the 1960s and 1970s, with major increases reported in the frequency of premarital sexual experiences by both men and women, a greater availability of contraceptive technology, and an increase in the number of individuals entering the age of sexual activity (the so-called baby boom generation).

It is likely that the pandemic has not yet had its full impact on the developing world, though the peak in industrialized nations seems to have passed. If so, the burden of morbidity, long-term sequelae, and mortality will continue to have a major influence on

80 percent of the world's population in the coming years.

History

Gonorrhea is the oldest, as well as the most common, of the venereal diseases. An Egyptian papyrus from approximately 3500 B.C. prescribes plant extracts to soothe painful urination. The Hebrew *Bible* makes reference to treatment of genital exudates, which may well refer to gonorrhea. Hippocrates recognized the venereal nature of transmission at about the beginning of the fourth century B.C., and Galen, in the second century A.D., is believed to have coined the name. In the fourteenth century, a description of the ailment that stressed a major symptom, *chaude pisse,* or "hot piss," led to the disease's receiving this appellation from the French.

By 1500 or so, interest centered on the distinction between syphilis and gonorrhea. The majority opinion appeared to favor the notion that they were different manifestations of the same disease, particularly because syphilis was so clearly protean in its manifestations. However, in the middle of the sixteenth century, a French physician, Jean Fernel, wrote of gonorrhea as a separate disease from syphilis in his *Medicina.* The British physician Francis Balfour, writing two centuries later, has also been credited with the belief that syphilis and gonorrhea were distinct.

Confusion set in, however, following John Hunter's argument that the cause of both diseases was the same and that gonorrhea was a manifestation of the disease on a secreting surface (mucosa) whereas syphilis was its manifestation on a nonsecreting surface (skin). To prove this, he infected himself with pustular discharge from a patient he thought had gonorrhea, and developed syphilis instead. The patient may have been dually infected, but at any rate,

this was an unfortunate instance of a brilliant and heroic use of the scientific method gone wrong, and it postponed scientific understanding of the two diseases for decades.

It was during this same period (1760–90) that the most lucid literary account of gonorrhea appeared. James Boswell, the biographer of Samuel Johnson, kept a meticulous diary of his own repeated encounters with gonorrhea. The diary details the clinical manifestations and psychological effects of 19 episodes. There is little question of the impact of gonorrhea on his life, and, by extension, on the life of countless others in the era. He is believed to have died of gonorrheal complications.

In the 1790s, Benjamin Bell of Edinburgh, who was in disagreement with Hunter, published several tracts that explored the clinical and epidemiological evidence for gonorrhea and syphilis as separate disease entities. He posed a number of simple questions: Why is gonorrhea more common when the skin of the penis is at greater risk of exposure than the urethra? Why are there geographic differences in the distribution of the two diseases? Why have their manifestations appeared in the same populations at different points in time?

It remained, however, for Philippe Ricord, in a series of clinical observations and direct experiments in the mid-1800s, to provide a definitive distinction between the two diseases. It is of interest that Ricord commented that there is no justification for experimentation with grave diseases in human beings, although he inoculated 17 prisoners with gonorrheal pus, producing occasional ulcers with prompt healing, but no evidence of syphilis.

In 1879, Albert Neisser, an assistant in dermatology at the University of Breslau, Germany, published his preliminary findings which confirmed the conclusions of Ricord by describing the organism that now bears his name. This was probably the second description of a major human pathogen (after Koch's identification of the anthrax bacillus 3 years earlier). In 1882, the organism was first grown in vitro by Ernst von Bumm. The first major preventive action was taken in the following year when Karl Siegmund Credé, at the Lying-In Hospital in Leipsig, recognized the benefit of instillation of 2 percent silver nitrate solution (later reduced to 1 percent) in the eyes of newborns. The occurrence of gonococcal ophthalmia diminished rapidly with the widespread adoption of this procedure.

Unfortunately, advances did not follow in rapid succession. In fact, after the initial diagnostic procedures were established, there were no major improvements in the understanding of gonorrhea until the sulfonamides (e.g., sulfamidochrysoidine, Prontosil) were introduced in 1937. This success was short-lived, and true antibiosis for gonorrhea appeared only in the 1950s with the general availability of penicillin. The next critical breakthroughs were the description of the different colonial morphologies by Douglas S. Kellogg et al. in 1963 and the development of a selective medium for culturing the gonococcus by James D. Thayer and John E. Martin in 1964. Subsequent events, including the worldwide pandemic of the 1960s and 1970s, and the major advances in immunology and molecular biology, were alluded to earlier. Clearly, it is only in recent times that gonorrhea's effect on us, and in turn, our ability to alter its course, have dramatically changed.

Geography

Through gonorrhea is found worldwide, the lack of systematic data precludes meaningful global mapping. But even if national rates were universally available, a local approach might be more informative. In its transmission, its endemicity, and its continued propagation, gonorrhea is a neighborhood disease. An understanding of the local geography is predicated on a coherent theory for transmission.

Epidemiology

The clinical epidemiology of the classic gonorrhea syndromes forms the basis for the population epidemiology of the disease. Gonorrhea is transmitted by sexual contact. The probability of transmission from male to female after a single contact is approximately 50 percent; from female to male, 22 percent. The incubation period is 3 to 5 days in men and slightly longer in women. A significant proportion of both sexes never becomes symptomatic. The incidence of disease in a given community, then, is a function of two major parameters: (1) the degree of sexual interaction, which includes the frequency of new partners, as well as the duration, intensity, frequency, and logistics of sexual contact; and (2) the duration of infectiousness, which takes into account the proportion of asymptomatic infection, the proportion of a population that will seek health care, the adequacy of therapy, and the extent to which sex partners are apprised of their risk. Clearly, the final epidemiological picture will be a complex interaction of biological, social, and individual events. In general, however, gonorrhea is a disease of high incidence but short duration and, hence, of low prevalence.

Transmission Dynamics

Beginning in the early 1970s, mathematicians Herbert Hethcote and James Yorke constructed a theoretical framework for the transmission dynamics of gonorrhea. Using some of the concepts of population ecology, they noted that the reproduction rate for gonorrhea (i.e., the ability of an infected person to replace him- or herself) must be determined when the disease is at endemic equilibrium. In the steady state, therefore, each infected person must have two "adequate" contacts for transmission on average ("adequate" means that the gonococcus is transmitted). There must be a "source" contact and a "spread" contact for disease propagation. Because not all sexual contacts are "adequate," it follows that the average number of total contacts must be greater than 2.

In constructing a model of transmission dynamics, several key epidemiological observations must be considered:

1. Gonococcal infection does not confer protective immunity; thus an individual is "immune" only when infected.
2. Individuals become infectious soon after exposure; there is, then, no "exposed, incubating" group to be considered in a model.
3. Seasonal variation of gonorrhea is well defined, with a peak in late summer in temperate climates, but the variation is small (about 10 percent) in comparison with other diseases. This implies that the parameters used in the model can be constant.
4. Data derived from interviewing gonorrhea patients about their sex partners suggest that the average number of "adequate" contacts is well below 2. In 1985, there were only 0.3 infected contacts found for each person with gonorrhea interviewed. Even with allowances for slippage in the system of interviewing cases, finding contacts, and bringing them to medical examination, this is far below the two infected contacts per case needed to maintain a reproduction rate of 1 and to preserve endemic equilibrium.

It was reasoned, then, that the observed number of infected contacts per case is a weight average of two groups: (1) those for whom one or no contacts were identified (*nontransmitters*); (2) those with two or more contacts identified (*transmitters*). Those in the first group – the vast majority of gonorrhea infectees – were unlikely to pass the infection to another person. Hethcote and Yorke hypothesized that the transmitters – those who actually main-

tain the endemicity of gonorrhea – were drawn from so-called *core groups*. These groups were defined as persons with stable sociodemographic and geographic characteristics who constituted a small minority of cases (under 5 percent), but who accounted – either directly or indirectly – for most gonorrhea transmission. It is within such groups that the epidemiological features of gonorrhea (no immunity, immediate infectiousness, year-round transmission) were fully operative. The limit to gonorrhea spread within a core group was termed the *saturation effect*: that is, sexual contact between infected persons.

In a series of elegant mathematical discussions, Hethcote and Yorke developed a model for the dynamics of transmission based on population compartments that included core and noncore groups. They were able to demonstrate the plausibility of an equilibrium state in which most cases were attributable to small groups of active transmitters. Parallel with this theoretical development, some empirical evidence for the physical existence of core geographic areas and definable core groups emerged.

It was shown in 1979, based on the routine reporting of gonorrhea morbidity data, that the city of Denver contained four different areas with high concentrations of infectees (see Figure VIII.62.4). Each geographic area housed a distinct population subgroup: black heterosexuals, Hispanic heterosexuals, white homosexual men, and military recruits.

Through analysis of over 120,000 geocoded cases
Figure VIII.62.4. Distribution of gonorrhea in Denver, Colorado, 1974–6. [From R. B. Rothenberg. 1979. Analysis of routine data describing morbidity from gonorrhea. *Sexually Transmitted Diseases* 6(1): 5–9; 6, fig. 1, by courtesy of Lippincott/Harper & Row, Philadelphia, Penna.]

of gonorrhea in upstate New York from 1975 to 1980, a general geographic pattern emerged. Within all 12 Standard Metropolitan Statistical Areas (SMSAs, the urban centers), there was intense concentration of gonorrhea in a small number of contiguous census tracts (core areas) within the inner cities. In a concentric circle surrounding the core were a group of census tracts with somewhat lessened gonorrhea rates (adjacent areas). The rest of the SMSA constitutes the peripheral area, with a markedly diminished gonorrhea burden. The concentration of gonorrhea in the core area was 20-fold higher than that for New York State in general, and several of the census tracts in the core had rates that were 40-fold higher. Not only was this pattern repeated in all SMSAs, but all the core areas were similarly characterized by high population density and low socioeconomic status. The geographic configuration for Buffalo, New York, is typical (Figure VIII.62.5).

This pattern was also documented in Colorado Springs, Colorado, using data collected from inter-

views of 97 percent of the cases that occurred during a 6-month interval. Again, clustering of over 50 percent of the cases was demonstrated in about 5 percent of census tracts. Social aggregation of cases was demonstrated by the consistent use of six drinking establishments by a major proportion of infectees, and by the aggregation of patients and their sexual partners in the same census tracts. Contrary to commonly held belief, the majority of sexual partners had known each other socially prior to sexual contact. The interconnection of individuals in networks could be demonstrated through linkage provided by the interview process. Further analysis demonstrated that the core groups in Colorado Springs generated a high *force of infectivity* (i.e., days of potential transmission in infected exposed partners),

Zenilman et al. 1988. Penicillinase-producing *Neisseria gonorrhoeae* in Dade County, Florida: Evidence of core-group transmitters and the impact of illicit antibiotics. *Sexually Transmitted Diseases* 15: 45–50; 47, fig. 2, by courtesy of Lippincott/Harper & Row, Philadelphia, Penna.)

and had a heightened degree of sexual interaction both inside and outside their core groups.

Similar geographic clustering was documented in Seville, Spain, where it was noted that all the STD syndromes appeared to exhibit a similar geographic pattern. The presence of penicillin-resistant *N. gonorrhoeae* has provided a convenient marker for the demonstration of core-group aggregation as well. In an initial outbreak reported from Liverpool in 1976, clustering of cases occurred within two small inner-city districts. In Miami, a major endemic area for resistant gonorrhea in the United States, the clustering of resistant cases within presumed core-group areas paralleled that for all of gonorrhea (Figure VIII.62.6).

It cannot be assumed that the geographic characteristics displayed in these examples are universal. In particular, differences in human ecology and sexuality in developing countries may dictate a different pattern, and data are not yet available. It might tentatively be concluded, however, that a concentric pattern of gonorrhea risk, which diminishes outward from the central inner city, exists in many major urban areas. The potential for use of geographic patterns in the development of disease control strategies, and in the understanding of other sexually transmitted syndromes, is an area for further development.

VIII.63
Gout

Gout is a chronic, intermittently symptomatic disease. It is manifested primarily by small numbers of acutely painful swollen joints that result from an inflammatory reaction to the precipitation of crystals of monosodium urate.

Etiology

The predisposing metabolic factor for *primary gout* is an abnormally high or rapidly changing concentration of uric acid in the blood. *Hyperuricemia* may result from an accelerated synthesis of uric acid, or decreased excretory capacity for uric acid in otherwise normal kidneys as a result of unidentified but probably heritable causes. Hyperuricemia leading to *secondary gout* occurs particularly (1) in diseases of the blood-forming tissues that increase the availability of precursors of uric acid; (2) in kidney failure, which limits the excretion of uric acid; or (3) as a

result of medications that either accelerate the breakdown of purine-rich cells (e.g., antineoplastic drugs) or interfere with the renal excretory mechanism (e.g., some diuretics). Dissolved in the serum, uric acid is harmless. However, because of unidentified local circumstances it may leak from capillaries and crystallize. The crystals of monosodium urate elicit the inflammatory reaction, which is the *gouty attack*, and the microscopic identification of the crystals in synovial fluid confirms the diagnosis. Why this inflammation occurs predominantly in joints, and why much more commonly in some joints (such as those of the feet or in the knee) than in others (such as the hip or those of the vertebral column) are unexplained characteristics. Unexplained as well is the question why *tophi*, which are urate deposits that form beneath the skin, are usually painless and the antiuricemic effect of estrogens.

Clinical Manifestations

Fully 90 to 95 percent of patients are male, and gout rarely develops in women before menopause. The first attack most often occurs in the fifth decade in men and in the sixth decade in women. The rate of production of uric acid and, related thereto, the onset of primary gout, thereafter diminishes.

The normal uric acid content, the "miscible pool," in men is about 1.2 grams, and in women, 0.6 grams (Seegmiller, Laster, and Howell 1963). Because of an imbalance between synthesis and excretion, uric acid accumulates in part as the subcutaneous deposits called tophi. About 50 percent of untreated patients have tophi 10 years after their first attack of gout. Thus 53 percent of the cases seen in the Mount Sinai Hospital (New York) Gout Clinic during 1948–53 had tophi, whereas tophi were found in only 14 percent of the cases of gout first seen at the Mayo Clinic in 1949. The difference presumably was the result of referral bias. However, the incidence of tophaceous gout has decreased steadily in both institutions: In New York during 1969–73, it was 17 percent of all gout patients, and at the Mayo Clinic in 1972 it was only 3 percent (Yu 1984). Statistics of cases gathered in London during 1958–67 revealed that 21 percent had tophi, whereas 28 percent of cases seen at a German health resort during 1955–64 had tophaceous gout.

Next to tophi the most common uratic manifestation of gout is kidney stones (*nephrolithiasis*). This association has been noted since at least the sixteenth century. Uric acid stones constitute no more than 5 percent of all kidney stones, but about 80 percent of calculi in cases of gout. How close the

relationship between gout and urate nephrolithiasis may be is uncertain. Although 22 percent of the 1,258 New York gout patients studied by T.-F. Yu and A. B. Gutman (1967) had renal calculi at some time, this condition antedated the first attack of gout in 40 percent, and in 14 percent the delay was from 11 to 39 years. The probability of nephrolithiasis is correlated with the serum urate content. Thus, 15 percent of their total cases of gout had serum urate of less than 8 milligrams per 100 grams of blood (mg%) without treatment, and nephrolithiasis developed in 15 percent of these; in 32 percent of the gout patients the urate concentration exceeded 10 mg%, and 43 percent of these had nephrolithiasis. In other large series of cases of gout, nephrolithiasis has ranged from 28 percent (German spa) to 4 percent (San Francisco private practice) (Table VIII.63.1).

Allopurinol therapy, which reduces the uric acid pool, decreases the incidence of uratic kidney stones and has the same effect in nongouty urate hyperexcretors who have a history of calcium stone formation.

History

For many centuries the term *gout* and *podagra* were as nonspecific as *arthritis* is in modern usage. The clinical differentiation of the disease was begun in the late seventeenth-century works of Thomas Sydenham, although his contemporary, Anton van Leeuwenhoek, using his simple microscope, described the appearance of crystals from a tophus. Nearly a century later, in 1776, Karl W. Scheele, a Swedish pharmacist, discovered an organic acid in urinary concretions which for that reason he called lithic acid. In 1797, at Cambridge, William H. Wollaston analyzed tophi and found that they contained "lithic acid." In 1798, this substance was renamed *acide ourique* by the French chemist Antoine F. de Fourcroy because he also found it to be present in normal urine.

Another half century passed before uric acid was shown to be even more intimately related to gout. In 1847 and in 1854, London physician Alfred B. Garrod devised two tests whereby uric acid could be detected in blood in hyperuricemic states such as gout and uremia. He also demonstrated urate in subcutaneous tissues and articular cartilage in cases of gout. Garrod hypothesized that gout might result either from a loss of renal excretory capacity or from increased formation of uric acid. A century after the publication of his 1859 monograph on gout, both concepts were proved to be correct. In 1876 Garrod

[a]Autopsied cases.

also postulated that acute gout results from the precipitation of sodium urate in a joint or adjacent tissue. This was proven in 1962 by the elicitation of gouty inflammation following the injection of suspensions of sodium urate crystals into human and canine knee joints (Rodnan 1965).

Beginning in 1871 numerous gravimetric assays of urinary uric acid were devised, but none was sensitive enough to be applicable to the much smaller concentration in the blood. The wide variations of uric acid excretion and the lack of understanding of uric acid metabolism cast doubt on the causative relationship of uric acid to gout. Two paradoxical effects on clinical practice resulted. One was that the old belief in "retrocedent" or "anomalous" gout – the idea that a wide variety of symptoms or diseases are caused by a "gouty poison" – gained new adherents. The other was that clinicians virtually ceased making the diagnosis of gout. For example, at the Johns Hopkins Hospital (Baltimore), only 42 cases were admitted with this diagnosis during 1889–1903. At the Massachusetts General Hospital, only 9 cases of gout were found among 1,033 medical admissions for rheumatic diseases during 1893–1903 (Benedek 1987). Likewise, at a hospital in Cologne the diagnosis of gout was made only 14 times among 23,870 medical admissions (0.06 percent) during 1895–1900. However, in that hospital the diagnosis was made in 10 cases or 0.35 percent of the admissions during the first year that Oscar Minkowski, who was interested in this disease, was in charge of a medical service.

The Devonshire Royal Hospital in England represented the other extreme. During 1896–1900, gout was diagnosed in 2.42 percent of 14,224 admissions (324 male, 20 female); during the next 5-year period, with changes in the physician staff, the frequency of the diagnosis more than doubled to 5.26 percent of 15,836 admissions (743 male, 91 female) (Hill 1938). Clearly, such data do not prove the traditional impression that gout was peculiarly prevalent in England but, rather, suggest that the diagnosis was being made or missed very subjectively.

The first practical colorimetric technique sensitive enough to detect normal concentrations of uric acid in blood was devised by Otto Folin at Harvard University in 1912. Its sensitivity was gradually improved so that in 1938 the uric acid content of the blood was shown to be greater in men than in women, thereby correlating with the rarity of gout in women. However, physicians continued to be poorly aware of true gout. Philip Hench (1936) commented on this as follows:

If more than 50–70% of his patients have tophi he is too exclusive and is probably omitting cases of bona fide (even if pretophaceous) gout. If less than 35–40% have tophi or if more than 2–5% are females he is too inclusive, diagnosing gout where it does not exist.

Methodological specificity in uric acid determination was achieved in 1953 with a technique that employs the enzyme uricase. Nevertheless, most laboratories continue to use less specific methods

that lend themselves to automation and give some-what higher than "true" values (Benedek 1987).

Treatment

Therapy of gout has two components: (1) treatment of the acute attack and (2) prophylaxis, which seeks to decrease the uric acid pool of the body. The former has always been predominantly medicinal, whereas the latter has been both dietetic and medicinal. Colchicum in the form of various alcoholic or aqueous extracts from the bulb, stem, or seeds of the meadow saffron came into use in the second decade of the nineteenth century in France and England. It was included in the *Dispensatory of the United States of America* in 1836, although its use was advocated somewhat earlier. Hesitation about using colchicum was due to recognition of its toxicity, as manifested by severe diarrhea, which also was believed to be the mechanism of its therapeutic effect. The active component, colchicine, was isolated in 1820. Colchicine was available in pill form by 1900, but crude tinctures were still in use in the 1950s (Rodnan and Benedek 1970).

Until about 1910, when cinchophen was introduced, colchicine was the only remedy for acute gout. Cinchophen not only was effective in the acute gouty attack but, in contrast to colchicine, also was an analgesic. Because of its chemical resemblance to salicylate, cinchophen was presumed to be tolerated better than colchicine, which it virtually replaced in the treatment of acute gout. However, by the 1930s it became evident that cinchophen may cause severe and even fatal liver damage. Hence, its use faded out over a decade, and colchicine again became the standard treatment.

The fact that both cinchophen and salicylates increased the renal excretion of uric acid and thereby reduced the uric acid content of the blood was discovered in 1913 and 1915, respectively, but was not adapted to therapy. Two pharmaceutical breakthroughs occurred in 1951. Probenecid, a drug that had been developed to retard the excretion of penicillin, was found to accelerate the excretion of uric acid. Although it has no analgesic or antiinflammatory effect, it was well tolerated and convenient to take. As it reduced the serum uric acid concentration, the frequency of gouty attacks diminished and tophi shrank. The other discovery was phenylbutazone, which proved to have therapeutic effects similar to cinchophen. Like probenecid, it increased the excretion of uric acid, but also like colchicine, it counteracted the acute attack, and it was a nonspecific analgesic as well. However, it proved to be toxic,

particularly to blood cell formation in elderly persons, and it has therefore fallen into disfavor.

Another pair of important pharmaceutical discoveries was introduced in 1963. Indomethacin effectively counteracts the acute gouty attack, and, although it does not alter the excretion of uric acid, it also does not depress blood formation; therefore, it gradually superseded phenylbutazone. Since then many other "nonsteroidal antiinflammatory drugs" have been found to be similarly effective. Allopurinol lowers the uric acid pool like probenecid, but by a different mechanism. It diminishes the synthesis of uric acid by inhibiting the activity of an enzyme (xanthine oxidase). Like probenecid, allopurinol is of no value in an acute gouty attack, but it has the advantages of effectiveness in the presence of renal failure, and the convenience of once per day dosage (Benedek 1987).

Dietetic attempts to treat or prevent gout are ancient. They were based on beliefs in the virtue of moderation in all things and, more specifically, in the belief that gout is caused in large measure by excesses in the consumption of food and alcoholic beverages. Aside from the demonstration in 1924 that starvation results in an increased blood uric acid concentration, scientific investigations of gout have been done only since the 1960s. The most important finding has been that circumstances that result in the formation of certain organic acids, particularly lactate and beta-hydroxybutyrate, block the excretion of uric acid and thereby increase the possibility that a gouty attack may occur. Starvation, substantial alcohol ingestion, especially without eating, and uncontrolled diabetes mellitus are such conditions.

Uric acid found in the body is not absorbed as such, but is synthesized from breakdown products of various foodstuffs, particularly those that are rich in nucleoproteins (Seegmiller, Laster, and Howell 1963). A low-fat, largely vegetarian (60 g/day protein) diet reduces the serum uric acid concentration by 1 to 2 milligrams below that found in a more typical American diet (Gutman and Yu 1955). The effect such diets have on reducing gouty attacks is equivocal. Since the advent of urate-depleting drugs such as probenecid and allopurinol, however, dietetic therapy has become irrelevant except for the general advantages of weight reduction for the obese gout patient.

Gout rarely is a direct cause of death, although premature death due to diseases with which gout is associated (principally hypertensive or arteriosclerotic cardiovascular disease) is fairly common. For reasons that are unclear, untreated hypertension

with grossly normal renal function is frequently associated with hyperuricemia. Because treatment of hypertension usually includes drugs that interfere with the excretion of uric acid, hyperuricemia is greater and more prevalent in treated than in untreated hypertensive patients. Thus, according to a survey in London, 31 percent of untreated hypertensive men and 23 percent of untreated hypertensive women had hyperuricemia, 12 percent having had attacks of gout, whereas 59 percent and 57 percent, respectively, of hypertensive men and women under treatment were hyperuricemic (Breckenridge 1966). Conversely, in a series of 354 gout patients in London, 52 percent had a diastolic blood pressure in excess of 90 millimeters (Grahame and Scott 1970), and of the cases studied by Yu (1984) in New York, 30 percent were considered hypertensive. Hyperlipidemia appears not to be correlated directly with hyperuricemia. Rather, both are associated with hypertension and obesity. According to the Framingham study, angina pectoris is twice as frequent among gouty as among nongouty men (Abbott et al. 1988), and Yu found that the causes of death among 427 gout patients were cardiovascular in 66 percent of the cases (Yu 1984).

Epidemiology

When considering the epidemiology of primary gout, one must focus separately on hyperuricemia and the factors that influence it. Although a rough correlation does exist between the level of hyperuricemia and the likelihood of an attack of gouty arthritis, the predictive value is poor and appears to be worse in certain groups than in others. Of the measurable factors that affect the serum uric acid concentration, the most important are the protein content of the diet and overweight. Weight and the rate of uric acid metabolism are to some extent genetically predetermined. However, the immediate cause of a gouty attack remains unknown.

Worldwide the severity and prevalence of gout have changed paradoxically since the 1940s. In the highly developed countries, as a result of the advent of effective prophylactic drug therapy, the disease is now rarely disabling. Elsewhere, however, it has become more prevalent, predominantly as a result of "improved" diets. Unfortunately, there were no epidemiological surveys of serum uric acid or gout in primitive societies before the 1960s, so that hypotheses about whether ethnic differences are genetic or the result of recent environmental changes are weakened by a lack of baseline data. The different biochemical techniques that have been used intro-

duce another obstacle to any comparison of data from various surveys.

The prevalence of gout that is reported depends on the diagnostic criteria used; on the population from which the cohort is drawn; and on whether the diagnosis is based on questionnaires or on single or repetitive examinations. For example, a predominantly younger population can be expected to have a lower prevalence of gout than one with a higher mean age; a workforce may have a lower prevalence than a random sample that may include persons who are disabled by gout and associated diseases. Secondary gout, in which the disease results from (1) accelerated purine metabolism inherent in another disease, usually of the blood, (2) diminished excretion of uric acid resulting from renal failure, or (3) effects of toxins such as lead, is not an epidemiological confounder because these circumstances are readily identified and uncommon. At present, secondary gout arises most frequently as an incidental effect of certain antihypertensive medications.

United States and Europe

Only a few of the larger American and European surveys of serum uric acid values will be cited. In a survey in Tecumseh, Michigan, 9.2 percent of men over 20 years of age had uric acid values greater than 7.0 mg%, and 8.7 percent of the women had values greater than 6.0 mg% (Mikkelsen, Dodge, and Valkenburg 1965). In Framingham, Massachusetts, 4.8 percent of men and 3.3 percent of women met this criterion (Hall et al. 1967). Racial comparisons in rural Georgia (31 percent black men, 35 percent black women) revealed no racial differences in mean uric acid values. However, the prevalence of hyperuricemia was high, ranging from 13.6 percent for white men to 21.1 percent for black women. This was attributed largely to the association between hypertension and hyperuricemia and the use of antihypertensive medications (Klein et al. 1973). A comparison of uric acid values between white U.S. and Brazilian male military recruits showed Americans to have higher uric acid concentrations: mean 4.87 mg% versus 4.05 mg%, with 3.26 percent versus 0.35 percent having a value above 7.0 mg%. The difference correlated best with the 17 percent greater mean weight of the Americans (Florey and Acheson 1968).

Several American surveys have compared the serum uric acid levels of executives and either lower-level employees or age-matched general population samples. The executives have consistently been found to have higher mean urate concentrations and

a larger proportion of cases of hyperuricemia (Montoye et al. 1967). This finding, which has been inconsistently confirmed in Europe, has not been explained by differences in physiognomy, blood pressure, or medications.

In a survey of nearly 24,000 men in Paris, 17.5 percent were found to have a uric acid value of 7.0 mg%, and 9.9 percent with a value of 7.5 mg% (Zalokar et al. 1972). Two English studies gave results more consistent with U.S. findings, with 7.2 percent and 10.8 percent of men having concentrations of 7.0 mg%. In Finland, 5.2 percent of men and 3.5 percent of women had uric acid values of 7.0 mg% and 6.0 mg%, respectively (see Table VIII.63.2). The relation of uric acid values to nutrition was demonstrated epidemiologically by an investigation conducted in East Germany from 1969 until 1980 with samples of 726 to 1,199 adults. During these 12 years the mean serum urate content increased by about 50 percent (4.2 mg% to 6.3 mg% in men; 3.4 mg% to 5.2 mg% in women), and the percentage with hyperuricemia increased from 2.4 to 29.0 in men and from 1.8 to 19.7 in women. These changes correlated well with increases in the meat consumption of 37 percent and

alcohol consumption of 68 percent (Thiele and Schroeder 1982).

A study based on the records of general practitioners in Great Britain showed the prevalence of gout over the age of 15 years to be 7.3 per 1,000 males in England, but only 2.8 per 1,000 in Scotland. Among females the prevalence was 1.3 and 0.7 per 1,000 in England and Scotland, respectively (Currie 1979). A survey among men between the ages of 45 and 74 in three English towns demonstrates that not only sex and age distribution but also how data are obtained influence the results. A simple questionnaire was mailed to over 15,000 men, of whom two-thirds completed it. In the three communities, 3.9 percent, 4.5 percent, and 4.8 percent (average 4.4 percent) claimed to have gout, which was more than three times the prevalence for age-matched English men obtained from physicians' records (Gardner et al. 1982).

In the Framingham investigation, gout was diagnosed in 2.8 percent of the men and 0.4 percent of the women (Hall et al. 1967). The biennial incidence has been 3.2 per 1,000 men and 0.5 per 1,000 women (Mikkelsen, Dodge, and Valkenburg 1965). A survey

[a]Hall et al. (1967). [b]Zalokar et al. (1972).

of more than 4,000 employed men in Paris found that 3.5 percent reported a history of gout and 3.0 percent had been treated for this disease (Zalokar et al. 1972) (Table VIII.63.3). However, most investigations of adult male Caucasian populations have identified gout in less than 1 percent. A large survey of industrial workers in New York, for example, revealed no cases among women or among men under the age of 40, and a prevalence of only 0.12 percent above that age (Brown and Lingg 1961). No instances of gout were detected among nearly 3,400 persons above age 15 in Holland in 1954, or among 4,300 persons in Sofia, Bulgaria. In a small Finnish town, one case was found among 787 men and none in 1,048 women.

Non-Caucasian Populations

Reports of gout in non-Caucasian populations are relatively recent. The first case report pertained to a 31-year-old African servant who died of an infection in Edinburgh in 1807, where he had often been subject to severe pains that occurred about midnight in one or the other of his great toes. A medical missionary in Hawaii in the early 1830s reported that rheumatism frequently occurred there, and, although gout might also be expected to be common because of indulgent eating habits, the mild quality of the food suggested otherwise and was unlikely to promote

the disease. Similarly, a military surgeon in New Zealand in the 1850s found that although "rheumatic affections" were much more frequent among New Zealanders than among the English, gout was unknown. Hench, a leading expert, wrote in the 1948 edition of Cecil's *Textbook of Medicine* that gout "is common in England and France, less common but increasing in North America. Hebrews are affected, prosperous American Negroes occasionally." Eugene Traut, in his textbook on rheumatic diseases, stated similarly in 1952 that gout "is unknown in China, Japan, and the tropics. . . . It is rare in Negroes."

The extent to which such statements reflected either ignorance or changing circumstances cannot be ascertained. They clearly are incorrect now. The most ubiquitous factor to account for an increased prevalence of gout is the increased proportion of proteins in many diets, which increases the amount of uric acid that is synthesized. Comparisons of mean serum uric acid values of most adequately nourished populations worldwide give similar values. The exceptions remind us that there are unidentified, presumably genetic factors that result in differences among groups that would be assumed not to differ empirically. A comparative study between Blackfeet Indians in Arizona and Pima Indians in Montana provides an example (Table VIII.63.4). The mean urate concentration and the prevalence of hyperuricemia of the Blackfeet of both sexes were significantly higher than among the Pima. Furthermore, although a high degree of correlation between obesity and hyperuricemia generally is found, more of the Pima, especially the women, were obese.

It was noted coincidentally in Honolulu and Seattle in 1957–8 that an unusually high proportion of Filipino men who visited outpatient clinics had gout or hyperuricemia. In Honolulu, remarkably, in a study of 100 men over 40 years of age, fully half were found to be hyperuricemic, and 32 had clinical gout. Among admissions to the county hospital in Seattle during 64 months, new cases of gout were diagnosed in 2.5 percent of Filipinos and in 0.13 percent of all

Table VIII.63.4. *Serum uric acid in two American Indian tribes*

other patients. The high prevalence of gout among Filipinos living in Hawaii was confirmed by other data, such as the fact that, in a 16-month period, 20 of 24 health insurance claims for treatment of gout were submitted by Filipinos. The mean serum uric acid of Filipino men in Seattle, as in Honolulu, was significantly higher than that of other ethnic groups. This contrasted with a diagnosis of gout in 0.004 percent of admissions to the general hospital of Manila and a normal mean serum uric acid among Filipino men sampled at four sites in the Philippine Islands. This difference could not be attributed entirely to the larger mean body mass of the Filipinos who lived in Hawaii or Washington State (Healey et al. 1967).

Although the ability of gouty individuals to excrete uric acid generally is normal, when this function is challenged by administering a purine (urate precursor) load, individual differences in the maximum excretory capacity can be identified. In such a study, 4 of 13 nongouty Filipino men were unable to increase their excretion of uric acid. The other 9 Filipino and all 10 Caucasian men exhibited the normal response of approximately doubling the quantity excreted (Healey and Bayani-Sioson 1971). This observation led to the hypothesis that some ethnic groups, such as Filipinos, include an unusually large proportion of persons who have a relatively low genetically determined limit to their renal excretory capacity for urate. As long as such individuals consume a low-protein diet, such as many of the Asian rice-based diets, or diets based on yams, their excretory mechanism is not saturated, serum urate remains in the normal range of Caucasians, and gout rarely occurs. When the protein consumption of persons with this latent defect increases – that is, as their diet becomes "Westernized" – the excretory capacity is overwhelmed, urate accumulates, and gout becomes more frequent.

There is a marked difference in the prevalence of hyperuricemia between Caucasian and various Pacific island populations. When 7.0 mg% and 6.0 mg% are used as the upper limits of normal for men and women, respectively, less than 10 percent of most unselected Caucasian populations, but more than 40 percent of many Pacific populations, exceed these values (Table VIII.63.2). Many surveys have been conducted since the 1960s: among Maoris in New Zealand, Polynesians on Rarotonga (south of Samoa) and in the Cook Islands, Micronesians in the Marianas and Nauru, Melanesians in Samoa, among others. The hyperuricemia cannot be attributed entirely to dietary changes, as discussed in regard

to Filipinos, nor is alcohol consumption necessarily a contributory factor. The highest prevalence of hyperuricemia has been found on the Micronesian island of Nauru (64 percent of men, 60 percent of women). The diet here, as among the Rarotongans and Samoans, had largely become Westernized by the time these surveys were conducted. However, disparate groups such as aborigines in northern Australia and natives of New Guinea and of the Tokelau Islands (north of Samoa) were hyperuricemic on their traditional diets. The complexity of the uricemia–gout relationship is illustrated by the unexplained observation that, although the New Zealand Maoris, Tokelauans, and Rarotongans have the same high prevalence of hyperuricemia, a fourfold difference exists in the prevalence of gout: 10.4 percent, 5.3 percent, and 2.5 percent, respectively (Prior 1981).

Nevertheless, a prospective study of gout in Maoris has shown a high correlation between the occurrence of acute gout and the level of uricemia (Brauer and Prior 1978). In 11 years, gout developed in 31 percent of men and 36 percent of women with a serum uric acid greater than 8 mg%, versus 2.8 percent and 0.6 percent, respectively, of subjects having uric acid concentrations below 6 mg% (Yu 1984). These data closely resemble the findings in Framingham, Massachusetts. In the larger sample of that community, clinical gout had developed in 36 percent of men with serum uric acid levels greater than 8 mg% and in 25 percent of women with a value greater than 7 mg% (Hall et al. 1967). The difference between these two cohorts lies in the 2 mg% greater mean serum uric acid content of the Maoris, and probably not in any other predisposing factor for the occurrence of gout.

Surveys in the early 1960s in the Osaka district of Japan showed a very low prevalence of hyperuricemia. Gout was diagnosed in 0.3 percent of men and in no women. With the continued Westernization of the diet, however, an anticipated increase in the prevalence of gout is occurring. Studies in Tokyo in the 1970s have shown mean uric acid levels to be the same as in Caucasian populations (males: 5.64 ± 1.45 mg%; females: 4.40 ± 1.09 mg%). The prevalence of gout in men has increased to 1.2 percent, but the proportion of gouty women was still much lower (0.9 percent of all cases) than in Caucasians. The clinical characteristics of gout are the same and occur in similar frequencies as in Caucasian populations (Nishioka and Mikanagi 1980).

A Chinese author claimed that the first case of gout to be described in China occurred in 1948, and

that by 1959 he could collect only 12 cases, 10 with tophi. This almost certainly reflects socioeconomic rather than biological circumstances. The general prevalence of gout may indeed have been low because of the widespread, inadequately low protein diet, but this would have pertained particularly to the large segment of the population that lacked medical care. In regard to the well-nourished upper classes, a lack of diagnostic acumen may have been at least partially responsible.

In the Taiwanese literature, only 19 cases of gout were reported between 1903 and 1964, according to one author. However, in 1963 another author reported 61 cases – 5 percent of the clientele of a rheumatology clinic. Of these, 35 were immigrants from the Chinese mainland.

A study of serum uric acid of 100 Chinese men who lived in British Columbia showed a higher mean value (5.44 ± 1.08 mg%) than that of 200 Caucasian men (4.55 ± 1.02 mg%) (Ford and de Mos 1964). The difficulty of interpreting such data is shown by a comparison of serum uric acid of Chinese living on Taiwan and in Malaya, using the same analytic technique. The mean concentration on Taiwan was 4.99 ± 0.91 mg% for men and 3.87 ± 0.78 mg% for women, whereas in Malaya these values were, respectively, 6.11 ± 1.29 mg% and 4.52 ± 0.9 8 mg% – significantly higher (Duff et al. 1968). At a hospital in New York, 13 cases of gout were seen among Chinese patients in 11 years, an incidence similar to that of other races. Only 1.9 percent of the 2,145 primary gout patients of the Mount Sinai Hospital of New York were Chinese. Yu (1984) interpreted this as evidence of the infrequency of gout among this racial group.

Aside from South Africa, there is little relevant information from the African continent, and most is derived from hospital admissions. Seven cases of gout (five "upper class") were seen at the principal Ugandan hospital in 6 years (1962–7). During 30 months (1960–2) 3 cases were diagnosed at a hospital in Nairobi, Kenya, which represented 11 per 100,000 admissions, whereas during the 5 years 1977–81, 19 cases were seen at the University Hospital in Durban, South Africa, which represented 4.7 per 100,000. Fifteen of these patients were male, and most were poor city dwellers (Mody and Naidoo 1984). A survey in a Nigerian village showed uric acid levels above 6 mg% in 34 percent of men and 13 percent of women. A more extensive investigation in rural south Africa revealed a normal Caucasian distribution of uric acid values, but no cases of gout among more than 1,000 adults.

Table VIII.63.5. *Serum uric acid in South African black and white populations*

Population	Age range	Subjects	Mean uric acid (mg%)
African males			
Tribal	18–75+	80	4.7 ± 1.03
Rural	14–84	128	5.0 ± 1.11
Urban	15–90	144	6.1 ± 1.45
White urban	16–95	213	6.2 ± 1.27
African females			
Tribal	15–75+	399	3.9 ± 0.85
Rural	14–96	242	4.6 ± 1.44
Urban	15–90	280	5.2 ± 1.34
White urban	16–88	298	5.0 ± 1.20

Source: Beighton et al. (1977).

The effect on uricemia of the urbanization of primitive people has been well illustrated by studies in South Africa that showed the lowest mean serum values in a tribal population, higher values in a village, and the highest levels, equal to those of urban whites, in urban (Soweto) blacks (Table VIII.63.5). The combined three black populations (621 men, 1,364 women) contained no cases of gout, whereas 3 of 240 white men and 1 of 332 white women had this disease (Beighton et al. 1977). A survey in Ethiopia in 1961–3 similarly showed the lowest values among rural Ethiopians, intermediate values among urban Ethiopians, and the normal, highest value among Caucasian and Indian urban professionals.

Data from Israel are analogous. Desert Bedouins were found to have lower serum uric acid values than villagers of the same Arabic stock, and the latter results were the same as were obtained from a nearby Jewish population in Haifa. These variations are presumed to be related to changes in nutrition associated with changes in life-style (Dreyfuss, Yaron, and Balogh 1964).

VIII.64
Herpes Simplex

Herpes simplex is caused by *Herpes virus hominis*, of which there are two distinct serologic types designated as HSV-1 and HSV-2. The first mainly causes disease above the waist, such as cold sores; the second most commonly causes disease below the waist, especially genital herpes. Exceptions to this generalization occur especially among the newborn. The initial active phase is followed by prolonged latency. But the virus can be reactivated by another infection, stress, exposure to sunshine, or any number of other bodily changes.

Etiology and Epidemiology

The herpes viruses are visible in infected cells by electron microscopy and may be grown in the chick embryo, in tissue cultures, and in laboratory animals that react differently to types HSV-1 and HSV-2.

HSV-1 is shed from cells in the lacrimal and salivary glands, and both types are shed from the primary and recurrent lesions of the mucous membranes and skin. Samples of infected adults show that 2 to 4 percent are excreting the virus at a given time.

Infection with the herpes simplex virus results from person-to-person contact. HSV-1 infections commonly are transmitted by oral secretions through kissing or the sharing of eating utensils, and thus herpetic infection can easily be spread within a family. Normally HSV-1 infections are painful and bothersome but have no serious consequences. An exception can be when the virus invades the cornea of the eye. Conjunctival or corneal herpes may produce scars that impair vision. It may occur among wrestlers from skin-to-skin contact. Another form of HSV-1 infection, called *herpetic paronychia*, may occur in dentists and in hospital personnel.

HSV-2 infections are generally the result of sexual transmission at a time the virus is being shed. Lesions appear on the penis, vulva, buttocks, and adjacent areas, and the mucosa of the vagina and cervix.

The prevalence of HSV-2 infection during pregnancy and its incidence in neonates are related to the socioeconomic level, age, and sexual activity of a population. In one urban population study, 35.7 percent of women attending an obstetrical clinic had serologic evidence of past HSV-2 infections. Moreover, of these women in a study of a lower socioeconomic sample, the antepartum infection rate was 1.02 percent. The infant was safe from infection if the mother's infection had cleared 3 to 4 weeks before delivery. On the other hand, the experience of 283 women with genital herpes suggests that those women who suffer from genital herpes during pregnancy are three times more likely to abort than other women during the first 20 weeks of pregnancy. In this same study, the risk of neonatal infection was 10 percent if infection occurred after 32 weeks of pregnancy, and increased to 40 percent if infection was present at confinement. Neonatal infection from infected mothers is almost certainly of the HSV-2 type, acquired by passage through an infected birth canal. In addition HSV-2 may be transmitted from infant to infant in the hospital nursery by its personnel.

The epidemiology of recurrent herpes is complicated by unknown factors that cause reactivation of the virus. Because the epidemiology of recurrence depends on recollection, the most acceptable studies of reccurent herpes labialis come from students in health care professions. These show inexplicable differences in recurrence: 45 percent in Wales and the United Kingdom, 40 percent in North America, 30 percent in Europe and Africa, 17 percent in Asia, and 16 percent in South America.

The possible relationship of HSV-2 to carcinoma of the cervix has been explored in recent years in light of its ability to transform cells in vitro, the incidence of antibodies to HSV-2 in cancer patients, and the demonstration of viral RNA in cancer cells from the cervix. No conclusive studies have been published to date.

Distribution and Incidence

Infection by herpes virus is reported worldwide, as determined by antibody studies, and is related to the socioeconomic state. The prevalence of positive antibody tests to HSV-1 approaches universality (100 percent) in the lower strata, falling to 30 to 50 percent among those of higher socioeconomic levels. Obviously, transmission is more likely among those living in a crowded and unhygienic environment. The prevalence of positive antibody response begins in early childhood and rises to its peak in adult life. Transplacental antibodies are present in infants up to 6 months of age. Then a sharp rise in antibodies occurs for those aged 1 to 4 years, mainly to HSV-1. This is followed by a slight rise from 5 to 14 years, and after 14 there is a marked rise in antibodies through late adulthood, which is in part due to HSV-2 infection (see Figure VIII.64.1).
Figure VIII.64.1. Percentage distribution of antibodies to HSV-1, HSV-2, and intermediate form (types 1 and 2) in 239 patients of various age groups. (From A. J. Nahmius and D. E. Campbell. 1983. Infections caused by herpes simplex viruses. In *Infectious Diseases*, 3d edition, ed. Paul D. Hoeprich, 859, by permission of Harper & Row, publishers.)

Because HSV-2 infection is a sexually transmitted disease, it has been studied more intensively in recent years than the more common HSV-1 infection.

On the other hand, most observers agree that herpes genitalis has been on the increase in recent years, and in 1983 the National Institutes of Health estimated that there were 20 million cases in the

United States, with 300,000 to 500,000 new cases developing annually. Undoubtedly, contributing factors include increased sexual activity as well as a preference for the use of oral contraceptives over the condom, although a wider use of diagnostic tests may account for some of the apparent increased prevalence. Certainly, publicity concerning herpes genitalis has alerted the medical profession to the disease and has made the public aware that "chafing of a menstrual pad" and lesions on the male genitals may entail more than temporary annoyance.

In any event, beginning with its *1983 Annual Summary, Morbidity and Mortality Reports,* the U.S. Public Health Service has included herpes genitalis. The report for 1984, based on physician consultations, office visits, and the first office visits for the disease, "reflects a 16 fold increase from 28,000 to 423,000 in the number of consultations for genital herpes in the period 1966–1983" (see Figure VIII.64.2).

Immunology

Antibodies to the herpes viruses last throughout the patient's lifetime. An antigen common to both HSV-1 and HSV-2 produces crossreacting antibodies to both strains that can be differentiated immunologically by immunofluorescence and microneutralization tests. Antibody to one type, however, precludes neither an infection with the other nor the development of specific antibodies to the second infection. Yet previous infection with HSV-1 does mitigate the clinical manifestations of the first episode of genital herpes caused by HSV-2. The antibodies that respond to an initial herpes simplex virus infection are complement-fixing, neutralizing, cytotoxic, pre-

Figure VIII.64.2. Number of consultations, all five office visits, and first of five visits for genital herpes, United States, 1966–83. All consultations (solid line) include any type of patient–physician interaction, such as telephone calls, house calls, and office visits. [From U.S. Public Health Service. Centers for Disease Control. 1984. *Morbidity and Mortality Weekly Reports,* Annual Summary (March) 33: 90.]
cipitating, and nonprecipitating antibodies, and appear early in the infection. Lawrence Corey (1984) has stated that although complement-fixing and neutralizing "antibodies usually are maintained and in high titer, and inactivate extracellular virus, continued replication of virus by cell to cell transfer ensues. These data help explain frequent reactivation of the disease in the presence of high levels of antibody titer." The relation of humoral antibodies to reactivation of disease is unclear. Whereas the humoral immune response remains at high levels, the in vitro cellular immune response to HSV antigens appears to fluctuate.

Pathology and Clinical Manifestations

The virus multiplies in the epithelium at the portal of entry. The epithelial cells increase in size and contain an enlarged nucleus with intranuclear inclusions. The developing blisterlike vesicle is intradermal and is surrounded by inflammatory cells, edema, and congestion. Viremia may develop in malnourished infants as an accompaniment to measles, and in patients with extensive burns or in those on immunodepressant drugs. Systematic disease accompanies viremia.

The initial lesion at the site of inoculation or at the site of recurrence, whether in the skin or mucous membrane, is a small reddened area that develops into a small, thin-walled, blisterlike vesicle filled with clear fluid. Equally as common is the appearance of a group of small vesicles on the erythematous base.

Gingivostomatitis is the usual type of primary or initial HSV-1 lesion in infants and young children and is seen occasionally in adults. There may be several days of prodromal symptoms such as malaise, fever, and usually cervical lymphadenopathy. Commonly, by the time a physician is consulted, the gums are inflamed and ulcerated. Pain is distressing and may interfere with eating; the course is normally a week to 10 days.

Labial herpes only occasionally represents the initial HSV-1 lesion, but the "cold sore" or "fever blister" of the lip is the most common lesion of recurrent disease. Here a cluster of vesicles appears after a couple of days of hyperesthesia and erythema, to last from several to 10 days. Most commonly these appear at the vermilion line of the skin of the lower lip or on the skin of the upper lip, at times extending to or into the nostril. The term "fever blister" stems from the frequency with which herpetic recurrence accompanies febrile illnesses. Before the age of antibiotics, it was more likely to accompany pneumococ-

cal pneumonia than other types of pneumonia or febrile disease.

Conjunctivitis with or without *keratitis* may be the primary lesion of herpes virus infection. Then the preauricular lymph node commonly is enlarged. Keratitis is characterized by dendritic ulceration.

Cutaneous herpes (HSV-1) may involve the skin of the body, anywhere above the waist and including the feet. (HSV-2 has been isolated from fingers from autoinoculation or genital-to-finger contact in sexual play.) It may be accompanied by edema, fever, lymphangitis, and lymphadenopathy.

Herpes genitalis also has the incubation period of several days following exposure to infection. It may be subclinical, especially in women having lesions only in the vagina or the cervix rather than on the vulva. Herpetic infection is more obvious in men with localized pain, erythema, and the development of one or a group of vesicles on the glans, prepuce, or elsewhere on the penis. The inguinal lymph nodes may be swollen and tender. Urethral involvement in both sexes is manifested by dysuria (painful or difficult urination), and a discharge may be noted in male patients. Pelvic pain accompanying the dysuria is common in women. (The virus can be isolated from the urethra of both sexes. Primary infection with HSV-2 virus often is accompanied by systemic symptoms during the first several days (see Figure VIII.64.3). Complications of primary infection reveal a generalized infection, especially as aseptic meningitis and other indications of viral invasion of the central nervous system.

In a study of 148 newborns with herpes, A. J. Nahmias and colleagues (1970) reported an incubation period of up to 21 days; almost all were infected with HSV-2 and had evidence of dissemination. The overall fatality rate was 71 percent, and 95 percent among those with disseminated infection. Of those recovering, 15 percent had sequelae, especially defects in the central nervous system.

Some studies show recurrences within the first year in 80 percent of infections with HSV-2. Recurrent lesions commonly present with milder symptoms initially, are generally of shorter duration, and are rarely accompanied by overt systemic symptoms. These lesions commonly appear on the genitalia, but may appear on the buttocks and elsewhere adjacent to the genital area. Latent infection presumably is established in the sacral-nerve-root ganglia. From a study of 375 patients, Stanley Bierman (1983) found that recurrences ceased in half of them after some 7 years following the onset of disease. In others, however, the recurrences may span many years.

DURATION VIRAL SHEDDING
Figure VIII.64.3. Schematic graph of the clinical course of primary genital herpes. (From L. Corey. 1984. Genital herpes. In *Sexually Transmitted Diseases,* ed. King K. Holmes et al., 453, by permission of the McGraw Hill Book Company.)

It is unclear what triggers recurrent genital herpes. Emotional stress, fever, heat, trauma, coitus, and the menses have all been suggested. But they lack the certainty that a febrile illness seems to play as a provoking factor in HSV-1 recurrences.

History and Geography

The word *herpes* is derived from the Greek verb "to creep," and the identification of disease in ancient writings depends upon one's interpretation of the description of physical signs. Thus, one may decide either that a described lesion was of the herpetic type or accept the translation of the term "herpes" itself. No doubt aphthae and herpetic lesions were not differentiated.

The oldest record of disease of the genitalia appears in the *Ebers Papyrus* (c. 1550 B.C.). The translator commented on the inflammation of the vulva and thighs of a woman in nonspecific terms, but in the same papyrus describes treatment for "herpes of the face." Hippocrates spoke of "herpetic sores" and, again in his *Epidemics,* that "many have aphthae and ulcerations of the mouth, frequent fluxations of the genital organs and ulcers." Herodotus described herpetic eruptions "which appear about the mouth at the crisis of simple fevers." H. Haeser (1875), in reviewing the medical writings of the Byzantine Empire, quotes from three physicians (the fourth to seventh centuries) concerning "superficial aphthae" and "vesicular eruptions" of the vulva. J. Preuss (1911), a Biblical scholar, in referring to the Talmud's permission to delay the rite of circumcision, said, *"Mila betzaraath* is probably harmless herpes of the foreskin."

The first definitive description of herpes appears in Jean Astruc's 1736 publication of *De Morbis Venereis,* translated into English and published in

London in 1754. His description of vesicles in both male and female patients unmistakably indicates those of herpes genitalis. Toward the end of the eighteenth century, the English physician Robert Willan developed a classification, published in 1808, of the bewildering varieties of skin diseases, among which was a category of vesiculae.

In his *Synopsis of Cutaneous Diseases* (1818), Thomas Bateman described herpes labialis, which "occasionally appears as an idiopathic affection . . . frequently in the course of disease of the viscera of which it is symptomatic." His accurate description of herpes praeputialis emphasized the hazard of interpreting a cluster of vesicles as a syphilitic chancre. He described the prodromes, development of the erythema and vesicles, and their course to healing, ending with, "I have not been able to ascertain the causes of this eruption on the prepuce. . . . Whencesoever it may originate, it is liable to recur in the same individual at intervals of six or eight weeks."

Jean Louis Alibert (1832) not only described herpes praeputialis but stated that the lesion may occur at the introitus of the vagina. F. L. Legendre (1853) described three instances of herpes of the vulva, with the observation that herpes may recur 2 or 3 days before menstruation.

The most descriptive paper on herpes progenitalis was presented by Boston physician F. B. Greenough (1881), at the meeting of the American Dermatological Association. He documented its frequency among private patients and its rarity among patients in the Venereal Disease Clinic of the Boston Dispensary. His explanation for this discrepancy was that patients in a charitable institution were less apt to complain of a trivial abnormality unless they believed it to be a manifestation of a more serious

disease. He made the important observation that one of the "three" venereal diseases had existed before the appearance of herpes genitalis. His summary included the statement:

[S]ome of its most interesting and important characteristics are, its tendency to relapse, the very great frequency with which it will be found to have been preceded by the act of coitus, the fact that it rarely, if ever, is found in patients who have been perfectly free from all venereal trouble, and that it is confined to the period of youth and early manhood.

In addition, Greenough made the surprising observation that he had never seen an instance of genital herpes in a woman. Among the numerous discussants of Greenough's paper was Louis A. Duhring (1881), president of the association, who commented in his discussion that though others had seen the disease in women, he, too, had never seen such an instance. This phase of the discussion prompted a paper 2 years later by Paul Unna of Hamburg (1883), published in an American journal. He, too, had never seen herpes genitalis in his private female patients, but cited observations made in Germany and France where medical examination of prostitutes was under police surveillance. In addition, he pointed out that among women admitted to the syphilis department of the Hamburg General Hospital, from 1878 to 1881, with admission of 1,357 to 1,459 patients annually, the incidence of herpes genitalis was 64, 126, 121, and 112 cases during the 4 years. For the same years, males admitted to the syphilis department, with admissions of 634 to 795 annually, had an incidence of herpes genitalis of 4, 9, 4, and 0, respectively.

Unna (1883) summarized:

It is now evident that the conclusions arrived at by members of the American Dermatological Society are correct, in so far as the *general rarity* of herpes vulvae is concerned; but, on the contrary, the conclusion that *women as such are therefore less* susceptible of being thus affected *is erroneous.* Indeed, herpes progenitalis is found more frequently in women *who are only distinguished by their vocation* than in men. We may therefore say only this much: *that women are just as susceptible to herpes as men* are; there is no immunity from herpes for the female *sex.* On the contrary, the exciting cause that induces virile herpes is usually absent in women; but when this is present (as in puellae publicae) herpes is frequently found; for women *herpes is so to say a vocational disease.* (Italics added)

Unna dismissed the usual theories to account for the disease and suggested that it was a variant of

herpes zoster, triggered by genital irritations: Just as there are "men who are habitually attacked by herpes after each act of coition, so, too, there are prostitutes who have an eruption of herpes every time they menstruate."

R. Bergh of Copenhagen (1890) confirmed a high incidence of herpes genitalis among prostitutes, reporting that the episodes were related to the menses in 73.4 percent of 877 women admitted to the hospital for the disease. Aware of the relationship of herpes labialis to bacterial infection, he was puzzled by the lack of such a relationship in herpes genitalis in spite of the not infrequent coincidence of herpes labialis and genitalis. He did not accept any relationship between herpes genitalis and venereal disease because he had seen it in a recently married woman and in youths who masturbated frequently. Therefore, he concluded the lesions were of a nervous origin, being due to congestion of the parts, as after masturbation or coitus in men and with menses in prostitutes. E. Levin (1906) reported observations on 1,584 women admitted to the venereal disease shelter in Berlin in 1898–9. There were 112 with herpes of whom 83 had genital herpes. Twenty-nine women had recurrent episodes, and thus 154 episodes were analyzed: 118 genital and 26 at other sites. Coincidence with menstruation occurred in 70 percent of the episodes.

A few years later, Prague physician O. Baum (1920) reported herpetic keratitis, following inoculation of rabbit corneas with vesicular fluid from two cases of herpes labialis, two of herpes genitalis (one in a recurrence), one of herpes faciei, and one each of herpes after the injection of bismuth and salvarsan. Results of such experiments with material from three cases of herpes zoster and several other vesicular skin diseases were negative. Four years later, investigators at the University of Turin, while carrying out successful experiments of inoculating blood and cerebrospinal fluid from patients having herpetic disease (or during a period between recurrences) into corneas, found instances of positive reaction among control subjects. This led to experiments with blood and cerebrospinal fluid from subjects who had not had herpetic eruptions for a long time; of 21 patients, only 3 gave negative results with both blood and spinal fluid. In 4, the spinal fluids were abnormal, and in 4 the Wassermann reaction was positive.

In 1921, B. Lipschütz successfully inoculated material from vesicles on the genitalia into the skin of human subjects. Four years later, S. Flexner and H. L. Amos (1925) demonstrated the herpes virus,

and in 1934 Albert Sabin and colleagues isolated it. K. E. Schneweiss (1962) identified two strains of herpes virus by neutralization tests, a finding confirmed by W. R. Dowdle and Nahmias in 1967. The literature in subsequent years has contributed to knowledge concerning epidemiology and immunology.

Herpesviruses

The family of herpesviruses (Herpetoviridae) includes herpes simplex 1 and 2 viruses, varicella zoster virus, Epstein–Barr virus, and the cytomegalovirus. All are double-stranded DNA viruses of icosahedral form, enclosed in a lipid-containing envelope, and ranging in size from 120 to 180 nanometers.

VIII.66
Histoplasmosis

Histoplasmosis is an infection caused by *Histoplasma capsulatum*, a soil fungus. Exposure occurs by inhalation, and the primary infection is in the lung. The disease is usually benign and self-limited, despite a strong tendency for invasion of the bloodstream during the primary infection. This fungemia seeds reticuloendothelial organs throughout the body. Under favorable conditions, the organism can cause progressive disease in one or in multiple sites, resulting in a wide variety of clinical manifestations.

Distribution and Incidence

H. capsulatum has been isolated from soil of more than 50 countries. It is most common in temperate climates along river valleys and has been found in North, Central, and South America; India; Southeast Asia; and rarely Europe.

By far the most heavily endemic area in the world is the east central United States, particularly the Mississippi and Ohio River valleys. It is most prevalent in the states of Ohio, Kentucky, Indiana, Illinois, Kentucky, Tennessee, and Arkansas. Surrounding states also have many infections.

Infection is almost universal in the most heavily endemic areas. Skin test surveys reveal that over 90 percent of persons living in some counties in the central United States have had histoplasmosis before age 20 (Edwards et al. 1969). Based on skin test surveys, there are probably 40 to 50 million people in the central United States who have had histoplasmosis, and there are several hundred thousand

new cases each year. The number of serious infections requiring diagnosis and treatment is very small, perhaps 1 or 2 percent of the total.

In contrast to the highly endemic central United States, only a handful of individual cases have been documented in Europe. Skin test surveys show about 0.5 percent of the population positive to histoplasmin. In Italy, positive skin tests are slightly more common (about 2 percent) (Mantovani 1972).

Etiology and Epidemiology

H. capsulatum is a thermal dimorphic fungus. At 25°C, it grows on Sabouraud agar as a fluffy-white mycelium, which bears microconidia and also characteristic tuberculate macroconidia. The organism is free-living in nature in this form. At 37°C, it grows as a small (2- to 4-μm diameter) yeast. The organism is found in this form in infected tissue.

A minor disturbance of fungus-laden soil may scatter spores into the air. The microconidia are inhaled, causing infection. Within the lung the organism converts to the yeast phase, which is not infectious. Person-to-person transmission does not occur. So-called epidemics of histoplasmosis are more accurately point-source outbreaks.

Within a highly endemic area, the organism is widely but not uniformly distributed. Microfoci with high concentrations of organisms are found by chicken coops and starling roosts, and in caves inhabited by bats. The nitrogen-rich excrement of birds and bats provides a favorable growth environment for the fungus. Exposure of small groups of people to high concentrations of organisms at such sites may result in outbreaks of symptomatic infection. These are fairly easy to identify because a severe respiratory illness occurs simultaneously in a group of people who were together for a particular activity 14 days earlier. Extremely large outbreaks of longer duration have occurred during excavation for road or building construction. A good example is the community-wide outbreak of histoplasmosis that occurred during the building of a swimming pool and tennis court complex in Indianapolis, Indiana, infecting perhaps over 100,000 people (Wheat et al. 1981).

Most cases of histoplasmosis, however, are sporadic and result from casual exposure to environmental spores. Patients with sporadic illness probably inhale fewer spores and are more likely to be asymptomatic or minimally symptomatic. The vast majority of these infections are never recognized and are known to exist only as a result of skin test surveys.

Immunology

Cell-mediated immunity is crucial in host defense. Inhalation of spores causes patchy areas of pneumonitis. The spores are transformed into the yeast form, which is engulfed by macrophages. The yeasts multiply intracellularly with a generation time of 11 hours (Howard 1965). The regional lymph nodes are quickly involved, and hematogenous spread occurs. The fungus is cleared from the blood by reticuloendothelial cells throughout the body. Specific cell-mediated immunity develops and rapidly checks the infection in the lung and at distant sites. Granuloma formation and necrosis occur at sites of infection.

Humoral antibody also develops. Although circulating antibodies are the basis of many diagnostic tests, they have little importance in limiting the infection. Hyperimmune serum is of no benefit in experimental infections, and hypogammaglobulinemic patients are not prone to progressive infections.

Clinical Manifestations and Pathology

Primary Pulmonary Histoplasmosis

This disease is asymptomatic at least half of the time. Symptomatic patients become ill about 2 weeks after exposure. They have an influenza-like illness with fever, chills, myalgias, headache, and a nonproductive cough. Rare manifestations include arthralgias, arthritis, and erythema nodosum. With or without symptoms, the chest roentgenogram may show patchy areas of pneumonitis and prominent hilar adenopathy.

A primary fungemia probably occurs in most cases. The calcified granulomas commonly found in spleens and livers of patients from endemic areas result from this primary, self-limited fungemia, not from progressive dissemination.

Following exposure to an unusually heavy inoculum, a more diffuse pulmonary involvement may occur, with an extensive nodular infiltrate on the chest roentgenogram. Dyspnea may be added to the other symptoms, and symptoms are more severe and last longer. Most patients recover without treatment, but extreme cases may progress to respiratory failure.

The chest roentgenogram often returns to normal after a primary pulmonary infection, but a variety of residual abnormalities may be seen. Initial soft infiltrates may harden and contract, leaving one or several nodules. Central necrosis may result in a dense core of calcium (a "target" lesion), but this is not universal. Infrequently, alternate periods of activity followed by healing may result in concentric rings of calcium as the lesion slowly enlarges. Lymph node calcification, either in association with a parenchymal nodule or as a solitary finding, is common. Finally, small "buckshot" calcifications may be scattered over both lung fields, a pattern characteristic of uneventful recovery after exposure to a heavy inoculum of organisms.

Primary histoplasmosis has several uncommon local complications within the chest. Involvement of the pericardium can cause a nonspecific acute pericarditis (Wheat et al. 1983). The inflammation probably represents a response to adjacent infection in the lung, as the cultures of pericardial fluid are usually sterile. Many cases are probably misdiagnosed as benign viral pericarditis. Rarely, the process progresses to chronic constrictive pericarditis. More delayed and more serious, an extensive fibrosing process in the mediastinum can cause vascular compression and result in the superior vena caval syndrome with edema of the head and upper extremities and development of superficial venous collaterals across the chest wall. Inflammation adjacent to the esophagus may cause a traction diverticulum. A lymph node impinging on a bronchus may cause a chronic cough. If a calcified lymph node erodes through a bronchus, it becomes a broncholith. Hemoptysis is a common clinical manifestation.

Chronic Cavitary Histoplasmosis

Although it may occur anywhere in the lung, chronic cavitary histoplasmosis usually involves both upper lobes and closely resembles reinfection tuberculosis in its roentgenographic appearance. The mechanism of infection, however, is not endogenous reactivation. Rather the infection is the result of a primary infection in abnormal lungs, typically the lungs of middle-aged or older male smokers who have centrilobular emphysema (Goodwin et al. 1976). Acute pulmonary histoplasmosis in this setting usually resolves uneventfully although very slowly. In about a third of cases, infected air spaces persist. A progressive fibrosing and cavitary process gradually destroys adjacent areas of the lung. Chronic cough is the most common symptom. Constitutional symptoms, including low-grade fever, night sweats, and weight loss, increase as the illness progresses.

Disseminated Histoplasmosis

This condition refers to any progressive extrapulmonary infection. There is a range of infection with different tissue responses. At one extreme there are

massive numbers of organisms in all reticuloendothelial organs with little tendency to granuloma formation. Clinical features include high fever, hepatosplenomegaly, lymphadenopathy, and pancytopenia due to bone marrow involvement. This type of disseminated histoplasmosis has been called the "infantile" form and may lead to death within days or weeks. Other patients, often older adults, have a more indolent illness, many months in duration, characterized by low or moderate fever, weight loss, and skin and mucous membrane lesions. Biopsies of involved tissues show well-formed granulomas similar to sarcoidosis. Organisms are scanty and often are demonstrated only with special stains.

Disseminated histoplasmosis also occurs as an opportunistic infection. The degree of granulomatous tissue response may vary from none to a considerable amount and has prognostic value. If the bone marrow biopsy shows epitheloid granulomas or even recognizable aggregates of macrophages, the response to treatment is quite good. If the biopsy shows no granulomas, tissue necrosis, and a large number of organisms, the prognosis is very poor (Davies, McKenna, and Sarosi 1979).

Disseminated histoplasmosis often presents as a nonspecific systemic febrile illness rather than as a pulmonary infection. There is usually no cough. The chest roentgenogram may be normal. If abnormal, it often shows a diffuse infiltrate, suggesting hematogenous spread to the lung, rather than a focal infiltrate.

Immunosuppressed patients probably get disseminated histoplasmosis in two ways. If they inhale the organisms while immunosuppressed, the primary infection will progress, as documented in the Indianapolis outbreak (Wheat et al. 1982). On the other hand, if they become profoundly immunosuppressed long after their primary infection, the disease may reactivate (Davies, Kahn, and Sarosi 1978). This is suggested by the systemic, nonpulmonary nature of the illness and is supported by the recent experience with the acquired immune deficiency syndrome (AIDS). Patients with past exposure to endemic areas are developing disseminated histoplasmosis while living in nonendemic areas such as New York City (Huang et al. 1988), San Francisco, and Los Angeles.

Disseminated histoplasmosis may also present as a more localized infection. Examples include central nervous system histoplasmosis, meningeal histoplasmosis, and isolated gastrointestinal histoplasmosis, which often involves the terminal ileum. All are extremely rare.

Diagnosis

The *histoplasmin skin test* is a valuable epidemiological tool that has permitted mapping of the endemic area. However, it is worthless in individual case diagnosis. A positive skin test means only that the person is one of many millions who have had histoplasmosis, probably remotely and without sequelae. It does not mean that a current illness under investigation is being caused by the fungus.

Primary histoplasmosis is usually not diagnosed at all. Sputum cultures are positive in less than 10 percent of cases. Most recognized cases are diagnosed by serology. Serologic tests include *immunodiffusion* (M and H bands) and *complement fixation* (yeast and mycelial antigens) tests. An M band by immunodiffusion is fairly specific. The H band is never found alone. When present with the M band (10 to 20 percent of the time), it adds further to specificity. Unfortunately, the immunodiffusion test is insensitive and appears slowly after primary infection. Less than 25 percent of symptomatic patients have a positive test 2 weeks after the onset of clinical illness (Davies 1986). The complement fixation test is more sensitive but less specific. The titer against the mycelial antigen is not important because it is almost always lower than the titer against the yeast antigen. A titer of 1 to 32 or higher against the yeast antigen is diagnostic if the clinical picture suggests histoplasmosis. Unfortunately, only 60 percent of patients have a positive test 2 weeks after the onset of clinical illness, and many have 1:8 or 1:16 titers (Davies 1986). What this means is the serologic tests are most useful for diagnosing patients who have already recovered. Patients with rapidly progressive pneumonias not responding to antibacterial antibiotics need urgent diagnosis, especially if respiratory failure is impending or actually develops. Some patients are diagnosed by serology. Others require lung biopsy for histopathological diagnosis, because a negative serology cannot exclude the diagnosis, and empirical treatment for all possible causes of progressive pulmonary infection is not possible.

Chronic cavitary histoplasmosis is easier to diagnose. The pace is slower. Tuberculosis is suspected first, but the tuberculin skin test is negative and the sputum is negative for tuberculosis by smear and culture. Sputum cultures for *H. capsulatum* are usually positive, as are serologic tests (immunodiffusion: 75 percent; complement fixation: 90 percent).

Disseminated histoplasmosis is difficult to diagnose because the illness is so nonspecific. Serologic tests are positive in over half of cases and may pro-

vide an important clue. Serodiagnostic tests are least helpful in the immunosuppressed because they are less sensitive and because the pace of the illness may be so fast that there is no time to wait for the results. Histopathological examination of tissue biopsies is the method of diagnosis in most cases. Bone marrow biopsy is particularly valuable in febrile illnesses without localizing features. Special stains, such as one of the many modifications of the silver stain, are necessary to ensure visualization of the organisms. Cultures of blood, bone marrow, and other tissues and of body fluids may also give the diagnosis in some cases.

History and Geography

Infection with *H. capsulatum* was first described in April 1906 by Samuel Darling (1906). From an autopsy of a laborer who died while working on the Panama Canal, he described a disseminated infection of the reticuloendothelial system caused by an organism that he believed was protozoan. Macrophages were filled with small organisms. Within a few years he reported two other similar cases. In 1913, H. da Rocha-Lima discussed the published photomicrographs of Darling's cases and speculated that the organism might be a fungus rather than a protozoan (Rocha-Lima 1913).

Another autopsy case was reported in Minnesota in 1926 by W. A. Riley and C. J. Watson (1926), who credited Darling with being the first to describe the infection in 1906. Later, however, there was some confusion as to whether a case report of R. P. Strong (1906) from the Philippines in January 1906 had described histoplasmosis first. But in a personal letter many years later, Strong stated his belief that the case he had described was not histoplasmosis, but rather a rare human infection with *Cryptococcus farciminosus*, the cause of farcy in horses (Parsons and Zarafonetis 1945). Thus credit for the first case description remains with Darling, who recognized that the disease was previously undescribed and who named the organism and the illness.

After Riley and Watson's paper, scattered autopsy reports of similar cases followed, mostly from the central United States. Then in 1934, the first premortem diagnosis of such a patient was made by finding the characteristic intracellular organisms on a peripheral blood smear (Dodd and Tompkins 1934). W. A. DeMonbreun (1934) isolated the infectious agent, proved that it was a fungus, and demonstrated its thermal dimorphism.

In January 1945, R. J. Parsons and C. J. Zarafonetis (1945) reported 7 cases, reviewed 71 previous

cases, and concluded that histoplasmosis was a rare systemic infection that was nearly always fatal. However, in the same year, A. Christie and J. C. Peterson (1945) and also C. E. Palmer (1945), using antigen derived from the first isolate, demonstrated that great numbers of asymptomatic persons in the central United States had been infected with the fungus. Furthermore, they showed that almost all tuberculin-negative persons with calcifications on chest roentgenogram had positive histoplasmin skin tests. Quickly the endemic area was mapped and fungus was isolated from soil in areas with high skin-test positivity. The new conclusion was that histoplasmosis is very common and almost invariably benign and self-limited. The fatal cases were rare and exceptional.

Most of the skin-test reactors in the early surveys had had asymptomatic or minimally symptomatic nonspecific infections. The retrospective discovery of a highly symptomatic but also self-limited form of primary histoplasmosis soon followed. Small groups of patients exposed to high concentrations of organisms, often in closed spaces, had been verified as victims of epidemics of an unknown but relatively severe acute pulmonary illness. An epidemiological investigation of one such outbreak, which occurred in 1944 and was reported 3 years later (Cain et al. 1947), demonstrated convincingly that *H. capsulatum* had been the offending agent.

Upper-lobe cavitary histoplasmosis resembling tuberculosis was first described in Missouri in 1956 by M. L. Furculow and C. A. Brasher among sanitorium patients being treated for tuberculosis. The mechanism of infection was most likely progressive primary infection in an abnormal lung, and not reactivation (Goodwin et al. 1976).

In 1955, the isolation of amphotericin B was described by W. Gold and colleagues, and within a few years the drug was available for treatment of a wide variety of fungal infections. This drug, despite some toxicity, proved highly effective for histoplasmosis and remains the agent to which newer alternatives must be compared. Ketoconazole, a nontoxic oral imidazole, arrived in the 1980s. It is not as effective as amphotericin B but is reasonable therapy for mild to moderately ill patients with chronic cavitary disease and indolent forms of disseminated disease.

With the increase in the use of glucocorticoids and cytotoxic drugs for malignant and nonmalignant diseases, disseminated histoplasmosis assumed increasing importance (Davies, Khan, and Sarosi 1978; Kaufman et al. 1978). Endogenous reactivation was suspected as a mechanism in some cases because the

illness presented as a nonspecific febrile illness. Treatment with amphotericin B was very effective if the diagnosis was made quickly and if the patient had some degree of cell-mediated immune response.

Finally, as previously noted, AIDS brought a new level of suppression of the cell-mediated immune system. The concept of endogenous reactivation received further support, for, unlike other immunosuppressed patients, even those AIDS patients who respond to treatment are not cured but require long-term suppressive therapy to prevent relapse of infection (Johnson et al. 1986).

Hookworm Disease

Ancylostomiasis, or hookworm disease, is caused by hookworm infection and is characterized by progressive anemia. In 1989, it was estimated that perhaps as many as one billion people, most of them living in tropical and subtropical regions, are afflicted to some extent with hookworm infection, although it is not known how many thus infected can be said to be victims of hookworm disease. It is difficult to define the difference between hookworm infection and hookworm disease because a host whose diet contains adequate amounts of iron may sustain a worm burden without debilitating consequences that would render a malnourished person anemic. A person exhibiting signs of the anemia associated with hookworm infestation, therefore, may be said to have hookworm disease regardless of the number of parasites present. Hookworm disease does not appear on the short list of major causes of death in developing countries, but it should be regarded as an important contributing factor in millions of deaths annually and as a source in its own right of widespread human suffering.

Two species of intestinal nematode, *Ancylostoma duodenale* and *Necator americanus,* are the parasites that cause ancylostomiasis. Although they apparently cause the same disease, there are important differences between the two species. *A. duodenale* is slightly larger, sickle-shaped, with hooks or teeth; *N. americanus* is smaller, "S" shaped, with shell-like semilunar cutting plates instead of teeth. Despite being named the "American killer," *N. americanus* is less pathogenic than *A. duodenale,* as measured by comparative blood loss. *A. duodenale* has a higher reproductive rate and a shorter life-span. It is also able to infect the host in more ways than can *N. americanus.* Hookworm disease has been called by nearly 150 different names, taxonomic as well as colloquial. Many, such as *geophagia* and *langue blanche,* describe physical symptoms, clinical features, or unusual behavior associated with the affliction. The name *Ancylostoma duodenale* itself was a subject of disagreement among parasitologists, until resolved in 1915 by the International Commission on Zoological Nomenclature. Commonly used variations at one time or another have included *Agchylostoma, Anchylostomum, Ankylostoma,* and *Uncinaria.* Ancylostomiasis was also known as uncinariasis.

Etiology and Epidemiology

Although *A. duodenale* can be ingested in contaminated food, water, or possibly breast milk, the more common route of infection, and the only one for *N. americanus,* is through penetration of the skin. Larvae in the soil typically enter through the skin of the feet, frequently causing dermatitis, once called "ground itch" or "dew poison" in the southern United States, and "water itch" or "coolie itch" in India. Then the parasites travel through the bloodstream to the alveoli of the lungs, climb the respiratory tree, and make their way into the esophagus. During their migration through the airways into the esophagus, the host sometimes develops a cough, wheeziness, or temporary hoarseness. The hookworms are then swallowed and pass into the gut, where some will successfully attach themselves to the small intestinal mucosa and begin nourishing themselves on their host's blood. In the small intestine, hookworms will grow to a length of about 1 centimeter and mature in 6 to 8 weeks after initial infection. Depending on the species, hookworms generally live from 1 to 5 years, although a few apparently live longer. The adult female may produce thousands of ova per day, which pass out of the body with the host's feces. Egg production varies with the species, the age of the worm, the number of worms in the gut, and the degree of the host's resistance. If deposited on warm, moist soil, the eggs will produce larvae that will molt twice over 2 weeks before becoming infective and can survive in a free-living state for over a month before finding a host.

Hookworms thrive on human ignorance and poverty. If the billions of people living in areas of hookworm infestation were able to eat moderately well, wear good shoes, and defecate in latrines, hookworm disease would soon no longer pose a serious threat to human health. Understood as an index of socioeconomic status, hookworm infection will likely remain a daunting public health problem as long as there are poor people, inadequately educated, living in warm climates. The historical record is not reassuring: Documentary and physical evidence suggest that hookworms have infected humans in different parts of the world for millennia. In the early decades of the twentieth century, massive campaigns launched to eradicate hookworm disease ended in disillusionment and failure. Modern public health officials now pursue the more modest goal of containment, with reductions in the incidence of acute infection. If anything resembling the optimism of the early days of antihookworm work still survives, it is in the possibility that a vaccine may yet be pro-

duced, thus permitting overmatched agencies to finesse the intractable political problems of malnutrition and poverty.

Distribution and Incidence

The earliest global survey of hookworm distribution was conducted in 1910, in preparation for a campaign against hookworm disease carried out by the Rockefeller Foundation. Responses from 54 countries led to a preliminary description of a "hookworm belt" girdling the Earth between 30° south latitude and 36° north. Another survey conducted at the same time estimated that 40 percent of the inhabitants of the southern United States suffered in varying degrees from hookworm infection. The larvae prefer shade, and light sand or loam soils. They thrive in the southeastern coastal plains of the United States, but not in the Piedmont clays. Although infection has not been eliminated in the United States, the public health menace of hookworm disease has disappeared, only in part because of the earlier treatment and control programs, but largely as an incidental consequence of the concentration of the population in cities and towns with sewer systems, and the general improvement in sanitary conditions and the standard of living for those remaining on the farms. Likewise in Europe and the United Kingdom, where the disease was sometimes found in mines, hookworm infection is no longer a problem. In Japan as well, rising living standards and antihookworm campaigns have eradicated the disease.

It is still, however, a chronic fact of life in most of the rest of the regions within the old "hookworm belt." In the Caribbean, Central and South America, Africa, China, India, Southeast Asia, and Oceania, endemic hookworm infection remains widespread and largely untreated. After a flurry of activity in the first three decades of the twentieth century, hookworm prevention and treatment programs have been sporadic and uncoordinated. This recent history of neglect has made it difficult even to estimate the incidence of hookworm disease in areas of the world where hookworm infection is known to be prevalent. A combination of factors helps to explain why hookworm lost the attention it once received from philanthropic organizations and public health agencies. The failure of earlier intensive efforts to make quick, dramatic reductions in the incidence of hookworm infection and hookworm disease led public health officials with limited budgets to conclude that a concentration of resources elsewhere would produce better results. Hookworm infection came to

be regarded as a stubborn condition of rural poverty in developing nations. The campaigns of the 1910s and 1920s seemed to demonstrate the futility of treating the condition in a systematic way without major improvements in the general standard of living. Other diseases such as smallpox and malaria were both deadlier and less obviously the consequences of social and economic circumstances beyond the control of public health workers.

Other parasitic diseases for which there are no effective anthelmintics were given research priority and funding, thus distracting workers in developed countries and signaling public health officials in developing countries that hookworms and other soil-transmitted parasites were no longer as important as they once had seemed. Geopolitical factors – the economic depression of the 1930s, the Second World War, the dismantling of the European and American colonial empires, the Cold War, and political instability in many of the countries where hookworm infection is endemic – have also contributed to the reduction of support for elaborate countermeasures.

Clinical Manifestations and Pathology

Theoretically, the presence of a single parasite is detrimental in some way to the host. In reality, however, adequately nourished persons with light infections are not likely to suffer discernible ill effects or to exhibit the clinical features associated with hookworm anemia. Children and pregnant women will begin to manifest symptoms of hookworm disease at lower levels of infection, as greater demands on their normal iron stores already exist. Efforts to establish a threshold of infection above which the host might be expected to begin to show signs of hookworm anemia have been frustrated by the inability to control other significant variables such as nutrition and general health in a population large enough to be statistically valid. An otherwise healthy person with a normal daily intake of iron can apparently tolerate several hundred hookworms without patently adverse effects. The likelihood of hookworm disease in an individual varies in direct proportion to the worm burden and in inverse proportion to iron intake.

Hookworm disease shares many of the same clinical symptoms accompanying other kinds of anemia. Persons suffering from severe hookworm infection often have a pale and wan appearance, a tell-tale yellow-green pallor to the skin that helps to explain why the disease was sometimes called "Egyptian chlorosis" or "tropical chlorosis" in the years before the parasite was discovered and described in the medical literature. In children, growth may be sig-

nificantly retarded. A distended abdomen and pronounced, sharply pointed shoulder blades ("pot belly" and "angel wings" in the American South) were once thought to identify children with hookworm disease, although the same features often accompany malnutrition as well. In pregnant women, hookworm infection increases the likelihood of fetal morbidity. Victims of hookworm anemia, regardless of age or sex, may be chronically sluggish, listless, and easily tired, symptoms that prompted a facetious American newspaper reporter early in the twentieth century to dub hookworm the "germ of laziness." Dropsy, dizziness or giddiness, indigestion, shortness of breath, tachycardia, and in very extreme cases congestive heart failure have also all been associated with advanced hookworm disease. Hookworm sufferers will sometimes eat dirt, chalk, or clay as well.

A diagnosis of hookworm infection can be made easily if ova are detected during a microscopic examination of a fecal smear. Quantitative methods have made it possible to estimate both the total number of eggs based on a quick count in the area under the cover slip and the quantity of hookworms lodged in the intestine. Since the nineteenth century, dozens of anthelmintic drugs have been tried, including thymol, oil of chenopodium, carbon tetrachloride, and tetrachloroethylene. More recently developed hookworm vermifuges include bephenium, mebendazole, pyrantel, and thiabendazole. A regimen combining chemotherapy with the simultaneous administration of iron tablets now seems to be the most effective way to eliminate the parasites and at the same time to restore the hemoglobin to a normal level quickly.

The probability of reinfection is high, however, if a person thus treated continues to walk barefooted on ground contaminated with hookworm larvae. This discouraging realization has bedeviled public health workers since the days of the massive early control programs. Numerous designs for sanitary latrines have come and gone over the years; their construction costs placed them beyond the means of impoverished agricultural workers. Cheaper and less sanitary latrines were often worse than no latrines at all, as they tended to concentrate the locus of infection in a small area where people habitually went to defecate. Reinfection would occur rapidly in such instances, although it would take somewhat longer to reach pretreatment worm burdens.

The problems posed by unsanitary latrines were universal. Other difficulties were specific to certain regions or cultures, though no less imposing for that.

For example, an extensive treatment and control campaign in China in the early 1920s foundered on the age-old practice of fertilizing mulberry trees with human feces, often infested with hookworm ova, acquired in massive quantities from brokers who collected it for that purpose in nearby villages. For centuries, then, the Chinese silk industry had sustained a disease afflicting its workers whose contaminated feces nourished the crop on which their livelihoods depended.

History and Geography

From Ancient Times Through the Nineteenth Century

Hieroglyphic entries on the *Ebers Papyrus* (c. 1550 B.C.) describe a mysterious affliction, *a-a-a disease*, thought by some to be hookworm anemia, but by others, schistosomiasis. In the fifth century B.C., Hippocrates described a pathological condition marked by dirt eating, intestinal distress, and a yellowish complexion. A handful of other sketchy descriptions from the Mediterranean basin in the ancient and early medieval periods now appear to be reports of hookworm disease. From the Western Hemisphere in the centuries after European colonization came scattered accounts from English, French, Spanish, and Portuguese settlers of epidemics among their slaves, called by a rich variety of colloquial names and now thought to be descriptions of widespread hookworm infestation.

The Italian physician Angelo Dubini was the first to report the discovery of hookworms in a human. He detected them first during an autopsy in 1838 and again in 1842. His interest aroused, Dubini examined 100 cadavers for hookworms and found them in more than 20. His 1843 article provided a detailed description of the parasite, which he named *"Agchylostoma"* (a faulty transliteration of the Greek words for "hook" and "mouth") *duodenale*. Dubini did not believe that hookworms had caused the deaths of any of the people he had examined, although he did detect a slight inflammation of the intestinal mucosa at the point of attachment. By 1846, Dubini's parasites had been found in Egypt and, by 1865, in Brazil. In 1878, a trio of Italian scientists – Giovanni Battista Grassi, Corrado Parona, and Ernesto Parona – announced that they had detected hookworm ova in the feces of anemic patients, thus making it possible for anyone with access to a microscope to diagnose hookworm infection.

In 1880, an outbreak of anemia among the miners digging the St. Gotthard tunnel in the Alps gener-

ated a wave of public concern in Italy. Within weeks, hundreds of miners were examined and found to be infected with hookworms. Edoardo Perroncito, a pathologist at the University of Turin who had found over 1,500 hookworms in a postmortem examination of a miner, argued that the presence of hookworms in large numbers and the epidemic of anemia were causally related. In 1881, Camillo Bozzolo reported that he had had success using thymol to treat the infection. For the next 35 years, thymol remained the most widely used drug in the treatment of hookworm disease.

Twentieth-Century Writings

In 1898, Arthur Looss in Cairo first suggested that hookworm larvae could penetrate the skin. He had accidentally infected himself by spilling water contaminated with hookworm larvae on his hand. Shortly afterward, the spot on his hand where the water had spilled began to burn and turned red. He surmised that the hookworm larvae were responsible. Two to three months later, he found hookworm ova in his feces. Although Looss's announcement was initially greeted with considerable skepticism, further experimentation by himself and others had by 1901 confirmed beyond doubt the percutaneous route of infection. Looss was later to describe the migratory path of the hookworm within the host.

While Looss was developing his theory of skin penetration in Egypt, a U.S. Army physician stationed in Puerto Rico, Bailey K. Ashford, discovered in 1899 that hookworm infection was rampant among the agricultural workers in the sugar cane fields (Ashford 1900). In 1903, Ashford persuaded the governor to budget funds for the creation of the Anemia Commission of Puerto Rico, the first large antihookworm program of its kind in the world.

Ashford had believed that the hookworms he found in Puerto Rico were *A. duodenale*. At the time of his discovery, no other species was known to infect humans. Charles W. Stiles, a zoologist trained in Germany working for the U.S. Department of Agriculture, examined a sample of Ashford's hookworms and others sent to him from different parts of the United States. He compared them with samples of *A. duodenale* and concluded in 1902 that these hookworms were indigenous to the Western Hemisphere and were a different species, which he named *Necator americanus*. In 1905, Looss found *N. americanus* in six Central African pygmies brought to Cairo for a music hall exhibition. He speculated that *N. americanus* originated in the Eastern Hemisphere and was brought to the Americas by African

slaves. Within 2 years, *N. americanus* had been found extensively not only in Africa but also in India and Australia. Whether *A. duodenale* might also have been introduced into the Americas at about the same time by the first Spanish explorers and the conquistadors has been the subject of some disagreement. The theory that *A. duodenale* existed in pre-Columbian America seems to have been bolstered by the discovery in 1974 of what appears to be an *A. duodenale* in the intestine of a Peruvian mummy dating from about A.D. 900. Both species are widespread in both hemispheres, although their origins remain murky.

In 1909, John D. Rockefeller created an organization to eradicate hookworm disease in the southern United States. Stiles, who maintained that eradication was an unrealistic goal, had nevertheless persuaded Rockefeller's principal philanthropic advisor, Frederick T. Gates, that hookworm infection was a serious problem. With $1 million at its disposal, the Rockefeller Sanitary Commission established operations in 11 American states. Over its 5-year existence, the Rockefeller Sanitary Commission awakened the public to the nature and extent of the threat, stimulated widespread concern for improved sanitation, treated almost 700,000 people suffering from hookworm infection, and invigorated long-moribund state boards of health. It failed, however, to eradicate hookworm infection anywhere.

At the invitation of the British Colonial Office, the Rockefeller Foundation in 1914 undertook a worldwide campaign modeled on the experience of the Rockefeller Sanitary Commission. They opened operations in the British possessions in the West Indies before extending the work into British Guiana, Egypt, Ceylon, and Malaya. By the end of the First World War, Rockefeller programs were underway or ready to begin in Central America, Brazil, and China. Shortly thereafter, Rockefeller-sponsored campaigns were in place in most of the countries in the tropics. Their earlier experience in the southern United States had led administrators of the Rockefeller Foundation programs to employ a combination of two approaches to the problem of hookworm infection. The dispensary method attracted people from the surrounding area to a day-long demonstration conducted by a Rockefeller physician assisted by microscopists during which examinations were carried out and treatments dispensed, while the crowd heard lectures on prevention and improved sanitation. The intensive method was based on a different approach to the problem of hookworm infection. A clearly delimited area was selected for a saturation

campaign of aggressive hookworm treatment and latrine construction.

Beginning in the early 1920s, the Rockefeller Foundation had begun to rethink its basic approach to hookworm work. The early days of extensive, protracted campaigns had produced negligible results. The incidence of hookworm infection in Puerto Rico, for example, was as high in 1920 as it had been in 1903, just before Ashford's Anemia Commission began to go to work. Not yet prepared to abandon hookworm work altogether, the Rockefeller Foundation gradually withdrew from massive treatment campaigns and began to redirect its efforts toward laboratory research, with field work restricted to the gathering of data and the testing of hypotheses and drugs. By the mid-1920s, disillusionment had set in and the days of the antihookworm crusades were over. Since then, although laboratory work has revealed much more about the relationship between humans and hookworms, little has been done in a practical way to rid the former of the latter, except where there have been improvements in living conditions.

Huntington's Disease (Chorea)

Huntington's disease (HD) is a rare progressive neurological disorder, in which normal central nervous system development is succeeded in early adulthood by premature and selective neuronal death. First-rank symptoms consist of rapid, involuntary jerking movements, or *chorea*, due to lesions in the putamen and the caudate nucleus, and a progressive *dementia* due to loss of cells in the cerebral cortex (Hayden 1981). Onset of symptoms is typically in the third or fourth decade, and the clinical course is progressive and relentless over a period of 10 to 30 years. At autopsy, gross examination of HD brains reveals severe, symmetrical atrophy of the frontal and temporal lobes as well as, to a lesser degree, the parietal and occipital lobes. The caudate nucleus is profoundly involved, and diffuse neuronal loss extends into the cerebral cortex, basal ganglia, thalamus,

and spinal motor neurons. Various neurotransmitter systems have also been shown to be progressively affected (Rosenberg 1986).

References to the disorder have been found as early as 1841, but the first full description of the disease was made by George S. Huntington in 1872 (Gates 1946). Referring to a large family on Long Island, Huntington distinguished this condition from other known choreiform movement disorders such as Sydenham chorea, or St. Vitus dance. The remarkable history of HD in the New World was recounted in a paper by P. R. Vessie (1932). The carriers of the mutant gene responsible for nearly all known cases of the disease sailed for Massachusetts from Suffolk in 1630. Upon arrival, these individuals founded family lines that included not only the Long Island cases but also the celebrated "Groton witch," whose violent and uncontrollable movements were recorded in 1671 as evidence of possession (Vessie 1932). Compilations of the pedigrees encompassing the various branches of the families founded in seventeenth-century Massachusetts demonstrated a clear pattern of autosomal dominant transmission, meaning that the disease will appear in one-half the offspring of an affected parent.

During the century that has passed since the first description of HD, numerous biochemical and histological studies have been carried out. However, the primary defect in HD remains unknown. A major breakthrough occurred in 1983 when J. F. Gusella and colleagues announced the discovery of an anonymous DNA sequence closely linked to the putative HD gene (Gusella et al. 1983, 1985). This molecular probe, which has been refined by subcloning, is now a tool for presymptomatic diagnosis of HD (Folstein et al. 1985). An effort is underway to clone and sequence the HD gene itself in order to determine the precise nature of the pathological changes leading to clinical HD (Gilliam et al. 1987).

Hypertension

Arterial hypertension is a condition characterized by abnormally high systolic and/or diastolic blood pressure levels. Systolic and diastolic blood pressure levels are usually estimated indirectly by use of an inflatable rubber bladder to compress the artery in the upper arm. The pressure exerted on the artery by the bladder is registered by a device called a *manometer.* The level of the blood pressure is a measure of the force exerted against the walls of the artery during each heart beat or pulse. The peak of the pressure wave occurs when the heart beats or contracts (systole) and is called the *systolic pressure.* The valley of the pressure wave occurs when the heart relaxes (diastole) and is termed the *diastolic pressure.* Blood pressure is recorded as systolic over diastolic.

Although longitudinal research studies such as the one in Framingham, Massachusetts, and the life insurance industry have noted that even slight elevations of blood pressure are associated with increased risk of premature death, the World Health Organization has recommended that the following blood pressure levels be used to classify adults (blood pressure levels defining juvenile hypertension are under review):

Hypertensive: Greater than or equal to 160 millimeters of mercury (mmHg) systolic and/or greater than or equal to 95 mmHg diastolic.

Normotensive: Less than or equal to 140 mmHg systolic and less than or equal to 90 mmHg diastolic.

Borderline Hypertensive: Between hypertensive and normotensive.

The condition is also divided etiologically into two types: *secondary* and *primary* or *essential* hypertension. Secondary hypertension, resulting from some

known cause (including diseases of the kidney or the adrenal glands), represents less than 10 percent of all the cases of the disease. Essential hypertension, occurring in over 90 percent of the cases, is defined as high blood pressure without evident cause. Most of the discussion that follows deals with this latter, more prevalent type of the disease.

Distribution and Incidence

In most societies the average blood pressure levels and the diseases associated with higher blood pressure increase as people get older. However, blood pressure does not increase with age in all populations. Indeed, the disease appears to be totally absent from societies described as "stone age." In such societies, blood pressure does not rise with age, and hypertension is extremely rare. However, a 1988 World Health Organization literature survey on high blood pressure in less developed countries revealed that the prevalence of hypertension there is increasing.

A recent international survey, the INTERSALT study, highlights the wide geographic variability of hypertension throughout the world. INTERSALT, a 52-center, 32-country study, found that the prevalence of hypertension (hypertensives were defined as anyone having greater than 140 mmHg systolic or greater than 90 mmHg diastolic or of persons on antihypertensive medication) between the ages of 20 and 59 ranged from zero percent in the Yanomamo Indians of northern Brazil to over 33 percent in an African-American population in Jackson, Mississippi. There was a significant within-continent variability as well (see Table VIII.69.1). It is likely that this wide variability in the prevalence of hypertension is due to differences in both environmental and genetic factors.

Etiology and Epidemiology

Many have hypothesized that environmental factors are primarily responsible for the development of high blood pressure. Principal evidence for this view consists of reports that unacculturated or "primitive" populations are virtually free of hypertension, but when members of these populations migrate to urban areas their blood pressures rise. There are conflicting interpretations of this phenomenon: Some postulate that the change in diet (especially salt intake) and/or the weight gain that often accompany the move to a modern area are the primary reasons for the development of high blood pressure in populations that were previously free from it. Others suggest that an increase in the level of psy-

chosocial stress is the culprit. Still others surmise that those who experienced the greatest rise in blood pressure may have inherited a genetic predisposition to the disease that is sparked by some environmental phenomena such as dietary salt or psychosocial stress. Interestingly, salt and stress have been assumed to be related to the disease for eons. A Chinese physician stated over 4,000 years ago that "if too much salt is used in food, the pulse hardens [and] when rebellious emotions rise to Heaven, the pulse expires and leaves the body."

A gain in body weight as a result of a generalized increase in food intake is most definitely associated with high blood pressure, and a sustained reduction in body weight is one of the most effective methods of lowering blood pressure.

Specific dietary factors that may affect blood pressure include salt (sodium chloride), potassium, mag-

nesium, calcium, fat, and even licorice. Most interest has centered around salt – more specifically, the sodium portion of the molecule. The most compelling evidence for the influence of salt on blood pressure is the fact that every low-salt-intake population ever studied has manifested very low blood pressure that does not rise with age. Significantly, INTERSALT reported a positive and statistically significant relationship between salt intake and blood pressure in their 52-center study.

Psychosocial stress is also believed to be associated with hypertension. In some population surveys, investigators have reported that societies under high stress also have higher mean blood pressure levels than those under low stress. Unfortunately, stress has been a difficult phenomenon to measure, and the association between stress and blood pressure has been difficult to demonstrate in human populations. One of the most compelling animal models for stress-induced hypertension has been that developed by J. P. Henry and associates (1975). This model makes it necessary for mice to compete for food and territory; most animals in the system develop very high blood pressure and die from kidney failure. Notable exceptions are dominant males whose blood pressure is less elevated. Some believe that this is a valid model applicable to human societies as well.

Heredity is known to be an important contributor to blood pressure regulation, and hence to abnormally elevated blood pressure or hypertension. Like many quantitative genetic traits such as height, levels of blood pressure tend to run in families; some have higher blood pressure, some have lower blood pressure. Other evidence of genetic influence is revealed by the concordance of hypertension in siblings, especially identical, or monozygotic (MZ), twins: If one member of a set of MZ twins has hypertension, there is a strong likelihood that the other will have the disease as well. Genetic influences on arterial pressure have also been demonstrated in inbred strains of rats, mice, and other animals. The hereditary mediators of these genetic influences on blood pressure are not known but probably reside in genetic influences on the major blood pressure control systems.

Many investigators believe that neither genetic nor environmental factors act alone, that in fact there is an interactive relationship between genes and environment. A compelling example of this is the simple breeding experiments in rats carried out by L. K. Dahl and colleagues in the early 1960s. By selective breeding they were able, in a very few generations, to develop two strains of rats: One, ex-

tremely sensitive to the blood pressure-raising effects of salt in the diet, was called "salt sensitive"; the other, resistant to the blood pressure-raising effects of salt, was termed "salt resistant." Humans manifest similar differences, in that some are "salt sensitive" and others are not, and the Dahl model may be applicable to understanding the evolution of "salt sensitivity" in human populations as well.

In former times, as isolated populations diverged and migrated into different ecological systems, they may also have experienced different "selection pressures" related to salt metabolism. These included different temperatures, salt intake, and mortality from salt-depletive diseases such as diarrhea and fever. These "selection pressures" may have resulted in a new genotype that enhanced survival in the new ecology environment by protecting against premature mortality from salt-depletive conditions. If this protective genotype included an enhanced ability to conserve sodium, then it is likely that these adaptations predispose to salt-sensitive hypertension today. It is argued that this may have occurred when many sub-Saharan Africans were forced to migrate to the Western Hemisphere. Mortality rates were very high from salt-depletive diseases, and it is surmised that those with the superior salt-retaining abilities survived and passed their genes on to present-day African Americans. This enhanced genetically based ability to conserve salt may, therefore, be found in greater frequency in Western Hemisphere blacks than in West African blacks, and may be part of the reason the former group today has a higher prevalence of hypertension than does the latter.

Clinical Manifestations

Although in the past a "hard pulse" or "dropsical swellings" (edema) may have signaled hypertension, today the only acceptable way to detect the condition is through the use of the blood pressure cuff (sphygmomanometer). Because the disease is usually asymptomatic, essential hypertension has been appropriately termed the "silent killer." Undetected and uncontrolled, it can damage the arteries, the kidneys, and the heart, and, as several important long-term studies revealed, hypertension is a precursor to premature death from coronary heart disease, stroke, congestive heart failure, kidney (renal) failure, and atherosclerosis.

History

For centuries, the only way to assess "blood pressure" was to feel the pulse, and interpreting its force and rhythm proved to be a useful predictor of disease

and death. In about 2500 B.C., for example, a Chinese physician remarked: "[W]hen the pulse is abundant but tense and hard like a cord, there are dropsical swellings."

More than 4,000 years later, in 1827, the British physician Richard Bright suggested that the dropsical swellings he encountered in a patient were due to obstruction in the kidney's circulatory system. Bright's argument was so persuasive that throughout the remainder of the nineteenth century most physicians considered a strong or tense pulse a symptom of kidney disease.

By the late nineteenth century, the earlier discoveries on the measurement of systolic blood pressure by Stephen Hales, Samuel von Basch, and others led to the invention of the sphygmomanometer (blood pressure cuff). Coupled with the 1905 description of diastolic blood pressure by N. Korotkoff, this device effectively replaced diagnosis by "pulse," and its widespread use led observers to the realization that most patients with elevated arterial pressure did not have a kidney disorder. This newly discovered condition was given various names including angiosclerosis, presclerosis, hyperpiesis, primary hypertensive cardiovascular disease, and essential hypertension. The condition was soon recognized as one of the most common types of cardiovascular disorders. Insurance companies led the way in quantifying the association between this new disease and premature death.

In the 1910s, the medical director of the Northwestern Mutual Life Insurance Company, J. W. Fisher, reported the results of several years of study of the relationship between blood pressure levels and premature death. Table VIII.69.2 provides a brief summary of the findings.

It was obvious to Fisher that the higher the systolic blood pressure, the greater the risk of death. Those with systolic blood pressure levels above 160 mmHg had a probability of premature death about 2.5 times greater than those with a systolic blood pressure of about 140 mmHg. In recommending that any insurance application with a persistent blood pressure of "15 mm Hg above the average for his or her age" should be investigated further, Fisher was probably the first to offer a quantifiable definition of "high blood pressure" (see Table VIII.69.3).

The scientific world was interested in what caused this newly discovered, deadly, and extremely prevalent disease. During the 1930s and 1940s, researchers conducted detailed examinations on the influence of the sympathetic nervous system, the endocrine system, and the renal system on arterial pressure, and were successful in cataloging several types of

Table VIII.69.2. *Relationship between blood pressure and mortality: Northwestern Mutual Life Insurance Company, 1907–14*

Age	Insurance status	Systolic BP	Observed deaths	Expected deaths	Proportion obs/expected
40–60	insured	142.43	85	91.17	0.93
"All ages"	insured	152.58	33	23.62	1.40
"All ages"	not insured	161.44	83	34.95	2.37

Note: Expected deaths = expected deaths in company (80% of M.A. table in source); systolic BP = systolic blood pressure; observed deaths = observed deaths of those with noted systolic blood pressure.

secondary hypertension. Pheochromocytoma was first reported in 1929, Cushing's syndrome in 1932, pyelonephritis in 1937, renal artery stenosis in 1938, and Conn's syndrome (primary aldosteronism) in 1955. In very few cases these "secondary" causes of high blood pressure were cured through surgery, but in the great majority of cases – those with essential hypertension – the ultimate determinant of elevated arterial pressure remained a mystery. One very important breakthrough in understanding the pathophysiology of essential hypertension occurred among investigators working in animal physiology.

In the 1920s, Harry Goldblatt progressively constricted blood flow to the kidney in a dog, which produced a rapidly developing high blood pressure that resulted in death due to heart failure. The experiment, said by T. A. Stamey to have "stimulated more medical research than any single experiment in medical history," sparked a worldwide search for a kidney (renal)-based pressor substance that produced hypertension. By the end of the 1930s, two

teams, one in the United States and one in Argentina, simultaneously discovered that the blood from a "Goldblatt kidney" contained a substance that caused vasoconstriction (squeezing of the arteries). The American group called their substance "angiotonin," while the Argentine group christened the compound "hypertensin." These two teams met and, deciding they were working on the same substance, combined their two names for the compound; the substance became *angiotensin*. These discoveries led to extensive biochemical research into the neural, cellular, and hemodynamic systems that control blood pressure, and eventually to the development of the most widely prescribed antihypertensive medications today. The discovery and elucidation of the biochemical mechanisms controlling blood pressure were extremely important in understanding and controlling high blood pressure, but researchers were still a long way from finding the ultimate cause of the disease.

In the 1950s and 1960s, an important debate occurred between two British physicians over the influence of heredity on high blood pressure in humans. Robert Platt argued that essential hypertension was a "qualitative" disease, controlled by a single gene, with a bimodal population distribution. George Pickering, on the other hand, reasoned that what was termed "hypertension" was only the upper end of a continuous unimodal distribution of blood pressure levels. He thought that hypertension was a "quantitative" disease and was controlled by multiple genes in combination with environmental influences. The debate was never resolved by the two participants. Epidemiological research since then has tended to favor Pickering's quantitative definition; however, in 1983 the analysis of a biostatistician showed the bimodal distribution of blood pressure values in a very large sample from Norway.

Today, both environmental and genetic factors are under intense study as possible etiologic factors at

the individual level and the population level. However, it is still the case that the cause of abnormally elevated blood pressure in over 90 percent of the cases remains unknown. Fortunately, however, successful efforts are being made to lower blood pressure through diet, stress reduction, exercise, weight control, medication, and other means, in the hope that the frequency of premature deaths from hypertension will be reduced throughout the world.

VIII.70
Infectious Hepatitis

Hepatitis literally refers to any inflammation of the liver. Even when restricted by the term "infectious," it has many causes, including malaria and many viruses including that of yellow fever. By convention, however, infectious hepatitis usually refers to a small group of diseases caused by several unrelated viruses, whose most obvious and most consistent symptoms are due to liver damage. Because these diseases are unrelated, except in liver involvement, they will be treated individually. Only their early undifferentiated history can be reviewed in general terms.

Even the distinction between infectious and noninfectious hepatitis is a problem. Autoimmune chronic active hepatitis will not be considered here, although there is evidence of viral involvement in triggering the autoimmune reaction. Liver cancer will be included as a late consequence of infection with hepatitis B virus, because that seems to be the main cause. Other clinically similar diseases that are not covered here are cirrhosis due to toxins such

as alcohol, and jaundice due to physical obstruction of the bile duct.

History

Until the mid-1900s, hepatitis was frequently equated with jaundice, although jaundice is only a sign of a failure to clear normal breakdown products from the blood. Under this terminology, hepatitis and other liver diseases played a very important role in early medical writings, but it is difficult to determine which references relate to hepatitis as we now know it, and which refer to the various other causes of jaundice. It is even more difficult to distinguish one type of hepatitis from another in the early references. Hippocrates identified at least four kinds of jaundice, one of which he considered epidemic and thus, by implication, infectious. Another was "autumnal hepatitis"; this condition, which appeared after an interval appropriate to the incubation period following the dry Mediterranean summer when water supplies would have shrunk, could have been hepatitis A. An emphasis on the liver has persisted into modern times in French popular medicine, where the liver is commonly blamed for ill-defined ailments.

Postclassical writers continued to have difficulty in distinguishing infectious forms from noninfectious forms of jaundice because of the long and variable incubation periods of the infectious diseases. Clear recognition of the infectivity of hepatitis is usually ascribed to Pope Zacarias (St. Zachary), who in the eighth century advocated a quarantine of cases. This had little effect on general thinking, however, because of the variety of circumstances that were associated with different outbreaks. Many cases seemed to be sporadic, but epidemics of what must have been hepatitis A, or enterically transmitted non-A, non-B, were known from the early seventeenth century to be common in troops under campaign conditions. An epidemic of hepatitis B, associated with one lot of smallpox vaccine of human origin, was well described by A. Lürman in 1885. In spite of this, as late as 1908, the dominant medical opinion held that all hepatitis was due to obstruction of the bile duct. The picture did not really begin to clear until the middle of the twentieth century.

Hepatitis A

Etiology

Hepatitis A is caused by an RNA virus 27 nanometers in diameter. It is very similar to poliovirus in general structure and also in its ability to spread through fecal contamination of food and water. The virus is very fastidious in its host range. It is known to infect only humans, apes, and marmosets, and it replicates in vitro only in a few primate cell lines.

Geography and Epidemiology

The virus of hepatitis A is essentially worldwide in its distribution, but it is very much commoner where drinking water is unsafe and sanitation inadequate. Like poliomyelitis, however, the prevalence of disease is often inversely related to the prevalence of virus. In the less developed countries most people become immune through infection in childhood, often with no apparent illness. In semideveloped countries, porcelain water filters may be used to remove the causes of acute bacterial and protozoal diseases, but not the cause of hepatitis virus. Persons from developed countries, especially when traveling in lesser developed areas, are likely to become infected as adults with serious consequences.

Clinical Manifestations

Hepatitis A is manifested by general malaise, loss of appetite, and often, jaundice. Definitive diagnosis of hepatitis requires the demonstration of elevated blood levels of bilirubin and of certain enzymes. Specific diagnosis can be confirmed only by electron microscopic examination of the feces or, more practically, by demonstration of specific antibodies. The disease is seldom fatal when uncomplicated by other conditions, and rarely leaves sequelae. Recovery normally occurs in 4 to 8 weeks.

History

As noted above, although the existence of a hepatitis transmitted by conventional infectious routes could be inferred from the early literature, specific identification of hepatitis A was not accomplished until the late 1960s and 1970s. Then, the development of methods for recognizing hepatitis B, and Saul Krugman's (1967) demonstration of two distinct agents in his studies of children in a home for the retarded, made its existence apparent. The agent of this disease remained enigmatic because it could not be propagated, except in humans. S. M. Feinstone, A. Z. Kapikian, and R. A. Purcell identified the virus in feces in 1973. F. W. Deinhardt and others showed in 1972 that the marmoset was susceptible. Finally, in 1979, P. J. Provost and M. R. Hilleman found a tissue culture line that could be used to grow the virus. An attenuated vaccine has been produced and successfully tested, but not marketed because of continuing production problems.

Hepatitis B

Etiology

The cause of hepatitis B is a very unusual virus. Most important, it is unusually stable and can withstand boiling temperatures and drying without inactivation. Although the virus is of moderate size, 45 nm in diameter, it has the smallest DNA genome known. It accomplishes all its necessary functions by using overlapping stretches of the same genetic information to produce different proteins. The protein that is used for the external surface of the virus is produced in such great excess that the host immune system cannot cope, and becomes paralyzed. To reproduce itself, the virus first makes a copy of its genome in RNA, then recopies that back into DNA. The virus DNA can be integrated into the human genetic material, to provide a secure resting place for the virus and, perhaps, to interfere with the host's growth control mechanism and cause cancer.

Geography and Epidemiology

The stability of hepatitis B virus means that it can persist on any article that is contaminated with blood, most significantly, used needles and surgical instruments. In developed countries it has usually been transmitted in this way. Disposable needles, and tests to make certain that blood for transfusion is free of the virus, have reduced the incidence of this disease in most of the population, but it continues to be a serious problem among intravenous drug abusers.

Hepatitis B can also be sexually transmitted. It is excreted in the semen and transmitted from male to female and from male to male in this way. Because the heterosexual transmission does not form a complete cycle, this has been less of a problem among heterosexuals than in the male homosexual communities of Europe and North America.

The ability of the virus to remain infectious when dried means that it can persist on sharp stones and thorns along paths and, perhaps, also on the probosces of mosquitos. This provides a particularly important mode of spread in primitive societies, where shoes are not worn and scant clothing is used. There, hepatitis B attains very high prevalence levels through gradual exposure over a lifetime.

The most serious pattern of hepatitis B infection is seen in South Asia and sub-Saharan Africa, where transmission from mother to child is common. Infection may occur during birth or via the mother's milk. The significance of this pattern of transmission is that persistent infection is particularly likely to fol-low infection in early life, and liver cancer is a common sequela to persistent infection. In these parts of the world, cancer of the liver is the most common of all cancers and a major cause of death in middle age. The situation is self-perpetuating, in that persons infected in infancy are most likely to become carriers and, hence, most likely to transmit to the next generation.

Clinical Manifestations and Prevention

Infection with hepatitis B can have a variety of outcomes. It may be inapparent, or it may cause a disease indistinguishable from that caused by hepatitis A. It may also, however, cause chronic active hepatitis with or without cirrhosis. Any of these forms may lead to a chronic carrier state in which large quantities of surface antigen, and sometimes infectious whole virus, circulate in the blood. This may damage the kidneys or, as described above, lead to cancer. Thus, although uncomplicated hepatitis B is not often fatal in the acute phase, the total mortality that it causes can be great.

A good vaccine is available. It was proven effective in an extraordinary trial, published by Wolf Szmuness and others in 1980, which was carried out with the help of the New York male homosexual community. Thousands participated, either as vaccine recipients or as part of a placebo group. Because of the high homosexual transmission rate, the incidence of disease in the unvaccinated group was high enough to provide a good level of significance in the results. The first vaccine was produced by purifying hepatitis B antigen from the blood of carriers. This method was efficient, and never proved unsafe, but it left open the possibility that some other disease might be transmitted with the vaccine. Bacterial clones have now been developed that carry the gene for the virus antigen, and the product of these clones has now replaced blood as a source of antigen in the United States. This technology has been expensive, however, and blood-derived vaccine is still used elsewhere. The Chinese of Taiwan have used this type of vaccine to immunize children of infected mothers, and, it is hoped, to break the cycle leading to liver cancer.

It must be remembered that the vaccine only prevents infection. There is as yet no way to cure the disease or abort the carrier state. A person who becomes a carrier is likely to remain so for many years. This means that many people already infected are still doomed to liver cancer, and it emphasizes the need for vaccination of health workers who may be exposed frequently.

History

Although it had been clear for many years that blood products could transmit hepatitis, the full import of this fact did not register on the medical profession. Normal human serum continued to be used to prevent measles in children and to stabilize vaccines. In 1942, a new yellow fever vaccine, mixed with human serum, was administered to U.S. troops headed overseas: Of those vaccinated, 28,000 developed hepatitis, and many died.

The discovery of hepatitis B virus followed an unusual course. In the early 1960s, Baruch Blumberg was studying blood groups in diverse populations and found a new antigen in the blood of Australian aborigines. Later, he found that one of his staff, who worked with the blood samples, had acquired the "Australia antigen," and he recognized that it was infectious. Ultimately, it turned out that this antigen was the surface protein of the hepatitis B virus.

Hepatitis C

Etiology

The virus of hepatitis C has neither been seen nor cultured to the time of writing. However, in 1989, a 3,000-kiloDalton strand of RNA from the blood of an experimentally infected chimpanzee was transcribed into DNA by Qui-Lim Choo and his associates. Propagated into a bacterial clone, this DNA codes for an antigen that crossreacts with the agent of an important transfusion-transmitted hepatitis virus. The discoverers suggested that this "hepatitis C Virus" might be structurally similar to the virus of yellow fever or equine encephalitis. This implies that the virus genetic material was the original RNA strand, not DNA. Hepatitis C is inactivated by chloroform, showing that, unlike the viruses of hepatitis A or B, it has a lipid-containing envelope. The agent of some other transfusion-transmitted non-A, non-B hepatitis is resistant to chloroform, indicating the existence of at least one more unidentified agent of this disease.

Geography and Epidemiology

Wherever hepatitis A and B have been distinguished, a residuum of non-A, non-B cases have remained. Some of these cases are associated with blood transfusions, whereas others, as described below, are not. Hepatitis C is the most common transfusion-transmitted non-A, non-B in the United States, but its role in the rest of the world is unknown. Although it is important as a cause of posttransfusion hepatitis, this is not its main mode of transmission, and it is encountered sporadically

in untransfused persons. Transmission by intravenous drug use is more frequent, and sexual transmission seems also to occur.

Clinical Manifestations

Hepatitis C is a serious disease in that a high proportion of cases develop permanent liver damage. In spite of the paucity of our knowledge about this disease, it is almost unique among viral infections in being treatable. Alpha interferon results in dramatic improvement of hepatitis C liver disease. Unfortunately, the disease often recurs when treatment stops, and the treatment is both expensive and accompanied by unpleasant side effects.

Hepatitis Associated with Delta Agent

Etiology

A fourth hepatitis virus, the delta agent, is unable to grow independently; it grows only in cells that are also infected with hepatitis B. Its defect is an inability to make coat protein, and it must, therefore, wrap itself in the surface protein of another virus to become infectious. As has been noted, hepatitis B produces large quantities of coat protein; in this way, delta can attain very high titers in the blood. Envelopment in the other's coat also gives delta the advantage of hepatitis B virus's freedom from immune attack, and the fact that hepatitis B is commonly persistent in infected persons gives delta a reasonably large field in which to forage. Like hepatitis A, but not B, delta virus has an RNA genome. It does produce one distinctive protein that permits serologic identification of the infection. Wrapped in the hepatitis B coat, it is intermediate in size between A and B, at 36 nanometers.

Geography and Epidemiology

Delta virus has been found in most countries of Europe and North America as well as in much of the rest of the world. Its distribution, however, seems to be more spotty than that of the A or B virus. Although there is no evidence that delta shares the unusual stability of hepatitis B virus, they are often transmitted together by parenteral injection.

Clinical Manifestations

Infection with delta virus, which is always superimposed on an underlying hepatitis B infection, has the highest acute fatality rate of all the hepatitides. Outbreaks of unusually severe hepatitis have often proven to have been caused by it. Otherwise, the symptoms caused by delta are not distinctive.

History

The antigen of delta virus was first recognized in Italy in 1977. Since that time, there has been a number of studies of its distribution and its molecular characteristics. No vaccine is available as yet.

Enterically Transmitted Non-A, Non-B Hepatitis (ET-NANBH)

Etiology

ET-NANBH is a virus structurally similar to but immunologically distinct from hepatitis A. It has recently been associated with a number of previously inexplicable hepatitis epidemics. As yet the virus has not been grown in culture, but it can be serially passed through monkeys and has been identified by electron microscopy. Biochemical characterization remains to be done.

Geography and Epidemiology

Most epidemics attributed to ET-NANBH have occurred in less developed countries at times when even the normally limited sanitation procedures have broken down. Most of these have been in South Asia, but there have also been epidemics in the southern former Soviet Union, in refugee camps in Somaliland, and in Mexican villages, where water supplies became grossly contaminated. All ages are commonly affected, but there may actually be a preponderance of adult cases. These circumstances suggest that ET-NANBH virus is less infectious than hepatitis A and that, even in conditions of generally poor sanitation, most people remain only minimally susceptible.

Clinical Manifestations

ET-NANBH usually causes a hepatitis that is indistinguishable from that caused by hepatitis A or B. However, infected pregnant women have an unusually high mortality rate, which may reach 20 percent.

History

A major epidemic of ET-NANBH occurred in New Delhi in 1955. The New Delhi sewage emptied into the Ganges River a little below the point of a water supply intake. In that year there was a drought, the river became low, and the sewage began to flow upstream. Alert water technicians recognized the problem and raised chlorination levels, so that there was no unusual outbreak of bacterial disease. However, a month or so later, 68 percent of the exposed population developed jaundice, and more than 10 percent of the affected pregnant women died. Careful investigations were made at the time, but the

cause of the epidemic remained undetermined until recently, when Daniel Bradley and his associates developed a test based on reactions (observed in the electron microscope) of immune sera and virus from feces of patients in a more recent Burmese epidemic.

VIII.71
Infectious Mononucleosis

Infectious mononucleosis is an acute infectious disease of children, adolescents, and young adults. It is caused by the Epstein–Barr virus (EB virus) and is followed by lifelong immunity.

Distribution and Incidence

On the basis of the populations investigated, it would seem that infectious mononucleosis occurs worldwide but attacks only those persons who have had no EBV antibodies. The virus replicates in the salivary glands, is present in the oropharyngeal secretions of patients ill with the disease, and continues to be shed for months following convalescence. As a lifelong inhabitant of the lymphoid tissues, it is excreted intermittently into the oropharynx.

In the underdeveloped countries it is a disease of childhood, and, since it spreads by contact with oral secretions, crowding and unhygienic surroundings favor its ready transmission. In more developed countries, it strikes especially those of the 15- to 25-year age group and is recognized clinically as infectious mononucleosis. In the United States, on college campuses, the disease is commonly known as the "kissing disease."

Children of low socioeconomic state almost universally show antibodies to the virus. (In Ghana, 84 percent of infants have acquired antibodies by age 21 months.) In a worldwide prospective study of 5,000 children and young adults without EB virus antibodies, 29 percent developed antibodies within a period of 4 to 8 years. Among susceptible college students the annual incidence of the disease is about 15 percent.

Immunology

Specific antibodies to EB virus are demonstrable early after the onset of the disease. Although the higher titers may decrease in subsequent months, they remain at detectable levels throughout life, along with immunity to the disease.

Pathology and Clinical Manifestations

Although the pathological findings may be multivisceral, the predominant finding is follicular hyperplasia of the lymph nodes. The lymphoid tissues show diffuse proliferation of the atypical lymphocyte that is present in the spleen and the walls of blood vessels, is periportal in the liver, and appears in the peripheral bloodstream. These monocytoid lymphocytes (Downey cells) may make up 10 percent or more of the white cells and are of diagnostic significance.

In childhood the disease is subclinical or masquerades as one of many episodes of upper respiratory infection. In the typical youthful adult, after an incubation period of about 5 or 6 weeks, clinical disease shows itself with prodromes of malaise, fatigue, headache, and chilliness followed by high fever, sore throat, and tender swollen cervical lymph nodes. Examination shows, in addition to the lymphadenopathy, paryngitis often with scattered petechiae and swelling of the pharyngeal lymphoid structures, hepatosplenomegaly, and, not infrequently, a transient maculopapular rash. Palpebral and periorbital edema may develop. Mild jaundice appears in some 10 percent of patients. Rarely are symptoms related to the central nervous system. Following an initial leukopenia, a leucocytosis of 15,000 to 20,000 or higher appears with an absolute lymphocytosis and with atypical lymphocytes prominent as noted above.

In most patients the disease is mild, and recovery occurs within several weeks. College students are generally up and about within a week or so. Complications in the nervous system may occasionally occur in adults, but death from the disease is extremely rare, splenic rupture being the most serious complication.

History and Geography

This disease was described first by a Russian pediatrician, Nil F. Filatov, in 1885, as idiopathic adenitis. Four years later, a German physician, Emil Pfeiffer, also described a disease that was epidemic in children and characterized by glandular enlargement. He gave it the name *Drüsenfieber* (glandular fever). In 1896, J. P. West wrote of a similar epidemic in the United States, but it was only in 1920 that Thomas Sprunt, of Baltimore, gave it the name infectious mononucleosis. H. Downey and C. A. McKinly described the characteristic mononuclear leucocytes in 1923. The Epstein – Barr virus was identified by W. Henle and associates in 1968.

Inflammatory Bowel Disease

The inflammatory bowel diseases (IBD) – ulcerative colitis and Crohn's disease – constitute a group of disorders of the small and large intestine whose causes and interrelationships remain obscure (Kirsner and Shorter 1988). Their course is acute and chronic, with unpredictable remissions and exacerbations, and numerous local and systemic complications. Treatment is symptomatic and supportive. The economic drain imposed by these diseases in terms of direct medical, surgical, and hospitalization expenses, loss of work, and interrupted career development is enormous. The emotional impact upon the patient and upon the family is equally substantial. In these contexts, the inflammatory bowel diseases today are one of the major worldwide challenges in medicine.

Ulcerative Colitis

Clinical Manifestations, Pathology, and Diagnosis

The principal symptoms of ulcerative colitis are rectal bleeding, constipation early (in ulcerative proctitis), diarrhea usually, abdominal cramping pain, rectal urgency, fever, anorexia, fatigue, and weight loss. The physical findings depend upon the severity of the colitis, ranging from normal in mild disease, to fever, pallor from loss of blood, dehydration and malnutrition, and the signs of associated complications. X-ray and endoscopic examinations demonstrate diffuse inflammation and ulceration of the rectum and colon in 50 percent of patients, and the adjoining terminal ileum. Ulcerative colitis begins in the mucosa and submucosa of the colon (the inner bowel surface); in severe colitis the entire bowel wall may be involved. The principal histological features are the following: vascular congestion, diffuse cellular infiltration with polymorphonuclear cells, lymphocytes, plasma cells, mast cells, eosinophils, and macrophages; multiple crypt abscesses; and shallow ulcerations. Chronic ulcerative proctitis is the same disease as ulcerative colitis, except for its restriction to the rectum and its milder course.

The laboratory findings reflect the severity of the colitis. The white blood cell count usually is normal except in the presence of complications. The hemoglobin, red cell, and hematocrit are decreased in propor-

tion to the loss of blood. The sedimentation rate may be elevated but frequently is normal. Blood proteins including serum albumin often are diminished. The stools contain blood. Cultures are negative for known pathogenic bacteria.

Complications are numerous. In the colon, they include pericolitis, toxic dilatation, perforation, peritonitis, hemorrhage, obstruction, polyps, carcinoma, and lymphoma. The many systemic complications include iron-deficiency anemia, hemolytic anemia, protein loss, malnutrition, retardation of growth in children, arthritis, iritis, sacroileitis, metabolic bone disease, skin problems (erythema nodosum, pyoderma gangrenosum), pyelonephritis, nephrolithiasis, liver disease (fat infiltration, hepatitis, pericholangitis, sclerosing cholangitis), and vascular thromboses.

The differential diagnosis includes specific bacterial infections, ischemic colitis, diverticulitis, and Crohn's disease of the colon.

Treatment

The therapeutic emphasis in ulcerative colitis involves a general program of nutritional restoration, emotional support, sulfasalazine, 5-aminosalicylic acid, antispasmodics, antibacterial drugs, adrenocorticotropin (ACTH), and adrenal corticosteroids. Proctocolectomy and ileostomy is a highly successful operation for ulcerative colitis. The Kock continent pouch, and total colectomy together with ileoanal anastomoses, with and without ileal pouch, offer useful surgical alternatives in selected patients. The prognosis of ulcerative colitis has improved considerably, and the mortality has diminished to less than 1 percent as a result of the many medical and surgical therapeutic advances.

Etiology

Ulcerative colitis is common among young people, especially below the age of 40 years, but no age range is exempt and the number of older patients is increasing. There is no sex predominance. The circumstances of onset of ulcerative colitis in most instances are not known. Patients usually appear to be in good health; occasionally, symptoms appear after visits to countries such as Mexico and Saudi Arabia, implicating an enteric infection. Initial thoughts as to etiology emphasized a microbial infection, and this possibility continues today. Many organisms have been implicated and discarded, including diplostreptococcus, *Streptococcus, Escherichia coli, Pseudomonas aeruginosa, Clostridium difficile, Sphaerophorus necrophorus,* Morgan's bacillus, *Shigella* organisms,

Salmonella paratyphi, Proteus organisms, viruses (e.g., lymphopathia venereum), parasites, and fungi (*Histoplasma,* Monilia). Immunologic mechanisms have been implicated on the basis of clinical, morphological, and experimental observations. The immunologic disorder may be one of defective immunoregulation, as in an altered response to a microbial infection or to usual bowel organisms. Nutritional deficiencies are common but are secondary developments.

Various circumstances such as acute respiratory illness, enteric infections, and antibiotics may act as a "trigger mechanism," precipitating the disease in genetically "vulnerable" persons. Genetic influences may be expressed through the immune response genes and the mucosal immune system of the bowel. Emotional disturbances are common in patients with ulcerative colitis, but they probably do not initiate the disease. The important interactions among the central nervous system, the gut, and the endocrine and immune systems now under investigation may clarify these issues.

Crohn's Disease

Crohn's disease, also called regional enteritis, jejunoileitis, ileocolitis, and Crohn's colitis, is an acute and chronic inflammatory disease of the small intestine, especially the terminal ileum, but actually involving the entire gastrointestinal tract, from the mouth to the anus. The disease occurs frequently among children, adolescents, and young adults, but is increasing in people over the age of 60. There is a slight female:male predominance.

Clinical Manifestations

The clinical manifestations include fever, diarrhea, cramping abdominal pain, anemia, and weight loss. Initial symptoms may include arthralgias suggesting an arthritis, gynecological difficulties, urinary symptoms (frequency, dysuria), or a combination of severe loss of appetite, weight loss, and depression, suggesting anorexia nervosa. Slowing or retardation of growth may be the first clinical indication of illness in children. Occasionally, the initial presentation is indistinguishable from an acute appendicitis.

The physical findings include fever, "toxemia," tenderness in the mid abdomen and right lower abdominal quadrant, and often a tender loop of bowel or an inflammatory mass composed of adherent inflamed bowel, thickened mesentery, and enlarged abdominal lymph nodes, palpated in the right lower abdominal quadrant. The laboratory findings include a normal or elevated white blood cell count, increased sedimentation rate, anemia, decreased total proteins

and serum albumin, and evidence of undernutrition. By X-ray, the intestinal lumen is found to be ulcerated and narrowed. Fistulas to adjacent structures are not uncommon. The histological features include transmural disease, knifelike ulcerations overlying the epithelium of lymphoid aggregates in Peyer's patches, profuse cellular accumulations, lymphatic dilatation, prominent lymphoid follicles, and granuloma formation.

The complications of regional enteritis include most of the problems enumerated for ulcerative colitis and, in addition, perianal abscess, perineal fistulas, abdominal abscess and fistual formation, intestinal narrowing and obstruction, carcinoma of the small and large intestine, and obstructive hydronephrosis. In patients with multiple bowel resections and significant loss of intestinal digestive capacity, the complications include altered bile salt metabolism, steatorrhea, increased absorption of dietary oxalate and hyperoxaluria, increased frequency of kidney stones, zinc and magnesium deficiencies, other nutritional deficits including vitamins B_{12} and D, bone demineralization, and osteopenia.

Treatment

As in ulcerative colitis, medical treatment is symptomatic, supportive, and individualized, with emphasis upon restoration of nutrition, antispasmodic medication, and antibacterial and antiinflammatory medication. Corticotropin and adrenal steroids reduce the inflammatory reaction, but do not necessarily cure the disease. Immunosuppressive drugs (6-mercaptopurine, azathioprine) may be helpful adjuncts but require continuing administration. Surgical treatment is necessary for complications, especially abscess and fistula formation, unrelenting intestinal obstruction, and uncontrollable hemorrhage. The recurrence rate is high.

Etiology

As in ulcerative colitis, etiologic hypotheses vary widely, from the excessive eating of cornflakes, refined sugars, or margarine, to bottle-feeding rather than breastfeeding, environmental pollutants, the indiscriminate administration of antibiotics, and the use of oral contraceptives among young women. A wide variety of bacteria and viruses have been implicated, and although none has achieved etiologic status, the "new" microbial pathogens now being identified have renewed interest in microbial possibilities including mycobacteria. Other suggested but unproven etiologies have included blunt trauma to the abdominal wall (e.g., seat belt injury); the ingestion

of foreign material (e.g., talc), producing an obstructive lymphangitis; sarcoidosis; altered intestinal neurohumoral mechanisms; and nutritional deficiencies.

Ulcerative Colitis and Crohn's Disease: General Aspects

Epidemiology, Distribution, and Incidence

Ulcerative colitis and Crohn's disease share similar epidemiological and demographic features. The incidence of ulcerative colitis, still considerable, apparently has stabilized or possibly diminished in many areas of the world, with several exceptions (Norway, Japan, Faroe Islands, northeast Scotland). Ulcerative colitis appears to be more prevalent in the United Kingdom, New Zealand, Australia, the United States, and northern Europe. It is less frequent in central and southern Europe, infrequent in the Middle East, uncommon in South America and Africa, but increasing in Japan.

Similarly Crohn's disease is most common in the United Kingdom, the United States, and Scandinavia, on the rise in Japan, but less frequent in central and northern Europe and uncommon in Africa and South America. The incidence of Crohn's disease has been increasing throughout much of the world (Great Britain, the United States, Norway, Finland, Switzerland, Israel, and South Africa) but appears to have stabilized in such diverse cities as Aberdeen (Scotland), Baltimore (United States), Cardiff (Wales), and Stockholm (Sweden). B. M. Mendeloff and A. I. Calkins (1988) estimate that in the United States the annual incidence "for the sum of both disorders" is 5 to 15 new cases per 100,000 population. The worldwide prevalence of Crohn's disease, especially in industrialized areas, and the worldwide similarity of its clinical, radiological, and pathological features, regardless of geographic, ethnic, dietary, and sociocultural differences, are noteworthy.

The inflammatory bowel diseases are more frequent among white than black populations; but Crohn's disease in particular is increasing among the black populations of the United States and Great Britain. Ulcerative colitis and especially Crohn's disease are much more common among the Jewish population of the United States, the United Kingdom, and Sweden than among other members of the population. In Israel, Crohn's disease is more common among Ashkenazi than among Sephardic Jews. Overall, ulcerative colitis and Crohn's disease occur among all ethnic groups, including the Maoris of New Zealand, Arabs (e.g., Kuwait, Saudi Arabia), and probably the Chinese, albeit infrequently. An

intriguing and unexplained epidemiological observation has to do with the scarcity of cigarette smokers in patients with ulcerative colitis and the apparently increased vulnerability of former smokers to ulcerative colitis, whereas by contrast there is an excess of smokers in Crohn's disease populations. It should be noted that the "smoking connection" does not obtain among children with IBD.

Genetic (Familial) Aspects

Ulcerative colitis and Crohn's disease are not "classic" genetic disorders. There are no inheritable protein or metabolic abnormalities, no antecedent chromosomal defects, no genetic markers, no consanguinity, and no Mendelian ratios. However, genetic influences are important in the development of ulcerative colitis and even more so in Crohn's disease, as reflected in their familial clustering (20 percent for ulcerative colitis and up to 40 percent for Crohn's disease). In addition to the initial patient, one more member of the family is usually affected, but up to 8 patients in a single family have been observed. IBD occurs with a high degree of concordance among monozygotic twins. The nature of the genetic influence in IBD is not known. Thus far, no universally distinctive histocompatibility haplotype linkage has been demonstrated. The occasional occurrence of Crohn's disease or ulcerative colitis in adopted children or later in the initially healthy mate of a patient with IBD supports an environmental (possibly viral) rather than a genetic mechanism. Current etiologic studies focus upon a genetically mediated abnormality in the immune response genes (defective immunoregulation in the bowel's mucosal immune system), possible linkage with a known genetic locus, or with specific T-cell antigen receptor genes.

Comparisons and Contrasts

Is there a pathogenetic relationship between ulcerative colitis and regional ileitis/colitis? In the absence of differentiating biological markers, a definitive answer to this important question is not possible at present. The simultaneous presence or sequential evolution of both active ulcerative colitis and active regional ileitis/colitis, and the sequential development of ulcerative colitis followed by Crohn's disease in a single patient, though they may occur, probably have never been documented to everyone's satisfaction.

The Similarities. Both disorders have significant familial associations. Approximately 25 percent of families with multiple instances of IBD show an intermingling of ulcerative colitis and Crohn's disease. Both diseases share the same epidemiological and demographic features. They also share many symptoms (abdominal pain, diarrhea, weight loss, rectal bleeding), local complications (hemorrhage, perforation, toxic dilatation of the colon), and systemic complications (erythema nodosum, pyoderma gangrenosum, arthritis, liver disease, kidney stones).

The Differences. Ulcerative colitis is a continuous mucosal disease, at least initially, with diffuse involvement of the colon. Crohn's disease is a transmural process, focal in distribution, penetrating through the bowel wall, and producing microabscesses and fistulas. Histologically, granulomas and prominent lymphoid aggregates are much more common in Crohn's disease than in ulcerative colitis.

Ulcerative colitis is limited to the colon and occasionally a short segment of terminal ileum; Crohn's disease focally may involve any segment of the alimentary tract, mouth to anus. Ulcerative colitis is a continuous inflammatory reaction; Crohn's disease, wherever located, is a discontinuous, focal process. Perianal suppuration and fistula formation (enterocutaneous, enteroenteric, enterocolonic, enterovesical, enterouterine) characterize Crohn's disease, but not ulcerative colitis. Immune-modulating drugs are more helpful in Crohn's disease than in ulcerative colitis. Proctocolectomy and ileostomy are curative in ulcerative colitis, but the same operation in Crohn's disease carries a recurrence rate of approximately 15 to 20 percent.

The answer to the question whether the two ailments are related would seem to be that ulcerative colitis and Crohn's disease are probably separate disorders, with limited morphological and clinical expressions accounting for overlapping manifestations.

History of IBD

Ulcerative Colitis

Early Literature to 1920

In all probability, we shall never know for certain who first described ulcerative colitis (UC) . . . for although the disease was initially referred [to] by name in the latter half of the century, it seems likely that its existence was recognized for over two millennia before that time. (Goligher et al. 1968)

Hippocrates was aware that diarrhea was not a single disease entity, whereas Aretaeus of Cappado-

cia in the second century described many types of diarrhea, including one characterized by "foul evacuations," occurring chiefly in older children and adults. Instances of an "ulcerative colitis" apparently were described by Roman physicians, including Ephesus in the eleventh century. "Noncontagious diarrhea" flourished for centuries under a variety of labels, such as the "bloody flux" of Thomas Sydenham in 1666. In 1865, medical officers of the Union Army during the American Civil War described the clinical and pathological features of an "ulcerative colitis-like" process in patients with chronic diarrhea. Several of these cases actually suggested Crohn's disease more than ulcerative colitis but in the absence of modern microbiological studies, the question is moot (Kirsner and Shorter 1988).

S. Wilks and W. Moxon (1875) wrote: "We have seen a case affected by discharge of mucus and blood, where, after death, the whole internal surface of the colon presented a highly vascular soft, red surface covered with a tenacious mucus and adherent lymph. . . . In other examples there has been extensive ulceration." Because the concept of microbial illnesses had not yet emerged, the possibility of a specific infection, in at least some instances, cannot be excluded. W. H. Allchin (1885), W. Hale-White (1888), and H. Folet, writing in 1885, are among those cited by G. Placitelli and colleagues (1958), who provided accurate clinical accounts. G. N. Pitt and A. E. Durham in 1885 described a woman of 29 years with a 5-year history of diarrhea:

[M]ore than half of the area of the whole colon was covered with small friable villous polypi . . . the intervening depressed white areas in the muscular coat, the mucous coat having entirely ulcerated away. . . . the circumference of the bowel is only 1⅓ – 2 inches, being narrower than the small intestine. (Kirsner 1988)

During the 1880s and 1890s, instances of an ulcerative colitis were reported by numerous physicians from England, France, Germany, Italy, and other European countries (Kirsner 1988). In 1888 Hale-White, a contemporary of Wilks at Guy's Hospital, described 29 cases of ulcerative colitis and remarked that "[t]he origin of this ulceration is extremely obscure . . . it is not dysentery." He cited similar observations by W. Leube (*Ziemssen's Cyclopedia*), K. Rokitansky ("Pathological Anatomy"), H. Nothnagel (*Beitrage zur Physiologie und Pathologie des Darmes*, 1884), and A. Bertrand and V. Fontana ("De l'enterocolite chronique endémique des Pays Chauds"), but again complete confirmation is not possible.

In 1895 Hale-White reported the association of liver disease and ulcerative colitis, and in 1920 R. F. Weir performed the operation of appendicostomy to facilitate "colonic drainage" in ulcerative colitis. J. P. Lockhart-Mummery (1907) described seven instances of colon carcinoma among 36 patients with ulcerative colitis, and emphasized the diagnostic value of sigmoidoscopy at the Royal Society of Medicine. By 1909, approximately 317 cases of patients with "ulcerative colitis" had been collected (between 1888 and 1907) from London hospitals, and in 1909 Allchin recorded perhaps the first instance of "familial" ulcerative colitis. Additional instances of ulcerative colitis were noted at the Paris Congress of Medicine in 1913. J. Y. Brown (1913) of the United States may have been the first to suggest the procedure of ileostomy in the surgical management of ulcerative colitis.

American and European Literature, 1920–45. During the 1920s, the number of reports increased steadily and included those by H. Rolleston, C. E. Smith, J. M. Lynch and J. Felsen of New York, A. F. Hurst, and E. Spriggs. During the same decade, Hermann Strauss of Berlin may have been the first to recommend blood transfusions in the treatment of ulcerative colitis. In 1924 J. A. Bargen of the Mayo Clinic published his experimental studies implicating the diplostreptococcus in the etiology of ulcerative colitis – a notion later discarded. More important was his (1946) comprehensive clinical study of the course, complications, and management of "thrombo-ulcerative colitis." C. D. Murray first drew public attention to the psychogenic aspects of ulcerative colitis in 1930, which were confirmed by A. J. Sullivan and C. A. Chandler (1932). This initiated the period (1930–60s) of intense psychiatric interest in ulcerative colitis.

Worldwide attention was directed to *"colites ulcereuses graves non-ambienne"* at the 1935 International Congress of Gastroenterology in Brussels; the amount of literature on the disease increased rapidly after this, with clinical contributions initiated by many physicians from many countries.

By the 1940s, ulcerative colitis, if not increasing in prevalence, at least was recognized more often than regional ileitis and was the dominant IBD disease. However, by the end of World War II, Crohn's disease (regional enteritis, Crohn's colitis) had become more frequent. Concurrently with an apparent stabilization of the frequency of ulcerative colitis in the United States, Crohn's disease has been the more prominent of the two prototypes of nonspecific IBD.

Crohn's Disease

Literature before 1900. The initial description of Crohn's disease may date back to Giovanni Battista Morgagni who, in 1761, described ileal ulceration and enlarged mesenteric lymph nodes in a young man who died of an ileal perforation; or, perhaps even earlier, to the "iliac passion" – claims that can never be substantiated. More suggestive early instances of Crohn's disease include an 1806 report by H. Saunders and that by C. Combe and Saunders (1813). Nineteenth-century descriptions of ileocecal disease consistent with today's concept of Crohn's disease, regional ileitis, or ileocolitis were authored by J. deGroote, J. Abercrombie, J. S. Bristowe, N. Moore, and Wilks. Wilks's (1859) description of the postmortem examination on the celebrated Isabella Bankes is of interest:

The intestines lay in a coil adherent by a thin layer of lymph indicative of recent inflammation; the ileum was inflamed for three feet from the ileo-caecal valve though otherwise the small intestine looked normal. The large intestine was ulcerated from end to end with ulcers of various sizes mostly isolated [t]hough some had run together.... Inflammation was most marked at the proximal colon and the caecum appeared to be sloughing causing the peritonitis.

Thirty years later, Samuel Fenwick (1889) described the necropsy findings suggestive of Crohn's disease, in a 27-year-old female:

Many of the coils of intestine were adherent and a communication existed between the caecum and a portion of the small intestine adherent to it, whilst the sigmoid flexure was adherent to the rectum, and a communication also existed between them. The lower end of the ileum was much dilated and hypertrophied, and the ileocecal valve was contracted to the size of a swan's quill.

Literature after 1900. Early in this century, T. Kennedy Dalziel (1913) of Glasgow described a group of 13 patients dating back to 1901 with findings closely resembling those recorded by B. B. Crohn, L. Ginzburg, and G. D. Oppenheimer (1932): "The affected bowel gives the consistence and smoothness of an eel in a state of rigor mortis, and the glands, though enlarged, are evidently not caseous." Many reports of single instances of a chronic stenosing inflammation of the last portion of the small bowel ("terminal ileitis") appeared subsequently. In addition, F. J. Nuboer (1932) of Holland described two patients with "chronic phlegmonous ileitis," manifesting the same gross and histological findings that Crohn and associates described. Similarly, M. Golob (1932) re-

ported a "chronic infectious granuloma" involving the ileocecal region in a 44-year-old male presenting with rectal bleeding.

Soon after Crohn's (1932) paper, A. D. Bissell (1934) of the University of Chicago reported on two patients. The first patient was a 39-year-old male with symptoms of 4 years' duration, including abdominal cramps, diarrhea, and weight loss who required resection of an ileocecal mass. The second patient, a 28-year-old male, also required resection of the terminal ileum and cecum. These early case reports depicted Crohn's disease ("regional ileitis") as a mass-producing, bowel-narrowing process, virtually always requiring surgical intervention.

The principal clinical differentiation in the early part of the twentieth century included intestinal tuberculosis and granuloma formation simulating tumor in the bowel. E. Moschowitz and A. D. Wilensky (1923), from New York's Mount Sinai Hospital, reflecting that center's interest in granulomatous inflammations of the bowel, described four patients with nonspecific granulomatous disease of the intestine. Ginzburg and Oppenheimer, in the Pathology Department of the same hospital, identified a dozen instances of a localized hypertrophic, ulcerative stenosis of the distal 2 or 3 feet of the terminal ileum. Specific causes such as amebiasis, actinomycosis, intestinal tuberculosis, and syphilis were ruled out. In 1930, Crohn had two patients with a similar process. Crohn's first case was a 16-year-old boy with diarrhea, fever, a mass in the right lower abdominal quadrant, and pain, requiring ileocecal resection. Interestingly, the patient's sister also required an operation for regional ileitis several years later – the first recorded instance of "familial regional ileitis." Bargen, anticipating the more extensive involvement of the small intestine, suggested the term *regional enteritis* instead of "terminal ileitis."

In 1925 T. H. Coffen of Portland, Oregon, referring to earlier reports of intestinal granulomas, described a 20-year-old man with abdominal symptoms since 1915, diagnosed as phlegmonous enteritis. In 1916, 8 inches of thickened bowel were removed because of obstruction. A second obstruction 5 months later necessitated the removal of 24 inches of ileum. Eight months later a third resection was performed for the same condition. The pathological description of the resected bowel today would be consistent with a diagnosis of Crohn's disease.

In other notable articles, H. Mock in 1931 and R. Colp in 1933 chronicled involvement of the colon. C. Gotlieb and S. Alpert (1937) described regional

jejunitis, and J. R. Ross (1949) identified "regional gastritis." W. A. Jackman and J. L. Kantor in 1934 and R. Marshak in 1951 described the roentgenographic appearance of Crohn's disease of the small bowel and the colon, and in 1936 Harold Edwards described a resected terminal ileum, with "the consistency of a hosepipe" from a 23-year-old woman with a history of persistent diarrhea, abdominal pain, and weight loss. R. Shapiro (1939) comprehensively reviewed the literature through the 1930s and identified numerous case reports mainly in the earlier German surgical literature of "inflammatory tumors" of the gastrointestinal tract, especially the colon; some of these probably were instances of Crohn's disease.

Authoritative descriptions of the pathological features of Crohn's disease have been provided by S. Warren and S. C. Sommers (1948), G. Hadfield (1939), and H. Rappaport and colleagues (1951). In 1952, Charles Wells of Liverpool distinguished between ulcerative colitis and what he termed "segmental colitis," and suggested that this latter form of colonic lesion was a variant of Crohn's disease. In 1955 Bryan Brooke and W. Trevor Cooke of England were among the first to recognize "right-sided colitis" as Crohn's disease of the colon rather than as ulcerative colitis, but it was not until reports in 1959 and 1960 by Lockhart-Mummery and B. C. Morson (1960) that Crohn's disease of the colon was generally accepted as a valid entity.

Eponym of Crohn's Disease. New instances of granulomatous inflammation of the small bowel were reported in Great Britain, occasionally designated as Crohn's disease, in 1936. In America the term "Crohn's disease" was first employed as a synonym by F. Harris and colleagues (1933) and later by Hurst of Great Britain. But others have also claimed priority. In Poland this entity was called "Lesniowski–Crohn's disease," whereas in Scotland the eponym of "Dalziel's disease" was recorded. H. I. Goldstein designated the condition "Saunders–Abercrombie–Crohn's ileitis."

To some American observers, this entity might well have been called "CGO disease," to include the important contributions of not only Crohn, but also Ginzburg and Oppenheimer, who provided 12 of the 14 cases constituting the (1932) *JAMA* paper. Whatever the "labeling" circumstances, the entity today carries the eponym "Crohn's disease" as the most convenient designation, which is now sanctioned by worldwide usage to designate a unique inflammatory process involving any part of the gastrointesti-

nal tract. It is to the credit of Crohn, Ginzburg, and Oppenheimer that their clinical description stimulated worldwide interest in this disease. Certainly much credit belongs to Crohn for his long clinical interest in the illness, his many publications and lectures on the subject, and his encouragement of others in the further investigation of the problem.

On the matter of eponyms, the comment of Thomas Lewis (1944) seems appropriate: "Diagnosis is a system of more or less accurate guessing, in which the end point achieved is a name. These names applied to disease come to assume the importance of specific entities . . . whereas they are, for the most part, no more than insecure and therefore temporary conceptions."

VIII.73
Influenza

Influenza, also known as flu, grip, and grippe, is a disease of humans, pigs, horses, and several other mammals, as well as of a number of species of domesticated and wild birds. Among humans it is a very contagious respiratory disease characterized by sudden onset and symptoms of sore throat, cough, often a runny nose, and (belying the apparent restriction of the infection to the respiratory tract) fever, chills, headache, weakness, generalized pain in muscles and joints, and prostration. It is difficult to differentiate between single cases of influenza and of feverish colds, but when there is a sudden outbreak of symptoms among a number of people, the correct diagnosis is almost always influenza.

There is at present no specific cure that is effective against this viral disease. In mild cases the acute symptoms disappear in 7 to 10 days, although general physical and mental depression may occasionally persist. Influenzal pneumonia is rare, but often fatal. Bronchitis, sinusitis, and bacterial pneumonia are among the more common complications, and the last can be fatal, but seldom is if properly treated. Influenza is generally benign, and even in pandemic years, the mortality rate is usually low – 1 percent or less – the disease being a real threat to life for only the very young, the immunosuppressed, and the elderly. However, this infection is so contagious that in most years multitudes contract it, and thus the number of deaths in absolute terms is usually quite high. Influenza, combined with pneumonia, is one of the 10 leading causes of death in the United States in the 1980s. The sequelae of influenza are often hard to discern and define – prolonged mental depression, for instance – but there is evidence that the global pandemic of encephalitis lethargica (parkinsonism) of the 1920s had its origin in the great pandemic of 1918–19.

Distribution and Incidence

In seemingly every year, there are at least some cases of influenza in every populated continent and in most of the large islands of the world. During epidemics, which occur somewhere almost annually, the malady sweeps large regions, even entire continents. During pandemics, a number of which have occurred every century for several hundred years, the disease infects a large percentage of the world's

population and, ever since the 1889–90 pandemic, in all probability a majority of that population. Not everyone so infected becomes clinically sick, but nonetheless influenza pandemics are among the most vast and awesome of all earthly phenomena. The disease strikes so many so quickly and over such vast areas that the eighteenth-century Italians blamed it on the influence of heavenly bodies and called it *influenza.*

Etiology and Epidemiology

The causative agents of influenza are three myxoviruses, the influenza viruses A, B, and C. The B and C viruses are associated with sporadic epidemics among children and young adults, and do not cause pandemics. The A virus is the cause of most cases during and between pandemics. It exists and has existed in a number of subtypes, which usually do not induce cross-immunity to one another. In most instances, influenza viruses pass from person to person by breath-borne droplets, and from animal to animal by this and other routes. Although the disease can spread in warm weather, its epidemics among humans in the temperate zones usually appear in the winters, when people gather together in schools, houses, buses, and so forth under conditions of poor ventilation. Geographically, the malady spreads as fast as its victims travel, which in our time can mean circumnavigation of the globe in a few months, with the pandemic veering to the north and south of the tropics with the changing seasons.

Immunology

Influenza A virus is distinctive in its genetic instability, which probably makes permanent immunity to the disease impossible, no matter how many times it is contracted. This, plus its short incubation period of 1 to 2 days and the ease with which it passes from person to person, enables the disease to swing around the globe in pandemics and, between them, to maintain itself not only in epidemics among the previously unexposed and newborn, but also among the previously exposed and adult majority. Between pandemics the proteins on the shell of the virus undergo slow but constant genetic change, rendering acquired immunity ever more obsolete. This genetic instability is the likeliest explanation for the fact that even during pandemics the virus seems to change sufficiently to produce repeating waves of the infection, often two and three in a given locale. Several times a century, the virus has changed radically, rendering obsolete the immunologic defenses of the great majority of humans vis-à-vis influenza,

including immunologically experienced adults. In the mildest of these pandemics, millions fall ill and thousands die.

The cause of the major changes in the virus that set off the pandemics is still a matter of mystery. Many theories have been devised, including those pertaining to the influence of sun spots and such. Currently the three most plausible theories are the following:

1. The influenza A virus currently circulating through the human population undergoes a series of mutations, which rapidly and radically transform the virus into an infection-producing organism for which human immune systems are unprepared.
2. An animal influenza virus abruptly gains the ability to cause disease in humans, with the same results.
3. A human influenza virus and an animal influenza virus recombine ("cross-breed") to produce a new virus that retains its capacity to infect humans but has a surface with which human immune systems are unfamiliar.

In the present state of research, the first of these three seems the least likely and the last the most likely explanation. Nothing, however, is certain yet, and the cause of influenza pandemics remains unknown.

History and Geography

Through the Eighteenth Century

The origins of influenza are unknown. It is not an infection of our primate relations, and so it is probably not a very old human disease. It has, as far as we know, no latent state, and it does create a usually effective (though short-lived) immunity, and so it was unlikely to have been common among our Paleolithic ancestors or those of our herd animals before the advent of agriculture, cities, and concentrated populations of humans and domesticated animals. In small populations, it would have burnt itself out by killing or immunizing all available victims quickly. But because the immunity engendered is ephemeral, it does not require the large populations that measles and smallpox do to maintain itself.

Although influenza could be among the older diseases of civilization, acquired from pigs or ducks or other animals thousands of years ago, there is no clear evidence of its spread among humans until Europe's Middle Ages, and no undeniable evidence until the fifteenth and sixteenth centuries. Yet,

since that time, the malady has been our unfailing companion, never absent for more than a few decades, if that. The association of the disease with Old World domesticated animals, and the extreme vulnerability to it of isolated peoples such as Amerindians, suggest that it was restricted to the Old World until the end of the fifteenth century. In that and the following centuries it spread overseas with Europeans and their livestock, and may account for much of the clinically undefined morbidity and mortality among the indigenes of Europe's transatlantic and transpacific empires. Large-scale epidemics of influenza did roll over Europe in 1510, 1557, and 1580. The last, the first unambiguously pandemic explosion of the disease, extended into Africa and Asia as well. There were further epidemics in Europe in the seventeenth century, but seemingly of only a regional nature.

At least three pandemics of influenza occurred in Europe in the eighteenth century – 1729–30, 1732–3, and 1781–2 – and several epidemics, two of which – 1761–2 and 1788–9 – may have been extensive enough to be termed pandemics. The pandemic of 1781–2 was, in its geographic spread and the number of people infected, among the greatest manifestations of disease of all history. Physicians guessed, for instance, that two-thirds of the people of Rome and three-quarters of the population of Britain fell ill, and influenza spread widely in North America, the West Indies, and Spanish America.

Nineteenth Century

By the end of the eighteenth century, accelerating population growth, urbanization, and improvements in transportation were changing the world in ways that enhanced the transmission of microbes across long distances. There were at least three influenza pandemics in the nineteenth century: 1830–1, 1833, and 1889–90, and a number of major epidemics as well. Even so, one of the most intriguing aspects of the history of influenza in this century was the long hiatus between the second and third pandemics. In fact, in Europe, from the epidemic of 1847–8 (defined a pandemic by some) to 1889, there were only a few minor upsurges of this disease.

When influenza rose up again in 1889, most physicians had only a textbook acquaintance with the disease, but by this time the medical sciences were making rapid advances, and public health had become a matter of governmental concern. The 1889–90 pandemic was the first for which we have detailed records. It reached Europe from the east (hence its nickname, the Russian flu), and such was the efficiency of transatlantic shipping that it swept over western Europe and appeared in North America in the same month, December of 1889. It struck Nebraska, Saskatchewan, Rio de Janeiro, Buenos Aires, Montevideo, and Singapore in February, Australia and New Zealand in March. By spring the pandemic was firmly established and widespread in Asia and Africa. Some Africans, who had never seen the disease in their lifetimes, called it a "white man's disease." Waves of this infection continued to roll across large regions of the world for the rest of the century, and although the mortality rates in this pandemic were quite low, the total of deaths was high. By conservative estimate, 250,000 died in Europe, and the world total must have been at the very least two or three times greater. Influenza killed many more than cholera did in the nineteenth century, but much of the mortality was restricted to the elderly, and thus its reputation as an unpleasant but not dangerous infection was preserved.

Early Twentieth Century

Its history for the first 17 years of the next century reinforced this view. Although rarely absent for long, influenza attracted little attention until 1918–19, when a pandemic of unprecedented virulence appeared. What was probably its first wave rose in the spring of 1918, perhaps first in the United States, attracting little attention because its death rate was low. Its most ominous characteristic was that many of the dead were young adults, in contradistinction to the malady's previous record. That spring and summer, this new influenza circumnavigated the globe, infecting millions and killing hundreds of thousands, and making ever more difficult the waging of wars in Europe and the Middle East. The name given this new disease was the Spanish flu, not because morbidity and mortality were higher there than elsewhere, but because Spain was not a belligerent and thus the ravages of the malady in that country were not screened from world attention by censorship. As in previous pandemics and epidemics, morbidity rates were vastly greater than mortality rates, and the latter, as a percentage of the former, were not impressive.

In August, that changed, as death rates doubled, tripled, and more. A second wave arose, sending hundreds of millions to sickbeds, as if they were as immunologically inexperienced as children, and killing millions. This wave tended to subside toward the end of the year, but returned again in a third wave in the winter and spring. In both the fall and winter waves, about half the deaths were in the 20- to 40-

year-old group. Fully 550,000 died in the United States, about 10 times the number of battle deaths of Americans in World War I.

In remote parts of the world, where influenza had never or rarely reached before, the death rate was often extremely high. In Western Samoa, 7,542 died out of a population of 38,302 in the last 2 months of 1918. The total of deaths in the world was in excess of 21 million, that number being an estimate made in the 1920s before historians and demographers sifted through the records of Latin America, Africa, and Asia, adding many more – millions, certainly – to the world total. It is possible that the 1918–19 pandemic was, in terms of absolute numbers, the greatest single demographic shock that the human species has ever received. The Black Death and World Wars I and II killed higher percentages of the populations at risk, but took years to do so and were not universal in their destruction. The so-called Spanish flu did most of its killing in a 6-month period and reached almost every human population on Earth. Moreover, its impact was even greater than these numbers indicate because so many young adults died. To this day, we do not know what made the 1918–19 influenza such a killer. Theories about wartime deprivation are clearly invalid because the death rates in well-fed America and Australasia were approximately the same as in the nations immediately engaged in the fighting. Perhaps as has been suggested, a chance synergy of viral and bacterial infection produced an exceptionally deadly pneumonia, or perhaps the 1918 virus was so distinctive antigenically that it provoked a massive immune response, choking the victims with inflammation and edema. We have no way of proving or disproving these theories.

In 1920, another wave of the disease rolled over the world, and in the United States this was, with the exceptions of the two preceding years, the worst for influenza mortality of all time. But morbidity and mortality rates soon shrank back to normal levels, and the disease lost most of its power to kill young adults. The medical profession, however, has subsequently worried about a resurgence of the killer virus, and has devoted great energy to identifying it, learning its secrets, and how to disarm it.

Prevention and Control

The medical profession, grappling with the great pandemic, labored under three major disadvantages: First, in the 1890s one of the premier bacteriologists of the world, Richard F. J. Pfeiffer, thought he had discovered the causative organism, common

in his time and again in the fall of 1918. Unfortunately, Pfeiffer's bacillus was not the cause, although it doubtlessly played a role in many secondary infections. Its chief significance is probably that it inveigled many scientists into wasting a lot of time discovering its insignificance. Second, influenza was believed to be an exclusively human disease, making it very awkward to work with in the laboratory. Third, bacteriologists of the early decades of the twentieth century had no means by which to see anything as small as the true cause of the disease, the influenza virus.

About 1930, Richard E. Shope discovered that he could transfer a mild influenza-like disease from one pig to another via a clear liquid from which all visible organisms had been filtered. (If Pfeiffer's bacillus was also present in the pigs, they became much sicker, a phenomenon that is one of the sources of the theory that the 1918 influenza may have been the product of synergistic infections.) In 1933, W. Smith, C. H. Andrewes, and P. P. Laidlaw succeeded in infecting ferrets with a filtrate obtained from a human with influenza, and after these events, researchers knew what to look for. In the following years, the A, B, and C viruses were isolated and identified and, thanks to the new electron microscope, seen and photographed.

It is possible that more is now known about the influenza virus than about any other virus, but its changing nature has defeated all efforts thus far to make a vaccine against the disease that will be effective for more than a few years at most. Vaccines were produced in the 1940s to protect the soldiers of World War II from a repetition of the pandemic that had killed so many of them in World War I, and influenza vaccines developed since have enabled millions, particularly the elderly, to live through epidemics without illness or with only minor illness. But the ability of the A virus to change and sometimes to change radically – as at the beginning of the 1957–8 and 1968 pandemics – and to race around the globe faster than suitable vaccines can be produced and delivered to large numbers of people, has so far frustrated all efforts to abort pandemics. Vaccines were effective in damping neither the pandemic of the so-called Asian flu of 1957–8 nor the Hong Kong flu of 1968.

At present, a worldwide network of 100 or so centers, most of them national laboratories, cooperate under the direction of the World Health Organization to identify new strains of influenza virus as quickly as they appear in order to minimize the time between the beginning of epidemics and the produc-

tion and distribution of relevant vaccines. The efficiency of this organization has been impressive, and certainly has saved many lives, but influenza is not yet under control. The frustration of flu fighters of the United States reached a peak in 1976, when a virus closely resembling Shope's swine virus and that of the 1918 pandemic began to spread among soldiers at Fort Dix, New Jersey. The medical profession and the U.S. government mobilized in order to prevent a recurrence of the disaster that had occurred 60 years before. Scores of millions of dollars were spent to devise a vaccine, to produce it in quantity, and to deliver it into the arms of millions of Americans. No pandemic appeared, not even an epidemic, and the single long-lasting medical result of this enormous effort seems to have been a number of cases of Guillain–Barré syndrome, a paralytic and occasionally fatal disorder, which were associated with the vaccinations. The number of these cases was tiny, relative to the tens of millions of doses of the vaccine administered, but the result in litigation has been massive.

VIII.74
Japanese B Encephalitis

Japanese B encephalitis is a relatively uncommon disease, even in areas where the infection is endemic. The disease is one of several caused by arthropod-borne viruses (arboviruses); carried by mosquitoes of the genus *Culex,* this one is a member of the family Togaviridae and genus *Flavivirus* and thus is an RNA virus. The species of *Culex* that is the most common insect vector for Japanese B encephalitis is *Culex tritaeniorhyncus.*

The disease was first recognized and described in 1871, and the virus was first isolated in 1935. The infection may appear in epidemic or in sporadic outbreaks, and is carried particularly in swine, but also has been isolated from a variety of birds and from equine animals. The virus is distributed principally in East and Southeast Asia.

Epidemiology

Epidemic outbreaks of Japanese B encephalitis, like those of arboviruses in general, tend to occur in regions that are usually dry and arid and, therefore, relatively free of viral activity; such areas may accumulate a large number of individuals who, because of lack of previous exposure, are relatively susceptible. Then with rain and the appearance of conditions favorable to the proliferation of the insect vector, epidemic outbreaks may occur, particularly where there are relatively high population densities of the human host and of the amplifying hosts such as equine or porcine animal species. In addition, there is evidence that for some arboviruses a change occurs in the relative virulence of the infecting strain, which may also account for an epidemic outbreak. Why, given the presence of Japanese B encephalitis virus in birds with wide-ranging migratory pat-

terns, the disease remains localized to certain geographic areas is not entirely clear, but presumably has to do with the specificity of the insect vector in carrying the infectious agent. The mosquito vector, *C. tritaeniorhyncus,* is found in rice fields and feeds on pigs and birds, as well as human and other hosts. However, the Japanese custom of raising pigs in the fall, after the flooding of rice paddies is over, and of taking the pigs to market early the following year, may also help to account for the general lack of large outbreaks as well as for the usual pattern of sporadic cases. As might be expected with such a pattern, the few large outbreaks tend to occur in more rural areas, street antibody to the virus is relatively common, and clinical cases account for about 2 percent of all of the infections, as judged by antibody surveys.

Pathology

Most of the information on the early stages of the disease has been gained from studies in the mouse. Pathological features of fatal human cases have generally been consistent with the experimental findings. Early in the disease, focal hemorrhages, congestion, and edema are found in the brain. Microscopically widespread damage to Purkinje cells of the cerebellum is noted, with pervascular inflammation and multiple foci of degeneration and necrosis. Extraneural evidence of spread of the virus is found in the form of hyperplasia of the germinal centers of the lymph nodes and of the spleen; multiple foci of round-cell infiltration in many organs, including the heart, kidneys, and lungs; and, in pregnancy, infiltration of the placenta with corresponding abortion and stillbirth. Multiple lesions in the offspring indicate cross-placental passage of the virus.

Clinical Manifestations

The clinical disease consists of the usual signs and symptoms of encephalitis, and no syndrome has been elicited that is specific for Japanese B encephalitis. Within a few days to several weeks (mean of 10 days) after a bite by a mosquito carrying the virus, susceptible patients manifest fever and evidence of damage to the central nervous system, which may include meningism, delirium, drowsiness, confusion, stupor, paralyses especially of the facial muscles, and, in the most severe cases, coma and death within a few days after onset.

The cerebrospinal fluid shows the presence of a nonpyogenic infection, with increased numbers of mononuclear cells, rarely over 1,000 per cubic millimeter, and elevated protein; sugar is therefore not generally decreased and may be elevated in the spinal fluid.

Diagnosis

The definitive diagnosis is made only from studies of the antibody status of the affected individual, with evidence of the absence of specific antibody at the time of onset of the disease followed by a 4-fold or greater rise in titer of the antibody during the following days or weeks. Complement-fixing antibody is the first to appear in most patients, but hemagglutinating and neutralizing antibodies are usually demonstrable shortly thereafter. More recently, antibody tests using fluorescein- or enzyme-labeled antibody, or the various modifications of these, showing specific rise in titer, are sufficient to establish the diagnosis. Antigenic variation is common among viral isolates, and at least two immunotypes have been delineated; thus the serodiagnosis must be performed in laboratories that have on hand the several subtypes that may be needed for a full serologic analysis of a given case or outbreak.

The disease is one of the most fatal among arboviruses, with case fatality rates of 50 to 70 percent having been recorded in outbreaks. Recovery may be complete, or there may be residual damage to the central nervous system; Japanese B encephalitis, in contrast to other arboviral encephalitides, is accompanied by relatively high rates of complete recovery despite the high case fatality rates.

There is no specific treatment, and supportive care is the major intervention that can be offered. The protective effect of antibody suggests that convalescent serum or other sources of antibody might have some therapeutic value, but this has not been systematically investigated on a suitable scale.

Prevention and Control

Vaccines have been available for many years for immunization of humans and of livestock. Live attenuated vaccines have been available in Japan since 1972, and in China more recently, and their effectiveness is shown by seroconversion rates of up to 96 percent. Vaccines are prepared by purification of viral suspensions from mouse brains, or from hamster kidney cultures, but several newer technologies are presently under active investigation. Widespread immunization campaigns have been successful in Japan, Taiwan, and China. At present, the vaccines are composed principally of the prototype Nakayama strain, and reasonable control of the disease has taken place. It is therefore unclear how necessary or desirable the addition of the newer iso-

lates, with slightly different antigenic specificities, would be.

Currently used vaccines require primary immunization with two injections at 7- to 14-day intervals, a booster within 1 year, and further boosters at 3- to 4-year intervals. Fortunately, the vaccine produces relatively few side reactions, and postvaccinal encephalitis must be exceedingly rare because few if any reliable reports of this complication following administration of the vaccine are in evidence.

Vector control has been investigated in some detail. Larvicides and adulticides aimed at the chief mosquito vector have reduced attack rates in areas where these have been tested, and programs of control of insect vectors, coupled with elimination of aquatic vegetation in irrigation channels and with spraying of insecticides in livestock pens, have had some success in China. Under epidemic conditions, spraying with appropriate insecticides has sometimes been necessary.

VIII.75
Lactose Intolerance and Malabsorption

</div>

Lactose malabsorption describes a physiological situation. It is the basis for lactose intolerance. The inability to digest lactose is a quantitative phenomenon related to the enzyme lactase and its amount and activity in the intestine. Lactose intolerance, then, is a clinical definition. It involves the concept that the individual is unable to tolerate physiologically the lactose present in milk and other dietary products because of an inability to digest the carbohydrate, due to insufficient activity of the lactase enzyme. Intolerance to lactose as a clinical entity has been recognized for some time. Early in this century, Abraham Jacoby hinted at the existence of lactose intolerance in speeches to the American Pediatric Society; later, in 1926, John Howland, in his presidential address to that same organization, was somewhat more explicit when he indicated that many of the infantile diarrheas were the result of a lack of "ferments" necessary for the digestion of carbohydrate (Flatz 1989).

More recently, interest of physicians and nutritionists in the digestion of lactose stimulated reports during the late 1950s. One by A. Holzel and colleagues (1959) reported on a severe diarrhea associated with the ingestion of lactose in two young siblings who, as a consequence, were "failing to thrive." Another report, by P. Durand (1958), diagnosed two patients with lactose malabsorption and lactosuria. Since then, innumerable articles and reviews have appeared in the world's literature (Scrimshaw and Murray 1988). Evaluations of that literature may be obtained by consulting G. Semenza and S. Auricchio (1989), G. Flatz (1989), and N. Kretchmer (1971).

Lactose: Chemistry, Digestion, and Metabolism
Lactose is a galactoside composed of glucose and galactose. This compound is found in the milk of

most mammals, although in marsupials and monotremes it appears in conjugated form. It is entirely lacking in the milk of the California sea lion and related pinnipedia of the Pacific Basin. The reason for the latter is that lactose is synthesized in the mammary gland from two monosaccharides, glucose and galactose, by the enzyme galactosyltransferase, which requires the presence of alpha-lactalbumin – not produced by the mammary glands of the sea lion. Thus the concentration of lactose in the milk of placental animals ranges from a low of zero to a high of 7 percent (Sunshine and Kretchmer 1964).

Lactose is digested in the small intestine by the lactase (a galactosidase), which is located in the brush border of the epithelial cells of intestinal villi. This enzyme is anchored to the membrane by a hydrophobic tail of amino acids. Detailed descriptions have recently been published of the intimate intracellular metabolism of lactase (Castillo et al. 1989; Quan et al. 1990).

In most mammals the activity of lactose-digesting lactase is high during the perinatal period; after weaning the activity declines to about 10 percent of its original value. But in certain human groups the enzyme activity remains elevated throughout the lifetime of most of their members (Kretchmer 1977). Examples of these groups include northern Europeans, people of Magyar-Finnish extraction, and two African tribes, the Fulani and the Tussi.

Clinical Manifestations

The clinical manifestations of lactose intolerance include increasing abdominal discomfort, borborygmus, flatulence, and finally fermentative diarrhea. Although an inordinate amount of any carbohydrate in the diet will produce a similar symptomatology, intolerance to lactose is the most prominent of these clinical syndromes. The basis of this phenomenon is primarily the activity of the lactase relative to dietary lactose. The lower the activity, the less the capacity for the hydrolysis of the lactose, although other factors – such as intestinal motility and the presence of other nutrients – also play a role in this phenomenon.

When the capacity of the lactase is exceeded, the nonhydrolyzed dietary lactose passes into the large bowel where it is fermented by the myriad of colonic bacteria. This action in turn yields propionic acid, hydrogen, methane, and alcohols, and results in a watery diarrhea, the pH of which is acidic.

In general, the activity of lactase in the intestine in almost all mammals by the time of weaning has decreased to about 10 percent of that encountered

during the perinatal period. This does not mean, however, that weaning is directly related to the decrease in activity of lactase. There has been no documentation indicating that there is any inductive relationship between the activity of the enzyme and the ingestion of milk. In fact, all the careful studies indicate that there is no relationship between the two events (i.e., the ingestion of milk and the activity of lactase).

Classification

Lactose malabsorption can be classified into three categories:

1. Congenital malabsorption of lactase, a rare phenomenon, which has been documented in only a few cases.
2. Primary malabsorption of lactose, a worldwide situation that is encountered in humans after the age of 5 to 7 years, and in other animals after weaning. (This is considered to be a normal physiological process, transmitted genetically; indeed it resembles a classical Mendelian recessive trait.)
3. An acquired malabsorption of lactose that can be encountered at any age in infants and children under 7 years, as well as in adults who had previously been lactose absorbers. This form can also be associated with nonspecific and specific diarrhea of infancy, drugs that affect the intestinal mucosa, and diseases such as cystic fibrosis and gluten-sensitive enteropathy.

An interesting phenomenon is that the colonic flora of the lactose-intolerant individual seems able to adapt to a nonfermentive type of bacteria. A study was launched in Nigeria in which six medical students, all proven lactose nondigesters, were fed graded doses of 5 grams of lactose to a final amount of 50 grams over a 6-month period. At the end of this time, all six of the individuals could tolerate the 50 grams of lactose, but were shown to be unable to digest it. Adults who should be intolerant to lactose can drink a glass, or even a pint, of milk with relative impunity, but nonetheless manifest no increase in lactase activity and consequently cannot digest the lactose.

History and Geography

The ability to digest lactose is a nutritional event that can be clearly associated with evolutionary pressures. During the Neolithic period, human adults began to drink milk, probably in association with the domestication of animals. These ancient pasto-

ralists who originated in the Euphrates River Valley were nomadic, constantly in search of new pastures for their animals. It is assumed that they migrated in two main directions: to the northwest, toward Europe; and to the southwest, across the then-fertile Sahara toward east and west Central Africa. The exact time of these migrations is unknown, but presumably the nomadic pastoralists of Africa (e.g., the Fulani, the Tussi, the Masai, and others) have their origins in these migrations as do those of northern Europe.

In the Americas, by contrast, there were no indigenous pastoral groups, and thus, in the Western Hemisphere, there was no ingestion of milk after weaning until the Europeans arrived. An absence of dietary milk after weaning was also the case in Australia, the islands of the Pacific, Japan, and the rest of Asia. In these regions the individual after weaning obtained calcium from small bones, limestone, dark-green vegetables, and fermented or pressed (and thus much reduced in lactose) dairy products.

Thus the present-day geographic distribution of peoples who can or cannot digest lactose fits with our historical knowledge of the distribution of ancient pastoral groups and the milking of their animals. Nonetheless, confusion arises over questions of levels of lactose intolerance among peoples with no history of pastoral activity. In the case of a native American population – the Pima-Papagos, for example – the inability to digest lactose has been reported at only 60 percent (see Tables VIII.75.1 and VIII.75.2). The 40

percent who can drink milk, however, represent the genetic penetrance of the pure genetic pool of native Americans with a gene that affords them the ability to digest lactose. Without that genetic penetrance, the percentage that could not digest lactose would have reached 100.

Flatz (1989) has compiled a list of figures that report the distribution of lactose phenotypes for many populations of the world (see Table VII.75.2). These data support the cultural hypothesis first promulgated by Frederick Simoons (1970), which states that the ability to digest lactose is associated only with a population that has a history of pastoralism. The hereditary pattern for the ability to digest lactose appears to be simple and to follow straightforward Mendelian genetics. The individual who can digest lactose carries the mutated gene, which in this case, is dominant. The lactose nonabsorber carries a recessive gene. Consequently, the cross between lactose malabsorbers always yields progeny who are lactose malabsorbers, thus perpetuating the absolute inability to digest lactose among a lactose-intolerant population.

Summary

Lactase has been shown in a number of careful investigations to be the same enzyme in the infant as in the adult who can digest lactose, and in the residual activity found in the nondigester. In general, the lactose digester has 10 times more enzymatic activity than the lactose nondigester. Thus, the biochemical genetics of lactose digestion is related to the amount and activity of lactase.

Today, lactose malabsorbers who would like to be able to drink milk can purchase various "lactase" preparations now on the market that "digest" the lactose in milk before it is ingested. Others who do not drink milk can overcome the potential dietary calcium deficiency by consuming fermented milks, pressed cheeses, dark-green vegetables, and small bones as in sardines.

The worldwide distribution of an inability to digest lactose after weaning in most human adults and all other mammals argues for this condition to be the normal physiological state. The ability to digest lactose would seem then to be evidence of a genetic polymorphism. It is only the bias of the milk-oriented societies of northern Europe and North America that casts lactose malabsorption as an abnormality.

VIII.76
Lassa Fever

Recognition of Africa's major endemic diseases of human beings was apparently well advanced by 1900. Malaria, trypanosomiasis, yellow fever, schistosomiasis, typhoid fever, brucellosis, and a long list of other afflictions had been characterized. But then, in 1969, a new member of the coterie of major endemic diseases of Africa entered the scene: Lassa fever.

The events leading to the discovery were dramatic. A nurse, Laura Wine, in a mission hospital in Lassa, Nigeria, became ill, progressed unfavorably, and died, despite the marshaling of antimalarials, antibiotics, antimicrobial agents, and supportive therapy. This death, as a statistic, would probably have been labeled "malaria" and thus been registered as such in national and World Health Organization disease records. But another nurse, Charlotte Shaw, who attended the first, also became ill. She was taken by small plane from Lassa to the Evangel Hospital in Jos, Nigeria, operated by the Sudan Interior Mission, where she died while being attended by physicians Harold White and Janet Troup, and nurse Lily Pinneo. Again, there was no firm diagnosis. Pinneo then got sick. Doctors at the hospital were thoroughly alarmed. She was evacuated, via Jos and Lagos, to America by plane, and was admitted to the College of Physicians and Surgeons at Columbia University, where she was attended by John Frame, E. Leifer, and D. J. Gocke.

The Yale Arbovirus Research Unit in New Haven, Connecticut, was alerted by Frame, who helped to get specimens for the unit. By a combination of serendipity and skill, an agent was isolated – a virus, unknown hitherto to humans. It was called "Lassa virus" (Buckley, Casals, and Downs 1970). Two laboratory-acquired cases occurred in Yale personnel working on the virus. One of them, Juan Roman, died. The other, Jordi Casals, was given immune plasma from the recently recovered nurse, Pinneo, and made a full recovery. In due course and with unfailing collaboration from many services, the agent was established as belonging to a grouping including lymphocytic choriomeningitis virus of nearly worldwide distribution. (Examples are Tacaribe virus from bats in Trinidad; Junin virus, the causative agent of Argentine hemorrhagic fever; and Machupo virus, causative agent of Bolivian hemorrhagic fever.) The grouping of these agents has

Table VIII.76.1. *Lassa fever outbreaks: West Africa, 1969–88*

Location	Dates	Statistics
Lassa and Jos, Nigeria	Jan.–Feb. 1969	3 cases, 2 deaths
Jos, Nigeria	Jan.–Feb. 1970	23 cases, 13 deaths
Zorzor, Liberia	Mar.–Apr. 1972	10 cases, 4 deaths
Panguma and Tongo, Sierra Leone	Oct. 1970–Oct. 1972	64 cases, 23 deaths
Onitsha, Nigeria	Jan. 1974	2 cases, 1 death
Sierra Leone, inland	Feb. 1977–Jan. 1979	441 cases, 76 deaths
Vom (near Jos), Nigeria	1976–7	5 cases, 2 deaths
Bombereke, Benin	Feb. 1977	1 case, 1 death

Note: Seropositive individuals have been detected in Senegal, Guinea, Central African Republic, and the Cameroons.

been officially designated *Arenavirus* in the family Arenaviridae (Fenner 1976). As portrayed in Table VIII.76.1, seven other outbreaks of Lassa fever are known to have occurred in Africa since 1969. Unfortunately, Nurse Troup, who attended cases in the 1969 outbreak at Jos, became infected through a finger prick in an outbreak at Jos the following year and died.

Clinical Manifestations, Morbidity, and Mortality

High fever associated with malaise, muscle and joint pains, sore throat, retrosternal pain, nausea, manifestation of liver involvement, bleeding tendency of variable severity, proteinuria, and erythematous maculopapular rash with petechiae are features of the illness, but not of themselves particularly diagnostic. The presence of an enanthem in the oropharynx has been considered by some to have specific diagnostic importance.

In early stages, the disease can simulate many illnesses occurring in Central Africa, prominent among them malaria (Downs 1975), although typhoid fever, rickettsial diseases, brucellosis, hepatitis (before appearance of jaundice), and even yellow fever can also be mimicked. Sporadically occurring Lassa cases are certainly not often diagnosed. When epidemics arise, the clumping of cases of mysterious illness can and has attracted attention, leading to diagnosis. It has become recognized from studies, such as one in Sierra Leone, that there are many

mild Lassa cases (McCormick et al. 1987a). This study of several years' duration was conducted by personnel from the Centers for Disease Control, U.S. Public Health Service, in two hospitals in central Sierra Leone. It determined that Lassa was the causative agent (determined by virus isolation) in 10 to 16 percent of all adult medical hospital admissions and in about 30 percent of adult hospital deaths. The fatality rate for 441 hospitalized patients was 16.5 percent.

Karl M. Johnson and colleagues (1987) have shown that mortality is directly associated with level of viremia, although it must be noted that by the time figures for viremia have been received from the overseas laboratory, the patient is either recovered or dead. Joseph B. McCormick and colleagues (1987b) estimate the ratio of fatalities in infections in general to be 1 to 2 percent, a rate lower than estimates based on hospitalized patients. How widely the findings on rates and outcome can be extrapolated to other hospitals and other settings in West Africa is not yet known. Studies simply have not been done to determine this. However, it is clear that when seriously ill patients are seen, the prognosis is highly unfavorable, even when the best of currently recognized therapeutic regimes are applied.

Virus Morphology, Size, and Structure

F. A. Murphy and S. G. Whitfield (1975) have given a detailed account of the morphology and morphogenesis of the virion and have related it to the other members of the *Arenavirus* group. The virus particles, on budding from the cell membrane, may be round, oval, or pleomorphic, with mean diameters of 110 to 130 nanometers and with spike-covered envelopes. The center of the particle contains variable numbers of fine granulations, measuring 20 to 25 nanometers, a characteristic that prompted the name *Arenavirus*. The nucleosome consists of single-stranded RNA. In 1984, F. Lehmann-Grube furnished a detailed account of the development and pathogenetic characteristics of the Arenaviridae.

Diagnosis

Laboratory findings include leukopenia and increasing thrombocytopenia, proteinuria, and hematuria, and evidence of coagulation. Diagnostic tests have been developed. Viremia is a constant feature in Lassa cases, and the virus can be isolated and identified in cell culture, using procedures that take a week or more to run. By this time, the patient, if indeed a Lassa patient, may be in dire straits. A rapid diagnostic test is sorely needed. Progress has been made in

survey methodology. Serum specimens from suspected patients, taken a few weeks after illness, and those taken in samplings of populations, can be examined for the presence of antibody to Lassa, using a special test plate developed in U.S. Army laboratories. "Spots" of inactivated antigens are made on a test plate, called colloquially a *CRELM plate*. A drop of serum from an individual is placed on each of the "spots" of, respectively, Congo-Crimean fever, Rift Valley fever, and Ebola, Lassa, and Marburg inactivated viruses, and incubated. A fluorescein-tagged anti-human globulin is then added to each drop. Development of fluorescence in one of the "spots" after incubation indicates presence of human antibody, coupled to the signaled antigen. This method has led to greater knowledge of several deadly diseases in Africa, and is a major step toward understanding the geographic location of these diseases.

Treatment

Treatment modalities are being explored. Ribavirin shows promise of benefits if administered early enough in the course of disease (McCormick et al. 1987a,b). An early hope in treatment, administration of plasma from recovered cases, has not been very successful. If given early enough, before a positive laboratory diagnosis is possible, it may have some value. Given later, there have been occasional dramatic recoveries, as in the case of Yale's Jordi Casals. But there have also been many failures. Renal shutdown has been a fatal feature of such treatment in some instances. All work with Lassa virus must be conducted under conditions of highest security (MMWR 1983), which slows down laboratory work. Several human deaths have occurred among laboratory workers, nonetheless.

Epidemiology

The association with the *Arenavirus* group helped to orient the studies in Africa, relating to determination of the transmission cycle of the Lassa virus. Predictably, like its congeners, it was determined to be an infection of small rodents, usually house-frequenting rodents. *Praomys (Mastomys) natalensis* in sub-Saharan, equatorial, and southern Africa is the most common house-frequenting rodent and has been found infected to varying degrees in several regions in Africa afflicted with Lassa (McCormick et al. 1987a,b). The infection in the rodent is persistent, with virus in the urine a common feature. As epidemics occurred in other localities in Nigeria, Liberia, and Sierra Leone over the course of several years, it became apparent that Lassa virus is widespread in West Africa and also may be found in East Africa (McCormick et al. 1987). Studies of distribution are far from complete.

Control

Control must proceed at several levels. At the village level, community-wide rodent control may be implemented, which should include rodent proofing of grain storage facilities, general trash cleanup, and rodent poisoning campaigns. At the householder's level, measures should include rodent proofing of dwellings, rodent trapping, and rodent poisoning. At the clinic level, the possibility of Lassa should be considered whenever fever cases are seen, and appropriate measures taken to protect the examiner and other patients at the clinic. At the hospital level, attention must be given to rodent control, and in addition, diagnosed or suspected Lassa patients should be isolated, with staff taking full precautions to avoid close contact with them. Special precautionary measures are indicated for obstetrical, gynecological, and surgical services. At the governmental level, Lassa should be made a reportable disease, and at the international level, Lassa *must* be made a reportable disease.

Lead Poisoning

Lead poisoning (*plumbism*) is defined simply as the undesirable health effects induced by that metal. Many of these, however, are "nonspecific"; that is, they are similar to or identical with symptoms and signs produced by causes other than lead, and some of the toxic effects are so subtle they require laboratory identification. This historical and geographic discussion concerns itself primarily with those overt effects obviously apparent upon even casual observation by nonmedical observers, which therefore are most likely to appear in the historical record. Principal among these are abdominal colic, muscle paralysis due to lead-damaged nerves, and convulsions.

Physiology

Lead gains access to the human body principally through the air we breathe and the substances we ingest. Residents of industrialized nations acquire about half of their "body burden" of lead from polluted respired air. Healthy adults only absorb about 10 percent of ingested lead, but children may absorb as much as half of the lead they eat or drink. Lead absorption is enhanced by a low level of calcium in the diet. Lead may also be absorbed through the skin. Prolonged applications of lead-containing substances such as poultices or cosmetics may result in health-threatening absorption of lead.

Absorbed lead is distributed throughout the body by the blood. The human body's ability to excrete absorbed lead is so limited, however, that normal life activities in Western countries will produce lead absorption in excess of the body's excretory capacity. About 5 percent of unexcretable lead is deposited in the liver, brain, and other viscera, where its resi-

dence time is only a matter of a few weeks. The other 95 percent is stored in bone for an extraordinarily long time, measurable in decades in the adult. If absorption ceases, such lead will be leached slowly from the skeleton over a period of many years, and is then excreted through the kidneys. Lead may be transferred to the fetus via the placenta.

Methods of exposure to lead as well as the nature of toxic episodes are discussed under History and Geography.

Clinical Manifestations

For many decades the appellation "lead poisoning" has referred to the clinically apparent symptoms manifested by this metal's toxic effects on the intestine, brain, and nerves. Before dealing with them in detail, however, the less obvious effects of lead poisoning are noted briefly.

Lead can interfere with the physiology of almost every body function. At "low" blood concentration (less than 40 micrograms [μg] lead/100 ml blood [dl]), there is some evidence that it can impair intellectual capacity development in children, an effect of potentially greater significance for a population than the more overt symptoms usually associated with the concept of lead poisoning. In the mouth, lead may combine with sulfur produced by local bacteria, producing a linear, black precipitate on the gums sufficiently apparent and unique to be of diagnostic value. Episodes of intense lead exposure may cause temporary arrest of long bone growth visible as a horizontal band of radiodensity ("bone lead line").

Lead produces moderate anemia with resulting facial pallor by poisoning enzymes necessary for the formation of hemoglobin, the blood's principal oxygen carrier. Lead excreted through the kidneys can poison the renal cells, eventually terminating in fatal renal failure. Effects well documented in animals, though less convincingly in humans, include suppression of gonadal function (with consequent decreased fertility or sterility) as well as carcinogenic and teratogenic activity associated with increased rates of abortion, stillbirth, and neonatal mortality.

The symptom of lead poisoning most commonly encountered in the historical literature is abdominal pain. Its cause is usually attributed to intestinal spasm, though the abdominal muscles may participate in the painful, uncontrolled contractions usually termed "colic." When they are severe and prolonged, such affected individuals may be driven to desperate measures for relief. Similar pain may be seen in the common forms of diarrhea, but that asso-

ciated with lead poisoning is accompanied by constipation, and hence the common reference to the abdominal pain of lead intoxication as "dry bellyache." In individual cases such a state could be simulated by inflammation of the gallbladder, pancreas, or stomach, and by stones in the kidney or bile passages, but these conditions neither would be accompanied by other symptoms or signs of lead toxicity, nor would they affect large segments of a population or occupation.

Lead also has a destructive effect on nerves (*peripheral neuropathy*), whose ability to transmit the electrical impulses to the muscle is then reduced or completely blocked, producing muscle paralysis. Peculiarly (and diagnostically) the nerves supplying those muscles (extensors), which normally raise the wrist or foot, are especially commonly affected, causing the unique affliction of "wrist drop" (often termed "the dangles" in the past) and "foot drop."

Serious disturbances of behavior leading to convulsions, coma, and death are the most severe and feared of lead's effects. Children are notoriously more susceptible to such brain toxicity, and even a single episode of convulsions, when not fatal, often causes permanent, residual cerebral damage. Meningitis, tumors, trauma, and other diseases may result in identical convulsive seizures, and their lead etiology may be recognizable in the literature only through their association with other features of lead toxicity.

Finally it should be noted that lead poisoning may cause gout. This condition is due to the reduced ability of the lead-poisoned kidney to excrete uric acid, a product of normal protein metabolism. The retained uric acid is frequently deposited in the soft tissue, often near joints, resulting in exquisitely tender inflammation. The etiology of the renal toxicity underlying most cases of gout is unknown, but when the kidney injury is caused by lead, it is known as "saturnine gout," in reference to the association of lead with that planetary god by the ancients.

A rough correlation exists between the amount of lead in the blood and the presence of these various signs and symptoms. At lead levels below 40 μg/dl, clinically evident effects are uncommon, but with progressively increasing concentrations above 80 μg/dl, symptoms become more probable. Many modifying and influencing factors, however, give rise to diagnostic difficulties.

Distribution and Incidence

The geographic distribution of lead poisoning is global, but it is not of equal frequency everywhere.

Because circumstances leading to lead exposure are of anthropogenic origin, the prevalence of plumbism correlates with practices and traditions of lead use. Predictably, the geographic pattern of such episodes has varied with time.

Although there are few recorded instances of major health problems due to lead in antiquity, some perspective on the extent of lead poisoning can be gained by reviewing lead production records. Figure VIII.77.1 represents an approximation calculated by C. C. Patterson and others. Because *galena* is the most abundant form of natural lead ore in Europe and Asia, and because its very low solubility produces little toxicity for its miners, one could reasonably surmise that lead poisoning probably was not common prior to the popularization of the smelting process about 3500 B.C.

The *cupellation* process, discovered about 3000 B.C., permitted the separation of the small amounts of the commonly "contaminating" silver from the much larger quantities of smelted lead, and was followed by a substantial increase in lead production as a by-product of the pursuit of silver in the Mediterranean area. We only speculate about the degree to which lead toxicity affected those involved in lead production in the Middle East and Mediterranean area during these periods, though the crude nature of the furnace facilities must have exposed many to a toxigenic degree.

Introduction of coinage during Greece's Classical Period resulted in a phenomenal increase in silver (and therefore, lead) production, which was exaggerated by Roman exploitation to the point of ore exhaustion, leading to a marked reduction of that form of mining after the decline of the Roman Empire. Reference to lead intoxication can be found in the various Greek and Roman writers of antiquity (details under History and Geography: *Historical Antiquity*). It was then not until the late Middle Ages that lead production rose again, this time in Europe, with recognition of lead's utility now justifying its acquisition for its own sake. Although the Spanish pursuit of silver in the New World was second only to that of gold, the miners' mortality was largely due to factors other than poisoning from lead in the ore, and heavy metal toxicity during the silver extraction process was related primarily to the mercury used after 1570. It was the Industrial Revolution, with its enormous surge in lead production, that was responsible for the recurrent endemics in France, Italy, Spain, Germany, and especially Great Britain, and later, their New World colonies. Even so, the 80,000 tons of lead generated annually worldwide at the apex of
Figure VIII.77.1. World lead production during past 5,500 years. [Adapted from Roger L. Boeckx. 1986. Report. *Analytical Chemistry* 58 (February): 275A, reprinted by permission from *Analytical Chemistry*, 1986, American Chemical Society.]

Roman productivity has expanded exponentially to reach more than 3 million tons worldwide today. With this exponential rise has come a staggering degree of lead exposure in the populations of Western nations.

History and Geography

Because various cultures indulged in activities producing serious lead exposure in different periods, this discussion focuses on those periods specifically relevant to lead poisoning.

Prehistory

By definition, this period contains no written record of lead intoxication, but some concept of the extent of lead use and the degree of presumed lead exposure by its consumers is made available by the archaeological record. A few lead pieces from Iraq about 5000 to 4500 B.C.; multiple lead items at the Troy I site; lead tumblers from Mesopotamian tombs; and galena beads in predynastic Egyptian graves from about 3500 to 3000 B.C.; lead pipes at Ur; leaded glazes from Babylon; and leaded bronzes from Thailand between 2000 and 1500 B.C. – all imply an active, working knowledge of lead smelting. Artifacts also reveal early experimentation with leaded bronzes in China's ancient metallurgical centers in the southwestern provinces by about 1700 B.C. Skeletal lead analyses by several workers, such as the study by Philippe Grandjean and others (1979) of the Nubian population from as early as 3300 B.C., demonstrate negligible quantities of lead stored in bone, suggesting that lead toxicity in this period was

probably limited to the few people directly involved in the smelting process.

Historical Antiquity

In Asia Minor, Cappadocian tablets record lead use as an exchange item as early as the third millennium B.C. By 2000 B.C., not only had the smelting of lead ore (conversion to and extraction of metallic lead from the ore compounds) become common knowledge, but also the process of cupellation – the separation of silver from the smelted lead – was widely practiced, as shown by the use of silver as the principal unit of exchange in Susa, Persia, at that time. Old Testament Biblical references testify that lead had broad utilitarian applications and was widely traded even prior to the Israelite departure from Egypt, though there are no comments on its negative health effects. Early dynastic Egyptians used lead for votive statuettes, net sinkers, and cosmetics. Mycenaeans exploited the later well-known mines at Lavrion near Athens and fashioned the product into lead straps. Amulets and loom weights from this period have been found in India. Surely such widespread use of lead must have been accompanied by lead intoxication on occasion, at least among the industrial workers and users of certain lead products including foodwares, but the record remains silent on such matters, implying a probable failure of recognition of its toxic manifestations.

Much of our knowledge about the use of lead in the Greco-Roman period is related to the mines such as the one at Lavrion (called *Laurium* after the Roman conquest) near Athens. The hilly terrain of the area

is laced with intersecting veins of "argentiferous galena," a lead sulfide ore including as much as 0.5 percent silver as a minor element. This silver was sought by the Athenians, who referred to Lavrion as a "silver mine," even though they needed to separate 100 to 200 ounces of lead for each ounce of silver retrieved from the ore. This same silver was also one of the sources of Athens's wealth and power, for with it Themistocles built the navy that defeated the invading Persians and established Athens as the premier Mediterranean sea power. Similar mines were also operated on a number of Mediterranean islands, Asia Minor, and the European continent. Mines have been identified in Spain, France, Italy, and Great Britain. Interestingly, the silver component of ores in England and Wales was so low that these were mined primarily for their lead content.

With the generation of huge quantities of metallic lead as a by-product of the silver refinement process, the obvious utilitarian value of lead was also exploited. Applications included household tableware, storage containers for oil and other fluids, encasement of iron bars to bind construction stones together, sheathing for ships' hulls, coins, toys, statues, bronze and pewter alloys, coffins, tablets, solder, and a thousand other purposes. During the three centuries of its peak production period, the Lavrion mine is estimated to have yielded over 2 million tons of ore. The most intensive Roman use of lead related to their water system. In addition to lining with sheet lead parts of their extensive aqueductal system and cisterns, Romans also rolled such sheets into tubular form and soldered them to produce pipes through which the water was distributed.

An even more dangerous application of lead lay in its use as a food or beverage container lining and, even worse, as a food additive. In the absence of sugar, Romans used concentrated fruit juice, commonly grape, as a sweetening and flavoring agent (sapa or defrutum). Such juice was concentrated by boiling in lead-lined containers to avoid the undesirable flavor imparted by copper. During the concentration process lead was leached from the container by the acid fruit juice. Replications of this product using original Roman recipes are reported to have resulted in lead concentrations of up to nearly 800 milligrams per liter, about 16,000 times greater than the upper limit for potable water defined by the U.S. Environmental Protection Agency! Eventually Romans acquired such an addiction to the sweet flavor of lead acetate that it was often made available as an optional seasoning additive to wine.

This massive production and utilization of lead in all its forms clearly exposed the majority of urban Romans to lead. Roman customs, however, probably resulted in unequal exposure. Poor and middle-class citizens of Rome and other major communities closely shared ingestion of the lead-contaminated water delivered through the lead-lined aqueducts and pipes of the public water systems. The wealthier class, however, additionally contaminated their wine and food through the more extensive use of lead-lined containers, expensive pewter tableware, and the food additives described above.

It is difficult to imagine that the health problems associated with excessive lead ingestion had not been recognized during this period, and references by contemporary authors indicate many were indeed aware of them. The Greek physician-poet Nicander is normally credited with the first, clear, unequivocal description of plumbism in the second century B.C., when he noted colic, constipation, paralysis, and pallor resulting from the ingestion of the lead compounds litharge and cerusse. Lucretius in the following century described "deadly exhalations of gold and silver mines" and the pallor of miners' complexions, calling attention to their "short life." The Roman architect Vitruvius, also in the first century B.C., cautioned that drinking water from surface pools in the vicinity of lead mines was apt to produce muscle cramps and gout. Pliny (first century A.D.) warned against the deadly fumes of silver mines, calling attention to their lethality by their effect on dogs and advising all exposed to such fumes to emulate the miners' and smelters' custom of tying an animal bladder over their faces as a mask. Pliny also identified red · lead as a deadly poison, whereas his contemporary Celsus described an antidote to white lead. Vitruvius additionally condemned the use of lead for water conduits, noting that lead fumes poison the blood, with consequent pallor as seen in lead workers. Emperor Augustus prohibited the use of lead for water pipes, though there is little evidence of enforcement of his edict. One of the clearest descriptions of lead poisoning affecting large numbers of the population during late Roman times is that by Paul of Aegina, who described an epidemic of colic, lower limb paralysis, and epilepsy in Rome and elsewhere during the seventh century. S. C. Gilfillan (1965) speculated that the well-documented precipitous decline in numbers of the Roman aristocracy during the century following A.D. 60 may have resulted from lead's toxic effects on fertility (noting that prohibition of wine drinking by women of child-bearing age was lifted about

that time) and believes this may have been a major factor in the decline of the Roman Empire. J. Nriagu (1983) suggests further that lead-contaminated wine could explain the bizarre behavior of many Roman emperors and may be the cause of Celsus's comment that most of them suffered from gout. Although some scholars of Roman history regard the suggestions of Gilfillan and Nriagu as extrapolations beyond available evidence, wine consumption by the wealthy does appear to have increased during the imperial age, and conformity to contemporary suggestions for its preparation would have increased its lead content.

The Industrial Revolution and Modern Europe

With the rapid increase in lead production during the Industrial Revolution and the explosive growth that followed, including the modern era of lead fuel additives, the scene of lead poisoning shifted to the European stage. During the sixteenth to the eighteenth and even into the nineteenth century, recurrent waves of tardily recognized lead poisoning epidemics swept the various continental countries and the British Isles, frequently in temporally overlapping inundations. Most of these were eventually traced either to industrial exposure to lead or to ingestion of lead-contaminated beverages or food.

The concept of industrial exposure as a cause of disease was crystallized for eighteenth-century physicians by the masterful studies so meticulously recorded by Bernardino Ramazzini in 1700 (*De Morbis Artificum Diatriba*), although he was not the first to suggest it. His publications established the clear relationship between certain diseases and occupations. Among them were lead poisoning in miners, potters, and painters.

The French epidemic of crampy abdominal pain termed the "colic of Poitou" began in 1572, but more than a century passed before the consumption of lead-contaminated wine was identified as its etiology. A half-century-long endemic of abdominal colic was initiated in Madrid about 1730. The suggestion that lead was its cause was not taken seriously until 1797, when the fact was made clear that its distribution among the poor was due to their use of badly glazed lead food containers. In the middle of the eighteenth century, Théodore Tronchin realized the "colica pictonum" in Holland constituted poisoning from the use of water draining from lead roofs and from lead water pipes. The eighteenth and nineteenth centuries also were characterized by British importation of Portuguese port wine in prodigious

quantities when the 1703 Treaty of Methuen reduced its price to less than that of the French products. The brandy used to fortify the natural wines was often prepared in stills containing lead parts. Such fortified wines are believed to have been responsible for a concurrent frequency of gout so high that this period is often called "the golden age of gout" in England.

Two eighteenth-century workers – Sir George Baker in England and L. Tanquerel des Planches in France – most clearly epitomize publicized recognition of lead ingestion and industrial exposure to lead as the etiology of specific symptom complexes. In the region of Devonshire, England, an epidemic of abdominal colic ("the colic of Devonshire") raged for decades in the middle of the eighteenth century. Occasional writers had noted its relationship to cider drinking, but its absence in the cider-producing neighboring regions remained puzzling. In 1767, Baker, a Devonshire native, published his report now acknowledged as a milestone in the history of lead poisoning. Baker established the feature that characterized the Devonshire colic: lead contamination of the cider. He had traced the origin of the lead to a type of millstone used in the cider's manufacturing process. The Devonshire millstones were unique in that they were made in multiple segments bonded together by lead keys exposed on the stone's surface. He also noted the custom of cider storage in lead-lined containers and the addition of lead to the cider as a flavoring and preservative agent. His publication, clearly indicting lead as the epidemic's cause, was followed by preventive practices and a gradual subsidence of the epidemic.

Similarly, for many decades in the eighteenth and early nineteenth centuries, Paris's Charity Hospital had become famous for its treatment of patients with the various "dry colic" syndromes. In 1839 Tanquerel des Planches reported how he had studied these patients' complaints, scoured their hospital charts, and eventually demonstrated that most were engaged in an occupation involving unequivocal lead exposure. His detailed clinical observations included paralysis, encephalomalacia, and such a thorough description of the other items comprising the lead poisoning syndrome that it can be used as a medical teaching exercise today.

The New World Colonial Period

There was hardly a pause in the spread of the European colics before they also appeared in the American colonies. These settlers had arrived in the New

World with a restricted hoard of tools and machinery; malleable lead could be and was employed to create substitutes for a myriad of items manufactured out of steel in Europe with consequent opportunities for lead exposure.

One such source exposure was the consumption of lead-contaminated liquor. The coiled condensation tube (usually called the "worm") of an alcohol still was most easily fashioned out of lead. The distillation of fermented sugar products in such a still for rum production caused sufficient lead leaching from the "worm" to render the rum toxic. By 1685, epidemics of abdominal colic ("dry bellyache" or "dry gripes") were common in North Carolina and Virginia. Upon suggestions from those consumers that their illness might be the result of lead-contaminated New England rum, Massachusetts protected its trade market with remarkable alacrity by enacting the Massachusetts Bay Law of 1723, prohibiting the use of lead parts in a liquor distillation apparatus. Although the law is often hailed as the first public health law in the colonies, it should be noted there is no evidence of any serious, objective investigation regarding the role of lead in the origin of the rum-drinkers' symptoms, nor does the medical profession seem to have been the principal instigator for the law's passage. It appears the legislators were responding primarily to customer complaints, motivated more by trade than by health concerns.

Both the continent and the West Indies had a similar problem. Whereas slaves on North American continental plantations developed lead poisoning infrequently, the afflicted individuals on Caribbean island plantations included both Caucasians and black slaves. Barbados was especially affected, with the literature from the latter seventeenth and much of the eighteenth centuries replete with references to "dry bellyache," clearly a clinical entity well known to both physicians and the laity but of undetermined cause. Jerome Handler and others (1986) provided the chemical support for the diagnosis of lead poisoning in the slaves of a Barbadian population from the eighteenth century by finding sufficient lead in their archaeologically excavated bones to predict that at least one-third of them probably had had lead poisoning symptoms of moderate or greater severity.

The reason for high bone lead values in island plantation slaves in contrast to those on continental plantations lay in the nature of the product: sugar in the islands; cotton, fruit, or tobacco on the continent. The sugar was collected in lead-lined tubs, ducted

through lead pipes into a lead-lined copper cauldron in the boiling-house (whose fumes would expose the boiling-house workers), and stored in lead containers, to be distilled later into rum through a lead still. In addition, the lead-laden rum was used as a work incentive with subsequent consumption in large quantities of this lead-contaminated liquor by the afflicted slaves.

In 1745 Benjamin Franklin published Thomas Cadawaler's treatise on dry gripes in which the role of lead was defined. This knowledge may have been carried to Europe by Franklin because Baker of Devonshire quoted Franklin in his well-known 1767 article. By the mid-eighteenth century, knowledge about the lead etiology of the dry bellyache was reaching Barbados. In 1788 John Hunter (*Observations on the Diseases of the Army in Jamaica*) detailed dry gripes symptoms and specifically attributed them to lead. The condition gradually subsided in the West Indies during the last quarter of the century.

Another common source of lead poisoning in colonial America was houseware, especially those items used in the preparation, serving, or storage of food and beverages. In England, expensive pewterware, some with more than 20 percent lead composition, was the symbol of social and economic success, and this was emulated in the colonies. Plates and goblets were commonly of pewter in the wealthier colonial homes; perishables such as milk, cream, or fruit juices were stored in lead-lined containers as were wine, drinking water, and other beverages. Indeed, in such a wealthy home almost everything the family ate or drank contained some lead. In a continental plantation where access to such lead-contaminated food was tightly controlled, Arthur Aufderheide and colleagues (1981) could demonstrate that the extent of differential lead exposure had a socioeconomic basis. The slave labor force of a 1670–1730 Virginia plantation had no more lead in their bones than the average, modern North American does, but the skeletons of their wealthy Caucasian masters contained a sixfold greater quantity. Colonists were also exposed through their use of lead bottles, funnels, nipple shields, dram cups, candlesticks, lamps, pipes, roof gutters, and many other items.

Mining also claimed its colonial victims. The eastern American mines were largely of the poorly soluble galena ore and generated little morbidity. It was in the western Utah mines, whose ore was predominantly lead carbonate, that lead poisoning reached epidemic proportions, with many thousands

of miners suffering from plumbism between 1870 and 1900.

The Present Era

Even though we have a more sophisticated understanding of lead poisoning today, our ongoing use of lead seems to provide new opportunities for exposure. Lead encephalopathy acquired by infants nursing at the breasts of mothers using lead-containing cosmetics constituted the fourth most common, fatal, pediatric malady in Manchuria in 1925. A poisoning episode from lead fumes occurred in a Baltimore neighborhood in 1933 when poor families there burned discarded battery casings as cheap fuel. Until C. C. Patterson (1982) called attention to it recently, lead solder was used to seal many food cans. The common practice of *pica* (dirt eating), partly biological and partly cultural in origin, has become especially dangerous for children playing in yards whose soils are badly contaminated from inner-city factory and vehicle-exhausted lead. Chips of lead-laden, old paint peeling from their aging houses constitute a toxic time bomb for the very young. Many surviving victims of childhood lead poisoning in Australia were found to suffer failure of lead-poisoned kidneys several decades later. A 1910 American pharmacopoeia still listed both a variety of therapeutic lead compounds and antidotes to lead poisoning! There is probably no purer example of the price exacted by historical ignorance than the plumbism rampant among the modern illicit liquor producers ("moonshiners") using lead-containing distillation units (automobile radiators soldered with lead) in the United States today.

American lead production peaked about 1975, with at least half of it converted into automobile fuel additive. Recent partial control of automobile exhaust fumes has been accompanied by a 37 percent reduction in average blood lead levels in Americans.

Statistical data for lead poisoning are difficult to acquire, but in the United States, 831 adult deaths could be identified between 1931 and 1940; whereas in England, Tony Waldron (1982) describes a reduction from about 115 deaths annually in 1900 to only an occasional few by 1960. In view of the known diagnostic inefficiency of lead poisoning, these are surely minimal figures.

Prevention and Control

For many centuries, humanity's flirtation with lead frequently has been its undoing. Its romance with this pedestrian metal has been inspired not by any gemlike allure it possesses but, rather, by its irresist-

ible utility. No other metal is so easily extracted from the soil and so readily fashioned into unlimited numbers of needed items. In every age, however, writers sounding the warning of its toxic hazards were ignored or decried. Reasons for such resistance remain enigmatic.

It may be that the nonspecificity of the lead intoxication syndrome confused earlier diagnosticians because other conditions can simulate some of lead's toxic effects. The mine fumes that several Greco-Roman period authors held responsible for lead miners' health problems were perhaps the obvious and unpleasant sulfur dioxide odors emitted by galena ore rather than by lead compounds. Yet Pliny even complained specifically that the practice of "adulterating" wine (adding lead to improve the flavor) produces nerve injury manifested by paralyzed, dangling hands. His contemporary, the physician Dioscorides, clearly described colic and renal failure resulting from drinking the lead oxide compound called *litharge*. Most ancient miners were slaves whose ailments may not have been treated by physicians. It is, of course, possible that Romans were not exposed to as much lead as we presume today and that a lack of concern by Roman physicians simply reflects a low frequency of lead poisoning in ancient times. This can be evaluated objectively only by lead analysis of appropriately selected ancient bones. To date, some of Waldron's (1982) Romano-British cemetery excavation studies have revealed elevated bone lead values, but further investigations on Italian samples with sharply defined socioeconomic status of the studied individuals will be needed to resolve this question.

Perhaps even more relevant is the fact that during most of history the cause-and-effect relationship between a specific agent like lead and a specific symptom was only vaguely appreciated by physicians whose theoretical concepts did not readily embrace such an association. More concerned with the balance of postulated body humors, they were apt to attribute a broad range of symptoms to general environmental (often climatic) disturbances. Even nineteenth-century French naval surgeons accepted lead as the etiology of the lead poisoning syndrome but rejected it as the cause of an identical symptom complex in their tropical sailors. They attributed it instead to the effect of high tropical temperatures, thus delaying recognition of its true origin in their custom of shipboard food storage in lead containers.

Surely, lack of a system for regular publication and wide dissemination of medical knowledge also contributed to delay in grasping the etiology of lead

poisoning. As early as 1656, Samuel Stockhausen, a physician to the lead miners of northern Germany, published his realization that their affliction was the toxic effect of the lead ore they mined. Forty years later, that observation led his south German colleague, Eberhard Gockel, to recognize lead contamination of wine as the cause of an identical problem in his clerical patients, and it was to be more than another century (and many more "colic-demics") before the translation of Stockhausen's report into French enabled Tanquerel to identify the same problem at Paris's Charity Hospital.

Josef Eisinger (1982) has noted the recurring need throughout most of Western history for governments to enact legislation restricting the population's exposure to lead. Serious and major efforts to reduce lead exposure, such as the 1971 Lead-Based Poisoning Prevention Act in the United States and more recent legislation involving lead air pollution by automobiles, are phenomena primarily since the 1970s. The history of the past two millennia, however, suggests that our knowledge of lead's potential hazards will not prevent at least some continuing problems with its health effects.

> # Legionnaires' Disease

Legionnaires' disease is an acute infection of humans, principally manifested by pneumonia, that occurs in a distinctive pattern in epidemics and is caused by bacteria of the genus *Legionella*. Typically the incubation period – the interval between exposure to the bacterium and the onset of illness – is 2 to 10 days, with an average of 5 to 6 days, and the attack rate – the proportion of people exposed to the bacterium who become ill – is less than 5 percent. Without specific antibiotic treatment, 15 percent or more of the cases are fatal, although the percentage of fatal cases rises sharply in immunosuppressed patients.

Legionnaires' disease is one form of presentation of *Legionella* infections, which are generally referred to by the umbrella term *legionellosis*. Another distinctive clinicoepidemiological pattern of legionellosis is *Pontiac fever*. Pontiac fever affects 45 to 100 percent of those exposed and has an incubation period of 1 to 2 days. Pneumonia does not occur, and all patients recover. More than 20 species of *Legionella* have been identified, 10 of which are proven causes of legionellosis in humans. The most common agents of human infection are *Legionella pneumophila*, *Legionella micdadei*, *Legionella bozemanii*, *Legionella dumoffii*, and *Legionella longbeachae*.

Legionellae are distinguished from other bacteria in being weakly staining, gram-negative, aerobic rods that do not grow on blood agar or metabolize carbohydrates, and have large proportions of branched-chain fatty acids in their cell walls and ma-

jor amounts of ubiquinones with more than 10 iso-
prene units on the side chain.

Distribution and Incidence

Legionellosis is easily overlooked, but has been
found essentially wherever it has been sought. The
weak staining of *Legionella* and its failure to grow
on the usual bacterial diagnostic media allowed it to
be missed for many years in the evaluation of per-
sons with pneumonia. Once the right combination of
staining and other diagnostic culture procedures
was identified, *Legionella* was found to cause 1 to 2
percent of the pneumonia cases in the United States,
or perhaps 25,000 to 50,000 cases annually.

Formal surveys of the incidence of legionellosis
have not been done in most countries, but large
numbers of cases have been identified in Great Brit-
ain and several European countries, and cases have
been reported on all continents.

Epidemiology and Etiology

Legionellae live in unsalty water and are widely dis-
tributed in nature. They thrive particularly well at or
slightly above human body temperature, and thus
are commonly found on the hot water side of potable
water systems and in the recirculating water in cool-
ing towers and other heat exchange devices.

The various ways in which *Legionellae* can go
from their watery environment to infect humans are
not all worked out, but one method is clear. Aerosols
created by some mechanical disturbance of contami-
nated water, such as in the operation of a cooling
tower, can on occasion infect people downwind. It is
likely that, after the aerosol is generated, the drop-
lets of water evaporate, leaving the bacteria air-
borne. Once airborne, they can travel a considerable
distance, be inhaled, and then be deposited in the
lungs. Potable water systems also can act as the
source of legionellosis outbreaks, but it is not known
whether this occurs through aerosols (as might be
generated by sinks, showers, or toilets), by coloniza-
tion of the throat and then aspiration into the lungs,
by direct inoculation (as into the eye or a wound), or
by ingestion.

Many outbreaks have been recognized, but most
cases occur individually (or sporadically). The risk of
Legionella pneumonia (including Legionnaires' dis-
ease) increases with age and is two to four times
higher in men than in women. No racial predisposi-
tion has been seen. Cigarette smokers are more sus-
ceptible, as are people whose cellular immune sys-
tem is compromised – for example, by medication

(such as corticosteroids) or underlying illness. Noso-
comial (hospital-acquired) legionellosis is an impor-
tant problem, probably because particularly suscepti-
ble people are gathered in a building with water
systems that *Legionella* can contaminate.

Few children have been shown to have legion-
ellosis, but one prospective study showed that one-
half developed serum antibodies to *L. pneumophila*
before 4 years of age, indicating that inapparent
infection may be common, at least at that age. In
contrast, studies of adults during Legionnaires' dis-
ease outbreaks have generally shown that fewer
than one-half of the *Legionella* infections are
inapparent.

Legionellosis can occur throughout the year but is
most common from June through October in the
Northern Hemisphere. The summer season predomi-
nates even in outbreaks unrelated to air-conditioning
systems, but whether warmer weather causes the
bacteria to flourish or, rather, humans to increase
contact with their environment is not known. The
fact that most bacterial and viral pneumonias are
most common in the winter makes the seasonality of
legionellosis one clue in diagnosis. Legionellosis does
not seem to spread from one person to another.

Travel and certain occupations put people at in-
creased risk of legionellosis. Several outbreaks have
occurred in tourist hotels, and a disproportionate
number of sporadic cases are in people who recently
have traveled overnight. Disease caused by *Le-
gionella* and serologic evidence of previous *Le-
gionella* infection are more common in power plant
workers who have close exposure to cooling towers.
Other outbreaks have occurred in people who used
compressed air to clean river debris out of a steam
turbine condenser, and in workers exposed to aero-
sols of contaminated grinding fluid in an engine
assembly plant.

Legionellosis outbreaks can be stopped by turning
off the machinery that is making infectious aerosols,
disinfecting that machinery, and heating or rechlor-
inating contaminated drinking water. Several chemi-
cal additives that are used in the routine mainte-
nance of cooling towers and evaporative condensers
can limit the growth of *Legionella* if used in combina-
tion with regular cleaning. Certain rubber materials
used in plumbing washers seem to provide nutrients
for *Legionella;* using different components may help
prevent legionellosis associated with drinking wa-
ter. Maintaining a temperature of 60°C on the hot
water side of institutional plumbing systems has
stopped some legionellosis outbreaks by lowering
the concentration of *Legionella* sharply.

Immunology

Legionella organisms live *inside* cells of all types, from various protozoa and freshwater amoebae in the external environment to various phagocytic cells in the human body. Given the location of *Legionella* inside cells, it might be expected that cell-mediated immunity is more important than humoral (antibody-mediated) immunity, and such seems to be the case in legionellosis.

This may explain why people with defective cellular immunity are particularly susceptible to legionellosis and why so few people exposed in an epidemic of Legionnaires' disease become sick even though usually fewer than 20 percent (and often fewer than 5 percent) have preexisting elevations of titers of specific antibody to *Legionella*.

Clinical Manifestations and Pathology

Two distinct clinical and epidemiological syndromes of legionellosis have been identified: Legionnaires' disease and Pontiac fever. Legionnaires' disease is a multisystem disease, characterized by pneumonia, high fever, chills, muscle aches, chest pain, headache, diarrhea, and confusion. Chemical evidence of involvement of the liver and kidneys may also be found. Pneumonia usually worsens over the first week of illness and resolves gradually thereafter. Without specific antibiotic therapy, the disease is fatal in about 15 to 20 percent of otherwise healthy people, and in up to 50 percent of those with compromised cellular immunity. It is not readily distinguished on clinical observation alone from several other forms of bacterial pneumonia.

Pathological changes are usually confined to the lungs, which often show a pattern of lobar pneumonia. Air sacs (alveoli) are filled with macrophages, other inflammatory cells, and fibrin. With the proper stain, large numbers of *Legionella* can be seen, mostly in the macrophages. The trachea and larger airways are generally spared, which may explain the relative lack of sputum in most cases and the lack of contagiousness.

Pontiac fever is characterized by fever, chills, muscle aches, and headache. Cough and chest pain are much less common than in Legionnaires' disease, and no cases have pneumonia. Victims are very ill for 2 to 7 days, but all recover.

History and Geography

From July 21 through 24, 1976, the Pennsylvania Department of the American Legion, a fraternal organization of military veterans, held its annual meeting in Philadelphia, with headquarters in the Bellevue Stratford Hotel. Within days of the end of the convention, reports began to reach Legion headquarters of conventioneers who had developed pneumonia and died. A massive investigation, begun on August 3, uncovered 221 cases in Legionnaires who had attended the convention and others who had been in or near the headquarters' hotel. The earliest case had its onset on July 20, the peak occurrence extended from July 24 through August 1, and decreasing numbers of cases continued through August 16. Ninety percent of those who became ill developed pneumonia, and 16 percent died.

Diagnostic tests for all known agents of pneumonia, infectious and otherwise, were negative. The epidemiological investigation suggested airborne spread of the agent, because risk of "Legionnaires' disease," as the press had dubbed it, increased with the amount of time spent in the lobby of the hotel and on the nearby sidewalk, but was unrelated to contact with other sick people or animals, eating, or participation in specific events at the convention. Those who drank water at the Bellevue Stratford had a higher risk than others, suggesting the possibility of a waterborne agent, but 49 of the cases had only been on the sidewalk outside and had drunk no water there.

The outbreak received considerable notoriety and prompted a congressional investigation. The failure to find immediately the agent led to much public speculation about toxic chemicals and sabotage, but the answer came through the more usual route of persistent scientific work.

In August, Joseph McDade, who worked on rickettsia at the U.S. Public Health Service Centers for Disease Control, had tested specimens from Legionnaires for evidence of rickettsia by inoculating lung specimens into guinea pigs and, if the animals died, putting tissue from them into embryonated eggs. The experiments were complicated by what seemed to have been some bacterial contamination, but overall the results appeared clearly negative. In late November, McDade received a draft report of the status of the investigation to that point. He noted that the liver was involved in many of the cases, a fact that was reminiscent of Q fever, the rickettsial infection most commonly associated with pneumonia. After mulling upon that coincidence, he returned to his laboratory over the Christmas holidays to reexamine the specimens from his August experiments. After some hours, he came across a cluster of what looked to be large rickettsiae or small bacteria in a section of liver from a guinea pig that had been inoculated with lung tissue from a fatal case of Le-

gionnaires' disease. Repeating the inoculation of eggs, he was able to grow these organisms in the yolk sacs. Using the infected yolk sac suspension as the antigen in an indirect fluorescent antibody (IFA) test, he was then able to show that the serum collected during the field investigation from patients who had recovered from Legionnaires' disease (but not that from unaffected people) had sharply rising titers of specific antibody to the yolk sac organism – indicating convincingly that this (which has since become known as *Legionella pneumophila*) was the causative agent.

In the 11 years before the Legionnaires' disease outbreak, the Centers for Disease Control had investigated two other large epidemics of respiratory disease for which an agent had not been found. One, in 1965, had involved 81 patients at St. Elizabeth's Hospital, a psychiatric institution in Washington, D.C. John V. Bennett, the epidemiologist who had led the original St. Elizabeth's investigation, communicated to the author in the early fall of 1976 that he was certain that the two outbreaks were caused by the same agent. Fortunately, serum specimens from the St. Elizabeth's outbreak had been stored at the Centers since 1965. When tested in early January of 1977, they unequivocally proved Bennett right.

In 1968, a remarkable outbreak of a severe, self-limited illness involved 95 of 100 employees in a health department building in Pontiac, Michigan. Some of the investigators from the Centers for Disease Control succumbed also, but only those who entered the building when the air conditioning system was turned on. Guinea pigs were placed in the building without any protection, with antibiotic prophylaxis, or in an isolator that filtered the air, and then were killed to look for evidence of pneumonia or other ill effects. Inspection of the air conditioning system showed two major defects. The exhaust from the evaporative condenser discharged on the roof just a few feet from the fresh air intake. In addition, the exhaust duct and a horizontal chilled air duct that was adjacent to the exhaust duct had defects that allowed water droplets from the exhaust to puddle in the chilled air duct. Water recirculating in the evaporative condenser was aerosolized (with or without prior attempts to sterilize it) in laboratory tests to expose guinea pigs in an attempt to induce disease.

When materials from the 1968 investigation of Pontiac fever were used in the tests that succeeded for Legionnaires' disease, scientists were intrigued to find positive results. Not only did people recovering from Pontiac fever show rising titers of specific antibody to *L. pneumophila,* but also *L. pneumophila*

could be recovered from the stored lung tissue of guinea pigs that had been exposed, unprotected, to the air in the health department building or to the evaporative condenser water. Thus a very different disease – both epidemiologically and clinically – was shown to be caused by a bacterium which, to this day, cannot be distinguished from the one that caused Legionnaires' disease.

Within a few weeks of the isolation of *L. pneumophila* in embryonated eggs, Robert Weaver found a way to grow it on agar plates. Subsequent improvements led to the development of charcoal yeast extract agar, which greatly facilitates the isolation of *Legionella.*

Investigations of legionellosis proceeded both forward and backward in time. In the summer of 1977, outbreaks of Legionnaires' disease were quickly recognized in Vermont, Ohio, and Tennessee. In 1978 an outbreak of 44 cases at a hospital in Memphis, Tennessee, started shortly after a flood knocked out the usual cooling tower, and required turning on an auxiliary that had been out of use for 2 years. Cases clustered downwind from the auxiliary cooling tower but stopped occurring 10 days after it was shut off. *L. pneumophila* was isolated from both patients and the cooling tower water, confirming the epidemiological evidence that Legionnaires' disease, like Pontiac fever, could be caused by *L. pneumophila* contamination of heat-rejection devices in air-conditioning systems.

But air conditioning systems were not the whole answer. Public health authorities in Scotland and Spain were investigating a series of pneumonia cases acquired by Scottish visitors to a hotel in Benidorm, Spain, over several seasons. The hotel was not air-conditioned, but the cases proved to be Legionnaires' disease. It would be some time before the source was found.

Other previously "unsolved" outbreaks were found to have been legionellosis. In 1973, all 10 men involved in cleaning a steam turbine condenser at a power plant on the James River in Virginia had developed what in retrospect seemed to have been Pontiac fever. Testing of stored serum specimens confirmed this. An outbreak of 78 hospitalized cases of pneumonia in Austin, Minnesota, in the summer of 1957 had been investigated at the time. Although the records had been preserved, the serum specimens had been lost in a refrigeration mishap. Survivors were recontacted in 1979, and they and the appropriate controls were bled to confirm the diagnosis of Legionnaires' disease in what is to date the earliest documented epidemic of legionellosis.

In 1979 reports began to appear of agents, some of which caused pneumonia, that resembled the *L. pneumophila* type strain in some ways but were clearly distinct. McDade and colleagues isolated an organism on artificial media that Hugh Tatlock had recovered in 1943 by inoculating into guinea pigs blood from a soldier at Fort Bragg, North Carolina, who seemed to have a case of "pre-tibial fever," an illness subsequently shown to be caused by *Leptospira*. Later that year, A. William Pasculle and colleagues isolated the "Pittsburgh pneumonia agent" in embryonated eggs but could not grow it in artificial media. Subsequently, the Tatlock organism and the Pittsburgh pneumonia agent were shown to be the same, and were named *L. micdadei*.

McDade and colleagues also grew the OLDA strain on artificial media. OLDA was another organism that resembled a rickettsia and had originally been isolated in 1947 by E. B. Jackson, by inoculating a guinea pig with blood from a patient with fever of unknown origin. When characterized in 1979, it turned out to be *L. pneumophila*. It remains the earliest documented isolate of that species.

In 1959 F. Marilyn Bozeman and colleagues isolated a rickettsia-like organism in guinea pigs from a navy man who developed pneumonia after practicing with scuba gear in freshwater swimming pools. Lester G. Cordes and colleagues isolated it on artificial media in 1979 and showed that it was distinct from *L. pneumophila*. It was subsequently named *L. bozemanii*.

Another line of discovery first reported in 1979 had important consequences in defining the biology of *Legionella*. George K. Morris and his colleagues reported the recovery of *L. pneumophila* from environmental water specimens, collected in the course of investigation of outbreaks of Legionnaires' disease. This quickly led to the discovery that *Legionella* organisms were widespread in nature, and could be found in about one-half of cooling towers. It also, for example, led to the discovery of additional *Legionella* species, not previously recognized to cause human disease.

In 1980, John O. H. Tobin reported the first isolation of *Legionella* from potable water systems, as part of an investigation of two kidney transplant patients who acquired Legionnaires' disease while in the same hospital room in England. Subsequent studies in hospitals in England and in the United State showed the importance of such systems as the sources for dissemination of *Legionella*.

As these studies were reported, the picture emerged of *Legionella* as a group of freshwater-associated bacteria widely distributed in nature, causing pneumonia in humans when particularly susceptible people are exposed by aerosols, or perhaps otherwise, to contaminated water. The presence of running hot water and other thermal pollution, often from industrial processes, favors its growth, suggesting that legionellosis may be expected to be particularly common in the developed world. However, the disease appears to be worldwide in its distribution.

VIII.79
Leishmaniasis

Leishmaniasis is primarily a skin disease produced by a number of different species of protozoa (genus *Leishmania*). The disease occurs in three basic clinical forms, each of which has several variants caused by different species, subspecies, or strains of the pathogen. The intermediate host is the sandfly.

Distribution and Incidence

Cutaneous leishmaniasis (often called "oriental sore") is found in Armenia, Azerbaijan, Turkmenistan, Uzbekistan (republics of the former Soviet Union), Afghanistan, India, Iran, much of the Middle East and North Africa, the Sahara, the savanna states from Sudan to Senegal, and in Kenya and Ethiopia. In the New World, species of *Leishmania* cause various clinical forms of the disease in Central America, the Amazon Basin, the Guyanas, and the Andes, especially Venezuela and Peru. In eastern South America a form of the disease mainly afflicting children extends from Argentina to Venezuela and north through Central America to Mexico.

Mucocutaneous leishmaniasis is restricted to the New World and occurs in Brazil, eastern Peru, Paraguay, Ecuador, Colombia, and Venezuela.

Visceral leishmaniasis is found in India, Burma, Bangladesh, China, Thailand, Somalia, Chad, Kenya, Gabon, Sudan, and Niger. A variant occurring primarily among children is spread over southern Europe, North Africa, and the Middle East as well as Romania and the southern part of the former Soviet Union.

As a result of high levels of disease in rodent and dog populations, leishmaniasis is so common in endemic areas that it leaves its mark on every inhabitant. Recent estimates indicate that some 12 million individuals have one form or another of this infection. Thus leishmaniasis can be regarded as second in importance only to malaria among the protozoal diseases of humans. Although the mortality is low for the skin disease, it is almost always fatal for *kala-azar,* an organ variant.

Epidemiology and Etiology

All forms of leishmaniasis are zoonoses transmitted to human beings from wild or domestic animals via the sandfly (usually *Phlebotomus*). The leishmanial form of the parasite lives in reticuloendothelial cells of the mammalian host where it divides by binary fission to destroy the host cell. The parasites are taken up by the sandfly while feeding on the skin of the host, and in the insect's intestine they develop into leptomonad forms. These divide, producing enormous numbers, and work their way to the pharynx and buccal cavity. There is a natural restriction of individual leishmaniae to specific sandflies, even though a wide variety of these insect species may be available.

Cutaneous leishmaniasis is caused by several members of the *Leishmania tropica* species complex. All produce chronic skin lesions, which tend to ulcerate. Some forms tend to be "urban" and closely linked to dogs as alternating hosts. Others are "rural," with nonhuman reservoirs including various rodents, marsupials, and foxes. In the Americas, sandflies of the genus *Lutzomyia* are often vectors. The initial lesion usually heals spontaneously, but often leaves a disfiguring scar.

Mucocutaneous leishmaniasis is caused by *Leishmania braziliensis*. In the form known as *espundia* in Brazil, the initial lesion develops into an infection of the mucosal tissues of the nose and mouth, resulting in gross deformities and sometimes death from secondary infections. *Lutzomyia* flies are the major vectors. (A clinically similar form, believed to be caused by *L. tropica,* has been described in Ethiopia.)

Visceral leishmaniasis, or kala-azar, is caused by at least three members of the *Leishmania donovani* complex. In visceral leishmaniasis, unlike other forms of the disease, the organisms parasitize reticuloendothelial cells beyond the subcutaneous and mucosal tissue, and a number of internal organs may be involved. Symptoms include swelling of the liver and spleen, fever, diarrhea, emaciation, anemia, darkening of the skin, and gross abdominal enlargement. Mortality in untreated cases has reached 75 to 95 percent over a 2-year period.

Clinical Manifestations and Pathololgy

Old World cutaneous leishmaniasis has an incubation period of 6 weeks to a year, depending on the species of *Leishmania*. The lesions may be multiple, and it is thought that they are the result of multiple bites. There is much local induration and possible lymphatic spread to the regional lymph nodes. Heal-

ing is slow, with the formation of scar tissue in a year or so.

The New World disease takes several different forms:

1. A self-limiting ulcer of 6 months' duration without metastases, caused by *Leishmania tropica mexicana,* is found in the Yucatan. It has a rodent reservoir in flat, low, rain forests.
2. *Espundia,* due to *L. braziliensis,* exists in the jungles of Panama through Amazonia to Paraguay. It starts as a painless ulcer and metastasizes to the oronasal or anorectal area in 5 to 23 years. The host is thought to be the paca (*Cuniculus paca*), a nocturnal American rodent.
3. A solitary ulcerative lesion known as *uta,* usually found at the base of the nose with no metastasis, exists in the Andean valleys of Peru and Argentina. The agent is *Leishmania peruviana,* and the host is the dog.
4. Leproid leishmaniasis is seen in Venezuela. It begins as a fleshy cutaneous nodule that slowly spreads over the body without ulcerating and is difficult to distinguish from leprosy. It is thought to be due to an immune response and is very chronic.

In the absence of demonstrable leishmania, reliance rests on the *leishmanin skin test,* which is positive in cutaneous disease when there is a tuberculoid histology. Generally it becomes positive early and remains so after healing is complete. Although most lesions are self-limiting, antimony, pyrimethamine, and amphotericin B are used to treat metastases. A persistent positive serology is an important sign of continued survival of the parasite, which may live for decades in asymptomatic individuals.

History and Geography

Leishmaniasis is an ancient disease of both the Old and the New Worlds. Old World cutaneous leishmaniasis was first described in English by Alexander Russell in the mid-eighteenth century. Designs on Indian pottery of the New World clearly show the disfiguring disease. The pre-Columbian Incas knew of the dangers of the disease in the lowlands east of the Andes where coca grew and thus used captives to cultivate it. The Spaniards who later took over the coca trade were less aware of the problem, and consequently, their labor policies resulted in much disfigurement and death.

Visceral leishmaniasis was known to nineteenth-century British doctors in India as kala-azar or *Dumdum fever* with its symptoms attributed vari-

Figure VIII.79.1. The *uta* form of leishmaniasis.

ously to malaria, Malta fever, and other diseases. It was in 1900 that W. B. Leishman, working at Nettley, noticed the similarity of the parasite to that of trypanosomiasis, and shortly thereafter Leishman's bodies were discovered to be the cause of kala-azar. Leishman published his findings in 1903, yet his work was duplicated independently by Charles Donovan. Leishman's name was given to the entire genus, but the agent of kala-azar got its specific name from Donovan.

Old World leishmaniasis or *oriental sore* had long been in northern Africa and India, where it was known geographically as the *Delhi boil, Aleppo boil,* and so forth. Its agent, *L. tropica,* was probably seen as early as 1885, but the first clear description was not published until 1898, by Peter Fokitsch Borovsky in a Russian military journal. However, the paper did not become known to the West, and thus credit for the discovery of the organism is often given to James Homer Wright of Baltimore, who in 1903 found it in an ulcer of a child from Armenia.

The first cases of cutaneous disease in the Americas were described by A. Carini and V. Paranhos in southern Brazil in 1909 – the same year that mucocutaneous leishmaniasis was described as a distinct disease, this also in Brazil. Gasper Oliveira de Vianna named the etiologic agent *Leishmania braziliensis* in 1911. The visceral form in the Americas was first seen in Paraguay in 1913. *Phlebotomus* was suspected of being the vector as early as 1911, but this was not proven until 1941.

The cutaneous and mucocutaneous form of the disease are relatively common problems among people working in heavily forested areas, such as the original area of Amazonia in Brazil. In Peru the *uta* form is seen on the lower eastern slopes of the Andes. In the Arica area of northern Chile there is an interesting case of what is probably the *uta* form (Figure VIII.79.1) of this disease dating back about 1,000 years. It is known that contacts were common with the jungle area for trade purposes, and this case is probably an example of an imported exotic disease to the Pacific coast.

Leprosy

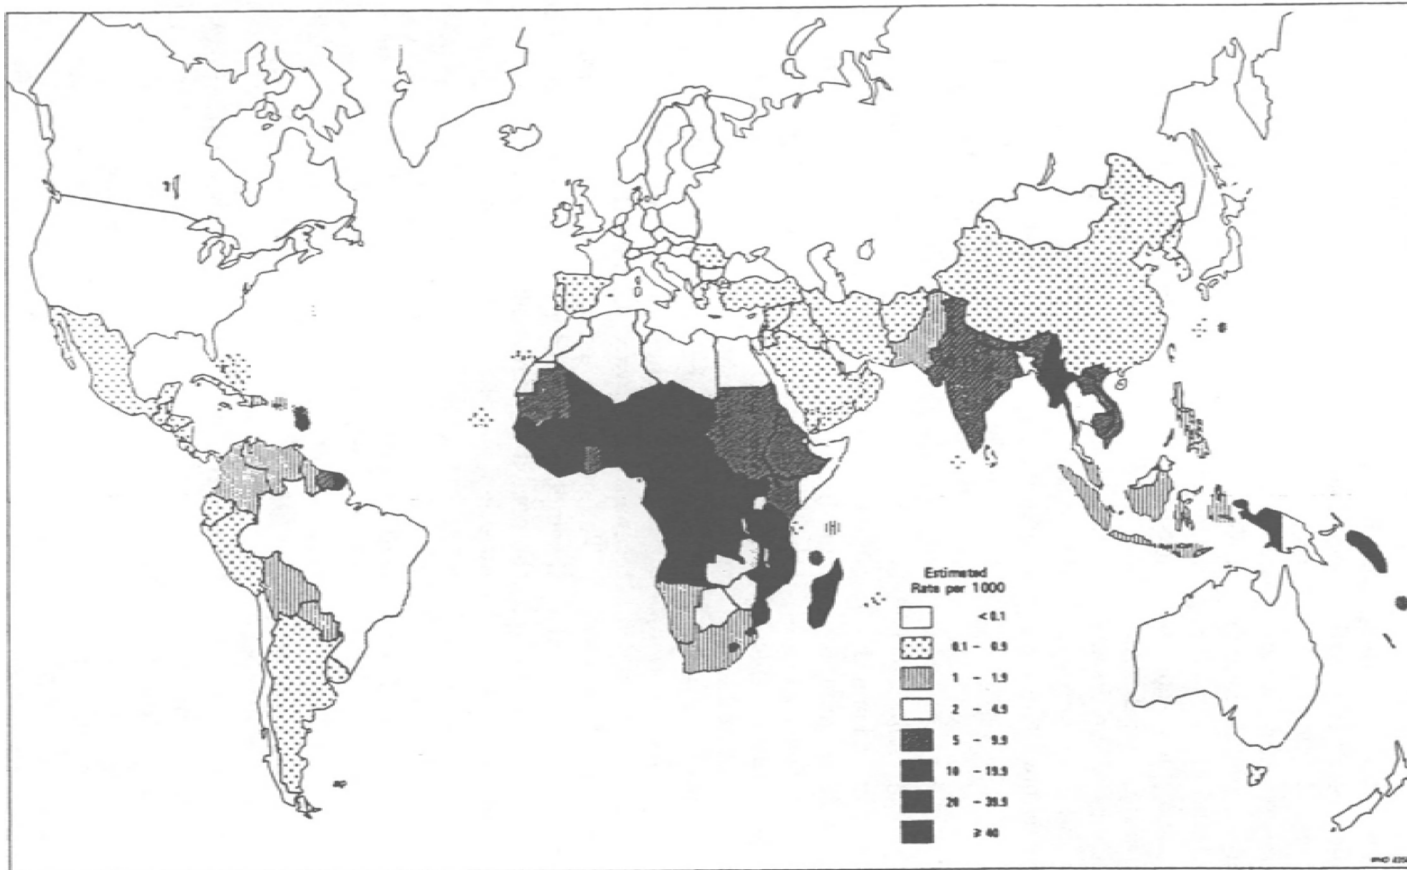
Leprosy occurs naturally only in humans and is caused by infection with *Mycobacterium leprae*. Known also in the twentieth century as "Hansen's disease," after the Norwegian microbiologist A. G. H. Hansen who first isolated the microorganism in 1873, true leprosy is a chronic, debilitating, and disfiguring infection. However, the long history of disease attributed to leprosy undoubtedly includes a broad range of skin and systemic afflictions that only resembled leprosy symptoms.

The leprosy bacillus multiplies quite slowly, usually in the sheaths of peripheral nerves. Losing sensation in discrete, patchy areas of the skin is often the earliest, but ignored, symptom of infection. Lacking adequate innervation, the affected dermis can be damaged without evoking a pain response as, for example, by a burn or a cut. Repair of the tissue is then hindered by poor regulation of local blood supply. Hence, secondary infection and inflammation of an involved area are common, leading to scarring and callusing of surviving tissues. This long process can result in the loss of fingers, toes, nasal tissue, or other parts of the body frequently exposed to the elements. A "bear claw" foot or hand becomes one of the characteristically maiming and stigmatizing features of the leper. Involvement of the nasal cartilage and vocal cords, common sites for the organism's growth, leads to profound disfiguration of the center of the face and also to the raspy, honking voice described in some historical accounts of true leprosy.

The early and more subtle physiological changes caused by leprosy have been noted consistently only since the nineteenth century. Owing to the involvement of nerves supplying the dermis, the heavily innervated face loses "free play" of expression and affect. Eyelashes and the lateral part of the eyebrows disappear long before other, grosser signs betray infection.

Distribution and Incidence

In the late twentieth century, leprosy occurs commonly only in tropical and subtropical regions, as indicated in Map VIII.80.1. There are at least 15 million lepers worldwide, most of them residing in Africa, South and Southeast Asia, and South America. However, this geographic distribution of the disease more likely reflects the poverty of these regions than it does the possibility that elevated temperatures and humidity facilitate infection. Despite cheap and effective medication (dapsone) to arrest the relentless progression of leprosy in infected individuals, the disease continues to spread in the rural regions of Africa, Southeast Asia, and the Indian subcontinent. Often because leprosy stigmatizes its victims socially, leading to loss of employment, alienation from family and community, and, ultimately, to confinement in a leprosarium, lepers deny infection or evade treatment as long as they can. In the process they ensure transmission of the disease to others. Leprosy is normally passed from one individual to another only with sustained exposure, but the disease continues to spread even in areas served by Western medical practitioners, because of the high social costs of early identification and treatment.

In the past, leprosy probably extended as far north as the Arctic Circle. Extensive paleopathological investigations of medieval gravesites thought to have belonged to leper colonies have produced evidence of leprosy among Danes and Norwegians of the thirteenth century. Interestingly, the distribution of leprosy in medieval Europe, like that of today, appears to have been rural, and the written or physical evidence of leprosy disappears with urbanization. The disappearance of leprosy in Europe historically progressed gradually northward from the urban Mediterranean areas of Italy and Spain. Cases of leprosy were still reported in England and Scotland during


Map VIII.80.1. Estimated endemicity of leprosy in the world, 1983. (From World Health Organization. 1985. *Epidemiology of leprosy in relation to control: Report of a WHO Study Group*. World Health Organization Technical Report Series 716. Geneva.)

the fourteenth and fifteenth centuries, and the disease persisted in Scandinavia until the late nineteenth century, where Hansen discovered the bacillus that causes the disease.

One of the odd features of the geographic distribution of leprosy is the increased prevalence on islands or near seacoasts. Late medieval and early modern theorists even attributed the cause of the disease to an exclusively fish diet, an explanation now discredited. Undoubtedly the low infectivity of the disease and its association with poverty and poor sanitation contribute to the slow spread inland once leprosy is introduced into a region.

Epidemiology

It is possible that the history of *Mycobacterium tuberculosis,* an organism related to leprosy and one that creates a limited cross-immunity to *M. leprae* infection, has affected the long-term distribution and incidence of leprosy, as may also have other atypical mycobacterial infections such as scrofula and avian tuberculosis. Increased population density in urban areas facilitates the spread of tuberculosis infection, which may have contributed to a declining incidence of leprosy as cities and large towns appeared. In large regions of West Africa today, leprosy's hold over rural, remote villages increases with distance from a city (Hunter and Thomas 1984), whereas tuberculosis infection, evidenced by positive reactions to a tine or tuberculin purified protein derivative (PPD) test, increases dramatically with population density. There is almost no evidence that leprosy existed in the Western Hemisphere, Australia, or Oceanic Islands before it was introduced from the Old World.

This epidemiological relationship between tuberculosis and leprosy, however, is obscured in individual patients. For despite cross-immunity, the most common associated cause of death in leprosaria is tuberculosis, illustrating how long-sufferers of leprosy lose the ability to combat other chronic infections. Moreover, geographic determinants of leprosy infection alone cannot explain the high prevalence of leprosy in densely settled eastern India. It could be, however, that more successful control of tuberculosis in the region permitted the persistence of leprosy and that stigmatization of lepers effectively delayed treatment of the illness by medical and public health authorities.

Etiology

M. leprae belongs to a large group of intracellular bacterial pathogens widely distributed in nature. Members of the family Mycobacteriaceae can infect mammalian and avian hosts, and, as exemplified by bovine tuberculosis and avian tuberculosis, a pathogen dominant in one host species can successfully infect an altogether different host. Thus humans have suffered from bovine tuberculosis transmitted through contaminated cow's milk and from atypical mycobacterial infections in the form of "scrofula" or infected lymphatic glands. But among these, only leprosy and tuberculosis can be successfully transmitted from one human to another, although *M. leprae* is the only one of these genera that cannot be transmitted naturally to species other than humans.

This feature of leprosy made difficult the search for a suitable experimental animal for research, and only during the mid-1960s did medical scientists succeed in transmitting the infection to armadillos of the American Southwest. In what period of human history *M. leprae* appeared, and from what other mycobacterial species it evolved are a mystery. Paleopathological evidence confirms the existence of true leprosy in the ancient eastern Mediterranean basin. It was probably African in origin and steadily disseminated among human communities from Pleistocene times onward (Grmek 1983).

The organism usually enters a new human host through respiratory passages or the skin. Because the period of incubation (i.e., the interval between infection and the manifestation of symptoms) is so long, the actual process of the microorganism's growth and dissemination through the body is not well understood. Commonly, early symptoms of disease appear 3 to 5 years after infection, but clinical evidence of infection may appear in as little as 6 months, or as long as 20 years post infection.

Clinical Manifestations and Pathology

Typically leprosy first appears on the skin as a patch or area thickened and differing in color from the surrounding skin. It may be darker or lighter in color, but is usually distinguishable because the area is unresponsive to touch or pain. As is true of other chronic infectious diseases, such as tuberculosis, syphilis, or acquired immune deficiency syndrome, the clinical features of leprosy can vary from one sufferer to another. Leprosy is in fact described as a "bipolar" disease because of two very different clinical forms of the illness, with "mixed" or "indeterminate" reactions to infection possible but less frequent. The intermediate type is sometimes called "borderline" as well. Individuals whose clinical course vacillates between the two polar types are also viewed as intermediate.

In tuberculoid leprosy, one of the polar types, the

areas of "patchy anesthesia" on the skin heal relatively quickly after injury, but new areas appear, more extensive and severe, and the untreated disease involves peripheral nerves to such an extent that desensitized skin cannot be protected from burns, exposure, or other insults to the body surface. Even though tuberculoid leprosy is thought to be milder than lepromatous leprosy, possibly because of a stronger immune response to infection, the secondary infections after skin injury make it a serious disease.

In the "leonine facies" of lepromatous leprosy, the other polar type, the reaction on the skin surface is dramatic and severely disfiguring, because the intermediate healing of involved skin produces thick, corrugated scar tissue. The lesions are often teeming with infective bacilli. The two clinical forms are not caused by morphologically distinguishable forms of *M. leprae*. Thus either a strong or a weak immunologic response (if this difference is the "cause" of the two forms of disease) produces crippling and disfigurement.

The leonine form is more distinctive by sight and thus is more frequent in historical accounts closely describing leprosy. Chinese surgeon Hua T'o's description (around A.D. 150) is a good one:

The skin is first numb without sensation, gradually red spots appear on it, when it is swollen and ulcerated without any pus. And later the disease develops to such an extent that the eyebrows fall, the eyes may become blind, the lips deformed and the voice hoarse. The patient may also experience ringing in his ears and the soles of his feet develop rotted holes; his finger joints may become dislocated and the bridge of his nose flattened. (Skisnes 1973)

On the other hand, exaggerated, grossly disfiguring ulceration of face and limbs is not necessarily caused by leprosy. Syphilis, repeated frostbite injury, and diabetes could also account for the features given in this eighteenth-century Japanese description:

[I]t is useless to attempt to cure a patient whose eyes have a yellow hue [a reflection of either liver damage or the destruction of red blood cells], whose fingernails have no white crescents at the bottom, whose hands are wholly anesthetic, whose palm or sole bleeds, whose eyeballs are ulcerated, whose penis is putrified, whose hands or feet are clawed, whose skin is spotted with black, whose fingers have melted off leaving frog-foot shaped ends, whose body hairs fall off, whose nose is gone, whose bones are poisoned and putrified. (Skisnes 1973)

In addition, secondary infection by many noninfectious diseases such as psoriasis, pellagra, eczema, and lupus erythematosis could easily have led to this historical diagnosis of leprosy. Thus the more subtle changes of early leprosy, such as the loss of the lateral third of the eyebrows, the hoarse voice, the areas of patchy anesthesia, and the loss of free play in facial musculature – all features of the diagnostic procedure described by tenth-century Persian physician Avicenna – provide more assurance of a correct diagnosis of leprosy than does simply loathesome appearance.

Untreated, the established leprosy infection today usually progresses slowly, although there are periods of rapid worsening in a person's overall ability to contain the disease. During these periods of exacerbation, severe pain can be caused by involvement of the nerves, and nodules on the skin may appear rapidly and in crops of lesions. It is rare to die, however, from unchecked Hansen's disease; secondary infection usually leads to the patient's demise.

Immunology

Because leprosy is caused by an intracellular pathogen, production of circulating humoral antibodies (the immunoglobulins) is of little use in combatting the infection of cells and the multiplication of the organism in human tissues. Cell-mediated, or T-cell, immunity is thus the principal bodily means of combating leprosy. Individuals in whom the expression of cell-mediated immunity is compromised or poorly developed, such as pregnant women and children younger than 2 years of age, are at greater risk for both infection (when initially exposed) and progression of the disease unimpeded by the immune system. Others with intact cellular immunity can live almost 20 years before the first serious, debilitating consequences of infection occur. It is not known to what extent recurrent viral infection, which also challenges cellular immunity, may hasten the onset of clinical leprosy.

Genetic factors may further mediate the clinical expression of leprosy among those already infected, predisposing some individuals to a more or less rapid course of the disease, or perhaps influencing the appearance of severe, lepromatous leprosy rather than the milder tuberculoid form. Nevertheless, there are only a limited number of cases in which some clear genetic determinant of susceptibility can be differentiated from the socioeconomic factors mediating exposure to the agent.

History and Geography

The history of leprosy has been dominated by three questions or problems. One question concerns stigmatization. Most ancient societies identified some

individuals as "lepers," and the leper was stigma-tized, although surely lepers as a group included many suffering from something besides Hansen's disease. Stigmatization of the leper has persisted into the late twentieth century despite advances and refinements in the medical diagnosis and treatment of leprosy. The second problem focuses on medical evidence for leprosy's changing incidence and preva-lence over time, particularly in western European history during the period between 500 and 1500 of the present era. Finally, the world distribution of leprosy and failures to impede its spread have emerged as a historical problem of the past 250 years.

In the Old Testament Book of Leviticus, the dis-ease zara'ath or tsara'ath was identified by priests and its victims were cast "outside the camp" as un-clean and uncleansable. They were viewed as both chosen and rejected by God and, consequently, not exiled altogether from the community, as were crimi-nals, but rather made to live apart as if the living dead. Thus, central problems posed by the disease zara'ath involved, on the one hand, the spiritual identity of diseased individuals who, although proba-bly morally "tainted," were not, apparently, person-ally responsible for their disease; and on the other hand, the delegation of the process of making the diagnosis to religious, not medical, authorities.

Because the opprobrium attached to leprosy was handled dramatically by writers of the Biblical Old Testament and because this Judaeo-Christian tradi-tion was of central importance to western European history for the next 2,000 years, stigmatization of the leper was derived from religious, medical, and social responses to individuals carrying the diagno-sis. Thus, during the High Middle Ages (A.D. 1100–1300), lepers were identified by priests or other spiri-tual authorities, and then separated from the gen-eral community, often ritualistically. Considered "dead to society," last rites and services might be said in the leper's presence, sometimes as the victim stood symbolically in a grave. Thereafter the per-son's access to his or her city or village was severely limited. Italian cities, for example, posted guards at the city gates to identify lepers and deny them en-trance except under carefully controlled circum-stances. Leprosaria, or isolation hospitals to house lepers, were constructed at church or communal ex-pense, although medical services to these facilities were limited. Where public services were less well organized, lepers had to depend upon begging or alms.

Laws in western Europe illustrated the exagger-ated fear of contagion lepers generated. Lepers had to be identifiable at a distance, leading to the cre-ation of legendary symbols of the leper: a yellow cross sewn to their cape or vestment; a clapper or bell to warn those who might pass by too closely; a long pole in order to point to items they wished to purchase, or to retrieve an alms cup placed closer to a road than lepers were allowed to go.

The stigmatization of lepers, however, was not limited to Western tradition, and in most societies of the past those labeled as lepers were denied legal rights in addition to being socially ostracized. In traditions of both East Asia and the Indian subconti-nent, marriage to a leper or the offspring of a leper was prohibited, and, as in Western tradition, the disease was often attributed to moral causes (sin) as well as to contagion. Interesting in this regard is the iconographic representation of the leper in Tibetan art, a man covered with vesicles and ulcers, which parallels Western depictions of Job as a man covered by sores in punishment by God for his sins. The stereotype of the leper as filthy, rotten, nauseating, and repulsive is so strong that most "hansenolo-gists" today advocate rejection of the name "leprosy" in favor of Hansen's disease. The only exception to this pattern of stigmatization seems to be in Islamic society, where the leper is neither exiled nor consid-ered perverse, promiscuous, or otherwise morally repulsive (Dols 1983).

In contrast to ancient Chinese texts of approxi-mately the same period, in which leprosy destroying the center of the face is well described, the clinical evidence for leprosy in the ancient Mediterranean is meager. Nowhere in the Biblical tradition is there more than a general description of the disease that created such a severe response. Hippocratic texts provide no evidence that true leprosy existed in an-cient Greece, but the Hippocratic, Greek word lepra, probably describing psoriasis, gave origin to the dis-ease's name. Thus a coherent and powerful tradition in the West stigmatizing the leper was begun in what appears to have been the absence of any orga-nized and reasonably accurate medical description of how these sufferers could be identified. Indeed, the earliest clinical description of leprosy in the West appears neither in the Hippocratic corpus (written in Greek between 400 and 100 B.C.) nor in the 20 surviving volumes of the works of the great second-century Greek physician, Galen, but rather in the writings of the tenth-century Persian physician Avi-cenna, and it is his Canon of Medicine that provides the description upon which medieval European phy-sicians relied.

The decline of leprosy in Europe coincided with increasing medical sophistication in diagnosing what we might recognize as leprosy. This decline may be due in part to an increase in another mycobacterial disease such as tuberculosis; to improvements in living standards; to high catastrophic mortality from plague and other epidemics, effectively reducing the number of lepers in the general population; or to the simple fact that medical authorities began to share the burden of diagnosis with religious and communal leaders. Surely other skin infections and afflictions that might earlier have been taken for leprosy were better recognized in the late Middle Ages. Nonetheless true leprosy certainly existed in Europe, as the exhumations of medieval skeletal materials from northern Europe have well illustrated (Møller-Christensen 1961; Andersen 1969; Steinbock 1976).

Knowledge of leprosy in modern medical terms evolved during the nineteenth century, coincident with development of the germ theory of disease. During this period, the precise description of the clinical characteristics of lepromatous leprosy by Danish physician Daniel C. Danielssen in the 1840s; the discovery of the microorganism by Hansen in 1873; and widespread attention to the contemporary geographic distribution of leprosy in European colonial territories served to identify the disease as a contagious tropical infection. As such it was believed to be eradicable by Western medical efforts in public health intervention. Methods of quarantine and isolation were enthusiastically employed, despite skepticism about these methods in general public health control.

In the same year that Hansen found the causal organism of leprosy, a devoted Catholic priest, Father Damien de Veuster, drew worldwide attention in an attempt to humanize the treatment of leprosy by going to live among lepers in Hawaii. But he may have underscored fear of the contagion of leprosy because he eventually contracted the disease. Thus in modern times, increasing medical knowledge of the incidence and prevalence of *M. leprae* may have served to increase alarm and fear as leprosy was "discovered" to be the resilient global problem it remains to this day.

VIII.81
Leptospirosis

The kind of leptospirosis manifested by severe jaundice was first described as a human disease in 1886 by A. Weil. Named *Weil's disease* the following year, the term was meant to designate a distinctive infectious jaundice, and it would not be known until much later that leptospirosis was caused by numerous leptospires that triggered various clinical syndromes. The first of the causative pathogens were independently discovered in 1915 by R. Inada among Japanese mine workers and by P. Uhlenhut and W. Fromme among German soldiers. *Leptospira,* a genus of the family Treponemataceae, order Spirochaetales, is a fine threadlike organism with hooked ends (see Figure VIII.81.1) that is pathogenic for humans and other mammals, producing meningitis, hepatitis, and nephritis both separately and together. In the past, the disease killed between 15 and 40 percent of those infected. Modern treatment has reduced mortality to about 5 percent. As a zoonosis, the disease is generally maintained in rodent reservoirs.

Figure VIII.81.1. Leptospires on dark field. (From O. Gsell. 1978. Leptospires and relapsing fever. In *Handbook of Clinical Neurology,* Part III, Chapter 18, 395–418, by permission of Elsevier Science Publishing.)

Etiology and Epidemiology

Leptospires are obligate aerobes and classified serologically as a bacterium, subdivided into two species. One is *Leptospira biflexa,* which includes the various water spirochetes, whereas the other, *Leptospira interrogans,* embraces the parasitic strains. The species *interrogans* (so named because of an appearance like a question mark) is now subdivided by the main antigen into 187 serotypes or serovars. Human leptospirosis generally results from direct or indirect exposure to the urine of infected animals, although it can also be transmitted by handling infected animal tissue, by animal bites, and by the ingestion of contaminated food and water. The leptospires can enter the body through breaks in the skin, as well as through the lining of the mouth, nose, and eyes.

Persons of all ages are susceptible to the infection, and although the disease may occur at any time, it is most often seen during warmer weather and periods of heavy rainfall. Its presence in mud and swamps has often placed soldiers at special risk. As a rule, it appears as isolated cases, but it can also manifest itself in small clusters and even in large outbreaks, depending on the type and the circumstances of its transmission.

In most of the world, leptospirosis is an occupational disease. Field workers and those who work around farm animals are at risk, as are employees of slaughter houses and poultry and fish production plants, and persons employed in sewers, mines, and in other wet places infested with rodents. Infected wild animals such as rats and mice are the source of infection for domesticated animals, especially dogs (*Leptospira canicola*), pigs (*Leptospira pomona*), and cattle (*Leptospira hardjo*), who may in turn infect humans.

As Table VIII.81.1 indicates, localized leptospirosis infections produced by one or another strain of the pathogen occur across the globe. The pig-raising areas of the European alpine region, northern Australia, and parts of Argentina see one form of the disease caused by *L. pomona* and *Leptospira hyos* or *tarassovi* and called *swineherd's disease.* Similarly, the sugarcane plantation regions of East Asia and rice-growing regions of Spain and Italy harbor other forms, which are the result of infection by field mice. Local names for the various forms of leptospirosis often reflect the circumstances under which it is contracted. Thus there is "harvest" or "swamp" fever, caused by *Leptospira grippotyphosa.* In Germany, agricultural workers contracted "field fever"; in Silesia, there was "mud fever"; in Russia, "water fever"; and in Germany and Switzerland, "pea pickers disease." On the other hand, leptospirosis can also be an urban disease carried by the ubiquitous *Rattus norwegicus,* as well as by dogs.

Clinical Manifestations

Figure VIII.81.2 shows the phases of leptospirosis and the relevant diagnostic procedures. The first phase of the disease is characterized by an acute onset of high fever, headache, malaise, conjunctival reddening, muscle pain, often meningism, renal irritation, hypotonia, and relative bradycardia (see Table VIII.81.2). In the second stage, there is danger of organ involvement, which is accompanied by the appearance of specific antibodies in the serum. The disease frequently causes the liver to become enlarged and painful, and can be life-threatening when renal damage is severe. Icterus, when it occurs, can be very intense and last for several weeks. Leptospirosis also causes kidney damage, although the most common second-stage symptom is serosal meningitis, and less frequently encephalomyelitis or neuritis. Swineherds' meningitis is particularly well known (Gsell 1952). Meningitis symptoms usually subside completely in the third week.

As Figure VIII.81.2 indicates, there can be other damage from the disease, but only rarely. When it causes death, postmortem findings reveal renal and hepatic failure represented by renal tubular necroses, hemoglobinemia, and liver cell necrosis with general jaundice and anemia. Hemorrhages can be found in almost any organ, and in muscles and subcutaneous tissue.

Treatment

Antibiotics are quite effective against leptospires but only if employed within the first 3 or, at the most, 4 days. After this, efforts should be directed at avoiding complications. Severe kidney insufficiency requires hemodialysis or peritoneal dialysis, and infusions or transfusions may be necessary as well.

History and Geography

Much of the history of leptospirosis appears as an effort to separate leptospiral jaundice and meningitis from other infections. The clinical portion of this history began with Weil's description of the disease in 1886; the bacteriologic phase began with isolation

of the pathogenic germs in 1915 by Inada and Uhlenhut and Fromme. In 1918, H. Noguchi gave the name *Leptospira* to the newly discovered bacteria. During the years 1917–18 Y. Indo, H. Ito, and H. Wani found cases of the disease that were not characterized by jaundice – described as the 7-day fever *"Nanukayami"* which has the field mouse as a carrier. In the following decades, numerous different serotypes were found throughout the world. Among these are *Leptospira pyrogenes* (Indonesia, 1923), *Leptospira autumnalis* (Japan, 1925), *Leptospira bataviae* (Indonesia, 1926), *L. grippotyphosa* (Russia, 1928), *Leptospira andaman* (Andaman Islands, 1931), *L. canicola* (Netherlands, 1933), *Leptospira australis* as well as *L. pomona* (Australia, 1937), and *Leptospira hebdomadis hardjo* (Great Britain, 1968).

In Switzerland during the year 1944, *L. pomona* was found to be the cause of swineherds disease with the pig as its carrier, and 4 years later *L. tarassovi* and *L. hyos* were discovered to be of the same serotype and also carried by the pig. Numerous other serovars have been discovered subsequently, and after 1950 a new classification of the serotypes was accepted which classified the clinical groups into malignant and benign human leptospires, while in serology it permitted the allocation of animal and human leptospires to different serovars. In looking back on a century of research on leptospirosis, it seems remarkable that serious and widespread epidemics have been so infrequent. Today the incidence of the disease has been reduced in developed countries, probably because of a decrease in the rodent populations and because of improved human hygiene in the presence of domestic animals.

Leukemia

Leukemia, commonly known as cancer of the blood, describes a group of malignant disorders that arise in the blood-forming cells. The bone marrow, where the cells of the blood are made, malfunctions to produce abnormal white cells (*leukemic cells*) in an uncontrolled manner to the detriment of all the other essential blood cells. Blood consists of a clear fluid (*plasma*), containing chemical substances essential to the body's needs, and three types of blood cells. The red blood cells (*erythrocytes*) are by far the most numerous; their main function is to transport oxygen to all the tissues of the body. They contain *hemoglobin,* an iron-rich protein that gives the blood its red color. A reduction in hemoglobin concentration is known as *anemia.* The white blood cells, *leukocytes,* of which there are three major groups, namely *monocytes, granulocytes,* and *lymphocytes,* play different roles in defending the body against infection. Platelets help to control bleeding.

Hematopoiesis

Blood cell formation, known as *hematopoiesis,* starts in the bone marrow, the spongy interior of the large bones, with a pool of immature or undifferentiated cells known as pluripotent stem cells, which contain the characteristics of all the major blood cell lines. These cells divide, either producing themselves exactly or producing more specialized cells that contain the characteristics of only one of the two major cell lines: One of these two specialized cells, known as the *mixed myeloid progenitor cell,* consists of the progenitor cells to the red blood cells, the monocytes and granulocytes (white cells), and the platelets. The other, the *lymphoid stem cell,* produces the lymphocytes that make up about 30 percent of the circulating white blood cells. The two types of lymphocytes – *T cells* and *B cells* – have different functions: The T cells attack and destroy virus-infected cells, foreign tissue, and cancer cells; B cells produce antibodies, which are proteins that help destroy infectious agents. The two types of white cells interact in complex ways to regulate the immune response.

The production process is continual through division and differentiation, with cell characteristics becoming increasingly defined with each division. The result is that cells are "committed" to evolution into one specific cell type, and thus, as mature cells, they

are released into the bloodstream at a rate consistent with the body's needs and the death of old cells. The exception is the lymphocytes: These are allowed to leave the bone marrow as immature cells, but they mature in the lymph system (thymus, spleen, lymph nodes, and so forth) before entering the bloodstream. In normal health, immature stem cells or *blasts* are present in the circulating blood only in very small numbers, and healthy bone marrow does not contain more than 5 percent of the total cell population.

From 6 weeks until about 6 to 7 months in utero, liver and the spleen are the main organs involved in blood formation. Thereafter, the bone marrow takes over. In infants, practically all the bones are involved, but in adults the production is limited to the vertebrae, ribs, sternum, skull, sacrum, pelvis, and the proximal ends of the femur. Because the entire blood cell formation, growth, maintenance, destruction, and replacement cycle is most efficiently organized, it follows that any abnormal reproduction of any type of cell will disrupt the blood cell balance and, in the absence of a self-regulating mechanism, will affect the body's general health.

Every day at least 200 billion red cells, 10 billion white cells, and over 400 billion platelets are produced in the marrow. The averagel life-span of the cells varies according to the cell type, and ranges from 1 to 2 days for white cells, to about 7 days for platelets, to 120 days for red cells. In normal circulating blood there are approximately 1,000 red cells to each white cell. But in leukemia, the normal production of blood cells fails. In all but its rarest form, one or more of the types of white blood cells reproduces abnormally and creates useless, immature blast cells or poorly developed cells of inferior quality. These leukemic cells begin to overpopulate the bone marrow, spill into the bloodstream and the lymph system, and infiltrate vital organs and glands, causing them to enlarge and malfunction. Because the bone marrow is severely impaired, it is unable to maintain production of sufficient levels of red cells and platelets. As a consequence, the whole balance of the blood cell population is seriously disturbed, and the body's defense mechanisms provided by the white blood cells and the platelets are rendered ineffective.

Classification of the Leukemias

Leukemia types are classified according to the type of white cell that is affected. The two main types of the disease are *myeloid* (also called *granulocytic* or *myelogenous*) and *lymphatic* (or *lymphocytic*). These two main types are derived from the two major cell lines: the mixed myeloid progenitor cell line, which

produces the white blood cell monocytes or granulo-cytes; and the lymphoid cell line, which gives rise to the lymphocytes. These are further subdivided into *acute* (progressing rapidly) and *chronic* (progressing slowly). In the acute form, there is abnormal growth of immature or blast cells whereas in chronic leukemia, more mature cells proliferate, although abnormal immature cells may also be present. The following are the diseases that mainly arise:

1. *Acute myeloid leukemia* (AML), also called acute myelogenous leukemia, acute myelocytic leukemia, acute myeloblastic leukemia, and acute granulocytic leukemia, is synonymous with the group known as *acute nonlymphocytic leukemia* (ANLL), which includes some of the rarer subtypes of the disease (e.g., monocytic leukemia). AML involves the neutrophils (one of the granulocytes) that stem from the myeloid progenitor cell line.

2. *Chronic myeloid leukemia* (CML), also called chronic myelogenous leukemia, chronic myelocytic leukemia, and chronic granulocytic leukemia (CGL), produces excessive numbers of granulocytes that accumulate in the bone marrow and blood stream.

3. *Acute lymphoblastic leukemia* (ALL), also known as acute lymphocytic leukemia and acute lymphatic leukemia, arises as a result of abnormal immature lymphocytes, which proliferate in the bone marrow and the bloodstream and affect the lymphocytes (the B cells and T cells) stemming from the lymphoid cell line.

4. *Chronic lymphocytic leukemia* (CLL), also known as chronic lymphatic leukemia and chronic lymphogenous leukemia, produces an abnormal increase in lymphocytes that lack their infection-fighting ability. It is the major type of a group of diseases known as lymphoproliferative disorders, which includes such rarer forms of leukemia as hairy cell leukemia and adult T cell leukemia.

Distribution and Incidence

Leukemia occurs worldwide and represents just over 5 percent of all cancers. The disease does not present in a regular pattern, and its comparative rarity helps to explain its irregularity. Leukemia can strike anyone, at any time, and at any age. The difficulties in collecting statistics relating to leukemia in populations throughout the world are due not only to the different methods of reporting cases and identifying the true leukemia cell-type specificity, but also to the variable standards and access to medical care. Comparing the incidence of leukemia and other cancers on a worldwide basis can therefore present problems.

The specific types of leukemia are very different in their age patterns and presentation:

1. *Acute myeloid leukemia* (AML) is the major form of leukemia. Its rate of incidence increases with age, yet it also occurs in early infancy and in those in their early 20s. With a mean estimated presentation at around the age of 40 years, the disease affects both sexes equally.

2. *Chronic myeloid leukemia* (CML) is considered an "adult" leukemia, attacking those in the 30- to 50-year age bracket, although it also presents in the older age groups. It, too, has an equal rate of incidence in males and females.

3. *Acute lymphoblastic leukemia* (ALL) is often referred to as "childhood leukemia" for the reason that it accounts for 85 percent of leukemia in children and only 15 percent of cases in adults. ALL has been reported in all races and all geographic areas; yet, for every child with leukemia there are about 10 adults with it.

4. *Chronic lymphocytic leukemia* (CLL) is primarily a disease of the elderly; it rarely presents in anyone below the age of 40. It is more common in males than females, with a male/female ratio of 2:1.

The estimated incidence of all cases of leukemia in the developed countries of the world is 10 per 100,000 of population, the most common now being CLL including the lymphoproliferative disorders, followed by AML and its subgroups, then CML, and lastly ALL. Incidence rates vary in some countries of the world and among some ethnic groups, but no variation is of great significance. The male/female incidence ratio is about 1.7:1.

Etiology

The etiology of leukemia is at present unknown. The basic question is what causes a healthy cell to change to become malignant and to proliferate in that state. The consensus of opinion is that the disease results from the interaction of a number of factors, including environmental agents, and investigations are being pursued on the following:

1. Genetic factors, involving chromosomal abnormalities and changes.
2. Disorders of the immune system (the body's defense system against infection).
3. Exposure to ionizing radiation from a single large dose or from repeated small doses.
4. Chemicals that suppress bone marrow function.
5. Infection – viruses: Retroviruses are known to cause leukemia and lymphomas in certain animal species but not in humans, although recently a

type of RNA virus has been isolated from patients with adult T cell leukemia known as human T cell leukemia virus HTLV1.

Epidemiology

As the cause of leukemia remains obscure, epidemiology has assumed an importance in two directions: first, the incidence, age, and sex differences in the various forms of the disease related to their geographic presentation, and second, the hunt for etiologic clues.

One of the first epidemiology studies on leukemia was by W. R. Gowers, based upon 154 cases and published in London in 1879. The study comprised age and sex data collected at a time when leukemia was recognized only as a chronic disease. It offered few etiologic clues other than exposure to malaria, which was then not confined to tropical countries.

Toward the close of the nineteenth century, a small number of cases of leukemia in its acute form were reported in Europe, and attention was focused on this new form of the disease, particularly in America. George Dock of the University of Michigan was a leading investigator of the complicated aspects of acute leukemia and its rapid onset. The literature, which Dock reviewed extensively in 1903, regarded infection and "some microscopic germ" as suspects.

The infective theory of acute leukemia was further discussed in a 1917 publication in the *British Journal of Children's Diseases* by G. Ward, who had collected a series of 1,457 cases of leukemia. This work added to the knowledge of the age–sex distribution of the disease and suggested that although acute leukemia resembled an infectious disease in many respects (e.g., the feverlike symptoms it caused), there was little evidence to suggest that it was by nature infectious or that it was hereditary.

Leukemia tends to present in an irregular pattern, evidenced by the number of "clusters" of cases that are regularly reported, clusters being defined as more cases of the disease than would be expected to occur in a specific area. The first report of a cluster of leukemia cases came from Paris in 1922, where four patients living within a short distance of one another were diagnosed with acute leukemia in a period of 7 weeks. It was the commonly held view that the cause was the water from a canal in the area. In this event, as with most clusters, the pattern was of normal or less than normal incidence of the disease both before and after the appearance of the cluster of cases.

Because of the sudden presentation of clusters of the disease, investigations are often launched to find

a cause. The identification of possible contributory factors within the environment is one approach, although the prime concentration is on what influences the basic cells and genes to change and begin the malignant process. The most established etiologic factor in human leukemias is ionizing radiation. The atom bombs dropped on Hiroshima and Nagasaki in 1945, for example, brought a rise in the incidence of leukemia, which began about 3 years after the atomic attack and reached a peak at 6 years, but then slowly declined to a normal incidence of the disease at 20 years. On investigation it was found that the greatest incidence was among those closest to the explosion, whereas at 2,000 meters or more the risk of leukemia was no greater than among unirradiated people.

Altogether some 250 cases of leukemia occurred between 1946 and 1965 in the 183,000 people exposed to radiation in Hiroshima and Nagasaki. From this information it followed that only a small proportion of those irradiated developed leukemia, and this led to the suggestion of individual susceptibility. Later, public concern about nuclear power causing leukemia was heightened by the number of clusters of cases of the disease reported in areas surrounding nuclear power stations. Indeed many questions have been raised on this issue, particularly because childhood cases appear to be more prominent in these reported clusters. The pattern – which became apparent in the aftermath of the attacks on Hiroshima and Nagasaki – seems to emerge in these clusters as well; for if nuclear power stations are emitting radiation, relatively few people are actually affected – again raising the etiologic question of possible susceptibility.

The issue of genetic susceptibility was studied by Frederick Gunz, a distinguished research physician at Sydney Hospital in Australia, whose biological approach to epidemiology resulted in his publications in 1974 and 1975 on the genetics of human leukemia. Gunz concluded that evidence from family studies reinforced the theory of a genetic basis in some people for chronic lymphatic leukemia in particular. Gunz also reported that certain chemicals, notably benzene along with viruses, were identified as triggering factors in some animal leukemias, but evidence for such a conclusion in human leukemia remained elusive.

A major epidemiology study embracing a population base of some 20 million people was started in 1984 in England and Wales, at the University of Leeds, by the Leukaemia Research Fund. This computerized program with diagnostic check controls

will be of major importance in assessing current trends in the presentation of the disease.

Clinical Manifestations and Pathology

Some of the first symptoms of acute leukemia are similar to those of common infectious illness. All the leukemias share common signs and symptoms arising from the infiltration of the bone marrow, with leukemic cells replacing the normal tissues. The lack of red cells causes fatigue and anemia, the lack of normal white cells results in infections and fever, and the lack of platelets produces bleeding and bruising. The lymph nodes, spleen, and liver may become enlarged as they are infiltrated with leukemic cells. Bone or joint pains are associated symptoms, and purpura is often present. Although the basic features of the leukemias are common, marked differences exist between the acute and chronic leukemias in their mode of presentation. In the acute leukemias, influenza-type symptoms and fever (present for only days or weeks) signal the sudden and rapid progress of the acute form of the disease. Weakness, exhaustion, enlargement of the lymph nodes, abnormal bleeding (from the gums for example), and a tendency to bruise easily are some of the chief symptoms.

By contrast, the symptoms of chronic leukemias are generally far more subtle. It is not uncommon for the disease to be discovered accidentally when a blood test is carried out for an unrelated reason. The most common symptoms are loss of energy, tiredness, fever, night sweats, and loss of appetite. There may also be enlargement of the liver and spleen and the lymph nodes.

Leukemia can be diagnosed only by microscopic examination of the blood and the bone marrow. A blood test may show low hemoglobin, low levels of normal white cells, and a low platelet count; and leukemic blast cells may be present. A bone marrow biopsy will confirm the diagnosis of leukemia and the predominant cell type involved, which will enable the leukemia to be correctly classified.

Treatment

The remedies for leukemia in the nineteenth century were few, and none was useful in controlling the disease for any length of time. In the first 50 years following its recognition (Bennett 1845), leukemia was generally accepted as a chronic disease, and the limited therapeutics in the armory of the general physician were applied. Quinine was used for combating fever; morphine and opium, for diarrhea; iron, for anemia; iodine, for external use as an antibacterial; and arsenic. In 1786, Thomas Fowler

of York, England, introduced a solution of arsenic trioxide for the cure of agues, remittent fevers, and headaches. In addition, it became a general tonic for animals and humans alike, and in 1865 a German physician prescribed this solution in the treatment of a woman with chronic myeloid leukemia. The patient became temporarily restored to health, and as a result, arsenic became the first agent of some beneficial use in the treatment of certain forms of leukemia, causing a shrinkage of the enlarged spleen and lymph nodes and a reduction in the leukemic cells.

The discovery in 1895 of X-rays by Wilhelm Röntgen soon led to X-ray therapy of leukemias with results similar to those produced by arsenic. However, X-ray therapy had a greater advantage because it was discovered to have the ability to prevent cell division and to inhibit cell growth. On the other hand, patients could eventually become resistant to treatment with X-rays. Thus William Osler commented in 1914 that he had not seen any striking permanent improvement in patients who had undergone X-ray therapy, and C. E. Forkner of Cornell University, New York, writing on the etiology of leukemia in 1938, stated that although much could be done to add to the comfort of patients with chronic forms of leukemia, acute leukemia did not respond to any form of therapy.

In 1946, two American research groups reported on nitrogen mustard therapy, which arose from the poisonous mustard gas research study initiated during World War II. It was found that the chemical analogues of the gas could cause depression of the blood cells, and that some patients in cases of leukemia and lymphoma who had become resistant to X-ray therapy responded to treatment with this agent. This new treatment triggered intensive efforts to find less toxic and more specific therapeutic agents. The result was the introduction of chemotherapy. The aim of all treatment of leukemia is to achieve a prolonged remission of the disease, a state in which all clinical signs of abnormal blood cells disappear and the normal balance of less than 5 percent of blasts in the bone marrow is restored.

Chemotherapy is the form of induction therapy used to effect a remission. A variety of drugs are used to attack the leukemic cells in diverse ways, and they are often given in combination to enhance the efficacy of treatment. However, as these drugs can affect both the leukemic and normal cells, their doses and the sequence of their use must be controlled with great care. Usually combinations of drugs belonging to different groups of chemical com-

pounds are used to attack leukemic cells at different stages of their growth to prevent leukemic cells from becoming resistant to the therapy.

Radiotherapy by deep X-irradiation may also be given; and in certain instances it is used to attack leukemic cells that may accumulate in certain areas of the body – for example, in the central nervous system, the testis, and the eye – and for which chemotherapy is less effective. The treatment and choice of drugs differ for each of the main types of the disease. The slowly progressing chronic leukemias are less responsive to the currently available therapies than are the acute leukemias, although in nearly all cases modern therapy can effect remission. The next stage is to keep the patient in remission through a second level of treatment known as *consolidation therapy,* to be followed by *maintenance therapy,* which aims to destroy any remaining or undetected leukemic cells. Antibiotics are available to treat infections, to which the immunosuppressed patient has an increased susceptibility. Complete remission does not always mean cure because some residual leukemic cells may still be present and remain undetected even by means of microscopic examination and will multiply over a period of time. If leukemic cell growth recurs, treatment is restarted to achieve a second remission. Survival rates differ for each type of leukemia. The most encouraging results are achieved in children with acute lymphoblastic leukemia; over half of those diagnosed are now long-term survivors.

A further form of treatment in suitable cases is bone marrow transplantation. This new therapy involves high-dose chemotherapy and total body irradiation followed by an infusion of bone marrow from either a suitable donor (an *allogeneic* transplant) or from the patient's own marrow taken and stored during remission (an autograft transplant). Apart from suitable donor availability, a major complication at present is graft-versus-host disease resulting from the reaction of the infused marrow with the recipient and, in autologous transplant, the risk of residual disease still being present in the marrow. This form of therapy has been responsible for the control of the disease in cases where other means would not have been successful.

History and Geography

Leukemia was identified as a new disease in 1845 by two independent observers. John Hughes Bennett, lecturer in clinical medicine and pathologist to the Royal Infirmary at Edinburgh, published his observations in the *Edinburgh Medical Journal* of October 1845, a month before Rudolph Virchow published his findings under the title *Weisses Blut.* Two years later, Virchow named the disease *leukemia,* Greek for "white blood," and Bennett in 1851 called it *leucocythemia,* Greek for "white cell blood." Both men, who were keen observers and in the early stages of what were to become distinguished careers in medicine, made their observations at the autopsy table. However, it is unlikely that the disease was new in 1845, for there had been earlier reports of what was described as peculiar conditions of the blood, pus in the blood, and "milky" blood, with some symptoms compatible with those of leukemia. David Craigie in Edinburgh and Alexandre Donné in Paris, among others, were physicians who in the decade previously were alert to something odd in the condition of the blood of certain patients.
